CHAPTER 77

Evaluation of the Burned Patient

Edward A. Bittner, MD, PhD,
Loreta Grecu, MD, and
J.A. Jeevendra Martyn, MD, FCCM

EPIDEMIOLOGY

In the United States each year, approximately 1.25 million people are burned, of whom 55,000 are hospitalized and 5500 die.[1] The natural history of serious burns is characterized by burn shock, which can be fatal within the first few hours to days, particularly in those with untreated large burns. Burn wound sepsis is the major cause of mortality among those who survive the burn shock. After recovery from the acute inflammatory phase, postburn deformities delay full functional recovery.[2] In-hospital fatality rates are approximately 4% among patients with major injuries who are treated in specialized burn units. Survival and outcome after major burn injury have improved over the last 20 years because of improved understanding of the pathophysiologic nature of burn injury, better and early resuscitation, development of multidisciplinary burn-treatment teams, and advances in control of postburn sepsis including early, aggressive surgical treatment and improved perioperative care.[2]

BURN INJURY PATHOPHYSIOLOGY

Severe burn injury results in significant hypovolemic shock and tissue trauma. The intravascular volume loss is related to the formation and release of local and systemic inflammatory mediators. In addition, pathophysiologic changes occur at local and distant sites even when the hypovolemia is corrected. Increases in pulmonary and systemic vascular resistance in association with myocardial depression occur despite adequate fluid resuscitation.[3–6] Mediators implicated in the pathogenesis of burn injury include histamine (HA), serotonin (5-HT_3), kinins, O_2 free radicals, and products of the arachidonic acid cascade.[7] Cytokines are primary mediators of inflammation after burns. Endogenous mediators that alter cardiovascular function are elevated several-fold after burn injury and include epinephrine, norepinephrine, vasopressin, angiotensin II, and neuropeptide Y.[8] Most recently, vascular endothelial growth factor (VEGF) has been implicated in tissue edema following ischemia–reperfusion injury.[9] Its relevance to burn edema is unknown.

Hypovolemia and Rapid Edema Formation

The generalized capillary leak leads to decreased plasma volume, cardiac output, urine output and increased systemic vascular resistance (SVR). In contrast to nonburn trauma, the fluid loss with burn injury leads to hemoconcentration. The initial therapeutic goal is restoration of intravascular volume so as to preserve tissue perfusion and minimize the inflammatory response. The fluid loss of burns occurs not only at the area of burn wound but also at distant nonburned tissues. Continued loss of plasma volume with hypovolemia as a result of edema formation can occur up to the first 48 hours—or even longer—after major burn injury. The immediate and rapid increase in the edema of burn tissue is followed by a more gradual increase in fluid extravasation in both burned and nonburned tissues. The edema in noninjured tissues occurs when the injury exceeds 25% of total body surface area (TBSA).[10]

Mechanisms of Burn Edema

Burn injury causes direct and indirect mediator-modulated changes in the capillary integrity leading to increases in protein and water permeability.[11] Circulating endogenous mediators play

KEY POINTS

1. Hemodynamics in the early phase of severe burn injury are characterized by a reduction in cardiac output, increased systemic and pulmonary vascular resistance with or without pulmonary edema. Approximately 3–5 days after major burn injury, a hyperdynamic and hypermetabolic state is seen with tachycardia, increased stroke volume, hyperthermia and increased protein catabolism.
2. Patients with severe burn injury often suffer from nonthermal traumatic injuries. Failure to diagnose these associated injuries during initial evaluation can lead to serious morbidity and mortality. All burn patients should be approached initially as multiple-trauma patients.
3. Inhalation injury is a major source of mortality in burn patients. If the history and physical examination are suggestive of inhalation injury one should have a low threshold for early intubation.
4. Multiple fluid resuscitation formulae exist for estimating fluid needs differing somewhat in their recommendations of the amount of crystalloid and colloid. The Parkland formula, one of the most popular, uses 4 cc per %TBSA (percent total body surface area) burn per kg administered over the first 24 hours with one-half of the calculated volume administered during the first 8 postinjury hours. The remaining half is administered over the next 16 hours.
5. The magnitude of burns is classified according to the total body surface area (TBSA) involved, depth of the burn, and the presence or absence of inhalational injury. TBSA burned in adults can be estimated using the "rule of nines," an age-specific diagram, or by estimation using palmar surface of the hand.
6. Prophylactic antibiotics have no proven role in burn care and are not routinely given. All burn injuries are potentially contaminated soft-tissue wounds, and therefore tetanus toxoid should be given to all burned patients.
7. Electrical burns can have acute and chronic effects not seen with other types of burn injury, and with morbidity much higher than expected based on burn size alone. High-voltage injuries are typically associated with loss of consciousness, arrhythmias, myoglobinuria, and extensive deep tissue damage that can result in compartment syndromes. However, significant injury can result from low- and mid-range voltage sources.

pivotal roles in the pathogenesis of edema formation and the cardiovascular abnormalities associated with burn injury. These mediators alter vascular permeability directly and/or indirectly by increasing microvascular hydrostatic pressure or surface area via arteriolar vasodilatation. Because of the multiplicity of mediators, therapy to antagonize one single mediator (e.g., histamine) has not proved successful.

Hypermetabolic Response to Burns

Severe burn injury results in a hypermetabolic response that is more severe and sustained than any other form of trauma.[12] The resting metabolic rate ranges from near normal with burns <10% TBSA to twice normal in burns >40% TBSA.[13,14] The early phase of burn injury (first 1–2 days) is characterized by decreased cardiac output, and metabolic rate. Cardiac output and metabolic rate increase over time plateauing around postburn day 5. This increase in metabolism in association with muscle catabolism lasts through the convalescent period—even as long as 12 months postinjury in patients with major burns.[15] As a result, lean muscle mass continues to decrease with a negative nitrogen balance despite aggressive nutritional support. This is concerning as loss of a quarter of total body nitrogen balance can be fatal and this limit can easily be reached within 3–4 weeks in burn patients who are not receiving maximal nutritional support.[16] Nutritional support, even with exogenous insulin, cannot, in isolation, prevent or reverse the catabolic response to burn injury.

HEMODYNAMIC RESPONSE TO BURNS

Altered Cardiac Output

There is an immediate depression of cardiac output even before any detectable reduction in plasma volume. This rapid depression suggests a neurogenic response and/or increased circulating mediators. Soon after, the hypovolemia contributes to the depressed cardiac output. The persistence of reduced cardiac output with repletion of fluid volume has been attributed to circulating myocardial depressant factors.[17–20] In addition, decreased adrenoreceptor affinity and second-messenger function may result in an attenuated response to catecholamines.[21,22] Approximately 3–5 days after major burn injury, supranormal cardiac output (sometimes more than double) is seen. This correlates with the onset of the hypermetabolic state.

Increased Systemic Vascular Resistance

Sympathetic stimulation and hypovolemia related to burn injury result in release of catecholamines, vasopressin, angiotensin II, and neuropeptide Y, leading to increased vasoconstriction and SVR.[8] Increased SVR immediately after burn injury is also partly the result of increased blood viscosity secondary to hemoconcentration. Organs particularly susceptible to ischemia and dysfunction secondary to inadequate resuscitation and vasoconstriction are the kidneys and gastrointestinal (GI) tract. Myoglobinemia as a consequence of muscle destruction can also contribute to the renal injury.[23,24] Sustained vasoconstriction of the GI tract can occur even with adequate resuscitation leading to ischemia and bacterial translocation.[25,26]

Pulmonary Edema

There is an increase in pulmonary vascular resistance (PVR) following major burns. Pulmonary edema may occur, especially after the fluid resuscitation phase and restoration of capillary integrity (48–72 hours after burn injury), when the edema fluid is reabsorbed leading to hypervolemia. Initially the edema results mainly from increased capillary pressure secondary to increased PVR. Pulmonary capillary wedge pressure is increased greater than left atrial pressure after experimental burn injury caused by postcapillary venoconstriction.[27] It is likely that some left-heart failure also contributes to the pulmonary edema. Developing hypoproteinemia may be an important contributing factor for postburn pulmonary edema.[27] Pulmonary dysfunction from inhalation injury may also occur.

INITIAL EVALUATION

Primary Survey

Between 5% and 7% of patients admitted to burn centers suffer from nonthermal traumatic injuries.[28] Because failure to diagnose these associated injuries during the initial evaluation can lead to unnecessary morbidity and mortality, all burn patients should be approached initially as multiple-trauma patients.

Securing the airway is the first priority during the initial evaluation; safe airway management begins with its assessment. The presence of airway injury, signs of airway obstruction and presence of preexisting airway abnormality should be assessed as soon as the patient arrives at the hospital. Airway injuries may not be evident initially but with massive fluid resuscitation airway edema may result. As a general rule it is safer to intubate the patient early than risk a difficult intubation after airway swelling has occurred. With injuries of the face or neck, direct laryngoscopy may be difficult or impossible. When the upper airway is severely damaged and the laryngoscopy and endotracheal intubation are anticipated to be difficult, a direct surgical approach to the airway may be indicated. Options include a cricothyroidotomy or tracheostomy.

INHALATION INJURY

Inhalation injury increases the resuscitation fluid requirements by up to 50% and is a major source of mortality in burn patients.[29] A history of exposure to fire in a closed space, loss of consciousness, and presence of chemical irritants in combination with the physical examination revealing carbonaceous sputum, and singed nasal or facial hair are all suggestive of inhalational injury. Chest radiographs are usually normal until secondary complications, such as atelectasis or pneumonia, develop. Fiberoptic bronchoscopy may be used to support the diagnosis, which may reveal carbonaceous debris, erythema, or ulceration.[30] The mechanism of inhalation injury consists of a combination of (a) direct thermal injury to the upper airway from inhalation of hot gases, (b) damage to the cellular and oxygen transport processes by inhalation of carbon monoxide and cyanide, (c) chemical injury to the lower airways caused by inhalation of the toxic products from the fire.[31]

Direct Injury to the Upper Airway

Direct heat injury to the airway usually only occurs to the depth of the carina because of efficient dissipation

of heat by the upper airway, low specific heat of air, and reflex closure of the glottis as a result of the irritant. Direct heat injury to the upper airway can lead to marked swelling of the tongue, epiglottis, and glottic opening, resulting in airway obstruction.[31] Because airway swelling may not occur immediately but may develop over a period of hours (especially with concurrent fluid resuscitation), a high index of suspicion and frequent reevaluations are essential. Upper airway edema will have more immediate consequences in smaller children. Signs of impending upper airway obstruction include hoarseness, retractions and stridor. If the history and physical examination are suggestive of inhalational injury, one should have a low threshold for early intubation, particularly in children. If intubation is delayed and significant swelling occurs, intubation can become difficult or impossible. Upper airway edema usually resolves in 3–6 days and is facilitated by elevation of the head of the bed and avoidance of excessive fluid administration.

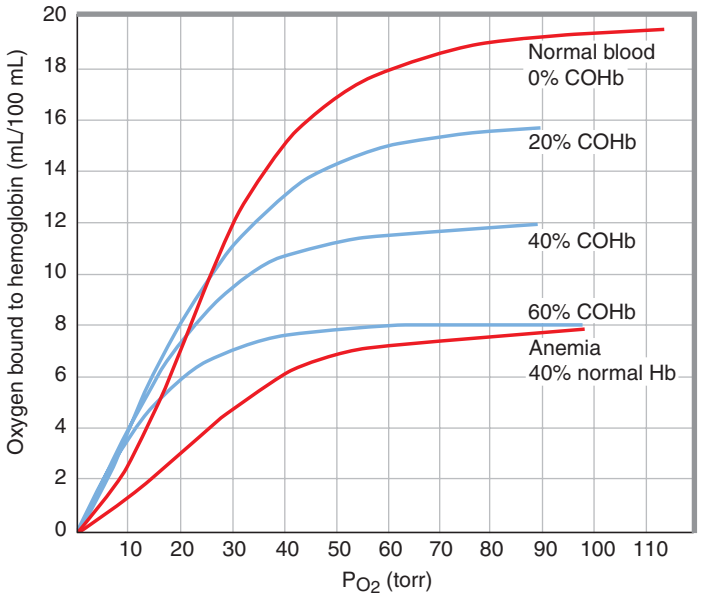

FIGURE 77–1. Carboxyhemoglobin dissociation curve. The changes in the oxygen–hemoglobin dissociation curve that occur with carbon monoxide poisoning. The oxygen bound to hemoglobin is decreased depending on the CO concentration and oxygen–hemoglobin dissociation curve is shifted to the left, resulting in less oxygen being delivered to tissues and the oxygen carried by hemoglobin being more tightly bound. (Reproduced with permission from McCall J, Cahill T. Respiratory care of the burn patient. J Burn Care Rehab 2005;26:200–206.)

Carbon Monoxide Poisoning

Carbon monoxide (CO) causes tissue hypoxia; the oxygen-carrying capacity of blood is decreased because both CO and oxygen compete for the same binding sites on hemoglobin (Hgb). Because CO binds to Hgb 200 times more readily than oxygen, it can significantly reduce the oxygen carrying capacity of blood.[32] Binding of CO to Hgb also shifts the oxyhemoglobin dissociation curve to the left and alters its shape (Fig. 77–1). In addition, CO interferes with peripheral oxygen use by binding to molecules such as myoglobin, nicotinamide adenine dinucleotide phosphate reductase, and cytochrome oxidase system, resulting in impaired oxidative phosphorylation at the mitochondrial level.[33] The mitochondrial dysfunction caused by CO has been best documented in the heart where it has been shown to produce myocardial stunning.[34] The consequence of these changes is decreased oxygen delivery to the tissues, impaired release of the available oxygen at the capillaries, and weakened ability to use the delivered oxygen resulting in tissue hypoxia and metabolic acidosis.

CO poisoning can be difficult to detect. CO is an odorless, tasteless, nonirritating gas. The clinical findings of CO poisoning are variable and largely nonspecific. Clinical signs and symptoms of tissue hypoxia as a result of CO poisoning include headache, nausea, shortness of breath, tachypnea, angina, and changes in mental status.[35] The half-life of carboxyhemoglobin is 4 hours for a person breathing room air. This is reduced to 40–60 minutes when breathing 100% oxygen. Hyperbaric oxygen will further reduce the half-life of carboxyhemoglobin to 23 minutes.[36] In those patients with more severe exposures (carboxyhemoglobin level greater than 30% or evidence of neurologic changes), hyperbaric oxygen has been suggested to diminish the incidence of long-term neurologic sequelae.[37,38] Unfortunately, hyperbaric oxygen chambers are not uniformly available.

The absorbance spectrum of carboxyhemoglobin and oxyhemoglobin are similar therefore standard pulse oximeters cannot distinguish between the two forms of hemoglobin. Consequently, oximeter readings will be normal even when lethal amounts of carboxyhemoglobin are present in blood.[39] The Pao_2 measured from arterial blood gas sample reflects the amount of oxygen dissolved in blood and does not indicate oxygen bound to hemoglobin (saturation). Thus the Pao_2 can be normal even with high levels of carboxyhemoglobin. The diagnosis of CO poisoning is made by measuring the carboxyhemoglobin level in arterial blood, expressed as a percent saturation of hemoglobin. Carboxyhemoglobin levels >15% are toxic; those exceeding 50% are lethal.[40] Because of the inevitable time delay between exposure and testing, the levels of carboxyhemoglobin measured may not reflect the true extent of poisoning especially when the patient has been breathing a high concentration of oxygen.

Cyanide Poisoning

Hydrogen cyanide is a toxic gas produced in fires by the burning of nitrogenous materials, including natural fibers (wool and silk) and synthetic polymers (polyurethane, polyacrylonitrile, and acrocyanate). Cyanide binds to mitochondrial cytochrome oxidase, which catalyzes the last step in the oxidative phosphorylation (adenosine triphosphate [ATP] formation) pathway, preventing use of oxygen by mitochondria. Cyanide also arrests the tricarboxylic acid cycle. The pathophysiologic sequel of cyanide poisoning is that cells can only generate ATP via anaerobic metabolism, which re-

sults in a metabolic acidosis from lactic acid production.

As with CO poisoning, cyanide toxicity can be difficult to diagnose. Cyanide toxicity should be suspected in any patient with a history of inhalation injury. Concentrations greater than 20 ppm are considered dangerous. Early symptoms include headache, dizziness, tachypnea, and tachycardia. Cardiac toxicity may manifest as ST-segment elevation on electrocardiogram (ECG), which can mimic an acute myocardial infarction. Cyanide increases minute ventilation through carotid body and peripheral chemoreceptor stimulation. Concentrations of 100 ppm can lead to seizures, coma, respiratory failure, and death.[41] Laboratory findings include an anion gap metabolic acidosis that does not respond to oxygen administration. The mixed venous oxygen saturation in cyanide poisoning is often elevated, suggesting inability to use oxygen.[42,43] Direct detection of cyanide poisoning in blood is difficult. Cyanide has a short half-life in blood and measurement is not universally available.

The treatment of cyanide toxicity has generated controversy as treatment may in itself be hazardous. The deleterious effects of cyanide are normally neutralized by the conversion of cyanide to thiocyanate, which is excreted in the urine. This can be enhanced by the administration of exogenous thiosulfate.[44] Cyanide can also combine with hydroxocobalamin (vitamin B_{12}), which forms cyanocobalamin. Nitrate administration results in the oxidation of hemoglobin to methemoglobin which can combine with cyanide to form cyanomethemoglobin. Methemoglobin, however, does not transport oxygen and may thus be harmful in a patient whose oxygen carrying capacity is already compromised because of carboxyhemoglobin.[45]

Chemical Injury to the Lower Airways

The burning of many materials in a house fire can release combustion products that are toxic and damaging to the lower airways, including respiratory epithelium and capillary endothelium of the airway and alveoli. The damage to epithelium results in destruction of mucociliary transport which impairs clearance of bacteria and mucosal debris. Alveolar collapse and atelectasis can occur because of loss of surfactant production or from plugging because of mucus debris.[46] Chemical damage to alveoli and its capillaries will lead to extravasation of plasma protein. Activation of injury-induced alveolar macrophages will lead to further inflammatory response and damage. Bronchial swelling and bronchospasm can lead to obstruction of both large and small airways. The end result is respiratory failure from increased ventilation–perfusion mismatch, decreased lung compliance, and increased dead-space ventilation, generally occurring 12–48 hours after the inhalation event.[31] The respiratory failure may further worsen several days later from continued airway mucosal sloughing, barotrauma, bacterial invasion, and pneumonia.[47,48]

INDIRECT RESPIRATORY INJURY

Injury to the lung can occur in patients with severe cutaneous burns in the absence of inhalational injury.[49,50] Mechanisms include inflammatory mediators from the burn-injured area, effects of fluid resuscitation, and infection. Pulmonary edema often occurs after a large burn injury as a result of decreased oncotic pressure and increase in pulmonary hypertension. After restoration of the capillary integrity, the edema fluid from throughout the body is resorbed and can lead to hypervolemic pulmonary edema.

FLUID RESUSCITATION

In 1930, Underhill first described "burn shock" that results from intravascular fluid loss as a cause of early death.[51] The appreciation of the exaggerated fluid requirements of burn patients and formulae for their estimation subsequently evolved. Multiple fluid resuscitation formulae exist for estimating fluid needs (Table 77–1). As a general rule, burns of <15% TBSA are not associated with extensive capillary leak and can be managed with fluid of 1.5 times maintenance rate and careful attention to their hydration status.

The commonly used resuscitation formulae differ somewhat in their recommendations of the amount of crystalloid and colloid. Most formulae recommend isotonic crystalloid initially and later use of colloids.[52] The times at which colloid administration is initiated varies from institution to institution, on the size of the burn, patient age, and other cardiorespiratory parameters. Lactated Ringer solution is often the crystalloid chosen as it contains physiologic concentrations of major electrolytes and lactate replaces some of the chloride in the solution, resulting in less hyperchloremic metabolic acidosis. In younger children and in patients where hypoglycemia is a potential concern, 5% dextrose solution can be added to the lactated Ringer solution.

Once capillary integrity returns, generally within 24–48 hours, most resuscitation formulae recommend administration of colloid. Most authorities advocate 5% albumin in isotonic crystalloid, which is ideally administered by continuous infusion at a dose adjusted by burn size. Some clinicians advocate use of fresh-frozen plasma but it is better used to correct significant coagulopathy as it has the added risks of transfusion. Side effects of

TABLE 77–1.

Formulae for Estimating Burn Resuscitation Fluid Needs

Crystalloid formulas		
Parkland	Lactated Ringer	4 mL/kg/%TBSA burn
Modified Brooke	Lactated Ringer	2 mL/kg/%TBSA burn
Colloid formulas		
Evans	Normal Saline	4 mL/kg/%TBSA burn
	Colloid	1 mL/kg/%TBSA burn
	5% Dextrose	2000 mL/24 h
Brooke	Lactated Ringer	1.5 mL/kg/%TBSA burn
	Colloid	0.5 mL/kg/%TBSA burn
	5% Dextrose	2000 mL/24 h

TBSA, total body surface area.

large-volume crystalloid resuscitation include pleural and pericardial effusions and intestinal ileus with abdominal compartment syndrome. Thus more burn units are advocating early use of colloids.

Hypertonic saline has been advocated for resuscitation in burn injury, especially for patients with large burns, inhalational injury, or circumferential burns, because the administered fluid volume is smaller and tissue edema is reduced.[53] However, in one study comparing hypertonic saline to lactated Ringer solution for resuscitation, there was a significant increase in renal failure and deaths in the hypertonic saline group.[54] Consequently, resuscitation with hypertonic saline is not part of most burn units' practice.

The Parkland formula remains the most widely used resuscitation formula for burn injury in the United States. The Parkland formula, 4 mL per %TBSA burn per kg, is administered over the first 24 hours with one-half of the calculated volume administered during the first 8 postinjury hours.[55] The remaining half is administered over the next 16 hours. If resuscitation is delayed, this volume is administered so that infusion is completed by the 8th postinjury hour. No matter which formula is used, it should serve only as a guideline and fluid resuscitation titrated to physiologic end points (see Table 77–4). Actual fluid requirements can vary, depending on size of the burn, patient's weight, interval from injury to start of resuscitation, presence of associated injuries, and presence of inhalational injury.

Cardiac index and oxygen delivery have been investigated as end points to guide fluid resuscitation.[56,57] Bernard et al. showed that patients who survived large burns had higher cardiac index and better oxygen delivery than did nonsurvivors.[58] Subsequently, some investigators proposed supranormal oxygen delivery as a means of ensuring adequate tissue delivery. Schiller et al. demonstrated improved survival in burn patients by maintaining hyperdynamic circulation using fluids and inotropes.[57] However, the literature on achieving supranormal cardiac output and oxygen delivery has failed to consistently show an improvement in survival or decrease in organ failure. One study, which used dobutamine to augment cardiac output and oxygen delivery, demonstrated increased mortality.[59]

Blood lactate and base deficit have been proposed as global markers of oxygen delivery and tissue perfusion in burn patients.[60,61] Lactic acid is produced during anaerobic metabolism and indicates inadequate oxygen delivery or use. Holm et al. found lactate level to be the most predictive index of tissue perfusion. Lactate levels < 2 mmol/L in the first 24–48 hours after burn injury correlated with improved survival.[62] Base deficit is another indicator of global tissue perfusion and is calculated from an arterial blood gas using normograms. In a retrospective study in burn patients, Kaups showed the base deficit was predictive of fluid requirements and survival.[63]

In burn injury, when tissue perfusion is not uniform throughout the body, an indirect measure of less-well-perfused tissues may prove useful. One such measure that has been described is the intramucosal gastric pH, as measured by gastric tonometry. After burn injury blood flow to the heart, brain, and kidneys is maintained at the expense of splanchnic blood flow. Several studies show that a lower intramucosal pH is predictive of organ failure and increased mortality and have suggested the use of mucosal pH as a guide to resuscitation.[64–66] This technique, however, has not become routine in clinical practice.

A small percentage of patients fail to respond to conventional fluid resuscitation. These patients frequently have large, deep burns, are at extremes of age, and have inhalational injury or coexisting medical conditions.[67] If the total fluid requirement exceeds 6 mL/kg/%TBSA/24 h, it is advisable to obtain more information regarding intravascular volume. This information can be obtained by physical exam or by measurement of central venous pressure and/or pulmonary artery pressure. Based on the information, inotropic support may be required. Echocardiographic evaluation of ventricular volume and function has been used in burns.[68] After 24–48 hours, capillary integrity returns to normal in nonburned areas especially with repletion of circulating volume. At this stage, fluid requirements dramatically decrease; it is important to decrease fluid administration promptly as overzealous administration of fluid can be associated with substantial morbidity.

A great deal of recent interest has focused on the use of antioxidants as adjuncts to fluid resuscitation. Reactive oxygen species generated by thermal injury are involved in edema formation associated with burns. In particular, high-dose vitamin C infusion during resuscitation has been studied in animals and shown to significantly reduce total fluid requirements.[69] Tanaka et al. demonstrated a 45% reduction in required fluid resuscitation using a vitamin C infusion in a small group of patients.[70] Antioxidant usage is not a standard adjunct to resuscitation at this time.

ESTIMATION OF SIZE/DEPTH OF BURN

The magnitude of burns are classified according to the TBSA involved, depth of the burn, and the presence or absence of inhalational injury. TBSA burned in adults can be estimated using the "rule of nines" (Fig. 77–2). The Lund Browder chart is an age-specific diagram that accounts for the changing body surface area with age (Fig. 77–3).[71] Estimation by palmar

FIGURE 77–3. Burn diagram. A careful burn diagram should be completed at the time of initial evaluation including wound size, location, and estimated burn depth.

surface of the hand (without the fingers, 0.5% TBSA) is age invariant and can also provide a quick estimate.[72] The depth of skin destruction is characterized as first-, second-, or third-degree, based on whether there is superficial, partial-thickness, or full-thickness destruction of the skin (Table 77–2). *Fourth degree* is used to describe burns that have injured deeper structures such as muscle, fascia, and bone. Deep second- and third-degree burns require surgical debridement and grafting, whereas more superficial burns do not. Revisions of burn-depth estimations are often necessary in the first 24–72 hours. This is especially true in patients with thin skin, who often sustain deeper burn injuries than may be evident on the initial examination of the wound. Skin can be presumed to be thin in young children and the elderly. Mortality from burn injury is related to the TBSA of deep second-degree or third-degree burns. A recent large analysis revealed three risk factors as predictive for death after burns: age older than 60 years, burn size greater than 40% body surface area, and inhalation injury. Mortality is a function of the number of risk factors present. The mortality was 0.3, 3, 33, or 90% depending on whether 0, 1, 2, or 3 risk factors were present, respectively.[73]

BURN CENTER REFERRAL

Data exist linking improved outcomes from major burns with early referral to a burn center.[74] It is recognized that

TABLE 77–2.

Classification of Burn Depth

Depth	Level of Injury	Clinical Features	Result/Treatment
Superficial	Epidermis	Dry, red; blanches; painful	Healing time 3–6 days
Superficial partial thickness	Papillary dermis	Blisters; moist, red, weeping; blanches; painful	Cleaning; topical agent; sterile dressing; healing time 7–12 days; hypertrophic scare rare; return of full function
Deep partial thickness	Reticular dermis	Blisters; wet or waxy dry; does not blanch; absent pain sensation	Treatment as for superficial partial-thickness burns; possible surgical excision and grafting; hypertrophic scar common; earlier return of function with surgery
Full thickness	Subcutaneous fat, fascia, muscle, or bone	Waxy white to leathery dry and inelastic; does not blanch; absent pain sensation	Treatment as for superficial partial-thickness burns plus surgical excision and grafting at earliest possible time; functional limitation more common

burn care requires specialized expertise, personnel, and equipment that are not cost-effectively maintained in low-volume centers. Table 77–3 lists the criteria for referral to a regional burn center.

SECONDARY SURVEY

The burn-specific secondary survey complements the trauma secondary survey and focuses on aspects of the neurologic, otolaryngologic, ophthalmic, chest, cardiac, abdomen, genitourinary, and extremity issues as related to patients with acute burn injury.

Neurologic

Central nervous system function (CNS) can be altered by inhalation of neurotoxic chemicals, effects of hypoxia and hypotension, and from the effects of anxiety and pain or their treatment. Signs of CNS dysfunction include delirium, hallucinations, personality changes, seizures, and coma. It is essential to rule out coexisting intracranial injury by history, clinical examination, and radiologic imaging. Patients with serious injuries commonly become obtunded because of hemodynamic instability as well as from the administration of drugs for sedation and analgesia, making it important to know that this change does not represent a missed intracranial injury. The need for radiologic evaluation of the neck is based on mechanism of injury. In rare instances, patients with deep neck burns may need escharotomies at that site to facilitate venous drainage.

Ear, Nose, Throat, and Eye

The primary otolaryngologic and ophthalmic evaluation includes assessment and initial treatment of burns to the airway, corneal epithelium, and the external ear. Signs of airway involvement include perioral and oropharyngeal burns, presence of carbonaceous sputum and signs of hoarseness. Hot liquid can be aspirated in conjunction with a scald injury to the face and can result in rapid airway compromise. One should have a low threshold for intubation when potential airway involvement exists. The globes of the eye should be examined early because adnexal swelling can make the examination difficult. Severe corneal burns are usually obvious by the cloudy appearance they impart, but less severe injury to the cornea is more often subtle requiring fluorescein staining. Topical antibiotics are the initial treatment if an injury is present. Burns to the external ear can be complicated by suppurative chondritis. Treatment with topical mafenide acetate cream may decrease its development.[75]

Chest

The focus of the initial evaluation of the chest is to ensure chest wall compliance of both hemithoraces. Impaired chest wall compliance can result from deep circumferential eschar impairing chest wall excursion and/or bronchospasm resulting from inhalation of airway irritants. The inhalation of toxic fumes may precipitate a bronchospastic attack in a patient with a previous history of asthma. A patient with decreased compliance because of a circumferential eschar will exhibit rapid shallow respirations. A patient requiring mechanical ventilation will show an increase in peak airway pressures. Escharotomy is the treatment of choice for the latter condition whereas bronchodilators, pulmonary toilet, and ventilation strategies to minimize breath stacking are used to treat bronchospasm. Severe inhalational injury may result in thick secretions and the sloughing of airway mucosa, which can occlude the endotracheal tube or distant bronchi resulting in atelectasis and collapse. In these instances, suctioning and bronchoscopy may be required.

Cardiac

If adequate intravascular volume and oxygenation are maintained and electrolyte abnormalities corrected, significant arrhythmias are unusual in otherwise healthy patients. Coexisting cardiac disease can result in the resuscitation and acute care being less well tolerated. Direct myocardial injury and arrhythmias resulting from electrical injury are discussed in Special Situations: Electrical Injuries below.

Abdomen

Primary objectives in the evaluation of the abdomen are to exclude associated injuries, ensure adequate compliance to permit ventilation, and decrease the risk of gastric dilation and gastrointestinal ulceration. Coincident abdominal trauma should be evaluated with imaging studies or diagnostic peritoneal lavage if indicated. Occult abdominal trauma can explain excessive fluid resuscitation requirements or a paradoxical fall in hematocrit in the early phase of burn injury. In some cases, torso escharotomies may

TABLE 77–3.

American Burn Association Burn Center Transfer Criteria

- Second and third degree burns on >10% of total body surface area (TBSA) in patients under 10 or over 50 years of age.
- Second and third degree burns on >20% of TBSA in other age groups
- Second and third degree burns that involve the face, hands, feet, genitalia, perineum, and major joints
- Third degree burns on >5% TBSA in any age group
- Electrical burns including lightning injury
- Chemical burns
- Inhalation injury
- Burn injury in patients with pre-existing medical disorders that could complicate management, prolong recovery, or affect mortality
- Any patients with burns and concomitant trauma (such as fractures) in which the burn injury poses the greatest risk of morbidity or mortality; in such cases, if the trauma poses the greater immediate risk, the patent may be treated initially in a trauma center until stable before bing transferred to a burn center; physician judgment will be necessary in such situations and should be in concert with the regional medical control plan and triage protocols
- Hospitals without qualified personnel or equipment for the care of children should transfer children with burns to a burn center with these capabilities
- Burn injury in patients who will require special social/emotional and/or long-term rehabilitative support, including cases involving suspected child abuse and substance abuse

be necessary to facilitate spontaneous respiration or mechanical ventilation in patients with deep circumferential eschars. Circumferential abdominal eschar, accumulation of intraperitoneal fluid, or bowel edema can lead to abdominal compartment syndrome, which leads to diminished urine output, decreased pulmonary compliance, and hemodynamic instability.[76] Obtaining bladder pressure measurements can be useful in the diagnosis.[77] In some cases, abdominal decompression may be necessary.

Patients with severe burns often develop a paralytic ileus and require nasogastric decompression for varying lengths of time. Gastroduodenal ulceration, likely due to reduced splanchnic blood flow, is a risk in severe burn injury and ulcer prophylaxis with H_2 receptor antagonists or proton pump inhibitors should be initiated as early as possible.

Genitourinary

Catheterization of the bladder is important in patients with moderate to severe burns who require intravenous fluid resuscitation, because it facilitates the use of urine volume as a indicator of adequacy of resuscitation. Soft-tissue swelling in the genital area can be significant with severe burn injury whether or not the burn involves the genital region. This can make urinary catheterization more difficult as time passes in the acute resuscitation phase. For this reason an appropriate-size Foley catheter should be inserted as early as possible. In males it is important to ensure that the foreskin is reduced over the urinary catheter after its insertion to prevent the development of paraphimosis as soft-tissue edema develops.[78]

Extremities

Exclusion of associated (nonburn) injuries and monitoring of peripheral perfusion are the initial priorities in evaluation of the extremities. Careful clinical examination and radiologic imaging, if necessary, should be preformed. Extremity perfusion can be compromised by soft-tissue swelling in the noncompliant fascial compartments or by a circumferential eschar.

Extremities that are at risk for ischemia, especially in those with circumferential burns or with electrical injury, should be monitored closely for tense fascial compartments and signs of impaired perfusion. Frequent checks of pulses, capillary filling, venous congestion, and Doppler blood flow are important. Dressings should be loosely applied to facilitate frequent examination. Tense extremities should be decompressed by escharotomy and/or fasciotomy when clinical examination reveals signs of impaired perfusion. Escharotomies can be performed at the bedside with use of electrocautery to minimize blood loss. The need for escharotomy usually becomes apparent in the early hours of acute resuscitation. Fasciotomies are generally performed in the operating room so as to minimize damage to the underlying structures that can be obscured by the tissue edema.

ANTIBIOTICS

Prophylactic antibiotics have no proven role in burn care and are not routinely given.[79] All burn injuries are potentially contaminated soft-tissue wounds, and therefore tetanus toxoid should be given to all burned patients.[80,81] If the patient has not been previously immunized, tetanus immunoglobulin as well as tetanus toxoid should be administered.

PEDIATRIC CONSIDERATIONS

Children suffering burn injuries have unique physiologic, medical, surgical, and psychosocial issues requiring additional considerations. Younger children are at higher risk of burn injury and up to 20% of their injuries are a result of abuse or neglect.[82] Approximately 70% of pediatric burns are caused by hot liquid, whereas flame burns are more common in working-age adults.[83]

Airway and respiratory considerations in children include the smaller airway, which can rapidly occlude with airway edema and swelling. In pediatric patients with scald injury, respiratory failure can occur during and after fluid resuscitation, even in the absence of inhalational injury.[50] Stridor and retractions should be taken as signs of airway compromise and need for intubation. The trachea in children is shorter and small changes in endotracheal tube positioning are more likely to lead to bronchial intubation. Bronchospasm, common in children suffering inhalational injury, should be treated early and aggressively. Fluid considerations include greater susceptibility to fluid overload, especially in young children, particularly if all administered fluids (flush solutions, medications, carrier fluids) are not taken into account. The kidneys of young infants have less concentrating ability. They are particularly susceptible to cerebral edema if they become hyponatremic, which can result in seizures or brain herniation.[84]

GERIATRIC CONSIDERATIONS

Caring for geriatric patients with burn injuries requires consideration of their

unique issues and needs. Burn injury in elderly patients is more likely the result of impaired dexterity or mobility and may indicate the inability to live independently.[85] Older patients do not have the physiologic reserve of the young. Coexisting cardiac and pulmonary disease can result in resuscitation and acute burn care being less-well tolerated. Preexisting renal disease can result in greater sensitivity to nephrotoxic drugs and hypotensive episodes. Resuscitation should be considered carefully in elderly patients with large burn injuries, especially in the presence of inhalation injury, as mortality can reach 90%.[73] Advanced directives, healthcare proxies, and families should be consulted as early as possible. Nutritional requirements are less-well-predicted by standard equations.[86] The skin of elderly patients is thinner and is therefore more susceptible to deeper burn injury. In addition, harvesting of donor skin repeatedly may not be possible because of poor healing. Finally, elderly patients may live alone or have a spouse who is unable to provide the care needed after discharge, including wound care, transportation, and support.

SPECIAL SITUATIONS

Electrical Injuries

Electrical burns can have acute and chronic effects not seen with other types of burn injury, and with morbidity much higher than expected based on burn size alone.[87]

Electrical burns are classified as high-voltage (>1000 V) or low-voltage (<1000 V) injuries. High-voltage injuries are typically associated with loss of consciousness, arrhythmias, myoglobinuria, and extensive deep tissue damage that can result in compartment syndromes. However, significant injury can result with low- and mid-range voltage sources.

Approximately 15% of patients who sustain electrical injury suffer other traumatic injury in addition to their burn.[88] These injuries often involve falls, being thrown against an object, or result from tetanic muscle contractions.

Both arrhythmias and direct myocardial injury can result from electrical injury. Creatine kinase and creatine kinase myocardial band enzymes are poor indicators of myocardial injury in the absence of ECG findings, particularly if muscle injury is present.[89] The diagnostic value of cardiac troponin levels has not been evaluated in this setting. The myocardial injury behaves more like a cardiac contusion than a myocardial infarction, with minimal hemodynamic consequences. This may be related to the fact that the heart, unlike the skeletal muscle cannot sustain tetanic contractions. Virtually any cardiac arrhythmia may be associated with electrical injury. Ventricular fibrillation is the most common cause of death at the scene of the injury. Arrhythmias from electrical injury are managed using the same medical therapies as those resulting from any other cause. Patients with electrical injury should have ECG monitoring during transport to the hospital, in the emergency room, and afterwards. Indications for more prolonged cardiac monitoring include (a) documented cardiac arrest, (b) cardiac arrhythmia on transport or in the emergency department, and (c) an abnormal ECG.[90,91]

The hidden (deeper) injury associated with electrical burn makes the standard fluid resuscitation formulae inaccurate. Adequate fluid resuscitation is achieved by reaching the standard resuscitation end points (Table 77–4).

Myoglobinuria as a result of muscle damage will manifest as pigmented urine and usually indicates more severe muscular damage. Myoglobin and hemoglobin pigments pose risk for acute renal failure and require prompt treatment with crystalloid loading to a target urine output of 2 mL/kg/h. Addition of sodium bicarbonate to intravenous fluid may facilitate pigment clearance and minimize renal injury. Mannitol and furosemide are also effective in promoting a prompt diuresis, but compromises the value of urine output as an indicator of adequacy of resuscitation.

Chemical Burns

Although only 3% of all burns are caused by chemical exposures, approximately 30% of burn deaths are as a consequence of chemical injuries.[92] The range of chemical injuries is vast. However, an understanding of general principles of treatment is essential to those caring for patients with these injuries. First aid begins with removing the offending agent from contact with the patient. This involves removing all clothing and removal (dusting off) of any powder. It is important for healthcare personnel to protect themselves from injury by wearing gloves and aprons. Copious irrigations with tap water should be performed for at least 30 minutes. Because alkaline substances are less soluble in water, longer irrigation times may be required.

TABLE 77–4.

Burn Resuscitation End Points

Arousable and comfortable
Warm extremities
Systolic blood pressure: for infants 60 mm Hg; for older children, 70–90 + 2 × age (in years) mm Hg; for adults, mean arterial pressure >65 or within 20% of baseline
Heart rate 80–150 beats/min (age dependent)
Urine output 0.5–2 mL/kg/h (glucose negative)
Base deficit <2 mEq/L

The large-volume lavage required to dilute chemical exposures can lead to hypothermia because of conductive and evaporative cooling particularly from unwarmed irrigation fluid. Recognition of this potential complication is essential for its avoidance.

Litmus paper can be used to verify the completeness of irrigation of acid or alkali. There is no role for neutralization of acid or alkali burns because such reactions generate heat which can further exacerbate the injury. Because of the wide range of chemicals involved in chemical injuries, consultation with a poison control center should be initiated early, as there may be systemic toxicities in addition to the burn itself.

Cold Injuries

Frostbite is a traumatic injury caused by failure of the normal protective mechanisms to protect against an environment that results in tissue temperatures falling below freezing. Terminology to describe cold injuries is not standardized. A number of factors have been associated with development of frostbite, including ethanol consumption, psychiatric disease, smoking, diabetes, fatigue, and extremes of age.[93] Cold injuries are initially managed by rewarming in water warmed to 104°F (40°C).[94] Injured parts are then elevated and protected from further injury. Topical wound care is performed until area of necrotic tissue is demarcated. Nonviable tissue is excised and reconstruction performed with primary closure, grafting or flaps.[95]

Toxic Epidermal Necrolysis

Toxic epidermal necrolysis syndrome (TENS) and Stevens-Johnson syndrome (SJS) are severe exfoliative diseases of the skin and underlying structures caused by immunologic reactions usually triggered by a medication or viral syndrome. Most authorities consider TENS and SJS to be the same disease entity, differing only in total body surface area involved. Cases with less than 10% TBSA involved are labeled as SJS; those with 30% TBSA involvement are labeled as TENS; and cases with between 10% and 30% involvement are labeled as overlap SJS-TENS.[96] The disease consists of cutaneous exfoliation together with varying degrees of mucosal and conjunctival involvement. Mortality for TENS has been reported in the range of 25–80%.[97–99] Because of their expertise in management of patients suffering skin loss from thermal injury, burn centers often provide care for patients with TENS. Treatment consists of airway protection if needed, fluid resuscitation, nutritional support, close monitoring for septic complications, and eye care.[100,101]

Purpura Fulminans

Purpura fulminans is a complication of systemic bacterial infection in which areas of skin and soft tissue become necrotic as a result of microvascular thrombosis, most likely related to dysfunction of the protein C anticoagulant system.[102] It is associated with infection by meningococcus, gram-negative bacilli, staphylococcus, streptococcus, and *Rickettsia* organisms. Involved areas begin with petechiae, which rapidly progresses to hemorrhagic bullae and frank skin necrosis. Management includes fluid resuscitation, treatment with systemic and topical antimicrobials, and prompt wound excision to facilitate control of sepsis.[102,103] The use of anticoagulants, vasodilators, and thrombolytic agents remains controversial.[104]

CHAPTER 78

Evaluation of the Trauma Patient

Edward George, MD, PhD

Providing care to the trauma patient can be one of the most challenging situations encountered by an anesthesiologist. The urgency of the event, often in a setting with little or no advance notice, places special burdens on the care team. Given the unpredictable nature of trauma, the anesthesiologist may be faced with caring for these patients in settings ranging from a level 1 academic hospital center with a complete array of specialists and capabilities, to a small rural hospital, with limited resources, where the anesthesiologist may be the only physician present. Adding to these complexities is the emerging awareness of the special burdens imposed by the scenario of mass casualties. Prior to September 11, 2001, medical centers planned for large traumatic events on the scale of an airline crash at the airport or an industrial accident involving dozens of injured patients arriving over a brief period of time. Now with heightened awareness as a result of events such as the World Trade Tower disasters and the recent events centered around Hurricane Katrina, it is critical that all medical personnel become familiar with the evaluation and care of the trauma patient.

To better understand the challenges of evaluating the trauma patient, it is important to appreciate the evolution of trauma care over the history of modern medicine. While trauma has been a major cause of morbidity throughout history, until quite recently, most progress in the area of trauma care was closely tied to the experience and expertise gained by providing care to the casualties of war. By examining the progress made in these arenas, coupled with the insights gained over the past few decades by investigators in the evaluation and care of the trauma patient, the anesthesiologist will be better positioned to contribute as a member of the trauma team.

Trauma is currently viewed, not as a specific insult to a restricted region of the body but rather as a process or disease, triggered by the traumatic event.[1–3] By appreciating the full nature of trauma and the resultant pathophysiology, the anesthesiologist will be better positioned to participate in the management of the trauma patient. Understanding the complex nature of these patients and the specialized approaches, such as injury severity scoring systems, resuscitation strategies, and organized trauma teams, enables all physicians to better contribute to the care of these patients. Ultimately, the systematic evaluation of the trauma patient will expose the anesthesiologist to the many new areas of investigation currently being undertaken in trauma medicine.

EVOLUTION OF TRAUMA CARE

Trauma remains one of the most common causes of death in modern society.[4] In the history of modern medicine, research and advancement in the care of the trauma patient has lagged well behind developments in other areas of science and technology. To better appreciate the issues underlying this discrepancy in comparison to the great strides made over the past 2 centuries in other areas of medicine, it is important to understand the context under which a large component of trauma research has been conducted.

Many of the significant advances in the care of the trauma patient have evolved from experience gained in the care of the military casualty. The Mexican-American War and the Civil War marked the first major experiences of U.S. military surgeons operating on patients receiving a general anesthetic. The advent of surgical anesthesia using ether and chloroform, discovered less than 2 decades before the war, offered a new opportunity. Surgery could be undertaken, not in the fastest manner possible to minimize the agony inflicted upon the unanesthetized patient, but rather in a manner permitting the surgeon time and an opportunity to perform a more detailed and delicate procedure.[5] This period also marked the development of a casualty evacuation system using ambulances to deliver casualties from the battlefield to the field hospital, the integration of nursing care into the field hospitals, and the use of antiseptics, such as bromine, to reduce the risk of wound infection.

With the advent of trench warfare in World War I came further advances in trauma care. Typed blood transfusions were now being given in field hospitals. Rapid evacuation of the casualty to treatment facilities to initiate care as soon as possible after injury and the dawn of the specialty of reconstructive surgery were a few of the major advances in trauma care that evolved from this conflict.

Advances after World War I, such as the discovery of penicillin and the development of the specialties of hand surgery and blood banking, further impacted the care of the combat casualty.

KEY POINTS

1. The impact of a traumatic injury(s) on the patient must not be considered a discrete injury, but rather a physical insult with the potential for major systemic complications.
2. Over the past decades improvements in trauma care, including the increased number of level 1 Trauma Centers, have contributed to increased patient survival.
3. Acute trauma life support (ATLS) provides a systematic approach to the evaluation and emergent treatment of the trauma patient, and a vital framework for the care of the trauma patient.
4. The inherently chaotic nature of traumatic injury places special burdens on the members of the trauma team, with the anesthesiologist playing a critical role.
5. Hypothermia remains one of the most significant issues to be addressed in the care of the trauma patient, extending from the time of injury through the period of immediate care.
6. Ongoing investigations in areas such as oxygen-transporting blood substitutes, resuscitation strategies, and control of hemorrhage offer possible new therapies for the care of the trauma patient.

Despite these major advances, the inability to treat shock adequately in the field during World War II remained a major cause of mortality in the battlefield casualty. During the Korean War deployment of surgical facilities in forward areas, closer to the front lines, along with the more widespread use of casualty evacuation by helicopter, reduced the delay in the treatment of casualties. New techniques in vascular surgery helped reduce the number of amputated limbs. The concept of the Mobile Army Surgical Hospital (MASH unit) now known as Forward Surgical Teams and Forward Resuscitative Surgical Sites, still remains as the entrance to modern-day battlefield surgical care. The Vietnam War saw greater improvements in the evacuation systems and a new understanding of the need for early resuscitation of the trauma patient. However the underlying physiology regarding respiratory distress syndrome (Da Nang lung) and hemorrhagic shock and resuscitation were still not well understood and these problems remained a major cause of mortality.[6,7]

The period leading up to and including the second Gulf War resulted in greater appreciation of issues impacting the trauma patient. Investigations of resuscitation and pharmacologic treatment for the hemorrhaging patient, and understanding the underlying pathophysiology became areas of active investigation. These investigations herald a new era of collaboration between military and civilian academic centers, perhaps even more robust than those seen during previous major conflicts.[8]

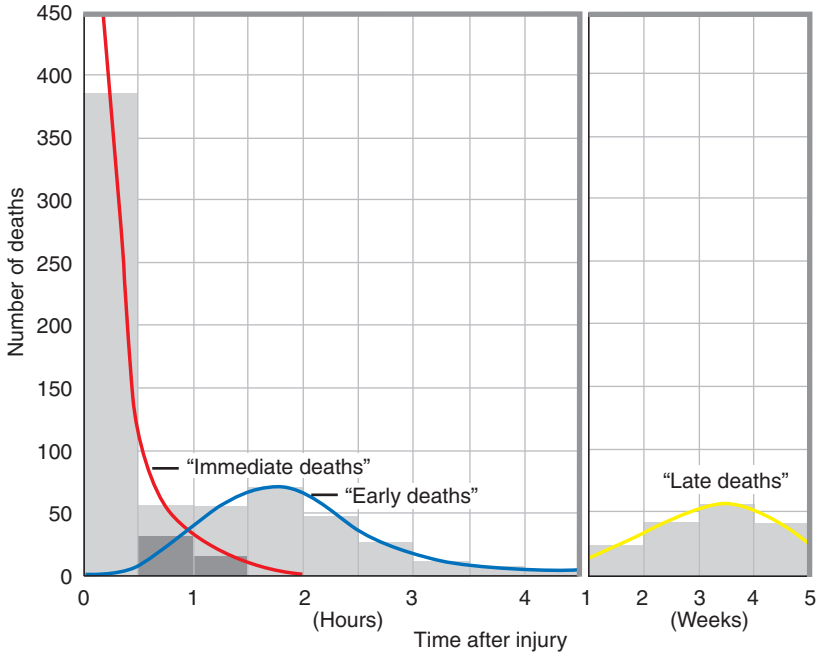

FIGURE 78–1. Trimodal distribution of trauma deaths is observed when the death rate for a large enough sample of such deaths is plotted as a function of time after injury. The first peak (*immediate deaths*) corresponds to people who die very soon after an injury; the deaths in this category are typically caused by lacerations of the brain, the brainstem, the upper spinal cord, the heart, or one of the major blood vessels. The second peak (*early deaths*) corresponds to people who die within the first few hours after an injury; most of these deaths are attributable to major internal hemorrhage or to multiple lesser injuries resulting in severe blood loss. The third peak (*late deaths*) corresponds to people who die days or weeks after an injury; these deaths are usually caused by infection or multiple organ failure. The graph is based on a sample of 862 trauma deaths recorded over a 2-year period by the author's group at San Francisco General Hospital (Trunkey DD, Trauma. Sci Am 1983;249(2):28–35).

NATURE OF TRAUMA

Trauma, both accidental and intentional, is the fourth leading cause of death in the United States.[4] Over the past several decades, death from trauma has been described by a trimodal pattern of distribution (Fig. 78–1), with peaks corresponding to deaths occurring at the time of injury (immediate), within several hours after injury (early), and finally those that occur days to weeks (late) after injury.[9] Deaths in the immediate group are most likely a result of severe injury to the central nervous system, the heart, or a major blood vessel. Early victims have often suffered injuries resulting in internal hemorrhage into the brain, the lungs, or other internal organs. These injuries may be amenable to treatment if the patient arrives in an appropriate facility in a timely manner, where ongoing resuscitation may later transition into more definitive therapy. It is during this "golden hour," the first hour after injury, that these patients are most vulnerable from delays in treatment. The late group is comprised of those patients with multiple injuries, often progressing to multiorgan system failure or death as a result of systemic infection, often occurring over the ensuing several days to weeks. The nature of the treatment facility and the degree of experience of the staff in dealing with victims of major trauma may well impact the survival rate of these patients.[10]

Recent analysis suggests that the original trimodal pattern of trauma deaths may not be uniformly applicable.[11] In the setting of modern-day urban trauma centers, the distribution of death appears bimodal, with late-occurring deaths far less common. This may in part be a result of the trimodal pattern being described in an era prior to the widespread development of major centers focusing on care of the trauma patient. This bimodal pattern suggests that experienced and accessible centers may have a marked positive impact on the survival of the trauma victim.

Although a trauma patient often presents at the hospital with multiple injuries, it important to appreciate that the nature of these injuries may be diverse and present different challenges to the urgent and emergent management of the patient. Injuries caused by trauma are broadly categorized into three main types, as a function of the mechanism of injury. Injuries are penetrating, blunt, or caused by burns, or produced by a combination of these modalities. Injuries can be further subdivided, as in the case of penetrating trauma, along the lines of high energy, such as a gunshot wound, versus lower energy, as in a stabbing. Burn injuries can be subdivided into those caused by chemical agents, flames, or electrical injury. Injuries are often complex and it may be vital to learn that a patient

presenting with several fractures from a motor vehicle accident, in the setting of a prolonged extraction from a burning vehicle, may have inhaled a great deal of smoke during the rescue.

A detailed and systematic method for the evaluation of the trauma patient is discussed in subsequent sections of this chapter. However a generalized description of the various types of injuries aids in the appreciation of the mechanism and forces involved in the traumatic insult. It is also important to appreciate that any categorization is only partially helpful in understanding the underlying forces associated with the various injuries. Trauma patients often present with multiple injuries inflicted by diverse mechanisms, and, as a result may be far more complex in their management than apparent on initial arrival.

Blunt Trauma

A common scenario involving blunt trauma, or circumstances where blunt trauma should be suspected, is a motor vehicle accident. The unrestrained occupants in a vehicle, particularly individuals not afforded protection by an air bag system, may present with blunt injuries to the chest, thorax, abdomen, or any other part of the body. It is important to understand that the outward appearance of the injury, such as a seemingly minor bruise on the abdomen or thorax, may belie the severity of the underlying injury. A minor bruise on the abdomen could signal a lacerated spleen or liver and the faint impression of a steering wheel on the anterior chest wall may signal underlying pulmonary contusions or a deceleration injury of the great vessels. A small contusion on the flank of a blast victim may not at first glance appear to be a serious injury. However in the setting of an attendant tympanic membrane injury or pneumothorax,[12] this injury may suggest a significant degree of force associated with the mechanism of injury and may signal the presence of severe and potentially life-threatening injuries. Additionally blunt trauma can be complicated by problems such as rhabdomyolysis, which are often associated with crushing injuries to the thorax and extremities.

Penetrating Trauma

Whether caused by a high-velocity projectile, such as a rifle bullet, or lower-energy insult such as a knife wound, it is vital to appreciate that the external appearance may mask the extent of the internal injury. In the case of knife wound to the left flank, a small wound, with little visible bleeding may mask a trajectory that injures the bowel, spleen, diaphragm, and heart. Similarly, a small entry wound caused by a gunshot, with no apparent exit wound and scant visible bleeding, may be associated with multiple internal injuries because of internal fragmentation of the projectile.

Burns

Although the care of the burn patient is addressed in detail in other chapters (see Chap. 71), basic issues regarding the challenges of evaluating and caring for the burn victim are briefly addressed here. Thermal injury can result in a severe physiologic impact on the patient, despite the minor outward appearance. Evaluation and care of burn patients require a thorough understanding of the insult caused by the burn; the disruption of the body's ability to maintain a normal fluid balance and the enhanced risk of infection are two areas of major importance. Chemical burns, often requiring specialized debridement, present special risks to the patient and the care team. Inhalation injury caused by smoke or toxic or high temperature gases can be life-threatening in a patient who may otherwise appear unhurt. These patients may be the most challenging to support with mechanical ventilation. Patients with an electrical burn may appear to have a small injury at the sites of contact and exit, yet may have experienced severe damage to internal structures and organs.[13]

PATHOPHYSIOLOGY OF TRAUMA

The physiologic response to trauma is complex and tightly regulated. A detailed discussion of these processes is offered in a separate chapter (see Chap. 70). However an understanding of the range and nature of the involved mechanisms is critical in the evaluation of the trauma patient.

Multiple injuries (polytrauma) in the trauma patient have long been associated with an increased morbidity and mortality. Patients, who survive the initial insult, are subject to a number of physiologic challenges that can induce immunologic and/or host defense responses. Both the initial physiologic challenges, such as hypoxemia, hypotension, fractures, and soft-tissue injuries, as well as subsequent insults because of reperfusion injury, a compartment syndrome, multiple operations, and infections all play a role in this response. The systemic inflammatory response (SIRS) is associated with the release of proinflammatory cytokines, arachidonic acid metabolites, proteins of the contact phase and coagulation systems, hormonal mediators, complement factors, and acute phase proteins.[14] However, in the body's attempts to maintain homeostasis, a parallel mechanism of antiinflammatory mediators is released. This compensatory antiinflammatory response syndrome involves the release of antiinflammatory mediators that serve to quench the initial inflammatory response. T-cell cytokines, such as interleukin (IL)-4, IL-10, and IL-13 are known to modulate monocyte activity. However, defective T cells, released after trauma, may synergize with activated monocytes and contribute to a further deterioration of the patient's clinical condition, impairing the body's ability to fight infection.[15] An imbalance of these two response systems may be an underlying element in the organ dysfunction and increased susceptibility to infections seen after trauma. Over time, endothelial damage, leukocyte accumulation, disruption in the microcirculation, and disseminated intravascular coagulation can lead to widespread apoptosis and necrosis. This can result in multiorgan dysfunction syndrome or multiple organ failure (MOF). While the early use of antiinflammatory agents in the trauma patient has not been encouraging, research into the detailed understanding of the immune response to trauma is providing new insight into the complexities of response with great interest in specific inhibitors of key steps in the cascade.[16] This may also serve to identify individuals at risk for posttraumatic complications and assist in creating early and specific interventions. This cascade of events can be characterized by two distinct mechanisms of cell death: apoptosis and necrosis. A better understanding of these naturally occurring processes may facilitate the development and testing of new therapies for use in the trauma patient.

Apoptosis

Programmed cell death, an energy-dependent mechanism, functions as a normal component of the development of the heart, brain, and the immune system. Regulation of apoptosis occurs at a number of levels and is characterized by DNA cleavage, nuclear condensation, and the degradation of specific proteins. Apoptosis may be initiated by extracellular receptors such as those of the tumor necrosis factor group of receptors, as well as a response to cellular stress, such as free radical generation or degradation secondary to irradiation. A highly ordered process, it is characterized by the presence of unaffected adjacent cells and may serve to isolate damaged from undamaged tissue. Apoptosis may represent an early response to injury and may serve as a trigger to subsequent necrosis.[17]

Necrosis

Typically necrosis is a more disorganized process that is characterized by disruption of intracellular organelles, disruption of nuclear and plasma membranes, and disintegration of nuclear and cytoplasmic structures. The overall degradation is disorganized, in contrast to apoptotic mechanisms, and is associated with the destruction of adjacent tissue. The process of necrosis is a likely response to tissue hypoxia, ischemia, and reperfusion, and may represent a later response to the initial insult of trauma. With advances in resuscitative care, the rapid ability to reverse the effects of shock suggests a possible role in attenuating the process of necrosis in a manner limiting the destruction of potentially compromised tissue to a point that may allow survival.[18]

Cell death and the destruction of tissue ultimately determine mortality. However the impact of trauma effects several systems vital to the potential survival of the victim. Complement activation and the coagulation pathway are systems vital to survival that are markedly altered in the trauma patient.

Complement Activation

A complex system of more than 30 proteins involved in the lysis of pathogens, complement is activated in the earliest phase of trauma. The extent of activation is a function of the severity of the injury. While activation is a vital mechanism of defense against pathogens, inappropriate complement activation may result in excessive tissue destruction. Activated by means of the classical, alternative and lectin pathways, complement activation is an important component of the immune response. Commonly seen as a result of binding to an antigen—IgG or—IgM complex, in the case of the classical pathway, the complement system is also activated by lectins binding to polysaccharide moieties on bacterial surfaces and by the exposure of cytokeratin to ischemic endothelial cells. In contrast to these specific interactions for activation, the alternative pathway uses a spontaneous mechanism of autoactivation. Thus, the alternative pathway represents a continuous complement activation process and, in the setting of impaired regulatory processes,[19] may represent the basis of several autoimmune diseases.

The mechanism of complement activation in the trauma patient is not well understood. While commonly known to be triggered by microbial infection, both the classical and alternative pathways are overactivated in the trauma patient in the absence of bacterial infection. In addition to complement activation during the clotting cascade, additional causes of activation in the setting of tissue injury may include triggering by reactive oxygen metabolites, exposed collagen, and adenosine triphosphate. Mechanisms of activation not withstanding, the potential for over activation results in an inflammatory reaction. This process can be a local phenomenon or it may result in a SIRS, adult respiratory distress syndrome (ARDS), or MOF. Complement activation may be a critical factor in injuries commonly associated with the trauma patient such as ischemia–reperfusion injury, trauma associated ischemia to the myocardium, intestine and central nervous system structures.[20,21] Targeted complement inhibition may provide a means to attenuate underlying issues related to the morbidity and mortality of trauma patients.[16]

Coagulation System

There is a marked physiologic reserve of the factors associated with the coagulation system in the healthy individual. Several issues common to the trauma patient can dramatically compromise coagulation and negatively impact the survival of the victim. While the reserve of coagulation factors in the healthy individual provides a significant buffer in the capacity of the system to correct for hemorrhage, the patient suffering from large scale blood loss as a result of injury is faced with a rapid exhaustion of the factors associated with coagulation. In the setting of aggressive crystalloid resuscitation, the resulting dilution of available coagulation factors can limit the ability of the patient to achieve hemostasis. An environmental factor further impacting the function of the coagulation system in the trauma patient is that of hypothermia. Trauma victims are often hypothermic because of factors associated with prolonged exposure, massive blood loss and resuscitation with fluids well below 98.6°F (37°C). Conditions for enzymatic pathways associated with coagulation are then less than optimal, resulting in further compromise of function. The combination of such events can result in disseminated intravascular coagulopathy and is often associated with a dismal prognosis for the trauma patient.[22]

TRAUMA MANAGEMENT

Improvements in both prehospital and emergency department care have resulted in a reduction in morbidity and mortality, as well as the identification of critical areas of vulnerability in the care of the trauma patient.

Prehospital Care

The scope of care in the prehospital setting ranges from ambulances in more rural areas, often staffed by local volunteers, to the more extensive emergency services systems seen in large metropolitan areas. These may be run under the direction of state or regional agencies, often in close coordination with major trauma centers. While there is diversity in the nature of assets available in any specific setting, there has been a major effort over the past few decades to improve standards of care, methods of delivery and the training available to the care providers across the United States. The evolution of air evacuation systems using helicopters has further extended our ability to rapidly respond to the challenges of the trauma patient.

First responders trained in basic cardiopulmonary resuscitation (CPR) and

first aid are often local law enforcement and fire department personnel. With the arrival of one or more emergency medical technicians (EMTs), a more detailed evaluation of the patient's condition takes place, integrating the mechanism of injury with the physical findings, making diagnoses and initiating treatment. Although the level of training and certification of the EMT ranges from a basic EMT to a paramedic capable of providing advanced cardiac life support (ACLS), the EMT provides early treatment, often guided by the treatment facility designated to receive the patient. In addition to airway, breathing, and circulation support, the EMT is able to address issues related to wounds and fractures, supplementing the basics of securing an airway, obtaining intravenous access, initiating resuscitation, and administering medications as indicated.

At the scene the overall process undertaken by emergency medical personnel is focused on assessment and management. An initial assessment for site safety is performed to ensure that any potential risks to cause further injury to the patient, or to emergency personnel are identified. Requirements for additional personnel or specialized equipment may be identified at this point. An appreciation of the nature of the incident resulting in the trauma also provides the EMT insight into potential patterns of injury. At this point, a primary survey of the patient is performed to identify and treat life-threatening injuries. In critically injured patients, minimizing delay in transport is critical. As such, treatment and resuscitation are instituted as quickly as possible, with transport measures often being instituted in a parallel process.[23]

Intuitively, the ability to provide more advanced care in the prehospital setting would be expected to positively impact patient outcome. However, studies suggest that the ability to provide more advanced care, such as tracheal intubation and ACLS has little impact on survival, whereas minimal resuscitation and rapid transport to a trauma center appears to make a positive effect improving outcome.[24,25] Certain interventions, such as tracheal intubation of the patient with a severe head injury and intravenous resuscitation of the hypotensive patient in shock caused by penetrating trauma, may represent special categories of patients who will benefit from field interventions.[26] However, the survival of severely head-injured patients who are not intubated in the field may be higher when compared to a similarly injured group of patients who are intubated in the field with rapid sequence induction.[27,28] It would appear that in the setting of improved capabilities for the delivery of prehospital care, the apparent lack of benefit to the patient suggests that there are underlying issues contributing to the morbidity and mortality of the trauma patient that are, as yet, not well understood.[29]

Hospital Care

The nature and setting of care for the trauma patient in the hospital can vary. While a markedly unstable patient may be brought directly from the ambulance entrance of the hospital to the operating room, the more commonly encountered sequence involves the arrival of the patient to the emergency department for a detailed evaluation, resuscitation, and development of a course of treatment. The effective organization of the emergency department is vital to the delivery of appropriate care to the patient. Figure 78–2 depicts the typical configuration of a trauma bay. Often a near-chaotic environment, a team of key personnel, with appropriate equipment and support services, is required to ensure the most expeditious assessment and treatment of the patient.

Organized around a team leader, the emergency team requires designated personnel with specific skills. Task organized in a manner to provide critical expertise and capabilities, this group often draws upon personnel from services throughout the institution. The team leader, often an emergency medicine physician, is responsible for directing all components of patient care, as well as obtaining pertinent information from the prehospital phase of care regarding patient information and mechanisms of traumatic injury. The team leader is also responsible for the conduct of the primary and secondary surveys of the patient. An airway expert from the department of anesthesia, respiratory therapy, emergency medicine, or surgery is tasked with securing the airway and regulating mechanical ventilation as required. The team leader may often function as the airway expert as well. In the setting of

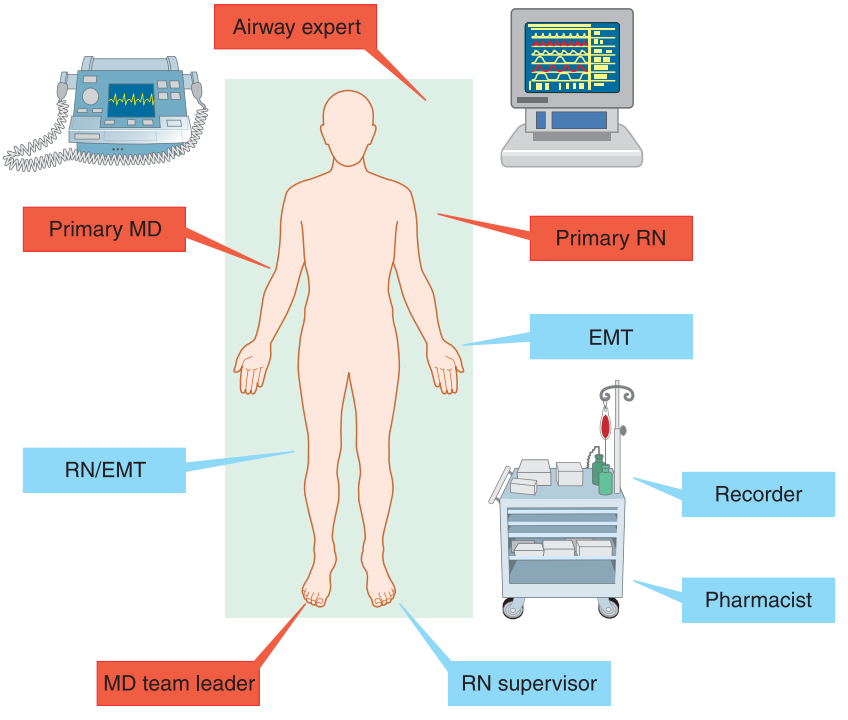

FIGURE 78–2. Configuration of a typical trauma bay. Designed to maximize efficiency of multiple key personnel and associated equipment for the care of an acutely injured patient. Specific roles and coordination are critical in effectively functioning in an often chaotic environment.

a trauma patient with obvious requirements for surgical intervention, the trauma surgeon will assume the role of the team leader. Procedural personnel may be used for placing intravenous access, obtaining lab samples, coordinating with the blood bank, the placing of monitors and performing additional tasks as determined by the team leader. Depending on the extent of the trauma, multiple personnel may play a role in performing procedures in the emergency department. Nurses comprise an integral portion of the trauma team. Responsibilities run from direct involvement in resuscitation to key roles in the interaction with supporting services as well as with patient families. Additional personnel involved in the trauma team may include radiography technician, recorder, family and patient care support personnel, mental health providers, pharmacist, specialty surgeon(s), and clergy.

One of the most important aspects of the trauma team is the ability to immediately respond to an injured patient in a timely, efficient, and reliable manner. This response capability is born of a specific training plan, with clearly identified roles and requirements for each team member.[30] This facilitates a coordinated approach to a trauma patient, in a setting that often requires multiple parallel tracks of assessment and intervention (Fig. 78–3).

The disposition of the trauma patient in the emergency department varies. A patient injured in a motor vehicle collision who is stable on arrival in the emergency department, may be sent to the radiology department for studies and then taken immediately to the operating room or admitted to the hospital for further treatment and/or evaluation. These patients must be carefully observed for acute changes in clinical conditions while being transferred from the emergency department to other sites within the hospital (e.g., CT scanner, interventional radiology) A similar patient, with unstable vital signs, may require resuscitation in the emergency department before proceeding to additional studies or the operating room. Some patients arrive emergently and are brought directly to the operating room for a lifesaving intervention or undergo emergency surgery in the emergency department. This serves to illustrate the diversity of presentations by a trauma patient, and the need for emergency departments to provide experienced and well-trained personnel capable of immediate adaptation of therapeutic plans to rapidly changing clinical conditions.

FIGURE 78–3. Trauma team caring for an acutely injured patient in the emergency department. Clockwise from left foreground: team leader (emergency department attending), primary physician. Respiratory therapist at the head of the stretcher, with assistance provided by an emergency department nurse at the patient's right, and primary nurse at patient's left.

PATIENT ASSESSMENT

The emergent presentation of an acutely injured patient presents one of the greatest clinical challenges for the anesthesiologist. The need to perform a critical assessment rapidly, often in a chaotic setting, requires that the anesthesiologist approach the situation in an efficient and focused manner. Additionally, the uncertainty associated with a trauma patient requires that the anesthesiologist be vigilant for changes in the clinical situation (Table 78–1). Typically, the most severely compromised patients offer the least amount of time to perform an in-depth survey.

Since the late 1960s, the American College of Surgeons Committee on Trauma has developed a systematic and stylized approach to the trauma patient. The advanced trauma life support system (ATLS) evolved from the experience of an orthopedic surgeon and his family involved in a private plane crash. The evaluation and treatment provided to this family in a small community hospital was disorganized and haphazard. The efforts precipitated by this experience have lead to a system that facilitates a prioritized approach to the trauma patient. This has resulted in a standardized and widely accepted protocol to initially address potentially life-threatening issues, using the principles of airway, breathing, and circulation (ABCs), followed by a more extensive survey to better determine the extent and nature of the injuries. This process also facilitates communication within an institution, as well as between institutions in the case of patient transfer requirements, providing assistance in the subsequent disposition.[31]

Primary Survey and Resuscitation

The well-establish approach to the ABCs remains the standard of approaching the trauma patient. Prioritization is based upon the immediacy of the threat to life. The need to support and/or secure the airway remains the highest priority. The inability to oxygenate a patient can result in irreversible damage to the brain in as little as 4

minutes. Supporting the airway may be as simple as opening the mouth and clearing away debris, to as complicated as securing the airway in a patient with severe trauma to the head and neck requiring the need of an emergency surgical airway. Managing the airway in a trauma patient often involves the physical constraints of maintaining cervical spine precautions. Protocols for clearance of the cervical spine may vary across institutions. However it is likely that the majority of trauma patients requiring intubation will also require cervical spine stabilization.[32] Specific issues regarding the approach to the difficult airway in the trauma patient are addressed in Chapter 35. Even in the setting of a protected airway, the respiratory drive may be impaired from an injury to the head, metabolic compromise, or depressant drug administration, and the anesthesiologist must ensure that adequate oxygenation and ventilation are maintained (Fig. 78–4). Issues affecting circulation are also addressed in this initial survey. Although the sequence of emergency treatment prioritizes airway and breathing, in the setting of the trauma bay, parallel efforts are often directed toward circulatory issues at the same time the airway issues are being addressed. The threat to life by hemorrhage can also occur as rapidly as a few minutes to a few hours after injury and, as such, occupies a priority following oxygenation (Table 78–2). The most commonly encountered issue in the hypotensive trauma patient is hypovolemia. In the setting of a stable cardiac rhythm a fluid challenge of 1–2 L of warm crystalloid is administered. A plan to treat ongoing hemorrhage needs to be developed and is roughly delineated along the lines of compressible versus noncompressible hemorrhage. Controlling or temporizing bleeding from an extremity may provide adequate time to obtain necessary studies (radiography, angiography), whereas an incompressible hemorrhage (torso, cranium) may require emergent treatment in the operating room or the emergency department.

This initial assessment phase requires that personnel be able to immediately recognize and treat issues that present an imminent threat to survival. The mechanism of injury, if known during this phase, may provide some insight to the team, however the primary issues in a systematic approach are

- Airway
  - Inadequacy
  - Obstruction
- Breathing
  - Pneumothorax
  - Hemothorax
  - Tension pneumothorax
  - Flail chest
- Circulation
  - Hemorrhage
  - Cardiac tamponade
- Shock
  - Cardiogenic
  - Neurogenic
  - Obstructive
  - Septic

Recognition and timely treatment of these conditions usually requires urgent intervention. It is imperative that the trauma team have the personnel, equipment, and supplies immediately available to intervene as needed.[33] The initial assessment then continues to

TABLE 78–2.

Physiologic Effects of Hemorrhage for 70-kg Male

	Class I	Class II	Class II	Class IV

Fluid replacement	Crystalloid	Crystalloid	Crystalloid/blood	Crystalloid/blood

address issues with regard to the extent of neurologic compromise, commonly referred to as D for disability, in the conventionally accepted ABCDE format. A brief examination, using the Glasgow Coma Scale (GCS) can coarsely evaluate the patient's neurologic condition with regard to verbal and gross motor function (Table 78–3). Pupillary response is also determined at this phase. A GCS score of less than 8 usually requires immediate tracheal intubation to protect the airway.[34] The final component of the initial assessment is termed as E for exposure and environment. Clothing is removed while attention is directed toward preventing hypothermia by ensuring that the patient's environment is adequately warmed.

During this initial phase resuscitation is initiated, monitoring is established, to include a Foley catheter and an orogastric tube for the intubated patient and any available history is obtained (often referred to as F, G, and H of the ABC... mnemonic). Information regarding the nature of the events resulting in the patient's injury and transport is obtained in coordination with the prehospital care team. At this point, samples for critical lab values, such as arterial blood gas tensions and pH, blood glucose, and hematocrit, if not obtained during the earlier establishment of intravenous access, are sent with additional lab tests. Plans for radiographs and/or additional studies are formulated. Throughout the primary survey, the evaluating physician is obtaining information and may determine that there is a need to transfer the patient to another facility. Support personnel, after direction by the team leader, may initiate the process of transfer. Physician-to-physician direct communication remains a critical factor in transferring a patient between institutions.[35]

A common error in management during the primary survey involves delay in securing the patient's airway. Trauma team leaders may be hesitant to secure the airway, because of distraction or inexperience. It is important for the anesthesiologist to be appropriately aggressive in this arena.[36–38] An unrecognized pneumothorax is another common error. Excessive fluid resuscitation often occurs to the trauma patient. Once again, the anesthesiologist can guide the fluid management of the trauma patient. As discussed in the section on resuscitation, the area of hypotensive resuscitation is being examined as a more appropriate management strategy in the trauma patient.[39] Failure to establish adequate intravenous access and failure to involve a surgeon early may also become problematic in situations such as a difficult or lost airway, as well as in the case of a patient with a noncompressible hemorrhage.

Resuscitation

Prehospital guidelines suggest the placement of 2 large-bore (14–16-gauge) intravenous cannulae and the infusion of warmed lactated Ringer solution for the resuscitation of the trauma patient. Field conditions limit the ability to treat many of the conditions underlying hypotension; as a result, emergency medical personnel are encouraged to avoid delays in transport, continuing fluid resuscitation as clinically indicated. Currently, the goal for resuscitation of the trauma patient upon arrival to the hospital is the restoration or optimization of oxygen delivery to the tissues in the face of hemorrhagic shock. Warmed crystalloids (normal saline, lactated Ringer solution), with the addition of specific blood products as clinically indicated are the rule. Initiated in what may be a chaotic field environment, resuscitation is often carried out without any laboratory values. Although crystalloid infusion may be the only means initially available for the treating of systemic hypotension, the hemodilution associated with massive crystalloid resuscitation is often accompanied by hypothermia, coagulopathy and acidosis. An additional concern is the inflammatory cascade initiated by trauma that is believed to be an underlying issue in the subsequent multiorgan failure of the trauma patient. In the face of ongoing uncontrolled hemorrhage, blood flow to tissue may be markedly reduced. Avoidance of tissue ischemia is likely to limit the impact of ischemic reperfusion. As such a goal of resuscitation to less than the normal physiologic state may offer some protection from the sequela of ischemia. The impact of resuscitation to less than optimal physiologic parameters may prove beneficial to the long-term survival of the trauma patient. Resuscitation targeted to lower mean arterial pressures may provide a greater margin of safety in the early attempts to locate and control hemorrhage. And permissive hypercapnia may help limit the negative hemodynamic impact of positive pressure ventilation on the hypovolemic/hemorrhaging patient. Current investigations may suggest a role for the targeted use of antiinflammatory therapies in early resuscitation.[40] During resuscitation limitation of crystalloid solution, a known activator of neutrophils, may also serve to attenuate the early inflammatory response. The use of hypertonic saline with dextran is beneficial, particularly in the setting of trauma patients with closed-head injuries.[41]

The manner of resuscitation has been a major topic for debate over the entire history of research into the care of the trauma patient. Knowledge gained through the care of the combat casualty and more recent investigations suggest that the tradition of resuscitation to normal physiologic values using isotonic fluids may be detrimental to the long-term survival of the trauma patient.[42]

During the past decade, controversy over the appropriate end points of intravenous fluid resuscitation in the

trauma patient has led to investigations regarding optimal resuscitation strategies. From the Vietnam War era, it was appreciated that systemic perfusion pressures needed to be maintained in the hemorrhaging patient. However there was a concern that in the setting of uncontrolled hemorrhage, aggressive fluid administration could interfere with thrombus formation and decrease the survival rate.[43] Several years ago an effort by the National Institutes of Health led to the establishment of the Post-Resuscitative and Initial Utility of Life-Saving Efforts (PULSE) Workshop. A Trauma Work Group has undertaken to endorse strategies and priorities for research into trauma resuscitation.[44]

Secondary Survey

The secondary survey only takes place after the primary survey has been completed, resuscitation is then underway and the patient's vital signs should demonstrate a trend toward normalization/stabilization. In the setting of treating a trauma patient, it is critical to continually review the vital signs for any indication of change or deterioration in the patient's condition. The secondary survey is a thorough head-to-toe examination of the patient in conjunction with a more detailed history of the patient's general health in the context of the mechanism(s) of traumatic injury. This purposeful and systematic evaluation reduces the likelihood of a serious injury being overlooked, particularly in the unresponsive patient.[45]

A comprehensive description of the secondary survey is provided in the advanced trauma life support manual.[31] However an overview of the systematic approach with the most common issues of concern for the preoperative patient is presented herein to sensitize the anesthesiologist to critical issues that can impact the preoperative trauma patient.

Head

The head requires a complete neurologic exam. An examination of the eyes (to include visual acuity), if possible, should be assessed as facial swelling may later preclude an eye examination. The possibility of fractures to the head must be considered.

Face: Assess for bony and soft tissue injury. Continue to reassess the airway for patency and security of any airway appliances and sources of supplemental oxygen.

Neck

Blunt trauma to the neck region may result in injuries that are not immediately appreciated, such as certain nerve and vascular injuries. Patients with distracting injuries, including intoxicated patients, are presumed to have an unstable neck and cervical spine precautions against injury must be maintained.

Chest

Recheck the chest for rib fractures. A pneumothorax may not be clinically significant until the patient is intubated and is being maintained on positive pressure ventilation. Also injuries to the great vessels may not become evident during the primary survey.

Abdomen

Special attention must be directed to the retroperitoneum as well as the genitalia. A diagnostic peritoneal lavage or a focused abdominal ultrasound for trauma may be performed in the emergency department.

Spine

The patient must be log-rolled for a complete examination of the spine. This process also facilitates examination of the back for evidence of injuries not appreciated during the primary survey.

Soft Tissues

Abrasions and contusions, often a consequence of the mechanism of injury, may provide insight into the presence of an occult injury.

It is also during the secondary survey that further investigation is considered. Additional imaging, computerized tomography, angiography, bronchoscopy and transesophageal echocardiography may be indicated. It is critical that the patient's hemodynamic status is stabilized before any attempt at further testing occurs.

At the conclusion of the secondary survey, the plans for further care of the trauma patient should be well-formulated. As the patient is being prepared for additional tests or transfer to the operating room, the tertiary phase is entered. This phase is designed to ensure regular reevaluation of the patient in recognition of the dynamic clinical situation of the trauma patient.[46]

TRAUMA SCORING

Since the 1950s attempts have been made to develop a scoring system to effectively characterize traumatic injury. In the 1970s, with the development of trauma centers and the appreciation of the epidemic nature of trauma, the need for a more effective means to quantify the severity of trauma was identified. Used as part of a field triage system, the scoring system can help the clinician decide the appropriate evacuation of a patient, or while in the hospital, it may be used to evaluate the impact of therapy, the appropriateness of intervention and/or to determine the patient's inclusion into a research study.

There are three major categories of trauma scoring systems (Table 78–4). These are divided into physiologic or anatomic groups, with a third group being a combined or specialized group.[47]

Anatomic Scores

These systems are based on the anatomic sites of injury. These scoring systems have evolved to correlate reasonably with in-hospital morbidity and mortality data. A disadvantage to using these systems is the relative complexity involved in the calculation process.[48]

TABLE 78–4.

Trauma Scoring Systems

- Anatomic
  - Abbreviated Injury Score (AIS)
  - Injury Severity Score (ISS)
  - New Injury Severity Code (NISS)
  - Anatomic Profile (AF)
  - Penetrating Abdominal Trauma Index (PATI)
  - ICD-based Injury Severity Code (ICES)
- Physiologic
  - Glasgow Coma Scale (GCS)
  - Trauma Score (TS)
  - Revised Trauma Score (RTS)
  - Acute Physiological and Chronic Health Evaluation (APACHE)
  - Systemic Inflammatory Response System (SIRS) Score
- Combined
  - Trauma and Injury Severity Score (TRISS)
  - A Severity Characterization of Trauma (ASCOT)
  - Harborview Assessment to Risk of Mortality (HARM)

Physiologic Scores

Using data that can be obtained noninvasively in the field, such as systemic blood pressure and heart rate, the physiologic scoring systems are often used by prehospital personnel in triage decisions (Table 78–5). Disadvantages are associated with the issue that physiologic patterns often change rapidly and the scoring system requires the conversion of measured values into standardized scores.[49]

Combined Scores

By combining assessment of both anatomic and physiologic compromise after an injury, these scoring systems have been used as predictors of mortality. While the most common of the systems is used to predict outcome in trauma patients, the combined systems require more complex calculations and bear the same limitations as the anatomic and physiologic based systems.[50,51]

CRITICAL ISSUES IN TRAUMA MANAGEMENT

Myriad issues may impact the trauma patient, during both the prehospital and in-hospital phases of care. Although the algorithm of the ABCs remains the primary focus of any approach to the trauma patient, the risks imposed by hypothermia and the consequences of resuscitation merit special consideration in any discussion of the approach to or evaluation of the trauma patient.

TABLE 78–5.

Revised Trauma Score (RTS)

Parameter	Range	Score
A. Respiratory rate (breaths/min)	10–29	4
	>29	3
	6–9	2
	1–5	1
	0	0

	1–49	1
	0	0
C. Glasgow Coma Scale Score	13–15	4
	9–12	3
	6–8	2
	4–5	0
		1
	<4	0

The Revised Trauma Score is the summation of the 3 categories above: RTS = A + B + C.

Hypothermia

Trauma patients are often hypothermic by the time emergency medical personnel assume care for the individual. Exposure to the extremes of environmental cold, as well as the physiologic effects of blood loss, and changes in mental status can lead to a marked reduction in core body temperature.[52] Coupled with cold fluid resuscitation in the field, this can place the patient at risk for the multiple physiologic effects of low body temperature (Table 78–6).

Resuscitation Strategies

Emergency medical personnel are often limited by field conditions in their ability to treat trauma patients in hypovolemic shock caused by hemorrhage. Fluid, most often isotonic crystalloids, are administered in a manner that is usually guided by the ability to monitor vital signs during transport. In the emergency department, the ability to use more advanced monitoring and to obtain laboratory data markedly improves the ability to measure the effects of intravenous infusion therapy. These methods of assessment, coupled with the less austere and controlled environment of the hospital setting, permit a more guided and controlled approach to fluid resuscitation.

TABLE 78–6.

Effects of Hypothermia

- Coagulopathy
- Cardiac dysrhythmias
- Peripheral vasoconstriction
- Increased metabolic demand (shivering)
- Decreased metabolic demand (attenuated metabolic rate)

FUTURE TRENDS

The care of the trauma patient has become a major subject of analysis and investigation over the past several decades. Areas of opportunity to improve care for the trauma patient, as well as the training of personnel involved in the care of these patients, have emerged over the past 15 years. Some of these topics offer the potential to markedly impact the care of the trauma patient.

Blood Substitutes

Acute hemorrhage remains one of the most challenging factors in the care of the trauma patient. In the setting of massive blood loss, resuscitation with crystalloid solutions is ineffective for the treatment of shock. Although the use of blood products is the standard of care, the nature and lack of availability of these products in the field presents cause for concern. An inherent risk of infection with transfusion, although small, is present and the potential for blood incompatibility must also be considered. Also, evidence suggests that reductions in morbidity and mortality over the past decade are associated with a decreased use of blood transfusion during resuscitation.[53] In circumstances where blood products are not readily available, such as in rural settings, there is a need for the development of effective blood substitutes with the ability to transport oxygen to tissues.

Particularly in the area of trauma care, blood substitutes offer obvious advantages over conventional blood products. Availability would be markedly improved as these agents would require minimum storage requirements, offer extended shelf-life, and would eliminate compatibility issues. Infectious risk and immunologic concerns would be eliminated and the potential for enhanced oxygen-carrying capability and improved rheologic properties would be beneficial.[54] Although this is obviously an exciting and needed area of development, investigation into blood substitutes is not without controversy. No synthetic blood substitute has been approved by the FDA. A current clinical trial in the United States is examining the use of a blood substitute during prehospital resuscitation and transport. Ethical concerns remain in the area of community, rather than individual, consent for the procedure, and the possibility that minority and socioeconomically disadvantaged groups may be unfairly targeted.[55]

Resuscitation Strategies

In the case of the exsanguinating patient, medical personnel in both prehospital and hospital settings infuse isotonic fluids to reverse hypovolemic shock until definitive surgical repair can be achieved. Evidence suggests

that hypotensive resuscitation reduces the risk of death.[56,57] End points or targets for resuscitation are varied and include a normal mean arterial pressure, systolic blood pressure, and urine flow rate. Although there is some debate as to the appropriate or best target for resuscitation, there also may be implications in the choice of fluids used for resuscitation. As noted in the era of the Vietnam War, aggressive resuscitation with large volumes of isotonic crystalloid solutions led to "Da Nang" or "shock" lung, now commonly known as ARDS. Thus the inappropriate choice of fluids for resuscitation may potentiate the cellular injury caused by hemorrhagic shock.[42,58] A recent investigation reports that the removal of D-lactate from Ringer solution is associated with a reduction in apoptotic cell death in swine liver and lung models of hemorrhagic shock.[59] Hypertonic saline, alone and in combination with dextran, improves the survival rate after traumatic brain injury. The development of blood substitutes offers additional potential for improved resuscitation without the deleterious effects of crystalloid solutions.[41]

Hemorrhage Control

Uncontrolled bleeding remains a primary cause of mortality in both the prehospital and early in-hospital course of the trauma patient. Although surgical control of bleeding is the paramount approach to the exsanguinating patient, attendant conditions, such as coagulopathy, anemia, and acidosis further complicate the timely resolution of hemorrhage. The infusion of recombinant activated factor VII, initially developed for the treatment of hemophiliacs, has been a subject of interest for the control of hemorrhage in the trauma patient.[60] Infusion of factor VII has been used as a therapy of last resort in trauma patients with active hemorrhage and clinical coagulopathy in which surgically accessible hemorrhage has been controlled.[61] Activated factor VII infusion markedly reduces blood loss and mortality in trauma patients with massive bleeding. However, given the desperate nature of the conditions under which factor VII has been administered, the ability to perform a controlled trial has been ethically limited.[62] The use of activated factor VII in the care of trauma patients with uncontrolled bleeding appears to be a valuable therapeutic modality and continues to be an area of active investigation. The usefulness of activated factor VII has been demonstrated in elective surgery. There is a need for well-designed prospective randomized trials in trauma patients.[63]

Hypothermic Resuscitation

Hypothermia and the associated physiologic changes of homeostatic mechanisms are critical factors in the acute care of the trauma patient. As a result of prolonged exposure, extrication and transport times, and resuscitation with cold fluids in the field, the severity of injuries in the trauma patient is further complicated by this physiologic compromise. However, controlled hypothermia has been effectively used in the treatment of refractory intracranial hypertension and traumatic brain injury.[64] Hypothermia has reduces morbidity and mortality in infants with hypoxic–ischemic encephalopathy.[65] Profound hypothermia is associated with intact survival after prolonged lethal hemorrhage and trauma in animal models. This approach of emergency preservation and resuscitation may offer the ability to extend the time from severe injury in the field to definitive therapy after evacuation to a hospital.[66]

Simulation Training

The past decade has seen a marked increase in interest regarding the use of simulation in many areas of medicine. Evolving in part from military applications, the use of simulation training, using computer-controlled mannequins, has been shown to be an effective means for trauma assessment and trauma team training.[67] The ability to reproducibly evaluate team performance also has been demonstrated using a human patient simulator. Additionally, using human performance-assessment tools, resuscitation training has been shown to improve after a focused refresher course in a simulator.[68] While continued investigation is needed to further develop and validate the use of simulation training, the potential to improve behavior and performance by trauma team members suggests the possibility of improved refinement of simulation as a critical component for team training in trauma care.[69]

Mass Casualties

The events of the last decade have brought a new interest in the management of incidents involving multiple casualties. Mass casualties may be the result of natural disasters, acts of terrorism, as well as result from industrial accidents.[70] Although victims of a hurricane may have different medical needs than victims of a terrorist act using a chemical or biologic agent, the demands placed on public health assets can be very similar. Augmenting the training of emergency healthcare providers and increasing their logistical support, as well as increasing the capacity and numbers of healthcare facilities, can maximize the emergency healthcare system's ability to rapidly expand capacity and capability, and can help reduce the severe strains being placed on medical resources.[71,72] The need to develop new strategies in anticipation of the large-scale burdens imposed by mass casualties remains an area of major concern to public health sector and hospital managers.

CHAPTER 79

Developing the Anesthetic Plan for the Critically Ill Patient

Jean Kwo, MD

Each day 55,000 patients are being cared for in 6000 intensive care units (ICUs) across the United States. Many of these patients will undergo a surgical procedure during their hospitalization either to correct the underlying cause of their illness or to deal with the complications of their illness. Similar to the healthy patient, the anesthesia plan for the critically ill patient should include a clear delineation of the goals of management, an assessment of the priorities of care, and alternative strategies to avoid or treat complications.

Many studies show that the patient's outcome depends on the interaction of several factors, including the type and extent of the procedure, the physiologic reserves of the patient, the presence of chronic health problems, and the nature of the acute physiologic derangements.[1] The number of complications attributable to anesthesia is 8 times greater for patients with American Society of Anesthesiologists (ASA) Physical Status grades P3 and P4 rather than for patients with ASA grade P1 or P2. Furthermore, patients with higher ASA physical status grades were more likely to have a negative outcome because of anesthetic-related complications.[2] One study found that the presence of an anesthesiologist intraoperatively, and certain characteristics of intraoperative and postoperative care were associated with a decreased risk for severe postoperative morbidity and mortality.[3] Thus, the plan for the critically ill patient should include preoperative optimization of the patient's condition, a chronologic plan for the treatment that the patient will receive intraoperatively, coordination of the timing of surgery to allow for the presence of adequate support personnel, ensuring the availability of additional equipment needed to adequately care for the patient, and a plan for postoperative care.

The critically ill patient often has many caregivers skilled in several medical and surgical specialties. Advance planning for the care of the critically ill patient is essential. There should be open communication regarding the likely outcomes and realistic goals of treatment between the anesthesiologists, surgeons, critical care team, and the patient and the patient's family. Preoperatively, one person or team should be designated as the coordinator of the patient's care and should ensure that everyone taking care of the patient in the perioperative period understands the goals and priorities of treatment. Because these may change with time, frequent communication to all is vital.

This chapter focuses on the key points in preoperative planning and some considerations for intraoperative management and optimization for the delivery of a safe anesthetic to the critically ill patient.

PREOPERATIVE ASSESSMENT AND OPTIMIZATION

Critically ill patients may have impaired function of some or all organ systems. An assessment of the degree of organ dysfunction and, whenever possible, optimization of the patient's condition should be undertaken before surgery to ensure that the patient is in the best possible condition to undergo the additional stresses associated with surgery and anesthesia.

Hemodynamic Considerations

A variety of cardiovascular abnormalities may be present in critically ill patients, including hemodynamic instability and dysrhythmias. Patients may manifest shock secondary to hypovolemia, vasodilatation, and/or myocardial dysfunction. Because shock represents the failure of the circulatory system to maintain adequate delivery of oxygen and other nutrients to tissues, cellular and organ dysfunction may ensue. Thus the ultimate goals of hemodynamic therapy in shock are to maintain or restore adequate tissue perfusion and organ function. Evaluation of the hemodynamic status of the critically ill patient should include the following: assess the patient's volume status, determine whether pressors or inotropic agents are needed to maintain an adequate blood pressure and cardiac output, and

KEY POINTS

1. Critically ill patients often need surgery to correct the underlying cause of their illness or to deal with the complications of their illness.
2. Advanced planning and open communication between the anesthesiologists, surgeons, the critical care team, and the patient and the patient's family is crucial to understanding the goals and priorities of treatment.
3. Critically ill patients may have impaired function of multiple organ systems. Preoperative evaluation of the degree of organ dysfunction and optimization of the patient's condition ensures that the patient is in the best possible condition to undergo the additional stresses associated with surgery and anesthesia.
4. The simplest surgical procedure resulting in the least physiologic upset is generally the best option for the critically ill patient.
5. Planning for the transport to the operating room is essential because patients are at high risk for adverse events during transport.
6. The anesthesiologist must decide which monitors are necessary for the assessment of the patient's condition taking into account the advantages and pitfalls of the different options.
7. While general anesthesia is most often necessary for surgery in the critically ill patient, regional anesthesia can play a valuable adjunctive role to achieve patient comfort and reduce physiologic stress.
8. There should be specific goals and end points defined in the management of the critically ill patient to optimize hemodynamics and minimize further end-organ damage.
9. The anesthesia team is responsible for the care of the critically ill patient until a full report is given to the ICU team and the team can accept care of the patient.

learn whether there are any clinical indicators of hypoperfusion.

Respiratory Failure and Ventilator Management

Critically ill patients may have respiratory failure and require mechanical ventilation. The preoperative evaluation should include a review of the ventilator settings, including the mode of ventilation, the ventilator rate, the FiO_2, the level of positive end-expiratory pressure (PEEP), tidal volume and airway pressures, and inspiratory-to-expiratory (I:E) ratios or inspiratory time. Arterial blood gas values should be reviewed for adequacy of oxygenation and ventilation on the ventilator settings. Because standard operating room anesthesia machine ventilators can be inadequate for patients with severe respiratory failure, if the patient's mode of ventilation cannot be supported by the operating room ventilator, arrangements should be made to transport the ICU ventilator to the operating room.

Neurologic Assessment

The critically ill patient may have compromised neurologic function because of a myriad of causes including drugs, infection, metabolic derangements, trauma, and cerebrovascular accidents. The preoperative evaluation should include an assessment of baseline neurologic function. Dosages and rates of infusions of sedative hypnotic and analgesic agents should be noted, and decisions should be made whether or not these agents should be continued intraoperatively.

Neuromuscular blocking agents are associated with critical illness polymyopathy/neuropathy. In general, the recommendation is that these agents should be avoided if at all possible in the septic patient because of the risk of prolonged neuromuscular blockade following their discontinuation.[4,5] However, because neuromuscular blocking agents may be needed to facilitate surgery, monitoring the depth of blockade with a train-of-four monitor is advised.

Because critical illness can be associated with prolonged immobilization and a severe myopathy, life-threatening responses after succinylcholine administration may occur. In these patients, the use of succinylcholine can precipitate severe hyperkalemia and/or rhabdomyolysis.

Evaluation of Renal Function

Critically ill patients often have renal dysfunction. Evaluation of the patient with renal failure should include an assessment of volume status, electrolyte balance, and acid–base status. As renal ischemia is the primary cause of acute renal failure in the perioperative setting, intraoperative maintenance of adequate intravascular volume, mean arterial pressure, and cardiac output are important measures to preserve renal perfusion. Furthermore, nephrotoxic drugs should be avoided to prevent further renal injury in these patients. Although the measurement of urine output is usually the primary means of evaluating renal function, invasive monitoring may be required to assure adequate volume repletion in the critically ill patient who is at risk for postoperative renal dysfunction.

Endocrine Abnormalities in the Critically Ill Patient

Recent clinical trials have focused on two particular endocrine abnormalities in critically ill patients, "functional" adrenal insufficiency and "tight" glycemic control (see Chap. 12).

Adrenal Insufficiency

Patients with septic shock frequently exhibit relative adrenal insufficiency. In a randomized, placebo-controlled, prospective trial, 229 of the 300 patients who were enrolled demonstrated adrenal insufficiency.[6] In those patients, corticosteroid therapy resulted in a reduction of the mortality rate. Currently, intravenous corticosteroids (hydrocortisone 200–300 mg/d, for 7 days, given either in 3 or 4 divided doses or by continuous infusion) are recommended for patients with septic shock who, despite adequate fluid replacement, require vasopressor therapy to maintain an adequate blood pressure. Intraoperatively, clinicians may consider administering a dose of dexamethasone until such time that an adrenocorticotropic hormone stimulation test can be administered in the ICU because dexamethasone, unlike hydrocortisone, does not interfere with the usual cortisol assay.

Glucose Control

Critically ill patients are frequently hyperglycemic. Whereas previous practice was to only treat marked hyperglycemia (e.g., ≥200 mg/dL), more recent evidence suggests that maintaining plasma glucose concentration between 80 and 100 mg/dL is associated with decreased ICU mortality.[7] As ICU patients will often receive insulin infusions to achieve these goals, consideration should be given to continuing these infusions intraoperatively. Patients receiving an insulin infusion should be given an external source of glucose to prevent hypoglycemia and blood sugar levels need to be checked frequently intraoperatively.

Coagulation Dysfunction and Anemia

Evaluation of the critically ill patient should include an assessment of their circulating hemoglobin or hematocrit levels and the patient's coagulation status.

Anemia is often present in patients with critical illness. Although the current recommendations for critically ill patients are that red blood cell transfusions should be given only when the hemoglobin level decreases to ≤7.0 mg/dL,[8,9] these recommendations should not be applied to individuals who are undergoing short-term resuscitation. In the operating room, the decision to transfuse must be based on how the patient responds to other interventions, including early, aggressive fluid resuscitation. In patients with evidence of hypoperfusion (e.g., low central venous oxygen saturation or lactic acidosis), a target hemoglobin of 10 g/dL has been suggested to maximize tissue oxygen delivery.[10]

Thrombocytopenia can occur in critically ill patients and may be a result of sepsis, drugs (Table 79–1), or hemodilution caused by massive transfusion. Platelet transfusions are given to patients who are bleeding or at risk of bleeding as a consequence of thrombocytopenia or impaired platelet function. Surgical bleeding may occur when platelet counts are less than 50,000/μL. Furthermore, factors such as a coagulopathy, fever, and renal failure may increase the bleeding risk from severe thrombocytopenia. Therefore, the threshold platelet count for triggering a prophylactic platelet transfusion should take these clinical considerations into account.[8,11] Platelets should never be given to patients with type II heparin-induced thrombocytopenia because of an increased risk of thrombosis after platelet transfusions.

Coagulopathies can occur in the critically ill patient and are evaluated by

TABLE 79–1.

Drugs That Can Cause Thrombocytopenia

- Acetaminophen
- Antidepressants
  - Amitriptyline
  - Desipramine
  - Doxepin
  - Impramine
- Antiepileptic drugs
  - Carbamazepine
  - Phenytoin
  - Valproic acid
- Antiinflammatory drugs
  - Diclofenac
  - Fenoprofen
  - Ibuprofen
  - Indomethacin
  - Meclofenamate
  - Mefenamic acid
  - Naproxen
  - Piroxicam
  - Salicylates
    - Aspirin
    - Diflunisal
  - Sulfasalazine
  - Sulindac
  - Tolmetin
- Antimicrobials/antivirals
  - Acyclovir
  - Cephalosporins
    - Cefamandazole
    - Cefotetan
    - Ceftazidime
    - Cephalothin
  - Ciprofloxacin
  - Clarithromycin
  - Fluconazole
  - Ganciclovir
  - Gentamicin
  - Penicillins
    - Ampicillin
    - Methicillin
    - Penicillin
    - Piperacillin
  - Rifampin
  - Sulfa group
    - Sulfamethoxazole
    - Sulfamethoxypyridazine
    - Sulfisoxazole
  - Vancomycin
- Antineoplastic drugs
- Benzodiazepines
  - Diazepam
- Cardiac medications
  - Amiodarone
  - Diltiazem
  - Digoxin
  - Procainamide
  - Enalapril
  - Captopril
  - Diazoxide
  - α-Methyldopa
- Diuretics
  - Acetazolamide
  - Chlorothiazide
  - Furosemide
  - Hydrochlorothiazide
  - Spironolactone
- H_2-antagonists
  - Cimetidine
  - Famotidine
  - Ranitidine
- Heparin
  - Unfractionated Heparin
  - Low-molecular weight Heparin
- Illicit drugs
  - Cocaine
  - Heroin
- Iodinate contrast agents
- Quinine/quinidine
- Miscellaneous drugs
  - Tamoxifen
  - Desmopressin
  - Cyclosporine
  - Levamisole
  - Lidocaine
  - Morphine
  - Papaverine
  - Ticlopidine
  - Octreotide
  - Ondansetron

measuring the prothrombin time, activated partial thromboplastin time, and fibrinogen levels. Plasma product infusions (fresh-frozen plasma or cryoprecipitate) are infused to stop active bleeding associated with a coagulopathy or to correct coagulopathies before invasive or surgical procedures. Vitamin K may be administered to raise the levels of vitamin K-dependent clotting factors (II, VII, IX, and X).

Recombinant human coagulation factor VIIa (rFVIIa) is used to treat bleeding and promotes hemostasis by activating the extrinsic pathway of the coagulation cascade (Table 79–2). It bypasses inhibitors to factors VIII and IX in patients with hemophilia A and B, and treats patients who have severe von Willebrand factor (vWF) deficiency caused by antibodies to vWF. Other uses of rFVIIa include treatment of congenital or acquired factor VII deficiency, congenital factor XI or factor V deficiency, the coagulopathy of severe liver dysfunction, hemostatic changes that arise from extensive surgery, trauma, and bleeding, reversal of warfarin-induced excessive anticoagulation, certain inherited disorders of platelet function (e.g., Glanzmann and Bernard-Soulier thrombasthenias), and bleeding from thrombocytopenia that is a result of antiplatelet glycoprotein antibodies that thwart the effects of platelet transfusion.[12] The minimum effective rFVIIa dose for managing these hemorrhagic disorders is uncertain. rFVIIa dose depends on the specific hemorrhagic disorder being treated; in studies the dose has ranged from 3–320 μg/kg.

Recombinant activated protein C (drotrecogin alfa) is a critical protein that functions to regulate excessive thrombosis in the microcirculation and has been shown to reduce the mortality from severe sepsis that is associated with organ dysfunction in adults who are at high risk for death (Acute Physiology and Chronic Health Evaluation [APACHE] II scores ≥25).[13,14] Because of its anticoagulant effects, bleeding is the most common serious adverse effect associated with drotrecogin alfa therapy. Drotrecogin alfa should be discontinued 2 hours prior to undergoing an invasive surgical procedure or performing procedures with an inherent risk of bleeding. Once adequate hemostasis has been achieved, initiation of drotrecogin alfa may be reconsidered 12 hours after major invasive procedures or surgery, or re-

TABLE 79–2.

Uses of Recombinant Factor VIIa

- Hemophilia
- Hemophilia with inhibitors and acquired inhibitors of factors VIII and X
- Other conditions
  - Liver failure
  - Liver transplantation
  - Drug-induced coagulopathies
  - Platelet disorders (thrombocytopenia and thrombasthenia)
  - After bone marrow transplantation
  - Renal failure
  - Factor VII deficiency
  - Factor XI deficiency
  - Severe von Willebrand disease
  - Amyloidosis with factor X deficiency
  - Postsurgical bleeding or bleeding as a result of trauma
  - Disseminated intravascular coagulation

started immediately following uncomplicated minor procedures.

The Elderly Critically Ill Patient

Increasing age is associated with an increased incidence of intercurrent diseases and declining physiologic reserve. Until the age of 60 years, both basal organ function and physiologic reserve (the difference between basal and maximal organ function) are generally well maintained. Subsequently, physiologic reserve diminishes. Both aging and a higher ASA Physical Status classification score are associated with an increased incidence of postoperative complications. In the healthiest patients, those who are ASA classifications P1 (free of systemic disease) and P2 (mild systemic disease), the major complication frequency increases gradually with age until about age 70 years. For ASA classification P3 patients, which includes less healthy patients, the incidence of major complications commences at an earlier age and increases rapidly with age. For ASA classification P4 patients (a patient with disease that is a constant threat to the patient's life), the complication curve rises even more steeply. Many studies show that age and comorbidity are independent predictors of mortality in both the general surgical population and in the critically ill patient.[15–17]

Mortality and complication rates have been well studied in the elderly (age ≥65 years) general surgical population.[18–20] Baseline characteristics in the elderly population include a reduced functional status, more emergency operations, a higher ASA classification (20% of patients age 80 years and older were ASA P4), and more frequent do-not-resuscitate (DNR) orders. Mortality rates vary widely across many types of operations and are higher for those age 80 years and older. Postoperative complications were also more common in patients of age ≥80 years (20% had one or more complications) and mortality was higher in those who suffered complications postoperatively. One study reported a 5% increase in perioperative mortality risk for every year of age after 80.[19]

Morbidity and mortality rates in elderly patients admitted to the ICU are higher than in younger patients. Compared with younger patients, elderly patients are more severely ill on admission, and more likely to have shock and renal dysfunction. One study reported that hospital mortality was more than doubled for patients age 75 years and older in comparison with patients younger than age 65 years.[21–24]

CONSIDERATIONS OF THE SURGICAL PROCEDURE

Critically ill patients may undergo myriad surgical procedures, including a tracheostomy for respiratory failure, surgery to remove a septic focus, or procedures for traumatic injuries. Whether definitive measures should be undertaken during the operative procedure or whether that should be preferentially delayed and performed electively when the patient has recovered depends on the stability of the patient and the nature of the intervention that is needed. In general, the simplest intervention resulting in the least physiologic upset is the best option for the critically ill patient. The decision to proceed to surgery and the extent of the surgical procedure must weigh the benefits and risks of the specific intervention as they may cause further complications, such as bleeding or inadvertent injury to other organs or tissues. Ideally, surgery should only be undertaken following adequate resuscitation. However, timely and emergent intervention may be vital and lifesaving in certain conditions, for example, patients with necrotizing soft-tissue infection or intestinal ischemia.

INTRAOPERATIVE MANAGEMENT

Transporting the Critically Ill Patient

Unless the surgical procedure is planned to occur in the ICU, the critically ill patient will need to be transported from the ICU to the operating room. These patients are at high risk for complications en route. Adverse events during transport include serious mishaps such as the loss of intravenous access, accidental extubation, occlusion of the endotracheal tube, and exhaustion of the oxygen supply, as well as physiologic deterioration of the patient's state (e.g., worsening hypotension or hypoxemia). Studies report adverse events rates of 5.9–66% during transport of critically ill patients.[25,26] One study reported a high incidence of hemodynamic changes requiring therapeutic intervention during and after transport from the operating room to the ICU.[27] Clearly, planning and acting to reduce or minimize this risk is an important area of patient safety (Table 79–3).

Prior to transport the anesthesiologist should check the size and placement of the patient's intravenous (IV) access. Patency of the IV routes should be assessed. The type of monitoring needed for transportation will depend on the patient's clinical status. Patients with arrhythmias should have continuous electrocardiogram (ECG) monitoring. Patients who are hemodynamically unstable should have continuous blood pressure monitoring.

The infusion rates of pressors should be noted and the patient should be hemodynamically stable before transportation. There should also be an adequate volume of drug to last during transport. Common drugs needed for resuscitation, such as epinephrine and atropine, should be readily available.

The patient should have a secured airway to allow safe transport. Patients should be assessed for their need for intubation prior to transport. Intubated patients are usually taken off mechanical ventilation and switched to manual ventilation with a self-inflating Ambu bag during transport. Adequate PEEP should be applied during manual ventilation. The oxygen tank should be checked to ensure an adequate supply at the required flow rate for transport. A mask, laryngoscope, and extra endotracheal tubes should be available should an accidental extubation occur during transport.

All drug infusions (e.g., sedatives, pressors, insulin), their rates, and the IV route that they are infused via should be noted. If total parenteral nutrition (TPN) is stopped, an alternate source of glucose must be provided. If a sedative and/or muscle relaxant is needed for transport, it should be administered in the ICU and the patient monitored for hemodynamic and respiratory side effects (e.g., hypotension) prior to transport.

Finally all infusion pumps should be securely attached to the bed or to specialized transfer devices. There should be adequate assistance to transport the patient and treat minor problems. The operating room should be ready to receive the patient prior to leaving the ICU.

TABLE 79–3.

Transport Checklist

Intravenous access	• Check size and placement • Check patency
Monitors—depends on patient's clinical status	• Consider Continuous electrocardiogram monitoring Continuous blood pressure monitoring Continuous pulse oximetry monitoring
Infusions	• Note infusion rate of medications • Is there an adequate volume to last during transportation? • Are infusions pumps securely attached to bed or transport unit? • If total parenteral nutrition is stopped, check that glucose infusion is running
Drugs for transport	• Consider Resuscitation drugs Sedatives Pressors Antihypertensive agents
Airway	• Assess airway; consider need for intubation prior to transport • Have self-inflating bag for ventilation available • Assess need for positive end-expiratory pressure • Oxygen—ensure adequate supply for transport • Have mask, laryngoscope, extra endotracheal tubes available for transport
Assess need for sedatives/muscle relaxant	• If needed, administer and monitor for side effects prior to transport
Ensure adequate help to transport patient	
Ensure operating room is ready to receive patient	

Monitoring Options

Standard Monitors

Basic standards for monitoring have been established by the ASA (Table 79–4) and should be adhered to in the critically ill patient.[28] The patient's systemic oxygenation (SpO_2), ventilation, circulation (blood pressure, heart rate) and core temperature should be continually evaluated during all anesthesia procedures.

Use of an oxygen analyzer to measure the oxygen concentration in the patient breathing system and a quantitative assessment of systemic blood oxygenation (e.g., SpO_2 via pulse oximetry) can ensure adequate oxygenation. Ventilation should be evaluated with clinical signs (e.g., chest excursion or auscultation of breath sounds) as well as quantitative continuous monitoring of the level of expired carbon dioxide ($PETCO_2$). Monitoring the tidal volume of expired gas is strongly encouraged. There should be a rapid audible alarm if any of the components of the breathing system is disconnected.

Every patient should have their electrocardiogram continuously displayed, and arterial blood pressure and heart rate should be determined and assessed every 5 minutes at a minimum. To ensure the adequacy of the patient's circulatory function, the patient should be continuously evaluated by either palpation of an arterial pulse, auscultation of heart sounds, observing the trace of intraarterial pressure, ultrasound peripheral pulse velocity monitoring, pulse plethysmography, or oximetry.

Core temperature monitoring should be employed when clinically significant changes of body temperature are possible.

Because of the possibly rapid changes of hemodynamic status occurring during anesthesia, the ASA standards also require the presence of qualified anesthesia personnel to monitor the patient and provide care throughout the conduct of all general and/or regional anesthetics and monitored anesthesia care.

Invasive Monitors

Additional monitors may be needed to provide an accurate picture of the patient's hemodynamic status. Invasive monitors may also be necessary to guide therapy to optimize the patient's condition. However, there are limitations to all these monitors and potentially some risk to the patient with the use of invasive monitors. Thus, the anesthesiologist must be cognizant of these limitations and weigh the risks and benefits of invasive monitoring in order to choose the appropriate monitors for the critically ill patient (Table 79–5).

Invasive Arterial Pressure Monitoring Because shock represents the failure of the circulatory system to maintain an adequate delivery of blood flow to tissues, and the goal of hemodynamic therapy is to restore adequate tissue perfusion, systemic pressure measurement is the most frequently used parameter to indirectly assess perfusion.

In healthy individuals, blood pressure as determined by noninvasive blood pressure (NIBP) monitors is, on average, within 5 mm Hg of those obtained from direct arterial pressure monitoring. Sources of error in NIBP measurements include incorrect cuff size or a highly irregular or rapid cardiac rhythm. However, in shock states, NIBP measurements are very often inaccurate. Therefore, inserting an arterial catheter provides a more accurate and reproducible measurement of arterial pressure. Invasive arterial monitoring allows beat-to-beat display so decisions regarding therapy can be based on continuous blood pressure analysis.

Blood pressure does not always directly equate to tissue blood flow, and the level of mean arterial pressure to aim for is not necessarily the same in all patients. Below a mean arterial pressure of 60 mm Hg, autoregulation of the coronary, renal, and central nervous system vascular beds is compromised and organ flow becomes linearly dependent on pressure. Thus, in adults, maintenance of a mean arterial pressure of ≥60 mm Hg is usually required to maintain and optimize flow. However, because the loss of

autoregulation may occur at different levels in different organs, some patients may require higher blood pressures to maintain adequate tissue perfusion. Furthermore, the degree to which autoregulation remains intact in septic patients is uncertain. It is may be necessary at times to supplement blood pressure measurement with other means of assessing regional and global perfusion (e.g., urine output).

Central Venous Pressure Catheter Systemic hypotension is the most common reason to initiate invasive central hemodynamic monitoring in the critically ill patient. The central venous pressure (CVP) reflects the pressure in the large systemic veins. Although the CVP is used to reflect intravascular volume, it does not measure blood volume directly and is influenced by right-heart function, venous return, right-heart compliance, intrathoracic pressure, and patient positioning. Consequently, the CVP level should always be interpreted along with other measures of cardiac function and fluid state (e.g., pulse, blood pressure, urine output). The absolute CVP value may not be as important as serial CVP measurements or the change in response to therapy.

Measurement of the CVP may provide useful information in patients with normal cardiac function who are hypotensive because of blood loss or widespread vasodilatation, as a decreased venous return will result in a falling right atrial pressure and CVP. A central venous catheter should also be inserted if infusion of vasopressors or inotropes is planned.

Pulmonary Artery Catheter In addition to the CVP, the pulmonary artery catheter (PAC) allows measurement of the pulmonary artery pressure, the pulmonary artery occlusion pressure (PAOP), the cardiac output, and the mixed-venous oxygen saturation (SvO_2). The PAOP reflects the pulmonary venous pressure and left ventricular end-diastolic pressure (LVEDP), and therefore provides a crude estimate of left ventricular end-diastolic volume (LVEDV). Blood gas and saturation measurements performed on specimens obtained from the superior vena cava and/or pulmonary artery (mixed venous) can serve as a reflection of global perfusion. Special pulmonary artery catheters are available which allow the continuous measurement of mixed venous

TABLE 79–5.

Comparison of Monitors Used in Critically Ill Patients

Monitor	Indications	Limitations
Central venous pressure (CVP)	• Reflects intravascular volume	• Depends on right-heart function, venous return, right-heart compliance, intrathoracic pressure, patient positioning
Pulmonary artery catheter (PAC)	• Measures pulmonary artery pressure, cardiac output, and pulmonary artery occlusion pressure, which reflects left ventricular end-diastolic volume	• Depends on right- and left-heart compliance, intrathoracic pressures, valvular lesions
Transesophageal echocardiography (TEE)	• Qualitative measurement of ventricular function, ventricular volume, and valvular abnormalities	• Requires training to perform procedure and correctly interpret images • Can consume anesthesiologist's time and attention
Gastric tonometry	• Indication of regional hypoperfusion • Reflects blood flow-to-demand ratio	• pH_{im} calculation affected by both systemic and respiratory alterations • Unproven utility to guide therapy

saturation, cardiac output, and even right ventricular volumes and contractile function (by thermodilution).

Indications for placement of the pulmonary artery catheter may be related to the planned procedure, or the patient's state of health, or both (Table 79–6). The pulmonary artery catheter may provide useful information in any procedure associated with acute, severe changes of preload, afterload, or the contractile state. For example, procedures where blood loss may be massive, or where partial or complete caval occlusion might occur can cause acute changes of cardiac preload. Similarly, proximal aortic cross-clamping can cause a rapid increase of afterload. Patient factors that can lead to the insertion of a PAC include septic shock or other significant cardiac, respiratory, or renal disease. In septic shock, hypovolemia and myocardial dysfunction can be important factors contributing to impaired tissue perfusion. The pulmonary artery catheter is often used to monitor cardiac output and assess ventricular stroke volume.

The use of the pulmonary artery catheter has been called into question by the publication of an observational study that demonstrated an increased mortality associated with the use of the pulmonary artery catheter in critically ill patients during the first 24 hours of intensive care as compared with case matched controls.[29] Multiple randomized controlled trials evaluating the use of the PAC in many different patient populations have shown neither an increased overall mortality nor any conferred benefit.[30–32] In all these studies, the PAC has proven to be a diagnostic tool. The studies highlight our lack of consensus and data about therapeutic interventions that will improve the outcome of the critically ill patient.

A major pitfall of central pressure monitoring is that pressure is used to estimate volume. Important variables other than the volume of the systemic and pulmonary circulations can affect the central pressure measurement. The relationship between pressure and volume is controlled by the compliance of the chamber. In patients with abnormal left ventricular compliance, the PAOP may over- or underestimate the LVEDV. Right ventricular (RV) dysfunction is common in critically ill patients and can be a result of pulmonary embolism, acute respiratory distress syndrome (ARDS), or other conditions that increase RV afterload, such as high levels of PEEP or an increased pulmonary vascular resistance as a consequence of other vascular, cardiac, metabolic, or pulmonary causes. Because the right and left ventricles are both enclosed within the relatively stiff pericardium, pressure and volume overload of the RV can lead to abnormal motion of the interventricular septum and impair left ventricular (LV) relaxation. In this situation, the pressure–volume relationship of the left ventricle is altered, and information obtained from the PAC may be misleading. Other factors that can affect the ability of central pressures to reflect ventricular filling volumes include increased intrathoracic pressures and valvular lesions. Increased intrathoracic pressure caused by positive pressure ventilation with PEEP or caused by increased intraabdominal pressures can elevate central pressures. Stenotic lesions of the atrioventricular valves can also elevate central vascular pressures.

Other potential pitfalls include problems with the transducer system (e.g., improper transducer placement or reference level zeroing), improper interpretation of waveforms, and erroneous thermodilution cardiac output measurements because of problems with the injectate volume or temperature. The presence of marked tricuspid valve regurgitation, which can occur in the critically ill patient as a consequence of high pulmonary artery pressures, can also lead to erroneous cardiac output measurements. Blood gas and saturation measurements may be invalid if the blood gas analysis is inaccurate or if the pulmonary artery specimen is "arterialized" by being withdrawn from a wedged or partially wedged pulmonary artery catheter.

There are major but uncommon complications associated with the presence of the pulmonary artery catheter itself. Rupture of the pulmonary artery is a rare occurrence (<1%) but a potentially catastrophic one with a mortality rate of 50%. Patients who have pulmonary hypertension, or are >60 years, or who are receiving anticoagulation therapy are at greater risk. The sudden onset of hemoptysis (especially after inflation of the pulmonary artery catheter balloon) is a sign of possible pulmonary artery rupture. Immediate management includes lateral decubitus positioning with the bleeding side down, intubation with a double-lumen endotracheal tube, and increasing PEEP. Embolization via angiography, or even a lobectomy may be necessary if bleeding continues or is massive. The incidence of pulmonary infarction associated with the use of the pulmonary artery catheter is less than 7% and usually caused by unintentional distal migration of the PAC tip. Catheter-related thrombi also may cause pulmonary infarction. Infection related to the pulmonary artery catheter is fairly common with a risk for clinical sepsis of <0.5% per day of catheter use.

Thus hemodynamic measurements obtained from a pulmonary artery catheter should be interpreted with the full knowledge of possible confounding factors. It may often be more

appropriate to respond to trends of change in central hemodynamic measurement (e.g. a slowly falling pulmonary capillary wedge pressure or CVP) rather than to the absolute values themselves.

Echocardiography

In view of the concerns regarding the risks and benefits of pulmonary artery catheterization, other methods of assessing the adequacy of resuscitation have been developed and evaluated. Echocardiography has been used in the operating room since the 1970s. Transesophageal echocardiography (TEE) is preferred in the operating room because the acoustic images of transthoracic echocardiography (TTE) are generally poorer than those of TEE.[33] Patients who are mechanically ventilated and require PEEP may be inadequately imaged by TTE, especially if more than 10 cm H_2O of PEEP is required. Furthermore, factors such as patient positioning, the surgical field, and surgical equipment, drapes, or monitors may block access to the chest, limiting the usefulness of TTE.

There are some important limitations to TEE.[33] Some regions of the heart and great vessels cannot be well visualized. Insertion and manipulation of the TEE probe can produce pharyngeal and/or laryngeal trauma, dental injuries, esophageal trauma, arrhythmias, and hemodynamic effects. The inaccurate interpretation of TEE images can generate incorrect information and may potentially result in improper clinical decisions by the anesthesiologist and surgeon. The performance of TEE can also consume the anesthesiologists' time and attention and detract them from other intraoperative responsibilities and delay important interventions.

Nevertheless, the role of TEE in the operating room, especially to monitor patients during cardiac surgery, is expanding. Current indications for the use of TEE intraoperatively include the diagnosis of myocardial ischemia, confirmation of the adequacy of valve reconstruction and other surgical repairs, and determination of the cause of hemodynamic instability and other intraoperative complications.[33] TEE can readily provide information on ventricular volume and contractility, valvular problems and wall-motion abnormalities.

The perioperative period is a time of increased risk of myocardial ischemia as a result of hemodynamic and other physiologic stresses associated with surgery. Wall-motion abnormalities generally precede ECG changes during myocardial ischemia[34] and thus may allow earlier detection of ischemia. The incidence of regional ventricular dysfunction detected by TEE ranges from 10–60%[33] in various surgical populations. Intraoperative TEE detection of ischemia may permit corrective interventions, including alterations in surgery, anesthetic management, and postoperative triage, which may prevent perioperative complications. There is a lack of studies demonstrating that the detection and treatment of regional ventricular dysfunction or other TEE evidence of ischemia can result in an improved perioperative clinical outcome or increased long-term survival.

Perioperative TEE is often used emergently to determine the cause of acute persistent, life-threatening hemodynamic disturbances. However, elective use of the TEE should be considered in the care of the critically ill surgical patient. TEE is largely a tool for assessing hemodynamic function qualitatively and for imaging the heart (e.g., to diagnose a hemopericardium, tamponade). It provides an assessment of LV function and an indirect measurement of cardiac output, contractility, and left, and possibly right, ventricular volume. Because of the limitations in using catheter-derived pressure data to estimate LVEDV, TEE may be better for determining the precise cause of hemodynamic instability (e.g., a low cardiac output) in patients with left ventricular dysfunction than the pulmonary artery catheter.

Gastric Tonometry

Sepsis is associated with microcirculatory abnormalities that may persist despite restoration of intravascular volume. These abnormalities can lead to a maldistribution of cardiac output, inadequate regional perfusion, and multiple organ system failure. Indices of organ function, such as ECG evidence of myocardial ischemia, urine output, chemical measurements of blood urea nitrogen and creatinine, and liver function tests can be used to indirectly assess the adequacy of regional perfusion.

Gastric tonometry is a method to assess regional perfusion in the gut. A balloon is placed in the stomach to measure the intramucosal partial pressure of carbon dioxide (PCO_2). This is, in turn, used to indirectly determine gastrointestinal mucosal pH (pH_{im}). Hypoperfusion causes mucosal carbon dioxide (CO_2) to increase and produces tissue acidosis. Because CO_2 readily diffuses across membranes, the PCO_2 in the gut lumen leads to an increase in the gradient between arterial and luminal PCO_2. Tonometry provides an indicator of the blood flow-to-CO_2 production ratio as hypoperfusion may arise as a result of either a decreased blood flow or an increased CO_2 production. A low gastric pH_{im} and increased gastric luminal PCO_2 are highly predictive of postoperative complications.[35] However, despite its promise, tonometry has not become a routine intensive care monitoring technique because of uncertainties related to both its physiologic basis and methodology.[36] Calculation of the pH_{im} involves both locally derived and systemic variables and therefore can be affected by systemic metabolic and respiratory alterations. Methodologic concerns include whether gastric acid secretion affects the measurement of pH_{im}, whether gastric feeding affects pH_{im}, and whether blood gas analyzers calibrated for blood or calibration fluids can accurately measure PCO_2 in saline or air. Although tonometry is a reasonably good predictor of mortality in critically ill patients,[37] its usefulness as a therapy guide in patients with sepsis and septic shock has not been proven.

Airway Evaluation and Management

There are myriad indications for endotracheal intubation of the critically ill patient. These patients may lose their airway, develop an inadequate respiratory drive because of central nervous system disease or the administration of sedative drugs, suffer disruption of the rib cage as a consequence of trauma, develop lung parenchymal disease secondary to ARDS or aspiration, or have an impaired ability to cough or protect their airway against the aspiration of gastric or pharyngeal contents.

As in the healthy patient, preparation for endotracheal intubation should begin with an assessment of airway anatomy. If a difficult intubation is anticipated, fiberoptic intubation should be considered early. Airway adjuncts such as a laryngeal mask airway, and oral and nasal airways of various sizes should be immediately

available. Additional personnel should be on hand and a surgeon should be available to perform a cricothyrotomy or tracheostomy should endotracheal intubation be unsuccessful and ventilation be inadequate via mask or laryngeal mask airway.

Studies show that an increased ASA classification and emergency surgery are associated with an increased risk of aspiration.[38] Information such as recent vomiting, bowel obstruction, morbid obesity, diabetes mellitus, or a depressed mental status should be factored into the assessment of aspiration risk in the critically ill patient. Prior to intubation, *nil per os* (NPO) status should be confirmed if possible. Consider placing a nasogastric tube to empty liquid gastric contents. In the conscious patient, an awake intubation is preferred although a rapid sequence intubation may also be considered.

Direct laryngoscopy to facilitate tracheal intubation produces a marked stress response.[39] Although these responses are short-lived, they may produce detrimental effects on the coronary or cerebral circulation of high-risk patients.[40] Thus, patients should first be assessed for the presence of angina or ischemia, dysrhythmias, and congestive heart failure. The patient's neurologic status including the presence of an increased intracranial pressure, intracranial aneurysms and hemorrhage should be determined. In these patients, hypertension should be avoided and heart rate and blood pressure should be maintained within a narrow range during laryngoscopy and intubation. Before intubation, adjuncts such as airway blocks with local anesthetics, use of adequate β-adrenergic blockade, and deep anesthesia with opioids or barbiturates should be considered.

In trauma patients, the presence of cervical and mandibular fractures and instability should be determined. All patients with multiple trauma, head, or facial injury should be presumed to have a cervical spine injury unless it has been excluded by a thorough radiographic and physical evaluation. A second skilled person should be present during intubation to provide in-line stabilization to maintain the head and neck in a neutral position. Nasotracheal intubations are relatively contraindicated in patients with oropharyngeal and facial trauma because of the possibility of cranial vault disruption.

Patients with recent spinal cord denervation injuries, crush injuries, or burns should not be given depolarizing muscle relaxants because of the risk of life-threatening hyperkalemia. The patient's coagulation status should be evaluated as mucosal trauma and subsequent bleeding associated with laryngoscopy can result in loss of visualization of the airway and an increased risk of aspiration.

Anesthetic Choices

General anesthesia is most often used for surgery in the critically ill patient because of multiple factors, among them surgical and hemodynamic considerations. However, a regional anesthetic can play a role as a valuable adjunct to general anesthesia, and in the management of postoperative pain in the critically ill patient to achieve optimum patient comfort and to reduce physiological stress.[41]

Epidural analgesia is probably the regional analgesic technique most often used in the intensive care unit. It has been employed to manage pain after chest trauma, thoracic and abdominal surgery, major orthopedic surgery, and intractable anginal pain. Studies show that to manage patients after chest trauma, thoracic epidural analgesia provided superior analgesia and improved measurements of lung function.[42] High levels of thoracic epidural analgesia (T1-T4) can provide effective treatment of myocardial ischemia refractory to conventional medical therapy.[43] Benefit probably occurs through both increased myocardial oxygen delivery as a result of coronary artery vasodilatation and decreased myocardial oxygen demand because of reduced heart rate and blood pressure. Issues such as local or systemic infection and coagulopathy can limit or prevent the use of epidural analgesia. Furthermore, there remains controversy over the safety of placing epidural catheters in sedated patients, and confirmation of catheter position can be difficult if sensory level testing is unreliable.

The use of peripheral nerve blocks to produce anesthesia in the critically ill population has not been evaluated by randomized, controlled trials. Continuous interscalene, infraclavicular, and axillary catheters may provide good postoperative analgesia for the shoulder and upper extremity. Similarly, a femoral nerve catheter in combination with a sciatic block can provide pain relief for the whole leg. These techniques can be used to provide surgical anesthesia for procedures such as external fixation, painful dressing changes, or debridement of burns and large soft-tissue wounds. Regional analgesia may be particularly advantageous in the patient with brain injury where opioid analgesic agents might mask the neurologic examination.[41] Although there are concerns in placing regional blocks in patients with an impaired mental status because of neurologic injury or sedation, ultrasonography and nerve stimulation to guide placement of the needle or catheter may minimize the risk of complications.

INTRAOPERATIVE MANAGEMENT

There should be specific goals and end points defined for the hemodynamic management of the critically ill patient. Therapies such as fluid administration, and vasopressor and inotropic support should be titrated to reach those end points. The results of these interventions should be evaluated on an ongoing basis by monitoring a combination of variables reflecting global and regional tissue perfusion.

Hemodynamic Management

Early Goal-Directed Therapy

The care of the critically ill patient is largely supportive. Based on the old observation that improved survival was associated with the ability to sustain a hypermetabolic state by increasing cardiac output and oxygen delivery, the hypothesis was proposed that by proactively increasing the systemic oxygen delivery rate, oxygen debt could be reversed and mortality from multiple organ failure might be reduced. Although a large, randomized, controlled trial investigating the effect of increasing oxygen transport on the outcome of the critically ill patient found no overall benefit,[44] some studies have found that the perioperative hemodynamic optimization of high-risk surgical patients appears to be associated with a reduction in morbidity and mortality.[45,46] This finding is consistent with another study that showed that early goal-directed therapy in patients with septic shock resulted in decreased in-hospital mortality.[10]

One of the challenges is to define the goals of goal-directed therapy. Some studies have targeted a systemic oxygen delivery rate of 600 mL/min/m^2 body surface area.[46] Others have used a central venous oxygen saturation of greater than 70% as the goal.[10] Another challenge is determining the best therapeutic maneuvers to achieve the targeted goal. Most studies have used fluid (either crystalloid or colloid) infusion and inotropic agents (dobutamine and dopexamine). One study required blood transfusions to a hematocrit of ≥30% to help achieve the goal of achieving a central venous oxygen saturation of greater than 70% (Fig. 79–1).[10] Although the goals of treatment and the ideal therapies needed to achieve those goals remain uncertain, it is clear that early optimization of hemodynamic status can have a significant benefit in reducing the mortality rate in patients with severe sepsis and septic shock.

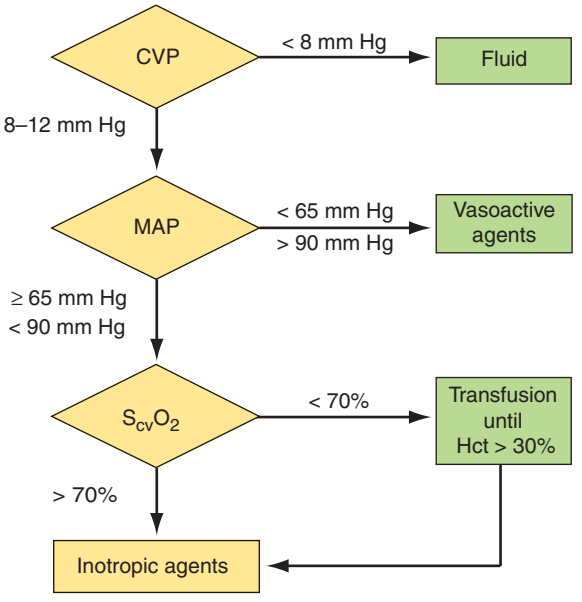

FIGURE 79–1. Goal-directed therapy. (Rivers E, Nguyen B, Havstad S, et al. Early Goal-Directed Therapy in the Treatment of Severe Sepsis and Septic Shock. N Engl J Med 2001;345:1368. Copyright 2001, Massachusetts Medical Society. All rights reserved.)

Fluid Management

Fluid resuscitation may consist of natural or artificial colloids or crystalloids. Meta-analyses of clinical studies comparing crystalloid and colloid resuscitation in general and surgical patient populations show no difference of clinical outcome between colloids and crystalloids.[47,48] This would appear to be generalizable to the critically ill patient. As the volume of distribution is much larger for crystalloids than for colloids, resuscitation with crystalloids requires more fluid to achieve the same end points and may result in more edema.

Pharmacologic Management

Although hypovolemia is the major common factor contributing to shock in the patient with sepsis, below a certain mean systemic arterial pressure, perfusion becomes linearly dependent on pressure because of the loss of autoregulation. Therefore, it is frequently necessary to infuse vasopressors to maintain an adequate blood pressure in patients with severe shock. Patients with a low cardiac output despite an adequate fluid resuscitation (e.g., high CVP or pulmonary capillary wedge pressure) may require an inotropic agent to increase their cardiac output.

Pressor Support Norepinephrine is the first-choice vasopressor agent to reverse the hypotension of septic shock.[49] Human and animal studies suggest some advantages of norepinephrine over epinephrine and phenylephrine. Epinephrine can produce a tachycardia and may have disadvantageous effects on the splanchnic circulation because of vasoconstriction. Use of phenylephrine may result in a decreased stroke volume because of its characteristics as a pure α-agonist, but it is least likely to cause tachycardia. Norepinephrine increases mean systemic arterial pressure due to its vasoconstrictor effects with little change of heart rate and stroke volume, as it has only weak β-adrenergic effects. Dopamine is also an acceptable pressor agent. Dopamine increases the mean arterial pressure and cardiac output primarily as a consequence of an increase in stroke volume and heart rate. Its use may be limited because it causes tachycardia and can be arrhythmogenic. Norepinephrine is more potent than dopamine and may be more effective at reversing the hypotension of patients suffering septic shock.

Vasopressin infusion should be considered in patients with refractory shock despite the infusion of adequate fluid volumes and administering high doses of conventional vasopressors.[49] Its vasoconstrictor effects are mediated by actions on peripheral vasopressin receptors. In contrast to catecholamine-mediated vasoconstriction, the effects of vasopressin are preserved despite hypoxia and severe acidosis. Exogenous infusion of vasopressin can reverse the natural arginine vasopressin deficiency that occurs in prolonged shock.[50] However, whether this is important to its mechanism of action is unclear. Additional vasopressin mechanisms that might be important in septic shock include facilitation of myocyte depolarization and vasoconstriction of vascular smooth muscle, attenuation of nitric oxide generation by cytokines and inflammatory mediators, enhanced adrenergic responsiveness, and stimulation of synthesis of endothelin-1, a potent endogenous vasoconstrictor.[51] When infused in adults, vasopressin should be administered at infusion rates of 0.01–0.04 units/min. Doses of vasopressin greater than 0.04 units/min are associated with myocardial ischemia, significant decreases of cardiac output, and splanchnic hypoperfusion.

Inotropic Support Dobutamine is the first-choice inotropic agent for critically ill patients with measured or suspected low cardiac output in the presence of an adequate left ventricular filling pressure or adequate fluid resuscitation.[49] Because a low arterial blood pressure may be caused by both a low cardiac output as well as vasodilatation, the use of both an inotropic agent such as dobutamine to augment cardiac output and a vasopressor such

as norepinephrine to achieve an adequate mean arterial pressure may be needed.

Dopexamine is a dopamine receptor agonist developed for use in the treatment of heart failure and low cardiac output states. It is not available for clinical use in the United States. Dopexamine has been used to increase oxygen delivery in some goal-directed therapy studies.[44] Dopexamine increases splanchnic blood flow in the critically ill patient and may possess intrinsic antiinflammatory properties. These additional actions may contribute to the reported reduction in sepsis-related mortality associated with the use of dopexamine. Additional controlled trials are needed to demonstrate these clinical effects of dopexamine.

Preservation of Renal Function

Patients with sepsis, cirrhosis, jaundice, hepatorenal syndrome, congestive heart failure, malignant hypertension, preeclampsia and toxemia, hypotension as a consequence of hemorrhage, or recent exposure to IV radiocontrast agents are predisposed to develop acute renal failure when exposed to a subsequent intraoperative ischemic insult. There are few large randomized trials assessing the effectiveness of many of the current strategies of possibly preventing renal injury in the surgical patient and thus all must remain experimental.

Sodium Bicarbonate and N-Acetylcysteine

The most extensive literature on renal failure protection comes from studies of radiocontrast nephropathy. Radiocontrast dye induces severe changes of intrarenal hemodynamics leading to ischemic injury. Studies show that hydration prior to the administration of contrast is effective in lowering the rate of acute renal injury.[52–54] Furthermore, hydration with sodium bicarbonate has been shown to be more effective than hydration with sodium chloride for the prophylaxis of contrast-induced renal failure.[55] The purported mechanism is by inhibition of free radical formation at the higher pH. The prophylactic administration of *N*-acetylcysteine, an antioxidant, improves renal outcome after radiocontrast administration.[56] Although there is no evidence that these maneuvers improve outcomes in the surgical ICU because of other types of renal injuries, these studies are often extrapolated to high-risk surgical procedures.

Dopamine

Many studies demonstrate that "renal dose" dopamine (1–2 μg/kg/min) has no beneficial effect on renal outcome perioperatively.[57] However, urine output frequently increases during dopamine administration. Unfortunately, urine output may not correlate with adequate oxygenation of the renal medulla. Dopamine causes an increase in renal cortical blood flow, leading to increased glomerular filtration, solute excretion, and urine output. These actions increase renal oxygen consumption. However, dopamine also has a diuretic and natriuretic effect, believed to be a result of inhibition of the sodium-potassium adenosine triphosphatase (ATPase) of the proximal tubule and medullary thick ascending limb. This inhibitory effect would decrease tubular energy requirements and medullary oxygen requirements. Thus, the net effect of a dopamine infusion on renal medullary oxygenation is unclear.

Mannitol

Mannitol has traditionally been given intravenously to patients considered at high risk for acute renal failure. It increases tubular diameter and decreases tubular resistance to fluid flow by decreasing endothelial cell swelling by dehydration. The enhanced urine flow is believed to help prevent tubular obstruction and further renal injury. Mannitol is a weak free radical scavenger. Although mannitol is beneficial in animal studies and small clinical trials,[58] there are no large, prospective, controlled trials demonstrating any benefit in surgical patients who are at high risk of renal damage.

Mannitol is usually administered as a single IV dose (0.5–1.0 g/kg) intraoperatively before the application of the cross-clamp in aortic surgery patients, or included in the cardiopulmonary bypass prime in cardiac surgery. Volume status and electrolyte balance, especially plasma potassium shifts, should be monitored after the administration of mannitol.

Furosemide

Furosemide inhibits the energy-dependent reabsorptive work in the medullary thick ascending limb and thus ameliorates hypoxia in the renal medulla. Because it can also cause cortical vasodilatation resulting in medullary hypoperfusion, prolonged administration of furosemide may be more deleterious than protective to renal function. Thus it may be prudent to administer furosemide in a single large-bolus dose shortly before the anticipated ischemic stress. There are no randomized studies evaluating furosemide as a sole renal protectant agent in surgical patients.

Fenoldopam Mesylate

Fenoldopam is a selective dopamine-1 (DA1) receptor agonist used to treat hypertension.[59] Unlike dopamine, it has no activity at dopamine-2 (DA2) or at α- or β-adrenergic receptors, and thus does not cause either tachycardia or hypertension. Fenoldopam reduces blood pressure in a dose-dependent manner while preserving renal perfusion and glomerular filtration rate.[60] It inhibits sodium reabsorption and thus may attenuate medullary oxygen demand while enhancing its supply. Large prospective trials evaluating fenoldopam as a renal protectant in humans have not yet been published.

Dopexamine

Dopexamine, a dopaminergic (DA1 and DA2) agonist with β_2-adrenergic activity, has generated interest as a renal protectant based on the hypothesis that it could improve renal perfusion without the risk of α-adrenergic stimulation.[61] Dopexamine lacks the myocardial side effects of dopamine although it may cause hypotension. Large, well-designed trials are needed to assess its usefulness as a renal protectant.

Future Agents

Renal vasodilators such as atrial natriuretic peptide, urodilatin, and prostaglandin E_1 have been tested as renal protectants in radiocontrast nephropathy.[62] Insulin-like growth factor-1 is an endogenous substance that improves recovery from acute renal failure in animal studies. Acidic fibroblast growth factor-1 (FGF-1) attenuates experimental myocardial ischemia–reperfusion injury and also attenuates acute renal failure after experimental ischemia–reperfusion injury of the kidney in rats. The antiinflammatory and vasodilating effects of nitric oxide may mediate the protective effect of FGF-1. None of these agents has been studied

in patients who are undergoing surgery associated with a high risk of renal damage. Further large investigations are warranted before adopting any of the previously discussed agents as a perioperative renoprotective strategy.

Intraoperative Glucose Management

Anesthesia and surgery are associated with increased catecholamine levels resulting in increased glycogenolysis, gluconeogenesis, and lipogenesis. Furthermore, glucagon levels increase and insulin secretion decreases. Thus, patients undergoing anesthesia and surgery are at risk for hyperglycemia caused by both an increased insulin resistance and decreased insulin secretion. Data regarding the outcome of intraoperative "tight" glucose control is lacking. One randomized study in diabetic patients undergoing coronary artery bypass grafting found that "tight" glycemic control (plasma glucose levels held between 125 and 200 mg/dL) resulted in a lower incidence of atrial fibrillation and a shorter postoperative hospital length of stay. Tight glycemic control was also associated with a survival advantage for the initial 2 years after surgery, decreased episodes of recurrent ischemia, and fewer wound infections.[63] Other studies have demonstrated the adverse effects of hyperglycemia on neurologic outcome[64] and renal failure[65] in patients who are undergoing cardiac procedures requiring cardiopulmonary bypass.

Perioperative normoglycemia can be hard to achieve despite infusion of large doses of insulin. One study showed that normoglycemia could be maintained during cardiac surgery by employing the hyperinsulinemic normoglycemic clamp. With this technique, insulin is infused at a constant rate to increase plasma insulin, and, concurrently, IV glucose is titrated to clamp the blood glucose concentration at the specific level.[66]

Awareness

Awareness is the postoperative recollection of events occurring during general anesthesia. The incidence of awareness is rare in the general surgical population (0.1–0.2%).[67] However, the incidence of awareness is greater in certain at-risk populations, especially those in patients who receive light anesthesia, usually because of hemodynamic instability. The incidence of awareness in patients who undergo surgery for major trauma is reported as high as 43%. Awareness can be difficult to detect clinically because the typical indicators of "light" anesthesia such as increased heart rate, hypertension, or movement may be masked by drugs or the patient's overall status. More than half of the patients who report experiencing intraoperative awareness have subsequent mental distress, including posttraumatic stress syndrome, after surgery. If light anesthesia is required because of hemodynamic considerations, then amnestic drugs such as midazolam, scopolamine, or subanesthetic doses of ketamine should be administered. When possible, neuromonitoring technologies to detect the presence of awareness should be considered. One randomized, controlled study found that bispectral index (BIS) monitoring of the electroencephalogram (EEG) of high-risk patients (defined as patients undergoing cesarian section or high-risk surgery, patients with a history of chronic benzodiazepine, opioid, or heavy alcohol use, and patients with acute trauma and hypovolemia) reduced their risk of awareness by 82%.[68]

POSTOPERATIVE CARE AND HANDOFF TO THE ICU TEAM

The critically ill patient should be transported back to the ICU from the operating room by an anesthesiologist. The considerations for transport back to the ICU should be similar to those for transport to the operating room. The patient should be hemodynamically stable and have a secure airway prior to transport. Emergency medications, ample oxygen, and supplies for airway management must be available. There should be ample and functional intravenous access. All infusions should be running well and sufficient medication to last the time needed for transportation to and restabilization in the ICU should be available.

The anesthesia team is responsible for the care of the patient until a full verbal report is given to the ICU team and the ICU team accepts the care of the patient. At this point, the anesthesiologist is the caregiver who is most aware of the patient's status and therefore should be available to assist with any problems that arise immediately postoperatively. A full report, including the patient's medical history, location of monitors and lines, anesthesia technique, including the amounts and types of drugs administered, surgical procedure, other medications administered, estimated fluid and blood volume loss and replacement, anesthetic and surgical complications, and any special issues (e.g., allergies, isolation precautions) should be given to the nurses and physicians who will be caring for the patient in the ICU. The report should include specific problems (e.g., oxygenation, ventilation, hemodynamic instability) that were encountered intraoperatively, the maneuvers, whether successful or unsuccessful, made to resolve the problems, and the rationale behind the maneuvers attempted. A well-considered plan for postoperative pain management should be conveyed. The ICU team should be informed of any special care plans for the postoperative period as well as any potential postoperative problems.

SUMMARY

Anesthesiologists may be involved in the care of critically ill patients in the operating room as they often need surgery to correct the underlying cause of their illness or to deal with the complications of their illness. Planning for the anesthesia management of critically ill patients begins with the preoperative evaluation as these patients may have impaired function of multiple organ systems. Ideally, optimization of the patient's condition should occur preoperatively to ensure that the patient is in the best possible condition to undergo the additional stresses associated with surgery and anesthesia.

Preoperative planning should include a plan for the transport to the operating room because patients are at high risk of adverse events during transport. The anesthesiologist must decide which monitors are necessary for the assessment of the patient's condition, taking into account the advantages and pitfalls of various different options. General anesthesia is most often planned for surgery in the critically ill patient. The anesthesiologist may need to plan a total intravenous anesthetic technique if the patient has severe respiratory failure and requires

an ICU ventilator intraoperatively for adequate oxygenation and ventilation. Regional anesthesia should be given due consideration as it can play a valuable adjunctive role to achieve optimum patient comfort and reduce physiologic stress.

There should be specific goals and end points defined in the intraoperative management of the critically ill patient to optimize hemodynamics and minimize further end-organ damage. Finally, advanced planning and communication between the anesthesiologists, surgeons, critical care team, and the patient and the patient's family are crucial to understanding the goals and priorities of treatment.

CHAPTER 80

Monitoring and Transport of the Critically Ill Patient

Michael G. Fitzsimons, MD, FCCP, and Nathaniel Sims, MD

Transport is assuming a more important role in the medical and surgical management of critically ill adult and pediatric patients. The first structured ground evacuation of the wounded occurred during the Napoleonic Wars when two of Napoleon's medical officers designed practical horse-drawn carriages for the swift evacuation of battlefield casualties.[1] Major John Letterman created an independent ambulance corps during the Civil War and a system of evacuation to clearing stations with secondary transfer to field hospitals as needed. Balloon evacuation of the injured first occurred during the Franco-Prussian War in the 1870s.[2] Specific air medical training was started during World War II along with the first helicopter transport. The Korean and Vietnam Wars saw the increased use and benefits of helicopter transport. In 1972, St. Anthony's Hospital in Denver, Colorado established the first civilian rotor-wing transport program.[3] Today patients with severe injuries are transported over long distances, between countries and continents, and across time zones for advanced care. Advances in medical technology and treatment options have resulted in the need to move critically ill patients within large hospitals for specialty care.

The anesthesiologist and critical care physician commonly encounter issues of transfer of the critically ill patient. Intrahospital transfer may be performed to the operating room urgently for surgery, the radiology suite for diagnostic and therapeutic procedures, and from the emergency department throughout the hospital for additional care. Interhospital transfer involves the movement of a critically ill patient from one treatment facility to another. Transport exposes these patients to multiple stresses that may

KEY POINTS

1. Transport of even the sickest patients can be accomplished safely between and within hospitals.
2. Intrahospital transport is performed within the same hospital to different sites for diagnostic and therapeutic interventions. Interhospital transport involves the movement of a critically ill individual from one treatment facility to another.
3. Clinical management is altered in approximately 40% of patients requiring transport out of the ICU for diagnostic procedures and facilitated interventions. Abdominal CT and angiography were most likely to result in a change of management, thus such transport is often well justified.
4. The incidence of complications occurring with patient transport has historically been high and constant vigilance is required both by caregivers and institution system engineers to keep these to a minimum. System-based and human-based problems can occur in equal proportions.
5. Hemodynamic changes commonly encountered in transport include systemic hypertension, hypotension, and tachycardia. No clear factors helping to predict hemodynamic deterioration during transport have been identified, other than the level of overall pretransport morbidity, instability, or the presence of a recent myocardial infarction.
6. Respiratory deterioration including hypercarbia, hypocarbia, and hypoxemia may occur in a significant fraction of transported patients. Factors that predict changes include the need for positive end-expiratory pressure (PEEP), an FiO_2 greater than 50%, and age › 43 years.
7. There is no evidence that "scoop-and-run" rapid transport without appropriate assessment and preparation is either safe or effective.
8. Appropriate assessment and management of the patient's airway is paramount in safe movement. Intubation during transport can be highly successful when performed by trained personnel, although patients with potentially difficult-to-manage airways are best intubated prior to transport.
9. Mechanical ventilation may maintain respiratory stability better than manual ventilation. Individuals trained in optimum manual ventilation (e.g., respiratory therapists, anesthesiologists) and those with excellent patient assessment skills tend to maintain satisfactory respiratory parameters in patients undergoing transport. On the other hand, transport ventilatory systems may lack optimum alarms and may require constant surveillance for malfunction.
10. Sedation with small does of intravenous short-acting benzodiazepines and opiates can safely be administered in transport and may reduce the inherent stress of transport, but persons skilled in monitoring and managing of oversedation should be in constant attendance.
11. The U.S. Emergency Medical Treatment and Active Labor Act (EMTALA, 1986) was established to mitigate financially motivated transport, and requires that hospitals with emergency medical departments provide appropriate medical screening examinations within the capability of that hospital's emergency department, including ancillary services, to any individual who enters the department. If an acute medical condition is found, the department must either provide care or stabilize the patient prior to transferring to another facility.
12. Current regulations and good medical practice require that the competent patient or a legally authorized representative give informed consent prior to transfer to another hospital.
13. Physiologic monitoring of patients during transport should be maintained at the current level of care in the interest of patient's safety.
14. Individuals skilled in basic and advanced cardiac life support should perform transport of the critically ill patient within the hospital.

Continued

Key Points—continued

15. The advantages of air transport include reduced transport time over long distances and the ability to transfer many patients at one time. The primary disadvantages include a need for dedicated landing space, vibration, and expense. Potential insults related to transport by air include hypoxemia, decreases in ambient pressure, and hypothermia. "Altitude restrictions" are commonly ordered for patients with eye trauma, pneumothorax, intracerebral air, and sinusitis.
16. When the decision to move a patient by ground transport is made, a decision about the necessary level of life support must also be made. Ground transport services commonly provide a choice of basic life support (BLS), advanced life support (ALS), or critical care transport.
17. Acute neurologic injuries, which may benefit from transfer to higher levels of care, include head injury, acute stroke, and spinal cord injury. Secondary insults are common during transport of the neurologic patient and include systemic hypertension, hypotension, hypoxemia, raised intracranial pressure (ICP), and a reduced cerebral perfusion pressure. The number of secondary insults correlates with instability prior to movement, and for these patients specialized neuromedical transport is indicated.
18. Up to 5% of transports are for high-risk obstetric conditions. In general, outcome is improved if the mother is transported prior to delivery of the fetus.
19. Joint Commission on Accreditation of Healthcare Organizations (JCAHO) requires that hospitals have protocols for dealing with hazardous materials exposures. These protocols must address transport of patients contaminated by such materials, and criteria for reopening of affected patient care areas.
20. Pediatric patients (newborns and older children) are transferred most commonly for pulmonary insufficiency, cardiovascular compromise and congenital heart disease, or neurologic injury. This population benefits from dedicated specialty transport teams with specialized equipment.
21. Transport system design must involve integration of space, monitors, and support equipment that is compatible among the various sites to which a patient will be moved. Equipment engineering teams must design systems that minimize discontinuation of monitoring, disconnection of infused medications and mechanical ventilation, and prevents loss of continuous hemodynamic measurements.
22. Dedicated specialty transport teams may improve outcomes for interhospital transport of critically ill patients with uncommon or complex, unstable illnesses. The benefits of a specialized transport team for moving patients within a hospital are less clear and require further study.
23. Protocols that outline the appropriate practices for movement of patients with a variety of specific conditions are well established among emergency medical services but are less common within hospitals. Protocol development is critical to quality and should address planning, preparation, care during transport, issues on arrival, appropriate documentation, education, and quality improvement.
24. Transfer of all known current medical information about the patient can be as imperative as safe patient movement.
25. Critical incident evaluation at single centers, coupled with reporting and collection of events among many facilities is expected to reveal system errors that, upon correction, should improve patient outcome with transport. Such systems must stress "fixing system problems" and not "searching for an individual to blame."

result in alterations of blood pressure, hypoxemia, arrhythmias, and potential airway compromise. These and other adverse events of transport can occur far from the skilled personnel, equipment, and monitoring of the intensive care unit (ICU) or operating room. Effective and safe transport of a patient does not simply involve movement but also the creation of compatible systems to minimize transport time, eliminate monitoring and medication interruptions, and reduce distractions that take the focus off patient care.[4]

INTERHOSPITAL TRANSPORT

Transfer of a patient to a referral center occurs when the perceived benefit exceeds the risks associated with moving the patient. The Society of Critical Care Medicine convened a task force to examine the benefits of regionalization of medical care based on benefits demonstrated in neonatal and perinatal medicine,[5] trauma,[6,7] and burn care. The quality of care benefits seen at referral centers includes a higher level of training of physicians, around-the-clock staffing, wider range of consultative services, increased exposure and experience with critically ill patients, data collection, clinical research, and the potential for improved outcomes in both medical and surgical patients.[8,9] Such a transfer is commonly referred to as *secondary transport*.[10] The reasons for transport vary among individual hospitals, within medical systems and across countries. Indications vary over time as technologic advances result in better care.

INTRAHOSPITAL TRANSPORT

Intrahospital transport involves the movement of a patient throughout the same hospital for additional care that cannot be performed safely or adequately at the patient's bedside. Certain technology has brought procedures that previously required transport (e.g., right-heart catheterization, certain computed tomographic studies, echocardiography, ultrasonography, closure of patent ductus arteriosus, tracheostomy, and inferior vena cava filter placement) to the patient. Other studies and treatment may require movement of the critically ill patient to distant and more isolated areas of the hospital (Table 80–1). The duration of the trip may be long because of complicated diagnostic and therapeutic procedures. Patients who are "too ill" for a procedure in the operating room are frequently taken to radiology or other sites by a single nurse and respiratory therapist.

The overall benefit of transporting a patient out of the safety of the intensive care unit for studies or procedures has been studied. The necessary "travel" results a change in patient management in 24–39% of cases.[11,12] Abdominal computed tomography and angiography most commonly result in changes.

Hazards and Complications of In-Hospital Transport

Cardiovascular	Pulmonary	Other Physiologic	Equipment
Hypotension	Hypercarbia	Hyperthermia	Power failure
Hypertension	Hypocardia	Hypothermia	Oxygen supply failure
Arrhythmias	Aspiration	Pain	Dislodgement of vascular access
Cardiac arrest	Extubation	Anxiety	
	Hypoxemia	Intracranial hypertension	
	Pneumonia	Physical injury	
	Airway obstruction		
	Increased risk of pneumonia		

RISKS OF PATIENT TRANSFER

Knowledge of the risks of patient transfer within a hospital or between facilities is imperative for informed decision making. Contraindications to transport may include the inability to oxygenate or ventilate a patient, uncontrolled hemodynamic instability, inadequate monitoring, inability to maintain an airway, and inadequate personnel. Despite these complicating circumstances the life-threatening condition may still necessitate transfer to other facilities or sites of treatment. Morbidity and mortality are primarily related to hemodynamic and respiratory deterioration, but also include interruption of medication administration, disconnection of intravenous access, loss of airway support, and human error (Table 80–2).

We do not know whether physiologic changes during transport are a result of preexisting morbidity, environmental change, or a continuation of the normal course of critical illness, or, in contrast, truly preventable mishaps or near-misses representing care that could have been better.

Patients transported within a particular hospital commonly experience hemodynamic and respiratory changes that can be associated with adverse outcomes or unexpected morbidity. These "complications" may be defined as inconsequential such as minor hemodynamic perturbations or may include major events resulting in death. In previously reported studies, the incidence of hemodynamic and respiratory changes varies widely from 5–68%.[11–15] The majority of mishaps occur at the destination (Table 80–3). Many complications occur in radiology where the physical isolation, need to move the patient from the stretcher to the imaging table and back, duration of the procedure, and delay at the site, may contribute to the occurrence of a mishap.[14] There appears to be no correlation of the mishap rate with severity of illness as defined by the Acute Physiology and Chronic Health Evaluation (APACHE) score, number of escorts, number of lines, monitoring, or time spent out of the ICU.[14] Szem found an overall mortality rate of 28.6% for patients requiring transport out of the ICU that was significantly higher than the control group (11.4%).[15] There were no deaths directly related to transport, although patients who required transport out of the ICU may have been sicker.

The Australian Incident Monitoring Study in Intensive Care evaluated all reports from 91 units submitted in relation to incidents occurring during transport within the hospital between 1993 and 1999. Of 7525 submitted reports, 176 described 191 incidents during intrahospital transport. Analysis revealed that 39% of the incidents were equipment-related and 61% were patient/staff management issues. System-based and human-based problems occurred equally.[16] Significant adverse outcomes to the patients occurred in nearly a third of the events. The high incidence of system-based problems may have arisen from a need to disconnect a patient from ventilation, interrupt the delivery of vital infusions while changing to pumps and monitors specific to the transport process, and the limited battery life of transport devices. Often another monitoring system was in place at the site of treatment or destination, requiring further interruptions. The anesthesiologist is often simultaneously responsible for monitoring the patient and making adjustments to medications to maintain hemodynamic stability.

Patient movement between hospitals may be associated with longer transport times, greater isolation from advanced care, stresses related to vibration, noise, and gravitational forces if transport is accomplished by air. In addition these patients may be more ill and transfer undertaken with more limited monitoring than usual within a hospital. Adverse events occurred in at least one-third of interhospital transports with 30% of these attributable to technical problems.[17]

TABLE 80–3.

Distribution of Locations on Transport when Mishaps Occur

Location	% Mishaps
In ICU, preparing for transport	2
On transport to the destination	19
At destination before procedure	29
During the procedure	41
At destination, preparing to return to ICU	5
During return transport	2
Arrival in ICU	2

Hemodynamic Changes

Adverse hemodynamic alterations are among the most common events during both intrahospital and interhospital transport. The cause of the instability may be interruption of vasopressor infusions, stress and anxiety, pain, inadequacy of sedation, or fluid redistribution with patient movement.

Hypotension or hypertension occurs in 25–50% of intrahospital transports.[12,18,19] Factors demonstrated to contribute include emergence from the effects of anesthetic agents, manual ventilation and spinal anesthesia in the obstetric patient.[18,20,21] Arrhythmias requiring treatment may occur in up to one-half of patients transported for "high-risk" cardiovascular conditions.[22] The care provider is often confronted with these changes while dealing with unfamiliar drug delivery systems, the need to disconnect and reconnect to a new monitor, and the need to search for therapeutic medications in an unfamiliar area or while maneuvering a stretcher through halls or elevators.

Hemodynamic changes are at least as common with secondary transport between hospitals. Unless blood pressure is monitored by invasive means, these changes may be missed with noninvasive means as a consequence of vibration and noise.

High-risk cardiac patients, including those with recent myocardial infarctions, may demonstrate instability when transferred to higher levels of care, often manifested as arrhythmias, pump failure, or cardiogenic shock.[23] The intubated patient may be "safer" from an "airway management" point of view, but pretransport intubation in this group of patients tends to be a marker for precarious and unstable hemodynamics. The era of thrombolysis means that many patients will have had some degree of reperfusion prior to transport to a center capable of definitive management and actually a lower incidence of difficulties than in earlier years.[24] Rubenstein's study of 755 acutely ill cardiac patients, the majority with class III or class IV New York Heart Association (NYHA) heart failure, transported from community hospitals to tertiary care centers showed no complications. However, half required urgent intervention (coronary artery bypass graft or percutaneous transluminal coronary angioplasty) upon arrival.

Studies show, however, that even the most tenuous patients can be safely transported including those on extracorporeal life support (ECLS).[25] The University of Michigan Medical Center reviewed the transport of patients on ECLS for various indications, including cardiac failure. Transport-related complications occurred in 17 of 100 trips, yet none were believed to have had an adverse effect on outcome.

Respiratory Impairment

Respiratory compromises encountered in patient transport include hypoxemia, hypercarbia with respiratory acidosis, hypocarbia with respiratory alkalosis, drying of secretions, plugging or displacement of the endotracheal tube, and unexpected extubation. The incidence of respiratory changes during transport varies widely in reported studies. Of note, data from Kollef shows an increased risk of subsequent ventilator-associated pneumonia compared to nontransported controls.[26] Factors potentially responsible for these changes include changes in the pattern of ventilation, mode of ventilation (manual versus mechanical), loss or absence of positive end-expiratory pressure (PEEP) with disconnection, endotracheal tube displacement, and equipment failure.

Hypoxemia (defined as a decreased Pao_2:FiO_2 ratio) occurs in up to 86% of transports involving patients artificially ventilated.[27] The need for PEEP and higher FiO_2 before transport correlates with a higher risk of deterioration.[27,28] Even brief interruptions of PEEP for connection and disconnection can be detrimental to systemic oxygenation. Decreases in measured Pao_2 end points of oxygenation may be less frequent with manual ventilation as the FiO_2 is more commonly increased to 100%, whereas transport ventilators may maintain the pretransport FiO_2.[29]

Inadequate or excessive ventilation may compromise the outcome of certain patients. Hypercarbia may have detrimental effects on patient populations including those with increased intracranial pressure, pulmonary hypertension, or an existing acidosis. Hypercarbia and a resulting acidosis do occur in a very high percentage of critically ill intubated patients transported within and between hospitals.[20,30,31] The incidence of respiratory acidosis and alkalosis appears to be less with mechanical as compared to manual ventilation during transport. Hypocarbia may result from overly aggressive ventilation and may be detrimental in patients with neurologic injury. Hyperventilation may also result in air trapping or dynamic hyperinflation, which is especially dangerous in the setting of hypovolemia. Failure of a ventilator during transport may be catastrophic, and yet transport ventilator alarms may be less sophisticated and not well heard in a noisy transport environment, hence a need for heightened team vigilance.

Drying of secretions and damage to the tracheobronchial tree as a result of prolonged exposure to desaturated air has been demonstrated.[32] Dried secretions may result in occlusion of the airways or endotracheal tube. Efforts should be made to humidify the air that intubated patients receive, especially those subject to the very dry dehumidified environment during flight at altitude (tank gas is always dry unless actively humidified).

Extubation can be a major catastrophe during transportation. Up to 15% of all extubations in the critically ill patient are accidental.[33] Patient transport is among the factors responsible. Difficulty was encountered in 20% of reintubations.[33] Moving the head or repositioning of the patient commonly results in accidental extubation even in the presence of sedation or restraints.[34] Transport of a patient with a new tracheostomy needs to be considered an especially dangerous event if extubation occurs.

Either manual or mechanical ventilation can be effective and safe in transport. One disadvantage to manual ventilation is that a care provider must focus on management of ventilation and the airway while potentially neglecting hemodynamic monitoring and other support activities. Other disadvantages include the need for 2 hands, management of decreased lung compliance, and fatigue with long transport.

Temperature and Injury

Patient transport removes the individual from the controlled setting of the ICU or operating room with both inter- and intrahospital movement. Use of fluid warmers is generally interrupted, warming blankets are disconnected, transport oxygen is commonly inhaled dry, and patients may require exposure for procedures in settings where room temperature cannot be optimally adjusted to protect the patient from hypothermia. Higher death rates are

reported among those individuals who develop hypothermia in transport between hospitals or from the scene of an accident to the hospital. The reduction of temperature does not necessarily correlate with gender, age, flight time, outside air temperature, or type of patient.[35] Hypothermia can contribute to coagulopathy, arrhythmias, tissue hypoxia caused by vasoconstriction, increases of pulmonary vascular resistance, and depression of neurologic status. Precautions are especially important in patients who are prone to hypothermia, including children and the elderly, burn patients, and victims of spinal cord injury. Shivering in an attempt to maintain body temperature increases oxygen consumption, and this may prove detrimental in patients with myocardial ischemia.

Other risks of transport include exacerbation of injury by displacement of fractures, movement of an unstable cervical spine, and dislodgement of tubes or drains. Finally, pressure injuries to limbs, eyes, and skin may result from contact with equipment or accidental trauma.

PATIENT ASSESSMENT AND PREPARATION

Appropriate assessment and preparation is imperative prior to transporting the patient within or between hospitals. Research has shown that even the sickest patients can be transported when appropriate interventions are established early. General assessment for transport between hospitals includes a review of the medical history, current condition, recent interventions, hemodynamic and respiratory status and stability, current monitors and therapeutic device settings and function, and any changes prompting transfer. Consent for transport from the family or guardian must be obtained for the critically ill and communication with the receiving physician, nurse, or hospital must be established. Assessment also includes planning for possible deterioration and establishing a course of action to deal with physiologic compromise. Wallace and Ridley identified 9 principles of safe patient transfer, which are listed in Table 80–4.[36]

Much effort has been expended to predict the physiologic deterioration and mortality associated with patient transport. Some studies examined hemodynamics, respiratory status, monitoring, pharmacologic support, and lab analysis but failed to predict which patient will do poorly.[37,38] Other studies looked at PEEP, Injury Severity Score, and Therapeutic Intervention Score before transport and demonstrated that the more ill a patient is, the more likely the patient is to demonstrate instability with transport.[39,40] Generally speaking there is no accurate and reproducible method to accurately predict which patients will experience difficulty with transport. Those patients who demonstrate hemodynamic and respiratory instability prior to transport are more likely to manifest these changes during movement. The difficulty in predicting instability may be a result of a bias that results in sicker patients being transported by specialized transport teams whereas those thought to be more stable may be subject to less-vigilant care and treated by more inexperienced personnel. Logically the more ill a patient and the more interventions required to maintain that patient, the more at risk the patient is for complications during transport.

The need for stabilization prior to transport within and between hospitals cannot be sufficiently stressed. There is no evidence that a "scoop-and-run" approach to interhospital transport of critically ill patients is beneficial. Stabilization before transport is similar to any resuscitation and follows the traditional ABCs (airway, breathing, and circulation). Checklists can prove invaluable in assuring that appropriate steps have been taken (Table 80–5).

Airway and Intubation

The benefits of appropriately securing a patient's airway prior to transport include avoiding the potentially difficult conditions for intubation found during ground transport, aeromedical evacuation, and in remote sites within the hospital. A patient whose airway is judged to be stable should receive supplemental oxygen in nearly all circumstances. Patients that are intubated prior to transport should be assessed for endotracheal tube (ETT) position, adequacy of tube function, and that it is appropriately secured. Auscultation of lung fields, exhalation fogging of the ETT, rise and fall of the chest, nail bed or lip color, and pulse oximetry, help to confirm effective intubation. Chest radiography confirms not only the ETT position but also may define underlying lung pathology. Colorimetric or infrared end-tidal CO_2 detection serves as an additional confirmation of appropriate tube position.

Certain patients may be successfully managed without intubation but are at risk for airway compromise during movement. These patients may benefit from intubation prior to transfer. Common indications for "elective intubation" in anticipation of transport include a Glasgow Coma Score of less than 9, respiratory acidosis or impending respiratory failure, status asthmaticus, severe hypoperfusion, or shock. Patients with anatomic airway compromise arising from burns, epiglottitis, angioedema, anaphylaxis, or tracheolaryngeal trauma can benefit from intubation as the course subsequent to injury may be downhill. Certain stable but combative patients may require airway intubation and paralysis or sedation to assure safety.

Emergency medical personnel are particularly skilled in management of the airway and their advanced training includes intubation.[41,42] The 97% success rate for intubation during transport by emergency medical services (EMS) personnel is the same as intubation prior to transport. Experienced and highly trained care providers are more likely to intubate those patients whose airway appeared to be difficult to manage prior to transport. This may account for the high rate of success and neglect the true difficulty that would be encountered if the same patients were transported without prior intubation.

The laryngeal mask airway (LMA) serves as a valuable alternative or

TABLE 80–5.

Pretransport Assessment Checklist

- Risk management
  - Correct identification of patient
  - Correct destination for correct therapy
- Airway/breathing
  - Endotracheal tube if present secured appropriately
  - Assesses need for intubation if not secure
  - Current ventilator settings (mode/V_T/RR/FiO_2/PEEP)
  - Current status (ABG/CXR)
  - Trends in stability
  - Airway supplies available
  - Plan for manual versus mechanical ventilation
  - Definitive plan for management of compromise
  - Adequate oxygen
  - Backup airway supplies present and functioning
- Circulation
  - Current monitoring
  - "Zero" reference established for all monitors
  - Current hemodynamic status (blood pressure, pulmonary artery, pressure, CVP, rhythm)
  - Intravenous access functioning properly
  - Current and recently used vasopressors
  - Blood available if indicated
  - Resuscitation drugs available
  - Adequate electrical supply for monitors
  - Definitive plan for compromise
- Neurologic status
  - Current function/Glasgow Coma Score
  - Cervical stability if indicated
  - Assessment of level of sedation
  - ICP monitor functioning is present
  - Appropriate "zero" reference on ICP monitors
  - Pain control/adequacy of sedation
  - Definitive plan for treatment of increases in ICP, hypotension, changes in mental status
- Extra
  - Assessment of stability of traction/fractures
  - Tubes, lines, and drains all functioning properly, secure

Recommended Airway Supplies for Transport

- Appropriate adult or pediatric bag-valve systems with oxygen reservoir
- Appropriate variety of masks
- Flexible adaptors
- End-tidal carbon dioxide detector
- Variety of sizes of MacIntosh and Miller laryngoscope blades and handles
- Appropriate endotracheal tubes (cuffed and uncuffed)
- Magill forceps
- Nasopharyngeal and oral airways
- Scalpel blade for cricothyroidotomy
- Nasal cannula
- Oxygen tubing
- Positive end-expiratory pressure

Adapted from Warren J, Fromm RE, Orr RA, Rotello LC, Horst M, American College of Critical Care Medicine. Guidelines for the inter- and intrahospital transport of critically ill patients. Crit Care Med 2004;32:256–262.

"backup option" to the endotracheal tube in the setting of difficult intubation. The LMA is not a definitive airway and does not protect against aspiration nor allow prolonged positive pressure ventilation. Routine suctioning of the airway is not possible. Generally the LMA does not depend on facial and tracheal anatomy and placement can be successful from almost any position.[43] Emergency medical personnel have used the LMA successfully in managing the airway in 89% of failed intubations.[44]

The American College of Critical Care Medicine and the Society of Critical Care Medicine recommend certain airway supplies be transported with patients (Table 80–6).[45] These supplies must be available even with a "secured airway" as inadvertent dislodgement and loss of an airway can occur. Appropriate-size bag-valve systems with an oxygen reservoir are imperative for transport in addition to a variety of masks, laryngoscope blades, endotracheal tubes, oral and nasal airways, and a portable oxygen supply.

Breathing and Ventilation

Adequacy of breathing and ventilation should be assessed prior to transport. It is imperative that tidal volume, respiratory rate, inspired oxygen concentration, positive end-expiratory pressure, and mode of ventilation be noted and recorded. The respiratory trend may actually be more important that the actual current status of the patient. Increases in $Paco_2$ may indicate pending ventilatory failure whereas decreases in arterial oxygen saturation or Pao_2 may herald further failure of oxygenation. Sedation or deepening of sedation should be considered to facilitate oxygenation and ventilation. Transfer at altitude by reducing alveolar oxygen concentration can contribute to hypoxemia.

The risks of positive pressure ventilation include barotrauma, hypercarbia and hypocarbia, and dynamic hyperinflation (auto-PEEP), resulting in a reduced venous return and hypotension. The benefits of manual ventilation versus mechanical ventilation during transport are commonly debated. Traditional volume-controlled ventilators used for transport cannot deliver the specialized modes, such as pressure support and inverse ratio ventilation, that may be required for critically ill patients. Comparisons between mechanical and manual ventilation for pediatric transport found greater variation in parameters with manual ventilation.[46] These changes may be more significant for longer- than shorter-duration transport and more important in patients who are subject to compromise of pulmonary or cerebral blood flow, such as newborns with persistent pulmonary hypertension or victims of traumatic brain injury. Weg and Hass compared manual and mechanical ventilation and concluded that manual ventilation can be both

safe and effective if the inspired oxygen concentration and minute ventilation are known prior to transport and ventilation performed by skilled care providers.[29] Most transport services use a combination of manual and mechanical ventilation. Some use mechanical ventilation exclusively. Only a small number of services use only manual support.[47] Austin has identified the ideal characteristics of a transport ventilator (Table 80–7).[48]

Both manual and mechanical ventilation are satisfactory for most patients. Those requiring complicated modes of ventilation or high PEEP, or who are subject to long transport times, should be transported with mechanical ventilatory support.

Transport within the hospital is commonly done on a stretcher with the patient in a supine position. The benefits of a slightly head up position in the ICU may be lost for several hours during transport increasing the risk of aspiration and pneumonia.[49] The supine position may need to be maintained for minutes to hours while a procedure is performed within the hospital. Patients transported between hospitals by ground or air may encounter turbulence that may exacerbate pain and interfere with the ability to cough. Precautions to protect the airway from aspiration must be taken, especially when sedatives are administered.

Continuous monitoring of saturation by pulse oximetry is imperative during transport for all patients. End-tidal carbon dioxide monitors are recommended for all intubated patients. Capnography may serve two purposes: to confirm appropriate placement of an endotracheal tube and to monitor respiration in an environment in which direct auscultation is difficult. Quantitative capnography may especially benefit head-trauma victims who are at risk from either hyper- or hypocarbia.[50] Less physiologic variability occurs when end-tidal carbon dioxide is continuously monitored during manual ventilation.[51] Continuous capnography is associated with a lower incidence of false alerts and malfunction as compared with pulse oximetry and is not as subject to motion artifact or loss of signal due to vasoconstriction.[52]

The options for treatment of a respiratory/airway complication during transport must be considered. Elevation of FiO_2 to 100% during brief periods of transport may avoid hypoxemia. Increasing PEEP levels to compensate for hypoxemia may be necessary but decreased venous return and barotrauma must be avoided. Administration of skeletal muscle relaxation may increase chest wall compliance and facilitate ventilation.

Cardiovascular

The hemodynamic stability of a patient prior to transport is imperative. Many of the hemodynamic changes seen with patient transport are reflections of the course prior to movement. Monitors of hemodynamic function should include displays of the electrocardiogram and blood pressure by either invasive or noninvasive means. Monitors must have visible and audible alarms, a long battery life, and illuminated displays. Transport defibrillators are essential for transport between hospitals and for patients within the hospital who are at a high risk of an arrhythmia (myocardial infarction, cardiac surgery). If transcutaneous pacing is possible (and likely to be needed) adequate capture should be confirmed.

Oscillotonometric or noninvasive measurement of blood pressure facilitates monitoring in the operating theater, postanesthesia care unit, and treatment wards. This form of monitoring may be subject to error during the movement of patients. Although this might not be important in hemodynamically stable, nonventilated patients, it may be critical for others. If invasive arterial monitoring is expected, it should be secured prior to movement. Invasive monitors must be calibrated to a "zero" reference point. Zero points change with patient positioning. Reestablishing the appropriate "zero" reference upon patient transfer or at altitude during flight is imperative.

Adequate IV access for delivery of fluids, continuous medication delivery, and intermittent treatment must be established. The confines and motion of any transport vehicle or stretcher can make placement en route difficult (Fig. 80–1). Adequate function and placement of backup or secondary lines should be considered. If transfusion is anticipated during transport blood should be brought with the patient.

Hemodynamic compromise may result from inadequate preload, afterload, impaired myocardial contractility, or disturbances of cardiac rate and rhythm. Assessment must include a strategy for addressing the hemody-

TABLE 80–7.

Ideal Characteristics of a Transport Ventilator

Person portable (4–6 kg)
Durable
Pneumatically powered or electrically powered

namic instability by: assessment, volume resuscitation, and infusion of inotropic or vasopressor support as needed. The resources needed to provide these therapies must be provided during transport.

Neurologic Status and Sedation

Secondary insults during transport of head-injured patients are common and may include hypoxemia, hypotension, and intracranial hypertension, each of which worsens neurologic outcome. Although physiologic instability during transport is correlated with instability prior to movement, anticipation of problems, and preparation for the management of problems is imperative.[53] Appropriate physiologic monitoring of oxygenation and ventilation is necessary. Transport patients may benefit from continuous end-tidal carbon dioxide analysis to avoid detrimental periods of hyper- and hypocarbia. In the patients with significant head trauma and cerebral swelling, invasive arterial access is necessary as even brief episodes of hypotension are detrimental to the brain. If an intracranial bolt or catheter drain is placed, an appropriate "zero" level must be established. Protection of the device must be assured to avoid dislocation. Increases of intracranial pressure (ICP) are detrimental in head injury. ICP is a dynamic measurement and the importance of a single measurement is unclear. A plan and resources for addressing an increase in ICP are necessary. Interventions include head elevation, hyperventilation, mannitol and/or Lasix infusions, and cerebrospinal fluid drainage. The effects of these interventions on other parameters (e.g., cardiovascular) must be considered. The effects of sedation on the neurologic assessment must be taken into consideration.

Sedation and pain control are rarely addressed in the transport literature despite the fact that transport subjects a patient to significant stress. The levels of epinephrine and norepinephrine in healthy male volunteers subject to EMS protocols are increased without sedatives, as compared with individuals receiving midazolam during the same protocol.[54] Increased catecholamine levels can increase myocardial oxygen consumption, cardiac ischemia, and infarction. Short-acting benzodiazepines are generally chosen as sedatives because of their ease of titration, intense analgesia, and historical success. Devellis et al. studied the use of small doses of fentanyl (0.33–5.0 μg/kg) in pediatric trauma victims. There was a statistically significant decrease in systolic blood pressure but no other major complications.[55] Small doses of fentanyl (25–200 μg per administration) with a total dose of 1.0–5.0 μg/kg were well tolerated in patients transported by air.[56] Complications associated with prehospital sedation seemed to occur more often in patients receiving both sedation and analgesia and are more common in patients who received sedation for endotracheal intubation.[57] Sedation during patient transport within the hospital has not been well studied. Planning must take into account the side effects of the medication and the potential pain and anxiety that the patient will experience during a procedure.

Consent

Many care providers do not consider transport of the critically ill patient a high-risk procedure despite its high complication rate. Although consent is commonly implied when a patient must be moved, good medical care requires that the patient or a proxy be aware of the risks. Current guidelines suggest that a competent patient or legally authorized representative of a patient give informed consent prior to transfer to another hospital.[45] Despite these recommendations a minority of patients actually give consent for a hospital transfer.[58] Unfortunately, at the time of the study, transfer of patients from private to public hospitals of minorities, the unemployed, and those without insurance was a common practice. The Emergency Medical Treatment and Active Labor Law (EMTALA, 1986) required that hospitals appropriately screen patients and provide treatment. If transfer is necessary the hospital is liable to ensure that within medical probability, no worsening of the patient's condition occurs during transfer.[59] Three principles result in compliance with EMTALA: avoidance of financially motivated transfer, transfer only in the best interest of the patient, and maintenance of standards of care during all transport.

Communication

Communication between those initiating patient transfer and those ultimately receiving the patient is imperative. The referring physician should identify and contact an admitting physician at the receiving hospital to accept the patient in transfer and confirm before the transfer occurs that an appropriate higher-level resources are available.[45] The patient remains the responsibility of the transferring team until a formal nursing and medical hand over has occurred in the receiving department.[10] Continual communication to provide guidance for transport personnel must be established. Mahoney recently analyzed the 2003 Rhode Island fire disaster and noted that poor communication between hospitals and emergency personnel resulted in the inappropriate transfer of several patients.[60]

Communication not only refers to the verbal transfer of information but that appropriate records, images, and consent accompany the patient. Duplication of records and studies is often needed and should be done early to avoid delaying transfer. The advent of regional health information systems may mitigate the problem of difficulty with transfer of information.

EQUIPMENT AND MONITORING

No specific national standards exist for monitoring or required equipment for the transport of patients. Guidelines for transport have been published by several organizations including the American College of Critical Care Medicine and the Society of Critical Care Medicine.[45] In general, the equipment for transport must be similar to that used in the ICU yet it must be portable, small, lightweight, and rugged.[61] Additionally equipment intended for aeromedical transport must be low in weight, compact, and should not interfere with navigation, communication, or control mechanisms. The electrical load must not overwhelm the aircraft's system. Incompatibility of monitors and medication infusion systems creates time delays and results in periods of inadequate monitoring in critical situations. Transport personnel are frequently required to disconnect and reconnect cables and reestablish zero references for invasive pressures. Medical infusion pumps may need to be discontinued briefly as a device capable of transport is prepared. Upon arrival at the receiving site another change in patient care technology may again be necessary.

TRANSPORT PERSONNEL

Personnel accompanying a patient in transport within the hospital and between hospitals must at a minimum possess all the skills of basic life support. Potential transport personnel include physicians, nurses, respiratory therapists, paramedics, and emergency medical technicians. Guidelines published by the Society of Critical Care Medicine for interhospital transport state that a minimum of 2 people in addition to the vehicle operator shall accompany the patient and at least one shall be a registered nurse, physician, or advanced medical technician skilled in airway management, IV therapy, and dysrhythmia interpretation and management.[62] Recently revised guidelines recommend that a physician with advanced skills in airway management and advanced cardiac life support accompany all unstable patients.[45] The safety of transport of routine patients without a physician has been demonstrated.[63] Of note, transport which mandates that a physician be in attendance may remove an essential healthcare provider from the transporting facility, so backup coverage should be provided.[23]

The efficacy of specially trained teams responsible for transport has also been demonstrated for adult[13] and pediatric patients.[64] Use of speciality teams allows continual training, development of specialized skills, and the ability to cross-train in the skills of others.

MODES OF TRANSPORT

The risks and benefits of ground versus air transport must be considered when transporting a patient between hospitals. Gray suggested 7 factors that should influence the choice of the mode of transport (Table 80–8).[10] Staff responsible for initiating and performing evacuation should be familiar with the physiologic factors that may potentially affect the patient in transport, especially when considering air transport. The special needs of neonates and pediatric patients must be understood. The American College of Emergency Physicians endorsed the following principle regarding patient transfer: "The health and well being of the patient must be the overriding concern when any patient transfer is considered. The patient should be transferred in a vehicle that is staffed by qualified personnel and contains appropriate equipment."[65]

Air Transport

Air transport can be divided into fixed-wing (aircraft) and rotor-wing (helicopter). Fixed-wing transport tends to cover distances greater than 250 miles whereas rotor-wing transport covers distances less than 250 miles.[66] Helicopter transport is primarily beneficial for distances greater than 45 miles when compared with ground transport.[67] Specific advantages of transport by airplane include long-distance capabilities, larger areas for patient care, space for more care providers, the ability to transport and care for many patients, less vibration, and generally less noise than rotor-wing transport. Disadvantages include the need to transport the patient by ground to and from the aircraft and the need for dedicated landing facilities. Advantages of transport by helicopter include the capability for rapid mobilization, vertical take-off and landing, ease of transport at lower altitudes, and the ability to transfer patients at speeds of up to 150 miles per hour.[66] The disadvantages include limited space for patient care, vibration, and noise, as well as greater dependence on good weather for flying (Fig. 80–1). Awareness of altitude sensitive conditions and specific preparation for transport by air will decrease complications (Table 80–9; see also Table 80–12).

Hypoxemia is a risk to any patient in transport but especially those with coronary ischemia, pulmonary compromise (acute respiratory distress syndrome [ARDS]), or neurologic injury. Hypoxemia commonly results in tachycardia and hypertension that may increase myocardial oxygen consumption. The barometric pressure of ambient air declines as altitude increases although oxygen concentration remains at a constant 21%.[68] At sea level, barometric pressure is 760 mm Hg with a partial pressure of oxygen of 160 mm Hg. Most aircraft cabins are usually pressurized to a pressure

TABLE 80–9.

Preparation for Transport By Air Checklist

Patient appropriate for air transport
Critically ill
Benefit justifies risk
No contraindications to air transport (weather, hostile environment, dangerous patient, contaminated area)
Airway
Airway secure
Endotracheal tube cuff pressure adequate for transport but unlikely to cause mucosal injury
Ability to humidify gases if long transport time or high altitude transport
End-tidal carbon dioxide monitor present
Breathing
Consideration of chest tube in setting of simple pneumothorax
Impact of altitude on respiratory dynamics (increases FiO_2 requirement, positive end-expiratory pressure, increased minute ventilation)
Circulation
Hemodynamics at risk with altitude (pneumothorax/pneumopericardium, gas embolism)
Monitors calibrated with plan to reestablish "zero" reference at altitude
Volume status optimized to prevent drastic changes with acceleration/deceleration
Neurologic
Condition at risk with altitude (pneumocephaly/decompression sickness/middle eustachian tube dysfunction)?
Risk of secondary brain injury from hypoxemia
Others
Fractures stabilized?
Gastric decompression (nasogastric tube) for intubated patients

equivalent to 5000–8000 feet, giving an atmospheric partial pressure of oxygen of 118 mm Hg.[69] This accounts for the fact that the oxygen requirement (FiO_2) of a patient on mechanical ventilation may increase at altitude. Lawless and colleagues demonstrated that animals with chemically induced ARDS were resistant to increases of FiO_2 yet responded to increased PEEP during transport.[70] Benumof suggests that hypoxemia, even at low altitudes (3281–9843 feet), may contribute to global hypoxic pulmonary vasoconstriction and pulmonary edema.[71] Helicopter transport may allow a patient to be transported at lower altitudes so as to minimize this effect.

The decrease in ambient pressure at altitude contributes to the expansion of air within a cavity in accordance with the Boyle law.[66] This effect may result in hemodynamic compromise (tension pneumothorax), barotrauma (sinuses), equipment malfunction (blood pressure cuffs), and possible patient injury or compromised monitoring.[66] Conditions such as pneumopericardium, subcutaneous emphysema, gas gangrene, systemic air emboli, decompression sickness, and gastric distension may be worsened at altitude. Equipment considered "altitude-sensitive" includes endotracheal and tracheostomy cuffs, pneumatic antishock garments (e.g., medical antishock trousers), air splints, colostomy bags, Foley catheters, orogastric and nasogastric tubes, ventilators, invasive monitors, and intraaortic balloon pumps. Additionally patients with a closed head injury may experience increases in ICP. An experimental model showed an increase in intracranial air volume by 30% at the usual maximum cabin altitude of 8000 feet.[72] "Altitude restrictions" are commonly ordered for patients with eye trauma, pneumothorax, intracerebral air, and sinusitis.[73] These restrictions and flying at low levels may result in more turbulence and longer transport times.

Temperature decreases with altitude. Cold air holds far less moisture than warm air. This contributes to the drying of secretions, potential occlusion of endotracheal tubes, and dehydration during transport at altitude.

The flight environment subjects the patient to other unique physiologic challenges. Acceleration and deceleration may induce hemodynamic changes, stress, and injury. These may be exacerbated in patients suffering from hypovolemia and spinal cord injury. Aircraft vibrations contribute to fatigue and discomfort along with interference with the appropriate function of equipment.[66]

The risks to transport personnel are rarely considered. Bledsoe studied helicopter evacuation of patients between 1993 and 2000. There were 84 medical helicopter accidents with 72 total fatalities and 64 injuries. The major cause was pilot error.[74] Krosen also determined that human error was the leading cause of accidents. Special problems with aviation that may have contributed included take-off without "situational awareness" of terrain or navigation issues, low-level flight below minimum safety altitude, bad-weather flight conditions when saving a life takes priority, unknown landing areas, and acceptance of higher levels of risk by the flight crew.[75]

Ground Transport

Most patient transports can be safely accomplished by ground transfer. The advantages of ground transfer are primarily related to lower cost, rapid mobilization of resources, less dependency upon weather conditions, and easier patient monitoring. The disadvantages include limited space to perform interventions and procedures, potential for delays because of traffic, and vehicle accidents with further injury to the patient and care providers (Fig. 80–2).

Modes of ground transport are not equivalent, and optimization of ground transport depends in part on equipment availability and to a larger extent on care provider skill levels available. Skills range from simple basic life support (BLS) to advanced cardiac life support (ALS), to specialized transport teams. The skills of the transport team must be known when transfer is arranged, and there must be optimum matching of patient acuity and type of illness with the transport team's skills and resources.[76] The critically ill patient with conditions requiring care at the level of a physician or specially trained nurse should be transported by a specifically trained physician or Critical Care Transport Team. The Commission on Accreditation of Medical Transport Systems (CAMTS) defines critical care transport as "the transport of a patient from an emergency department or a critical care unit who receives care commensurate with the scope of practice of a physician or registered nurse."[77] The Association of Air Medical Services defines 6 conditions appropriate for transport by a specially trained critical care ground team:

1. Patient in critical condition.
2. Potential for deterioration into critical condition during transport.
3. Unstable vital signs.
4. Patient is intubated and ventilated for an acute medical condition.
5. Patient is receiving continuous infusion pharmacologic blood pressure support.
6. Conditions require time-sensitive treatment.

Prior to ground transport it is imperative that the transferring physician be

FIGURE 80–2. Limited space of ground transport vehicle. (Courtesy of Boston MedFlight.)

aware of the strengths and limitations of the team with respect to personnel, equipment, and training.

SPECIAL CONSIDERATIONS

Certain patient disease categories deserve discussion including neurologic injury, obstetrical patients, chemical injuries and toxic agent exposure, pediatric patients, and transport for mass casualty.

Neurologic Conditions

Three populations of neurologic patients are commonly transferred, traumatic brain injury, spinal injury, and stroke.

Patients transported with traumatic brain injury are commonly subject to secondary insults that can potentially worsen the injury, including systemic hypertension, hypotension, raised ICP, reduced cerebral perfusion pressure, hypoxemia, and hyperthermia. The most common of these are hypertension and raised intracranial pressure. In a study by Andrews, complications occurred in about half of transfers for neurologic injury.[78] The number of insults during transport mimics the number of insults both before and after the move. The higher an individual's injury score (based on systemic and mean blood pressure, intracranial pressure and cerebral perfusion pressure, temperature, heart rate, oxygenation, and ventilation) prior to transport, the more likely the occurrence of a transport complication. The Working Group on Neurosurgical Intensive Care of the European Society of Intensive Care Medicine has recommended guidelines for pretransport stabilization of the head injury patient (Table 80–10).[79]

Benefits of transport for the patient with acute spinal cord injury to centers skilled in this type of specialized care have been reported.[80] The earlier the transfer, the greater the benefit.[81] Outcome is best for patients transported within 12 hours. Benefits are less certain for those transferred more than 48 hours after a cord injury. The Congress of Neurologic Surgeons recommends that patients with acute spinal cord injury be expeditiously and carefully transferred from the site of injury to the nearest capable definitive medical care facility. The mode of transport should be chosen based on the clinical characteristics of the patient, distance to the receiving facility, and geography.[82] Despite the best efforts of healthcare providers, additional movement of the spine-injured patient is associated with risk of further cord injury. Del Rossi demonstrated that both a log roll and lift-and-slide technique of movement can cause additional injury at the site of cord damage.[83]

Patients with acute stroke are commonly transferred for specialized medical care to provide diagnostic angiography and intraarterial thrombolysis after a hemorrhagic stroke has been ruled out.[84] Studies demonstrate that thrombolysis delivered within 3 hours after the onset of an occlusive stroke significantly improves outcome. Benefit may be seen with treatment up to 6 hours after occlusion but these are inconsistent. Delays in transport commonly occur because of geographic characteristics, delayed patient/physician awareness of stroke symptoms, slow referral pathways, and in-hospital factors. Nedeltchev notes that patients with symptoms consistent with stroke may benefit from direct referral to a tertiary care center equipped to provide thrombolysis without delaying them at a community hospital for CT imaging.

High-Risk Obstetrics

Obstetric patient transfers comprise only a small percentage of transports between hospitals, approximately 5% in one study.[85] Common indications include premature labor, premature rupture of membranes, eclampsia, preeclampsia, and multiple gestations. The greatest concerns of those transferring these patients include in-flight delivery of the fetus, inadequate fetal monitoring, and inexperience with this type of transport. General crew configuration is frequently a nurse and paramedic. A physician is directly involved in only 5% of transfers. Complicating factors include systemic hypertension, hypotension, increased contractions, and decreased maternal respiratory drive.[86] Nausea and vomiting occur often. The potential for a difficult airway to be managed must be recognized. Placenta previa and placenta accreta have the potential for sudden deterioration and such patients should be transported rapidly with appropriate volume line access. Outcome is improved if the mother is transferred prior to delivery of the fetus.[87]

Chemical Injury and Disaster Transport

Exposure to toxic chemical substances occurs in a variety of ways including industrial accidents and the deliberate release of toxic substances by terrorists. The health service must assure that appropriate care is provided to the injured without endangering the lives of healthcare providers. The Department of Health Emergency Planning Coordination Unit of the United Kingdom released a series of consensus statements addressing transfer and transport of chemical casualties (Table 80–11).[88] According to a study in Washington State,

TABLE 80–10.

Pretransport Stabilization of the Head Injured Patient

Pulse oximetry >95%
End-tidal $Paco_2$ 35 mm Hg
Mean arterial blood pressure >90 (adults) and systolic blood pressure >120 mm Hg
Intracranial pressure ≤20 mm Hg
Cerebral perfusion pressure >70 mm Hg (adults)
Central body temperature 96.8 °F (36 °C)

Data from Ferdinande P, Recommendation for intra-hospital transport of the severely head injured patient. Intensive Care Med 1999;25:1441–1443. With kind permission of Springer and Business Media.

TABLE 80–11.

Consensus Statement on Transport for Chemical Incidents

Transportation requirements depend on the number of casualties
Once decontaminated, priority for transport is determined as for nonchemical incidents
Chemical casualties should only be transported to hospitals with chemical personal protective equipment and decontamination facilities
Vehicles should be reused at the incident
Helicopters are not acceptable as a mode of transport

Adapted from Crawford IW, Mackway-Jones K, Russel DR, Carley SD. Delphi-based consensus study into planning for chemical incidents. Emerg Med J 2004;21:24–28. With permission from the BMJ Publishing Group

the majority of victims of hazardous material events will be transported to a hospital (70%) yet only a small percentage will be admitted for further care (5%).[89] Victims of trauma, thermal burns, dizziness, or CNS symptoms such as headache are most likely to require admission. Burgess studied the evacuation of patients and personnel from hospitals due to hazardous material exposure. The emergency room was the site of 64% of the evacuations. In the majority of evacuations the local fire department hazardous materials team responded to assist in the evacuation and subsequently determined when the emergency department could be safely reopened. Standards of the Joint Commission on Accreditation of Health Care Organizations require that all hospitals have protocols for hazardous materials incidents and staff be drilled for emergency preparedness.[90] It is imperative that physicians involved in the care of critically ill patients be familiar with the hospital's plan for evacuation and transport of such patients.

Pediatric Transport

The development of neonatal transport systems in the 1970s preceded the focus on pediatric transport programs in the 1980s and 1990s.[91] The primary indications for pediatric transport to referral centers are respiratory failure and cardiovascular insufficiency followed by neurologic compromise.[92] Today improved care at centers of excellence in the management of pediatric conditions such as congenital heart disease results in more transfers.[93] Common complications encountered during transport in the pediatric population include hypotension, decreased arterial oxygen saturation, and hyperthermia.[94] Adverse technical events such as loss of intravenous access, failure of monitors, and dislodgement or malposition of the endotracheal tube occur in nearly 36% of transfers. Clinically adverse events such as hypotension, hypoxia, or hypoglycemia occurred in 27% of transfers reported by Hatherill.[95]

Pediatric transport is highly specialized. Interviews with pediatricians reveal that nearly one-half report insufficient knowledge of sophisticated transport equipment.[92] Transport complication frequencies are higher in children transported by a referring physician compared with children transported by a specialized pediatric transport team. The higher rate of complications is believed due to a lower rate of appropriate pretransport interventions, lack of expertise with equipment, insufficient specialized equipment, materials, and lack of medications usually available to specialized teams and indeed all transport teams. The complexity of neonatal and pediatric transport and improved outcomes at tertiary care centers has resulted in the creation of specialist retrieval teams comprised of physicians and nurses. Bellingan et al. compared transport by a pediatric specialist retrieval team to standard practice. Patients transported by standard support teams commonly led by a trainee physician were more acidotic and demonstrated more hypotension than those moved by specialist teams.[96] Patients transported by standard teams also had a higher mortality within the first 12 hours. Transport of the complicated pediatric patient is an area where clear benefit is demonstrated by specialized teams.

The key to safe pediatric transport is adequate preparation. A high percentage of patients require some preparatory intervention prior to transport.[94] Those who receive these interventions have a lower rate of decompensation during transport or upon arrival at the receiving center. Routine resuscitation priorities take precedence. Preparation requires appropriately securing the airway and assuring correct ventilation. More than one-third of pediatric transport patients require a change of the mode of ventilation prior to departure, whereas intubation is required by the transport team in 16.1% of patients.[94] Fluid resuscitation is initiated in nearly one-third of transports and approximately one-quarter require the IV infusion of vasoactive drugs.[94]

Several factors increase a child's susceptibility to hypoxemia and respiratory compromise, including a more compliant lung cage, reduced diameter of the airways, increased pulmonary vascular reactivity to hypoxia (infancy), and a predisposition to a decreased respiratory drive in the setting of hypoxia (up to 1–2 months of age), and reduced surfactant production (neonates).[67]

Coordination, Integration, Data Collection, and Quality Assurance

Changes in the system of patient transport over the years have resulted in many improvements, including an ability to transport sicker patients over long distances for specialized care. This need for transport will continue and will likely expand as technology results in increasingly sophisticated treatment. Smaller hospitals and medical centers may not be able to support the financial burden of expensive technology and teams, resulting in the expanded regionalization of services. Improvements have been made but an apparent threshold of morbidity has been reached that will not be reduced unless systemwide changes are implemented. These changes should include the integration of technology and transport system design, generalized use of critical care transport teams for certain categories of patients that can benefit from advanced care, establishment of key protocols and guidelines, establishment of Internet-based electronic medical records for efficient transfer of information, collection of data and analysis of the metrics that indicate a satisfactory or unsatisfactory transfer, and critical care reporting systems which track the outcome of inter and intrahospital transfer.

Technology and Transport System Design

Safe movement of a critically ill patient requires the coordinated effort of numerous trained individuals. Often the patient, monitors, and infusion pumps must be changed several times during one movement. Poorly designed or antiquated systems may even require the disconnection of medications and monitors and reconnection to completely different infusion systems and monitoring systems even within the same hospital, increasing transport time as well as subjecting the patient to periods without observation of vital signs or infusion of vital drugs. Systems that are not efficient, compact, and uncluttered can harm patients. Current work is being done on "mobile ICU" models that have integrated monitoring and support systems including ventilators, defibrillators, suction, point-of-care blood chemistry analysis, invasive monitoring of blood pressures, pulse oximetry, temperature, oxygen flow, and electrocardiography. The benefits of such compact, contained systems include the need for fewer transport personnel, shorter preparation time, reduced periods of manual ventilation, and the potential

to provide continuity of care and monitoring from the site of injury, transport to the hospital, emergency department admission, studies and transport to the intensive care unit.[97,98] Not only must equipment be compact and standardized for transport, ideally it should be compatible among and between the emergency department, operating room, intensive care unit, and common sites of patient treatment (e.g., cardiac catheterization, radiology). It is recognized that a system of universal compatibility among different hospitals may be too costly and difficult, but within a single transport system and hospital it is not only feasible, but should be imperative.

The Cleveland Clinic Foundation and the Massachusetts General Hospital have established systems that allow the easy transfer of support equipment without interruptions in therapy or the flow of vital information.[4] The same monitors and infusion pumps used in the operating room are used during transfer and upon arrival in the intensive care unit. Transport monitoring merely becomes an extension of the familiar bedside monitor. The benefits seen include more rapid preparation of the patient for movement, fewer personnel needed for transfer, and improved patient care.[99]

Critical Care Transport Teams

Teams specialized in the transport of distinct categories of patients have proven to be beneficial by decreasing morbidity and mortality while increasing provider satisfaction. Specialist retrieval teams were initially developed to transport critically ill pediatric patients. Such studies suggest that specialized transport teams are needed to provide consistent safe care with a low rate of transport-associated complications and morbidity. Other populations best served by specialized teams include patients with ARDS or who require extracorporeal oxygenation or left ventricular assist devices, and perhaps those with head injuries. Factors to consider in the creation of these teams include the quality and scope of patient care, costs, medical justification, medicolegal issues, and return on investment based on the analysis of patient volume, overhead, and logistics.[100]

Protocols and Guidelines

Multiple organizations have developed and published guidelines for the transfer of critically ill patients.[45,62] These guidelines are general in nature and have not been adopted as standards. Four critical elements are required for the development of transfer plans: a multidisciplinary planning team, a medical needs assessment, a written standardized transfer plan, and continual evaluation and refinement as needed.[45]

Emergency medical services have established protocols. Transfer protocols are detailed in nature and address not only common populations (pediatric patients, traumatic brain injury, asthma, myocardial infarction) but also specialized conditions and devices (intraaortic balloon pumps, ventricular assist devices, inhaled nitric oxide).

Boston MedFlight has developed complete protocols for both air and ground transport of patients. All protocols have 6 "organizing principles" (Table 80–12). Protocols may lead to improved outcomes when conditions are repeatedly encountered. Protocols also allow the stocking of standardized medications and acquisition of equipment based on these plans. Over time care providers develop comfort working within a common framework, and systematic "reiteration" of the protocols leads to improved quality and efficiency.

Transfer of Medical Information

Transfer involves not only the efficient movement of the patient but the exchange of vital information from the transferring physician, care provider in route, and to the final receiving system. Direct verbal communication between the transferring and receiving physicians along with nurse-to-nurse reporting prior to patient movement ensures that the receiving facility is appropriate for current patient needs or condition and is prepared for receipt of the patient (medications, ventilation, studies, surgery if necessary). Clinical course may dictate that transfer be delayed or changed to another facility. Other factors important to communicate include directions to the receiving station or unit within a facility.

Electronic medical records and teleradiology should allow easier exchange of complete vital information. Internet-based record systems facilitate the receiving physician's ability to fully assess whether a transfer is appropriate.

TABLE 80–12.

Protocol Outline

1. Planning prior to arrival
   a. Specialized equipment
   b. Vehicle type or configuration
   c. Changes in disposition, destination, weather
2. Preparation of patient for transport
   a. Full assessment
   b. Monitoring
   c. Pretransport interventions
3. Intratransport care
   a. Issues specific to condition prompting transfer
   b. Medical/procedural interventions during the transfer
4. Arrival at the receiving facility
   a. Communication
   b. Transfer of care
5. Documentation issues
   a. Medications administered and side effects
   b. Deviation from established protocols
6. Education/quality improvement

Reporting and Critical Incident Evaluation

Reporting of unsafe practices, complications during patient transport, and critical analysis of patient safety practices is imperative if the etiology of adverse events and errors are to be determined and rectified. The Australian Incident Monitoring Study in Intensive Care was developed in 1993 as an anonymous voluntary reporting system to identify critical incidents and determine their underlying causes and contributing factors.[16] A review of events related to patient transfer was carried out in 2004. The study revealed a high rate of serious outcomes (nearly one-third of the incidents had significant adverse outcomes) almost evenly divided between system-based and human-based factors. Most events occurred between the ICU and operating theater or radiology. Failure of equipment was primarily related to either battery or drug infusion pump failure. Other significant events included insufficient oxygen reserve within canisters. The most common patient/staff management issues were problems related to communication between the ICU

TABLE 80–13.

Recommendations from the Australian Incident Monitoring Study in Intensive Care

Recommendations for transportation

a. The decision to move a critically ill patient within the hospital should be made by a senior medical practitioner after careful consideration of the benefits to be gained weighed against possible risks.

b. A dedicated team should be available for the entire duration of the transport. The team members need to be familiar with the critically ill patients, skilled in airway management and resuscitation, patient monitoring and moving, and be familiar with all equipment.

c. Adequate monitoring of the critically ill patient should include electrocardiogram, blood pressure, oxygen saturation, and, if ventilated, end-tidal carbon dioxide monitoring.

d. Careful preparation for transport is essential, including patient and equipment checks and liaison with staff at the destination. A checklist should be used to assist in preparation. Oxygen supply, including the amount of oxygen in cylinders, and battery-life assessments are imperative. Transferring the patient to or from his/her bed must be carefully planned and appropriate equipment used by trained staff. All lines and tubes should be checked and simplified if possible.

e. All battery-operated transport equipment should have charge indicators and backup batteries. Regular servicing and checking of transport equipment is essential. The use of specialized transport trolleys, which include improved power supply, has been advocated.

f. Patient observations should be documented during transport.

g. Guidelines by professional bodies need to be update in line with recommendations. Guidelines should develop a pretransport checklist.

Recommendations for monitoring outcomes

Local units need to be able to monitor compliance with these standards, including adequate in-servicing/training of staff, enhanced communication between destination sites, as well as monitoring the occurrence of incidents and their contributing factors.

Other recommendations

Because of the documented hazards and the expense of intrahospital transport, it is important to continue to develop the technology with which to perform diagnostic and therapeutic procedures at the bedside.

Reproduced with permission from Beckman U, Gillies DM, Berenholtz SM, Wu AW, Pronovost P. Incidents relating to the intrahospital transfer of critically ill patients. An analysis of the reports submitted to the Australian Incident Monitoring Study in Intensive Care. Intensive Care Med 2004;30:1579–1585.

and site of destination or origin. The value of incident monitoring lies not only in the systematic gathering of information but in the detailed analysis of the root causes of the events.[16] Several key recommendations arose from this important study (Table 80–13). These recommendations primarily emphasize careful consideration of the risks, careful preparation, dedicated transport teams, checklists, careful documentation of events in transport, and monitoring of compliance with established standards.

Incident reporting systems in healthcare arose from examinations of the benefits of safety reporting systems in the aviation industry. The aviation systems have been characterized by an organized process for collecting, analyzing, and dissemination of events, sentinel events, and near-miss events in a "no-fault" environment that focuses on fixing "systems" rather than identifying and blaming individual operators. Recently the Institute of Medicine of the National Academy of Science has emphasized this strategy, reporting that system failures rather than individual incompetence are the primary cause of healthcare errors.[100] A reporting system optimized for the area of patient transport should be voluntary, nonpunitive, easy to carry out, and capable of providing feedback to participants.[101] Holzmueller et al. developed an Internet-based reporting system to deal with common barriers to success in reporting systems including underreporting, fear of reprisal, patient confidentiality, time pressure, duplication, and a generalized opinion that efforts were wasted because of little feedback. Their work, although preliminary, has demonstrated that a Internet-based system that collects data from multiple different intensive care units across the United States is possible. Internet-based reporting systems may allow collection of data easily at multiple centers and facilitate sharing the findings. Although a single event at a particular reporting center may not lead to prompt action, the discovery of several similar events at various locations may acquire significance and require action.

Critical incident reporting and review results in better training of staff, implementation of guidelines for the maintenance and readiness of equipment, and a reduction in the number of adverse events.[102]

CHAPTER 81

Postoperative Care of the Noncardiac Surgical ICU Patient

Michael C. Banks, MD, and
C. William Hanson, III, MD

The surgical intensive care unit (SICU) is a specialized patient care floor designed to manage and treat critically ill surgical patients, and care may include preoperative, postoperative, and postinjury management. Critical care is an increasingly expensive and constrained resource because of shortages in qualified physicians, nurses, and ancillary personnel, and it is ever more necessary to find models of care delivery that ensure the provision of optimal care most efficiently.

The kinds of patients admitted to intensive care units have changed dramatically over the past several decades. The evolution of trauma systems, with rapid transportation of critically injured patients has resulted in the concentration of complex, multitrauma patients in trauma centers. The development of ventricular-assist devices, aortic surgery, and lung transplantation has revolutionized cardiothoracic surgery and changed the nature of cardiac intensive care. New approaches to the management of head injury and respiratory failure require increased technological sophistication in cerebral monitoring and mechanical ventilation, as well as increased expertise on the part of intensivists, nurses and respiratory therapists. At the same time, endoscopic approaches to thoracic surgery and epidural analgesia have allowed many thoracic patients to be sent directly to the hospital floor after surgery rather than the ICU. Aortic stents have had the same effect on vascular surgical patients who would have undergone a laparotomy and several day ICU stay a decade ago and may now go directly to a general floor.

As our ability to prolong life has improved, so has the complexity of ethical decision making in ICU care. The fact that we can replace the function of the heart, kidney or lung increases the frequency with which we are confronted by questions about the appropriateness of doing so.

ICU TRIAGE

Critical care bed occupancy can have a major effect on the flow of patients through the operating room, and it is essential to make optimal use of this often scarce and invariably expensive resource. The criteria used for ICU admission should be based on prioritizing care for those patients who would benefit the most from ICU care.[1,2] Ideally, this would eliminate from consideration those who are "too well" and those who are "too sick" to benefit from care.

Screening Tools

The Task Force of the American College of Critical Medicine and the Society of Critical Care Medicine ICU developed admission screening tools based on three different models: prioritization, diagnosis, and objective parameters. The *prioritization* model classifies patients into 4 priorities (Table 81–1).

The *diagnosis* model (Table 81–2) identifies 8 systems: cardiac, pulmonary, neurologic, drug ingestion and drug overdose, gastrointestinal disorders, endocrine, surgical, and miscellaneous, and divides them into admissible disease states.

The *objective* model (Table 81–3) is based on 5 objective criteria for admission into the ICU, as opposed to the subjective criteria in the prior two models . The five categories are vital signs, laboratory values, radiology, electrocardiogram, and physical findings.

These criteria were requested and reviewed by multiple healthcare centers in an effort to comply with the Joint Commission on Accreditation of Healthcare Organizations review of special care units. These criteria are used by many healthcare organizations in the United States and abroad.[3,4]

When the demand for an ICU bed is greater than the number of beds available it becomes necessary to triage patients in and out of the unit and a triage plan should be developed by the

KEY POINTS

1. ICU bed management is increasingly important because of escalating demands for beds. Both anesthesiologists and intensivists play a major role in ensuring that this expensive resource is used responsibly.
2. New approaches to pain management have revolutionized certain fields of surgery (e.g., thoracic and major vascular), permitting patients to undergo major procedures without the need for prolonged high-intensity intensive care following surgery.
3. Critical illness *polyneuropathy* and *myopathy* are acute illnesses that result in weakness and paralysis in intensive care patients.
4. Critically ill patients are at risk for a variety of pulmonary complications including aspiration, ventilator-associated pneumonia and acute lung injury. Intensive care management is directed at minimizing the risk factors that predispose patients to these complications
5. Pulmonary artery catheter (PAC)-guided therapy does not improve outcomes in critically ill patients with acute lung injury. Conservative fluid management approach improves lung function and shortens the duration of both mechanical ventilation and intensive care stay without altering the rate of nonpulmonary organ failures.
6. The stress response after major surgery or injury is often accompanied by a period of impaired endothelial cell function and loss of plasma volume into the "third space." The reasons for this are varied, but include tissue hypoperfusion caused by inadequate fluid therapy, ischemia–reperfusion injury, cytokine activation, and, in some cases, exposure of the blood to extracorporeal circuits (i.e., cardiopulmonary bypass).
7. Renal replacement therapy is a field that has changed significantly over the past decade, and venovenous ultrafiltration and dialysis are now the predominant modalities.

TABLE 81–1.

Prioritization Model

Priority 1	Patient requires vasopressors, ventilatory support, and/or invasive monitoring.
Priority 2	Patient with acute disease complicating a chronic condition; patient needs monitoring.
Priority 3	Patient with acute disease complicating a severe chronic condition.
Priority 4	Too well or too ill to benefit from ICU care.

TABLE 81–2.

Diagnosis Model

System	Disease State
Cardiac	Acute myocardial infection with complications; cardiogenic shock; complex dysrhythmias requiring monitoring or intervention; acute congestive heart failure with respiratory failure; hypertensive emergencies, unstable angina; cardiac arrest; cardiac tamponade; complete heart block
Pulmonary	Acute respiratory failure requiring mechanical ventilation; pulmonary emboli with hemodynamic instability; massive hemoptysis
Neurologic	Acute stroke with mental status change; coma; intracranial hemorrhage with possible herniation; acute subarachnoid hemorrhage; meningitis with altered mental status; central or peripheral nervous system disorder with deteriorating function; status epileptics; vasospasm; traumatic head injury; brain death with organ donation potential
Gastrointestinal	GI bleed with hypotension, angina, or continued bleeding; fulminant hepatic failure, severe pancreatitis; esophageal perforation
Endocrine	Diabetic ketoacidosis; thyroid storm, myxedema coma with hemodynamic instability; hyperosmolar state with coma or hemodynamic instability; adrenal crisis with hemodynamic instability; severe hypercalcemia with altered mental status; hypo- or hypernatremia with seizures and altered mental status; hypo- or hyperkalemia with dysrhythmias or hemodynamic instability; hypophosphatemia with muscular weakness
Surgical	Postoperative patients requiring hemodynamic monitoring, ventilatory support, and/or extensive nursing care
Drug ingestion or overdose	Seizures; hemodynamic instability; altered mental status with inadequate airway protection
Miscellaneous	Septic shock; hemodynamic monitoring; environmental injuries (lightening strike, near drowning, hyper-/hypothermia); experimental therapies with potential complications; conditions requiring extensive nursing care

Data from Egol A, Fromm R, et al. Guidelines for intensive care unit admission discharge and triage. Crit Care Med 1999;27:633–638.

hospital, perhaps by an ICU committee.[5] The ICU committee should be composed of healthcare professionals, ethic advisors, and legal advisors.

Triage should be directed by a triage officer and the principles of triage should be available to the public and to patients and/or their surrogates.[5] The triage plan should not be arbitrary or prejudicial. The triage officer should evaluate patients in the ICU to determine which patients are receiving the greatest benefit from ICU care. An example of a patient who might be deemed inappropriate for ICU admission is the patient with an advanced directive directing that cardiopulmonary resuscitation and/or mechanical ventilation not be initiated. A brain-dead organ-donor patient may, although legally dead, be kept in an ICU until organ harvest. The creation of explicit guidelines for ICU admission, discharge, and triage facilitate bed management when a family or physician wishes to admit a patient to an ICU bed for inappropriate reasons.

The triage plan should prioritize admissions to the ICU. The hospital has an obligation to treat patients who are already admitted to the institution and inpatients who have suffered an acute decompensation should be evaluated for ICU admission as top priority. A level 1 trauma center has obligations to the state and community to admit critically injured patients as a top priority. A hospital may also choose to prioritize admissions of certain patients for specialty care. These priorities may require the deferral or cancellation of elective surgical cases on rare occasions. Third the triage plan should evaluate the capacity of all ICU beds in the hospital in addition to beds in the post anesthesia care unit and the emergency department. In times of great demand, all critical care beds must be used with appropriate patients being placed in specialty intensive care areas that can care for the patient's disease. The triage plan must also facilitate the transfer of patients to outside healthcare centers should the need arise.

Intraoperative Evaluation for ICU Care

Certain operative procedures routinely necessitate postoperative ICU care for the patient, such as cardiac surgical procedures and certain neurosurgical procedures. These patients have predictable postoperative periods of instability during which intensive nursing and physician care is required. Many other patient populations, including those who have undergone major vascular or general surgical procedures typically go to the intensive care unit following surgery. Patients may also have intraoperative events that necessitate unplanned admission to the SICU. Finally, some patients who are scheduled to go to the SICU postoperatively may end up not needing critical care because, for example, a planned procedure was aborted or went better than expected. Decisions as to the necessity for a postoperative ICU bed can be made by the anesthesiologist or surgeon either prospectively or as dictated by the intraoperative course.

A variety of intraoperative events may prompt unexpected admission to

TABLE 81–3.

Objective Parameter Model

Objective Parameter	Value/Limit
Vital signs	Pulse ‹40 or ›150 beats/min; systolic arterial pressure ‹80 mm Hg or 20 mm Hg below baseline; meat arterial pressure ‹60 mm Hg; diastolic arterial pressure ›120 mm Hg; respiratory rate ›35 breaths/min
Laboratory values	Serum sodium ‹110 mEq/L or ›170 mEq/L; serum potassium ‹2.0 mEq/L or ›7.0 mEq/L, Pao_2 ‹50 torr; pH ‹7.1 or ›7.7; serum glucose ›800 mg/dL; serum calcium ›15 mg/dL
Radiological findings	Cerebral vascular hemorrhage, contusion, or subarachnoid hemorrhage with alter-mental status or focal signs; ruptured viscera, bladder, liver, esophageal varices, or uterus with hemodynamic instability; dissecting aortic aneurysm
Electrocardiogram	Myocardial infection with complex dysrhythmia, congestive heart failure, or hemodynamic compromise; sustained ventricular tachycardia or fibrillation; complete heart block
Acute-onset physical findings	Unequal pupils in an unconscious patient; burns covering ›10% of body surface area; anuria; airway obstruction; coma; continuous seizures; cyanosis; cardiac tamponade

Data from Egol A, Fromm R, et al: Guidelines for intensive care unit admission discharge and triage. Crit Care Med 1999;27:633–638.

the ICU, including airway management problems, intraoperative aspiration of gastric contents, major blood loss, drug reactions, and cardiac events. The ICU admission criteria described in the previous section can serve as objective guides as to whether ICU admission is necessary or warranted. For example, a patient with an unexpectedly difficult airway discovered during induction of anesthesia typically would not require ICU admission in the absence of some physiologic derangement such as hypotension or hypoxia. Categorized by the three admission models described above, the patient would be admitted for:

Prioritization model—Priority 1. The patient is hemodynamically unstable and needs ventilatory support

Diagnosis model—Pulmonary: acute respiratory failure requiring ventilatory support

Surgical: postoperative patient requiring vent support and hemodynamic monitoring

Objective model—Vital signs: mean arterial pressure < 60 mm Hg, pulse < 40 beats/min, Pao_2 < 50 torr

Another common occurrence in the operating room is the patient who develops an unexpected requirement for large volumes of crystalloid or blood products. This patient is at risk for the development of postoperative complications from fluid shifts such as congestive heart failure, respiratory failure, and hypoxia. These complications may warrant ICU admission for the following admission criteria:

Prioritization model—

Priority 1: The patient requires intensive monitoring to assess hemodynamic stability and end-organ perfusion

Priority 2: If the patient has chronic comorbid conditions that were exacerbated, such as coronary artery disease

Diagnosis model—

Cardiac system: acute congestive heart failure

Pulmonary system: acute respiratory failure

Miscellaneous: hemodynamic monitoring

Objective Model: respiratory rate > 35 breaths/min; Pao_2 < 50 torr (on 40% FiO_2)

Objective ICU admission guidelines can be used to assure appropriate use of this costly and often scarce resource.

MANAGEMENT OF THE POSTOPERATIVE ICU PATIENT

Transport Between the Operating Room and the ICU

Intrahospital transport of critically ill patients is recognized as a hazardous maneuver associated with complications that include hypoxia, hypotension, cardiac arrest, and ventilator-associated pneumonia.[6–8] Studies show that a majority of transport-related complications occur during travel between the ICU and the operating room or the radiology suite.[8] The first step made prior to transporting a patient is to assess the need for transport. For example, certain procedures can be performed in the ICU or postponed rather than subjecting a patient to a potentially hazardous transport. Many procedures can be done at the bedside, such as a tracheostomy or percutaneous gastrostomy tube. A review by Braxton et al. describes three studies where care plans changed with in 48 hours after transport for 24%, 30%, and 39% of transports.[9] Thus the portability of the test or procedure should be considered before transporting a patient.

After determining the requirement for patient transport to or from the ICU, a comprehensive transfer plan should be used. The transfer plan should include pretransport preparation, transfer personnel, communication, and monitoring. Pretransport preparation is a crucial step in safe patient transport. A checklist is recommended to prevent steps from being missed. A checklist should include evaluation of oxygen supply, emergency resuscitation drugs, IV fluids and pressors (if needed), monitors with charged batteries, portable ventilator or ventilatory device with airway management equipment, and pretransport vital sign check.

Appropriate personnel are necessary for transport. Some institutions require a critical care nurse and a respiratory therapist, whereas others have dedicated transport teams trained to care for critically ill patients and experienced in transport of these patients. There should be a minimum of two people for the transport of a critically ill patient. One person should be an experienced healthcare provider, such as a critical care-trained nurse or physician. Studies show that major causes of transport complications are failure to follow protocol and failure to recognize

a problem has occurred during transport.[9] If the patient is physiologically unstable, a physician should be present during transport.

Communication is the next step to a safe transport. The transport team must notify the receiving unit or location that the patient is coming and communicate details about the patient's history and present status. Doing so ensures that the receiving area has the appropriate monitors, equipment, and drugs ready for the patient. The last step to safe transport is appropriate monitoring during transport. This should include continuous electrocardiogram, blood pressure (invasive or noninvasive as appropriate), oxygen saturation, and end-tidal CO_2 (if the patient is ventilated) measuring . All portable monitoring devices should have fully charged batteries with a charge light-emitting diode (LED) to indicate the need to recharge the battery.

Each patient care unit should have written transport policies as recommended by the American College of Critical Care Medicine, Society of Critical Care Medicine, and the American Association of Critical Nurses.[10] These policies should be modified for each healthcare institution.

Postoperative Labs and Vital Signs

Standard ICU monitoring includes heart rate, blood pressure, pulse oximetry, respiratory rate, and electrocardiogram. Frequent labs that are checked include complete blood count, electrolytes, coagulation panel, and arterial blood gas (as warranted by the patient's respiratory condition). Capnography is used in some ICUs as a respiratory monitor as well as an adjunct to the assessment of respiratory dead space in acute and chronic diseases of the critically ill, such as chronic obstructive pulmonary disease and pulmonary embolism. A variety of laboratory studies are used to evaluate the critically ill patient, including serum electrolytes, glucose, blood urea nitrogen and creatinine, hemoglobin and hematocrit, platelets, and clotting studies. Serum lactate can be used to follow the adequacy of resuscitation and diagnose conditions such as ischemic bowel. Serum calcium (ionized or unionized) and magnesium are important cations. When checking lab values and physiologic parameters, it is often not the actual value that is most important, but the trends in values.

MANAGEMENT OF POSTOPERATIVE ANALGESIA AND SEDATION IN THE ICU

Pain management in the ICU is important both for patient comfort and satisfaction, as well as an increasingly recognized contributor to patient outcomes—the combination of epidural analgesia and endoscopic techniques, for example, have revolutionized thoracic surgery in the past decade. There are many ways to manage postoperative pain, including patient-controlled epidural analgesia (PCEA) and intravenous patient-controlled analgesia (PCA). The caveat to this type of pain control is that the patient must be awake, alert, and oriented in order to used the pump effectively. There are risks particular to each of these techniques. PCA can cause somnolence and narcotization, but this is rare if the basal and bolus rates are set appropriately. PCEA is extremely effective after certain surgical procedures, particularly those involving the chest and upper abdomen. One disadvantage of PCEA in critically ill patients is the hypotension and bradycardia caused by sympathectomy, even at therapeutic levels. These physiologic responses must be differentiated from pathologic problems (e.g., evolving myocardial infarction). Hypotension and bradycardia do not mandate discontinuation of the infusion; rather the level of the block should be evaluated, and the infusion rate adjusted if it is too high. If the patient is still hypotensive, the concentration of the local anesthetic can be decreased and blood pressure can be managed with fluid boluses or pressors. In a recent meta-analysis by Wu et al., epidural analgesia provided better analgesia than intravenous PCA.[11]

In mechanically ventilated patients, a continuous opioid infusion can also used to help control pain. The advantage of a continuous infusion is that at high enough doses, the attendant sedation may make it easier for the patient to tolerate the endotracheal tube. Frequent nursing assessment and dosage adjustment is needed to avoid overnarcotization, particularly with long-acting opioids, which can lead to prolonged intubation, wake-up, and hospital stay.

Continuous infusion of propofol, benzodiazepines, and muscle relaxants are also used in the ICU to sedate or immobilize postoperative patients, particularly following procedures where excess movement can be harmful to the patient, such as certain muscle flaps or tracheal repairs. Propofol, benzodiazepines, and muscle relaxants have no analgesic properties and should therefore be supplemented with a narcotic where appropriate. Also muscle relaxants have no sedative properties, and should never be used without concurrent administration of a sedative/amnestic.

Another analgesic/anxiolytic drug that is used in the ICU for postoperative pain and sedation is dexmedetomidine. Dexmedetomidine is a centrally acting α_2-agonist that is more potent than clonidine, and with a faster onset and shorter length of action. Dexmedetomidine is also a potent analgesia and anxiolytic.

To objectively and reproducibly evaluate a patient's degree of anxiety and discomfort, many units make use of a sedation/analgesia protocol. Although there are many approaches to the measurement of sedation/analgesia they can be divided into objective and subjective methods. Objective measurements include plasma drug concentration, frontalis electromyogram, and bispectral index (BIS) electroencephalographic analysis. Plasma drug levels are not a reliable method because the concentration of drug that is needed for analgesia varies from patient to patient. Frontalis electromyelogram (EMG) is not sensitive for monitoring sedation. BIS analysis method has been studied as a monitor for sedation, but its results have not been confirmed in critically ill patients.

Subjective methods include scales such as the Ramsay scale, visual analog pain scales, the modified Glasgow coma scale by Cook and Palma, and the sedation–agitation scale. The Ramsay scale is the most widely used scale for sedation monitoring (Table 81–4).[12] It has shown good interobserver agreement and reliability. The Glasgow coma scale modified by Cook and Palma (Table 81–5) gives a numerical score to patients who are mechanically ventilated. This scale has proven reproducibility and interobserver reliability.

Potential complications of poorly managed analgesia and sedation range from prolonged intubation to ICU delirium or myocardial ischemia. Oversedated patients can require longer ventilator support, and a longer ICU and hospital stay. Prolonged ventilation increases the patient's risk of ventilator-

TABLE 81–4.

The Ramsey Sedation Scale

Level	Characteristics
1	Patient awake, anxious, agitated or restless
2	Patient awake, cooperative, oriented and tranquil
3	Patient drowsy, with response to commands
4	Patient asleep, brisk response to glabella tap or loud auditory stimulus
5	Patient asleep, sluggish response to stimulus
6	Patient has no response to firm nail-bed pressure or other noxious stimuli

associated pneumonia, which increases morbidity and mortality. Studies also show that inadequate pain control can lead to ICU delirium, which leads to increased morbidity and hospital stay.

MANAGEMENT OF ORGAN-SPECIFIC ISSUES AND SYSTEMS IN POSTOPERATIVE ICU PATIENTS

Neurologic Issues

Management of the postoperative neurosurgical patient is beyond the scope of this chapter.

This section addresses the management of common neurologic disorders seen in postoperative ICU patients.

New-onset seizures are a major postoperative comorbidity in ICU patients. The incidence has been reported to be 12% in ICU patients without a neurologic primary diagnosis.[13] The causes of postoperative seizures include medications, metabolic disorders, primary neurologic disorders, infection, hypoxia, and drug withdrawal (Table 81–6).

Accurate diagnosis of new-onset seizures is important. One must first differentiate seizure from myoclonus and other rhythmic movements. This can be done with electroencephalogram evaluation. Once new-onset seizure has been diagnosed, laboratory tests, CT or MRI of the brain, and, in patients suspected of an infectious etiology, a lumbar puncture are needed to elucidate the etiology. The most common causes of new-onset seizures in ICU patients are metabolic disturbances with an incidence of 28.6%.[13] The initial treatment for new-onset seizures is to stop the seizure with benzodiazepines like lorazepam or midazolam, barbiturates such as thiopental, or with propofol.[14] The patient should then be started on a primary anticonvulsant medication. First-line anticonvulsants include phenytoin, Keppra, and carbamazepine.

Critical illness neuromuscular diseases are relatively rare but important complications seen in ICU patients. These abnormalities are divided into polyneuropathies and myopathies of critical illness. Critical illness *polyneuropathy* is an acute degenerative disorder of motor and sensory nerve axons. Symptoms are flaccid tetraparesis and failure to wean from the ventilator. Critical illness *myopathy* is an acute degenerative illness of the myocyte that results in weakness and paralysis. There are three histologic types of myopathy: diffuse necrotizing, necrotizing, and myosin thick-filament loss. The risk factors for development of critical illness neuromuscular abnormalities include systemic inflammatory response syndrome (SIRS)/sepsis, multiorgan dysfunction, corticosteroids, neuromuscular blocking agents, hyperglycemia, and aminoglycosides. The mechanisms by which these risk factors contribute to neuromuscular abnormalities are unknown, but there are some theories. Balton et al. suggest that cytokines, free radicals and complement that are released during SIRS/sepsis, lead to axonal injury.[15]

The incidence of critical illness polyneuropathy in patients varies substantially depending on the diagnostic method used, the patient case mix, and the timing of the diagnosis. In septic patients, the incidence has been stated to be as high as 70–80%.[16] Studies show an association between corticosteroids and critical illness myopathy in patients with severe asthma;[16] however, no mechanism has been found. Neuromuscular-blocking agents are also associated

TABLE 81–6.

Causes of New-Onset Seizures in Postoperative Patients

Hypoxia/ischemia	
Metabolic disorders	Eclampsia, hyponatremia, hypophosphatemia, renal dysfunction, hepatic dysfunction
Medications	Antibiotics, antidepressants, antipsychotics, local anesthetics, cocaine, amphetamines, phencyclidine
Traumatic head injury	Contusion, hemorrhage
Infection	Febrile seizures, abscess, encephalitis
Drug withdrawal	Barbiturates, benzodiazepines, opioids, alcohol
Surgical injury	Craniotomy

Adapted from Mirski MA, Varelas PA. Diagnosis and treatment of seizures in the adult intensive care unit. Contemporary Critical Care 2003;1(4):1–12.

with acute myopathies. Concurrent administration of a neuromuscular blocking agent (NMBA) with steroids or aminoglycosides increases incidence of myopathies. High blood glucose is associated with critical illness polyneuropathy in one study of septic patients with multiorgan dysfunction. Van den Berghe reported that axonal injuries were decreased by 50% in patients who received intensive insulin therapy.[17] It is not clear if catecholamines and hyperglycemia lead to polyneuropathy, or if insulin or euglycemia protects neuronal axons.

The diagnosis of critical illness neuromuscular abnormalities by clinical presentation can be extremely difficult in critically ill patients as a result of the presence of encephalopathy or sedation. Consequently, objective studies can be used to help diagnose the disease. Nerve and muscle biopsies can help identify pathologic evidence of disease. Nerve biopsies, however can lead to permanent neurologic deficits. Electrophysiologic studies such as nerve conduction studies and electromyography are the gold standard for diagnosis of critical illness neuromuscular abnormalities. Nerve conduction studies measure the latency and amplitude of the response. The muscle's electrical response can also be evaluated. This is called *compound muscle action potential* (CMAP). In critical illness polyneuropathy CMAPs are reduced and abnormal spontaneous activity is present, which is indicative of axonal neuropathy. Electromyography records the electrical activity of active and resting muscle. In patients affected by critical illness neuromuscular abnormalities, abnormal fibrillation occurs. To differentiate between neuropathy and myopathy, motor unit action potentials are evaluated using EMG. If a motor unit shows increased amplitude and latency, critical illness polyneuropathy is diagnosed. If the motor unit shows decreased amplitude and latency, critical illness myopathy is diagnosed.

Treatment of critical illness neuromuscular abnormalities is very limited. It consists of intensive physical therapy with minimized use of muscle relaxants, corticosteroids and tight glucose control. The long-term outcome of this disease is not well studied. Recovery depends on the severity of the disease. Although patients with critical illness neuromuscular abnormalities may regain normal strength after weeks to months, some never recover.

Pulmonary Issues in the Postoperative ICU Patient

Postoperative patients almost invariably undergo a period of relative hypoxemia because of the effects of anesthetics and or surgery, and critically ill postoperative patients are no exception. The most significant respiratory issues specific to postoperative critically ill patients pertain to mechanical ventilation, the timing of its termination and the prevention of complications.

Postoperative patients often come to the intensive care unit following surgery with an endotracheal tube in place. The importance of safe intrahospital transportation has already been addressed above. The newly arrived patient should have chest radiography performed on arrival to determine the location of intraoperatively placed central lines and the endotracheal tube, specifically to look for proper line and tube placement and to rule out pneumothorax. If the tip of the endotracheal tube is at or above the level of the clavicles on a standard anteroposterior chest film, it should be advanced. The tube should be withdrawn if it is at the level of the carina or in one of the (typically right) mainstem bronchi.

So-called fast-track weaning, where ventilatory support is withdrawn automatically as the patient meets certain milestones, is prevalent and reduces the duration of mechanical ventilation in routine patients.[18] The development of new approaches to noninvasive ventilation and their application to a variety of patient populations has lowered the barrier to extubation. Continuous positive airway pressure and bilevel positive airway pressure (BiPAP) are effective in preventing reintubation in marginal patients who develop respiratory insufficiency after extubation. BiPAP can be administered by face or nasal mask and is used in patients with obesity, chronic obstructive pulmonary disease, and respiratory muscle weakness by allowing them to be extubated and then rested with periods of noninvasive ventilation.[19]

Nosocomial pneumonias include ventilator-associated pneumonia and hospital-acquired pneumonia. Technically speaking, in-hospital aspiration pneumonia is a form of nosocomial pneumonia, although it is usually discussed separately. Both of these diseases occur in postoperative critically ill patients. The definition for the former is an infection occurring greater than 48 hours after admission that is radiographically consistent with pneumonia. Aspiration pneumonia can develop after endotracheal intubation in patients who regurgitate gastric contents; and it is more likely to occur when the pH of the aspirated material is low and the volume is greater than 0.3 mL/kg of body weight. Critically ill patients are at risk for the development of both of these conditions; predisposing factors include inadequate endotracheal cuff seal, supine position, increased gastric contents, and bacterial colonization of the oropharynx.

Acute lung injury and adult respiratory distress syndrome (ARDS) occur in the postoperative patient population. The two diseases represent different points on a continuum of lung diseases and have a multitude of etiologies, including trauma, transfusion reactions, and sepsis. Although a variety of approaches have been investigated for the prevention and treatment of these diseases, the most effective therapy is "protective ventilation," in which low tidal volumes are used to prevent overdistension of the alveoli. The ARDS Network, funded by the National Institutes of Health, published the results of a landmark study of the disease in 1999,[20] which showed that the use of lower (6 mL/kg) volume breaths conferred a mortality benefit compared to traditional (12 mL/kg) volume ventilation. The same group recently published data from a factorially designed study comparing ARDS patients managed with a pulmonary arterial catheter (PAC) versus a ventral venous line and patients with a conservative versus liberal approach to fluid management.[21] The results of this study showed that PAC-guided therapy did not improve outcomes and was associated with more complications (than patients managed with a central venous catheter), specifically those associated with the placement of a PAC. The fluid management data showed that the conservative approach improved lung function and shortened the duration of both mechanical ventilation and

intensive care stay without altering the rate of nonpulmonary organ failures.

Cardiovascular Issues in the Postoperative ICU Patient

Postoperative cardiac management is directly analogous to intraoperative management in terms of the indications for and methods of treating abnormalities such as intravascular volume depletion, hemorrhage, and brady- and tachydysrhythmias. Intensive care monitoring invariably includes noninvasive or invasive blood pressure measurement, continuous electrocardiography, and pulse oximetry. The stress response after major surgery or injury is often accompanied by a period of impaired endothelial cell function and loss of plasma volume into the "third space." The reasons for this are varied, but include tissue hypoperfusion as a result of inadequate fluid therapy, ischemia–reperfusion injury, cytokine activation, and, in some cases, exposure of the blood to extracorporeal circuits (i.e., cardiopulmonary bypass).

Third-space losses of intravascular fluid from the vascular and intracellular spaces can occur into the bowel, peritoneum, and thoracic cavities, as well as into the extracellular fluid. Postoperative patients require ongoing fluid resuscitation commensurate with the magnitude of their surgical or traumatic injury, and in some cases the requirement may exceed 10 mL/kg/h. In healthy patients, the need for fluid resuscitation typically ends after a period of 24–48 hours, and the accumulated excess volume and solute load is eliminated during a period of diuresis over the following days. The time courses of these phases may be altered in patients with underlying diseases such as hepatic or renal failure, and in some instances, extend to weeks. As distinct from the volume requirement, a progressive decrease in the serum hemoglobin suggests ongoing bleeding.

Patients in whom routine intensive care monitoring is insufficient for comprehensive evaluation of a patient's cardiovascular state may require invasive or radiographic monitoring. Patients with unexplained hypotension may require an intrarterial, central venous, or pulmonary arterial catheter to better assess intravascular volume status and cardiac performance. The usefulness and safety of the pulmonary artery catheter is the subject of much recent debate,[22] but newer catheters permit concurrent measurement of continuous cardiac output, right ventricular performance, and mixed venous oxygen saturation—all of which can be used to guide short-term fluid resuscitation.

Monitors such as the central line (venous pressure), pulmonary artery catheter (pulmonary pressures, wedge pressure, mixed venous oximetry, cardiac output), or echocardiography (ventricular filling and performance, valve abnormalities) can be used to guide resuscitation and the prescription of inotropes or vasopressors. In some circumstances, the cause of a hemodynamic abnormality may be self-evident (e.g., hypotension in a patient with a PCEA), and treatment with volume resuscitation or a vasopressor may be empiric.

Cardiac dysrhythmias are relatively frequent in the operating room and ICU, where metabolic, ischemic and neurohormonal stresses may cause premature atrial and ventricular contractions, conduction block, or atrial fibrillation. Dysrhythmias are more prevalent in a patient with structural heart disease[23] and the dysrhythmias may be a result of surgical stress, electrolyte abnormalities, sympathetic stimulation, or device malfunction.[24] Dysrhythmias can be separated into narrow and wide QRS rhythms. Narrow QRS rhythms are almost always supraventricular dysrhythmias and include sinus tachycardia, premature atrial complexes, atrial flutter/fibrillation, accessory pathway tachycardia, and sinus bradyrhythmias.

In patients with wide complex QRS rhythms, it is often difficult to differentiate between supraventricular dysrhythmias and ventricular dysrhythmias. Premature ventricular contractions (PVCs) are common and can be caused by structural heart disease, electrolyte imbalances, acidosis, and hypoxia. PVCs are usually benign and do not require antiarrhythmic treatment in patients without structural heart disease.[25] However, studies show that when PVCs have a frequency of 10 or more per hour, there is an increased risk of developing a life-threatening dysrhythmia, especially in patients with structural heart disease.[26,27]

Atrial fibrillation is far and away the most common perioperative dysrhythmia.[28] The differential diagnosis for postoperative atrial fibrillation is long, and includes increases in catecholamine levels caused by the stress response, electrolyte disorders, hypo- and hypervolemia, and hypoxia. The incidence in cardiac surgical patients is as high as 30–40%, and 3–4% of routine perioperative patients may develop the problem. The first line of therapy is to identify and remedy correctible causes. Pharmacologic treatments include β-blockers, calcium channel blockers, and amiodarone. In most instances the dysrhythmia is self-limited, but in some patients anticoagulation may be appropriate.

Myocardial ischemia and infarction can occur in the postoperative period as a consequence of anemia, underresuscitation, tachycardia, volume overload or the relatively hypercoagulable state that occurs 2–3 days after surgery. Proactive management of hyper- or hypovolemia, β-blockade in selected patient populations, and anticoagulants decreases the incidence of these problems.

Gastrointestinal Issues in the Postoperative ICU Patient

The most common gastroenterologic issues in the perioperative intensive care patient relate to the timing of enteral feeding and gastrointestinal bleeding caused by stress ulceration.

Following surgery, patients go through an inflammatory phase proportionate to the magnitude of surgical injury. The patient often becomes hypermetabolic as the reparative process begins. When glucose and glycogen-based energy stores are depleted, the body begins to breakdown protein from muscle to meet energy demands, becoming hypercatabolic. Nutritional therapy is designed to meet daily energy requirements in critically ill postoperation patients and prevent protein loss. Several questions typically arise when discussing nutrition, including when to start, how to asses nutritional needs, and what route.

The timing of initiation of supplemental nutrition depends on both the baseline nutritional status of the patient and the magnitude of the injury. Patients with hypercatabolic diseases states like burns, sepsis, and cancer, and malnourished patients have different requirements from most other ICU patients. They require more calories and need nutritional support more urgently in order to heal and prevent infection. Laboratory parameters are

often used to help clinicians determine when to start nutrition. Albumin, prealbumin, and transferrin are some of the common laboratory assays used to determine a patient's nutritional status. The inflammatory response to surgery or trauma alters the reliability of these laboratory values, however. Depending on the route of delivery, nutritional support has different complications. Enteral nutrition may result in pulmonary aspiration, enteral anastomotic leak, or intestinal ischemia. Parenteral nutrition can result in central line infections. It is common to initiate nutritional support 1–5 days following surgery in patients.

The advantage of enteral nutrition is that it is physiologic and preserves the guts barrier function and thereby translocation of bacteria from the intestinal lumen into the vasculature. In addition, enteral nutrition preserves the immunologic function of gut-associated lymphoid tissue, and it is less expensive than IV nutrition. There are several contraindications to enteral feeds. Enteral nutrition should not be given to patients who have an intestinal obstruction and it is riskier to give to patients with altered mental status. These patients are at increased risk of aspiration. Parenteral nutrition can be given through a peripheral vein or central vein. Central delivery of nutrition allows for the delivery of higher concentration of carbohydrates and protein that would otherwise irritate peripheral veins. The disadvantages of parenteral nutrition are risk of infection and sepsis, intestinal atrophy, and risk associated with obtaining central venous access.

Abdominal compartment syndrome (ACS) is an increasingly recognized entity in critically ill patients. The intraabdominal compartment is a potential space and when it fills with fluid or blood, pressure increases and impairs perfusion to intraabdominal organs. Intubated patients often demonstrate elevated peak airway pressures during positive pressure breaths. Unintubated patients may become dyspneic. Renal function can be compromised as evidenced by decreased urine output which is thought to be due to decreased renal blood flow and decreased glomerular filtration rate. Increased renal parenchymal and vascular pressure can cause release of renin aldosterone and alcohol dehydrogenase. Signs of increased intrathoracic pressure can also develop with increased central venous or pulmonary capillary wedge pressure, suggesting that the patient is volume overloaded. The elevated pressures actually are transmitted from the abdominal compartment and the patient is actually volume deficient because of compression of the inferior vena cava and decreased venous return. Abdominal compartment syndrome also decreases ventricular compliance and increases peripheral vascular resistance. Together these intrathoracic effects decrease cardiac output.

Early detection of ACS relies on a strong clinical suspicion. In the postoperative ICU patient, abdominal compartment syndrome can be observed in the trauma patient with bleeding and large resuscitation requirements, in the GI surgery patient who requires abdominoplasty, and in the patient with edematous bowel from fluid resuscitation. Intraabdominal pressure is measured using bladder pressures. A urinary catheter is placed in the bladder and the bladder is filled with 50 mL of saline. Bladder, and therefore intraabdominal, pressure is then measured.

Abdominal compartment syndrome can be temporarily treated medically in the ICU with fluids, vasopressors, and pharmacologic muscle relaxation to relax the abdominal wall. Definitive therapy is decompressive laparotomy. There is controversy as to when to take the patient to the operating room for laparotomy. Opening the abdomen for decompression has several risks: infection, sepsis, dehydration from large insensible loses, and fistula formation if the abdominal contents are covered with synthetic mesh material to prevent evisceration. Although the pressure at which the abdomen should be opened is not clearly defined, a grading system has been proposed (Table 81–7).

Following laparotomy, there is often a dramatic improvement in the cardiac performance and the organ perfusion, although in some cases, reperfusion injury ensues. The open abdomen may be covered with a VAC dressing, or a Bogota bag. The VAC dressing helps to quantify abdominal fluid losses, protects the abdominal contents from infection, and helps prevent the abdominal wall musculature from contracting laterally; thus preventing future fiscal closure. The Bogota bag only helps protect from infection. Once the edema has resolved, the abdomen can be closed primarily or with mesh.

Hematologic Issues in the Postoperative ICU Patient

Anemia is a common problem in surgical intensive care unit. It is a risk factor for morbidity and mortality in critically ill patients. Transfusion of packed red blood cells is essential to maintain end-organ perfusion. However, red blood cell transfusion is also associated with risks in critically ill patients. Transfusion of blood products can lead to virus transmission, transfusion reactions, graft versus host disease, and depression of natural killer cell function. Poor wound healing, risk of anastomotic leak, and postoperative infections are associated with perioperative blood transfusion. Because of the divergent opinions on transfusion practices for critically ill patients, clinical studies were performed to develop

TABLE 81–7.

Diagnosis and Treatment of Abdominal Compartment Syndrome

Grade	IAP (mm Hg)	Associated Signs	Treatment
I	10–15	No signs of ACS	Normovolemia
II	16–25	May have increased PAP and oliguria	Hypervolemic resuscitation with caution
III	26–35	Anuria, decreased CO, increased PAP	Consider abdominal decompression
IV	>35	Anuria, decreased CO, increased PAP	Abdominal decompression

ACS, abdominal compartment syndrome; CO, carbon monoxide; IAP, intraabdominal pressure; PAP, positive airway pressure.

transfusion practices for various types of critically ill patients.

In 1999, Hebert et al.[29] conducted a randomized multicenter clinically controlled trial of transfusion requirements in critical care (also known as the TRICC trial). The purpose of this study was to determine if a restrictive transfusion protocol that maintained hemoglobin of 7.0–9.0 g/dL had an equivalent risk of morbidity and 30-day mortality as a liberal transfusion protocol that maintained a hemoglobin of 10–12 g/dL. The results showed that although there was no mortality difference between the two groups, in a subgroup of patients who were younger than age 55 years and who had a low predicted risk 30-day mortality was decreased in the restrictive group and survival was greater in that same group.

In 2001,[30] the same group did a subgroup analysis of the TRICC trial to compare the morbidity and mortality of restrictive transfusion strategy and liberal transfusion strategy in critically ill patients with cardiovascular disease. Cardiovascular disease was defined as patients with a primary or secondary diagnosis of myocardial infarction, angina, congestive heart failure, dysrhythmias, and cardiogenic and other forms of shock, vascular procedures and cardiac procedures (except open heart surgery). The study results showed that there was no statistical difference in either strategy with respect to survival, ICU mortality, and 30- and 60-day mortality, suggesting that the lower hemoglobin did not confer additional harm to this subpopulation with cardiovascular disease.

Several other studies looked at transfusion strategies in patients with acute coronary syndrome. Patients with acute coronary syndrome have myocardial ischemia, angina, or myocardial infarction and it was thought that this was caused by the imbalance in O_2 supply and demand attributable to anemia. In 2001, Wu et al.[31] conducted a retrospective study of 78,974 Medicare patients older than age 65 years with confirmed acute myocardial infarction. To determine the risk associated with anemia in these patients and the effect of blood transfusion on mortality. The results showed that 3680 patients (4.7%) received blood transfusions. It also showed that transfusion was associated with a lower 30-day mortality in patients who had admission hematocrits ≤33% and an increased mortality in patients with hematocrits ≥36.1%.

In another study in 2005, Rao et al.[32] looked at the association between blood transfusions and mortality among patient with acute coronary syndrome who developed bleeding, anemia, or both during their hospital course. This was a retrospective analysis of 24,112 patients compiled from three separate glycoprotein IIb/IIIa inhibitors trials: GUSTO (Global Use of Strategies To Open Occluded Coronary Arteries in Acute Coronary Syndromes) IIb, PURSUIT (Platelet Glycoprotein IIb/IIIa in Unstable Angina: Receptor Suppression Using Integrilin Therapy), and PARAGON B (the Platelet IIb/IIIc Antagonist for the Reduction of Acute coronary syndrome events in a Global Organisation Network). The study showed that 2401 (10%) of the patients had received transfusions and that these patients had a significantly higher unadjusted risk of 30-day mortality and 30-day myocardial infarction. At a hematocrit of 30% or greater, there was a significantly higher risk of 30-day mortality.

Given the conflicting data and the absence of studies specifically applicable to postoperative patients, it is prudent to transfuse blood to maintain hemoglobin above 7 g/dL in patients without a history of cardiac disease. In patients with cardiac disease, it is reasonable to transfuse blood to maintain hemoglobin greater than 10 g/dL.

Coagulopathies that are commonly seen in postoperative ICU patients include dilutional coagulopathy, heparin-induced thrombocytopenia, and disseminated intravascular coagulation. Dilutional coagulopathy is often seen after massive transfusion in patients with exsanguination. Clinical findings include diffuse oozing of blood from mucosal and serosal surfaces, as well as wounds and vascular access sites. Transfusion of multiple units of packed red blood cells leads to the dilution of clotting factors, platelets and prolongation of prothrombin time/partial thromboplastin time.[33] A study by Cosgriff et al.[34] described several risk factors for severe coagulopathy. In a 2-year prospective study that evaluated patients who received >10-unit transfusion of packed red blood cells and performed multiple logistic regression analysis showed that there were 4 significant risk factors: (a) pH <7.10, (b) temperature <93.2°F (34°C), (c) injury severity score >25, and (d) systolic blood pressure <70 mm Hg. Patients with no risk factors had a 1% chance of life-threatening coagulopathy, whereas 1 risk factor was associated with a 10–40% chance, and patients with all 4 risk factors had 100% incidence of life-threatening coagulopathy.

Disseminated intravascular coagulation (DIC) is a consumptive coagulopathy that can appear in the postoperative ICU patient. Triggers of DIC include sepsis, marrow fat embolization from bone fractures, amniotic fluid embolization, and brain material. Embolized material contains tissue factor and thromboplastins, which leads to the initiation of the clotting cascade and consumption of clotting and anticlotting factors. There is loss of localized clot formation and intravascular thromboembolism. DIC is treated by addressing the triggering problem, as for example by fracture fixation or administration of antibiotics in sepsis. Blood products may be administered if the patient actively bleeding .

Hemodilutional thrombocytopenia resulting from crystalloid administration paradoxically causes enhanced coagulation as measured by thromboelastogram.[35–37] The mechanism responsible for this hypercoagulability is unknown.

Thrombocytopenia is common in critically ill patients. Although sepsis and hemodilution are the most common causes, heparin-induced thrombocytopenia (HIT) is a relatively unusual, but significant cause due to its thrombotic aspects. There are two types of HIT. Type 1 which has an incidence of 10–20%, has a nonimmune mechanism, and is not associated with thrombosis. Type 2 HIT, has a 30–80% incidence and is an autoimmune-mediated thrombocytopenia associated with thrombosis. Treatment for HIT consists of discontinuing all forms of heparin and starting anticoagulation with an alternative anticoagulant, argatroban or lepirudin.

Therapeutic anticoagulation (as for the patient with atrial fibrillation) is typically interrupted during the perioperative period, when the risks of bleeding outweigh those of clotting. Patients who are at high risk for thrombosis or embolism are started on intravenous heparin concurrent with discontinuation of oral anticoagulation. Heparin is then discontinued for the immediate operative and perioperative period and resumed as soon as the risk of bleeding from operative sites has stopped, typically around 12 hours following surgery. Oral anticoagulation is

resumed at the same time and the heparin is then discontinued when the international normalized ratio (INR) has reached the desired target.

Renal Issues in the Postoperative ICU Patient

Acute renal failure (ARF) increases the morbidity, mortality, and length of hospital stay in affected patients. In critically ill patients, the mortality from ARF ranges from 23–64% depending on the criteria used to define ARF. Currently, there is no universally accepted definition of ARF. The incidence can range from 17.2%[38] to 24.7%[39] in critically ill patients. There are several causes of ARF in ICU patients, but in postoperative patients, there are a few that are common: sepsis, ischemic acute tubular necrosis, drug-induced acute tubular necrosis, and pigment nephropathy. All of these are subgroups of acute tubular necrosis (ATN), which is caused by the injury and death of tubular epithelial cells that slough off and obstruct the tubule and the vasculature reactively constrict.

Common causes of ischemic acute tubular necrosis are cardiac arrest, hypotension from shock, and hypovolemia, as can be seen postoperatively after large abdominal procedures with third-space losses, or vascular procedures with large fluid shifts. The treatment of ischemic ATN is to increase the mean arterial pressure by fluid administration for hypovolemic patients, vasoactive pressors to increase vascular tone in shock patients, or inotropes to improve cardiac function in patients with cardiac insufficiency.

Drug-induced ATN is commonly caused by radiocontrast agents. Although the exact mechanism of injury is unknown, it is believed contrast induces the production of free radicals that injure the nephron. Several studies have looked at ways to prevent ATN from radiocontrast agents. In 2000, Tepel et al.[40] showed that oral administration of the antioxidant *N*-acetylcysteine actually decreased the serum creatinine in patients with chronic renal insufficiency. In 2004, a study by Merten et al.[41] showed that giving a patient sodium bicarbonate before and after exposure to intravenous radiocontrast, decreased the incidence of contrast-induced nephropathy when compared to equal mEq/L of sodium chloride. Merten's hypothesis was that free radical production is increased in an acidic environment, and by raising pH, the production of free radicals is decreased. Other treatments, such as mannitol and Lasix, are ineffective in preventing ATN. Dopamine has also been used to treat various causes of acute renal failure. Extensive research shows that dopamine increases renal blood flow, short-term glomerular filtration, and urine output. The rationale for the use of "renal dose" dopamine (1–3 μg/kg/min) stems from the hypothesis that increased blood flow will restore oxygen delivery to hypoxic areas of the kidney and help treat ATN. In 2001, Kellem and Decker[42] did a meta-analysis to determine whether low-dose dopamine decreased the incidence of acute renal failure, the need for dialysis, or the mortality in critically ill patients. They showed that dopamine did not significantly decrease the risk of mortality (relative risk [RR] 0.83 [0.39–1.77]), development of acute renal failure (RR 0.79 [0.54–1.13]), or the requirement for dialysis (RR 0.89 [0.66–1.21]).

Patients dependent on renal replacement therapy are defined as having end-stage renal disease (ESRD). The ICU mortality of ESRD ranges from 11–40% in various studies.[38,43] It is interesting to note the ICU mortality associated with ESRD is less than the mortality associated with ARF. In a study by Clermont et al., ICU mortality was 5% for patients with no renal failure, 20.4% for patients with ARF and no renal replacement therapy (RRT) needed, 57% for patients with ARF requiring RRT, and 11% for patients with ESRD. This suggests that increased mortality associated with ARF often results from more systemic diseases.

There is no consensus regarding the appropriate timing of initiation of RRT in the ICU. There are, however, a set of common indications for starting RRT: (a) excessive intravascular fluid in a patient with ventilatory or hemodynamic compromise, (b) electrolyte abnormalities (i.e., hyperkalemia), (c) metabolic acidosis, (d) uremia, and (e) treatment for overdose of a dialyzable toxin/drug. The dialytic techniques that are used most frequently in the ICU are intermittent hemodialysis and continuous venovenous hemodialysis (CVVHD). Continuous arteriovenous and peritoneal dialysis, where once prevalent, are no longer standard therapy. There are conflicting opinions concerning the survival advantages of CVVHD versus intermittent hemodialysis in acutely ill patients. In a retrospective study by Gangji et al. in 2005,[44] CVVHD was associated with decreased mortality in the subgroup of patients with multiorgan dysfunction syndrome.

Endocrine Issues in the Postoperative ICU Patient

Postoperative patients have a complex endocrine response to surgical stimulus. The sympathetic response to surgery results in the release of epinephrine, glucagon, and cortisol to help repair the injured tissue and fight off infection. However, critically ill postoperative patients often have an abnormal response to stress, which leads to increased morbidity and mortality in the ICU. Tight glucose control and steroid replacement therapy are ICU protocols used to help decrease morbidity and mortality of the ICU patient.

In 2001, Van Den Berghe et al.[45] studied the effects of intensive insulin therapy on critically ill patients. They hypothesized that hyperglycemia during critical illness would increase the risk of severe infections, multiorgan failure, and death. They found that by maintaining glucose levels between 80 and 100 mg/dL, the risk of mortality in the ICU decreased by 32%. This observed risk reduction occurred in patients who stayed longer than 5 days in the ICU.

Corticosteroid replacement therapy was first studied in 1952 when Fraser et al.[46] described a patient with perioperative shock secondary to adrenal insufficiency. Cortisol is a natural corticosteroid that is produced by the adrenals. It is integral in the maintenance of vascular tone, vascular integrity, distribution of total body water, glucose metabolism, electrolyte homeostasis, catecholamine production and immunity (just to name a few). In healthy patients during nonstress periods, cortisol levels follow a circadian rhythm, increasing in the early morning and decreasing in the evening. After an operation, cortisol levels increase and there is no circadian rhythm. During periods of severe stress (burns, trauma, and sepsis), serum cortisol concentration reach their highest level. When cortisol production is insufficient, as in patients suffering from Addison disease, the body shows signs of shock (decreased

systemic vascular resistance and myocardial contractility and increased cardiac output) during stress states. In postoperation patients, as well as the critically ill patients, the incidence of total adrenal insufficiency is rare (2–3%).[47] However, functional or relative adrenal insufficiency is much more common, with an incidence of 30%.[48] The serum cortisol level fails to increase appropriately during stress states in patients with relative adrenal insufficiency. Diagnosing these patients is critical to their survival. They may present with signs of shock and do not respond to volume resuscitation and escalating vasopressors. A laboratory test to identify these patients is a corticotrophin stimulation test where 250 μg of cosyntropin is given IV. A cortisol level is drawn at t_0, t_{30} and t_{60} minutes. If the cortisol response in 1 hour is ≤9 μg/dL, the patient is considered a nonresponder. Annane et al.[49] showed that nonresponders have a decreased risk of death when given 50 mg of hydrocortisone every 6 hours and 50 μg/d of fludrocortisone for 7 days.

PROPHYLAXIS AND PREVENTION BEST PRACTICES IN POSTOPERATIVE ICU PATIENTS

Nosocomial infections are a major source of morbidity and mortality in the ICU. Nosocomial infections increase ICU length of stay and healthcare costs. A report from the Centers for Disease Control and Prevention (CDC) on nosocomial infection control states that a third of all nosocomial infections may be preventable through infection control practices.[50] As this evidence has emerged, a series of best-practice infection-control measures have developed, including handwashing before and after examining patients, periodic surveillance of patients for antibiotic-resistant organisms, collocation of patients infected with or colonized with antibiotic-resistant organisms, and gowning and gloving when caring for patients with antibiotic-resistant organisms. In addition, the CDC recommends wearing a sterile gown and gloves and fully draping a patient when placing any invasive monitoring devices. Finally, the development of antibiotic guidelines is important; the guidelines will vary depending on the bacterial flora of a given institution. The first 5 measures noted above are designed to decrease the horizontal transmission of nosocomial infections from healthcare worker to patient. Antibiotic guidelines are designed to help physicians choose the appropriate antibiotic therapy and length of therapy for a particular infectious disease. These guidelines help decrease the inappropriate use of antibiotics and decrease the risk of developing antibiotic resistant organisms. Other prophylactic measures that help decrease the nosocomial infection rate relates to central line placement and maintenance. The following measures decrease catheter-related bloodstream infections: full barrier precautions during central line insertions, preparation of the insertion site with chlorhexidine,[51] and using single-lumen instead of multi-lumen catheters when possible.[52]

Stress-related gastrointestinal mucosal damage occurs in many critically ill patients and can develop within 24 hours. The incidence of clinically significant GI bleeding with hemodynamic changes and decreasing hemoglobin as a result of stress ulceration has been estimated at 1.5% in the ICU population.[53] The incidence for occult bleeds is near 100% in the ICU population. ICU stays can increase by 8 days because of clinically significant bleeds, and mortality can increase by 4-fold. Gastric hypoperfusion plays a major role in the pathogenesis of stress ulcers. Decreasing blood flow impairs the ability of gastric mucosal cells from regenerating, which leads to ulcers. While gastric acidity may exacerbate stress ulcers, it does not cause them. Risk factors for stress ulcers in critically ill patients include major trauma, burns, respiratory failure, coagulopathy, hypotension, sepsis, hepatic failure, renal failure, and surgery. Prophylaxis is the best option for ICU patients at risk for stress ulcers. Therapies that are proven to decrease the risk for stress ulcers are antacids, sucralfate, H_2 blockers, and proton pump inhibitors. The goal of these therapies is to maintain a gastric pH of 4.0 or higher.[54]

Deep venous thrombosis (DVT) is a common medical problem seen in all hospitalized patients, especially the critically ill. The risk of DVT in general surgery patients is 15–40%. Patients who have sustained a major trauma, spinal cord injury, or who are critically ill, can have a risk as high as 80%. DVTs occur more frequently with increasing age, with an incidence of 200

TABLE 81–8.

Deep Venous Thrombosis Prophylaxis in At-Risk Populations

Level of Risk	Risk of DVT	Risk of PE%	Antithrombotic Therapy
Low (e.g., minor surgery in patients <40 years with no risk factors)	0.4–2%	0.2%	Ambulation only
Moderate (e.g., minor surgery in patients with risk factors or age 40–60 years)	2–20%	1–2%	UH BID, LMWH daily, or ECS
High (e.g., surgery in patients >60 years, major surgery in patients 40–60 years with risk factors)	8–40%	2–4%	UH TID, LMWH daily, IPC if anticoagulant contraindicated
Very high (e.g., major surgery in patients >40 years with risk factors, major orthopedic surgery, neurosurgery, major trauma, or spinal cord injury)	20–80%	4–10%	LMWH daily plus ECS/IPC, or warfarin (INR 2–3)

DVT, deep venous thrombosis; ECS, elastic compression stockings; INR, international normalized ratio; IPC, intermittent pneumatic compression; LMWH, low-molecular-weight heparin; PE, pulmonary embolism; UH, unfractionated heparin.
Risk factors: prior venous thromboembolus, cancer, metabolic hypercoagulable state.

per 100,000 in persons older than age 70 years.[55] Prevention of DVTs not only decreases the risk of fatal pulmonary embolisms, but also prevents the long-term sequelae of DVT: leg swelling, dermatitis, leg ulcers, decreased quality of life. Therapy for the prevention of DVT varies and has been stratified based on risk of acquiring DVT. Table 81–8 describes the thrombotic risk stratification for surgical patients and evidence-based guidelines for the use of antithrombotic prophylaxis.

CONCLUSIONS

Intensive care is a rapidly evolving specialty, particularly so in the perioperative population. As new surgical procedures develop, and as we are increasingly able to safely anesthetize high-risk populations such as the elderly, morbidly obese, patients with respiratory disease, and patients with heart failure, the demand for critical care services escalates. Critical care practitioners have specialized, with anesthesia- and surgery-based intensivists staffing surgical critical care units. Areas of subspecialization have emerged in certain centers, where some practitioners focus on cardiothoracic critical care, others on neurocritical care and still others on transplant, burns, or trauma. As the promise of and the demand for critical care services has increased, so has its potential expenses. New therapies with niche applications come at great cost. Modern intensivists must act as responsible stewards of these life-giving, or sometimes merely life-prolonging, expensive resources.

CHAPTER 82

Hemodynamic Support of the Critically Ill Patient

Jean-Louis Vincent MD, PhD

The most common cause of organ failure in the critically ill patient is inadequate tissue perfusion related to acute circulatory failure. This may result from persistent fluid deficits and/or alterations in regional blood flow or tissue oxygen use. Whatever the cause, early and adequate hemodynamic support of these patients is crucial if organ function is to be preserved and multiple organ failure, a common cause of death in critically ill patients, prevented. This chapter briefly reviews the main causes and symptoms of acute circulatory failure before focusing on the hemodynamic support of such patients.

ACUTE CIRCULATORY FAILURE (SHOCK)

Clinical Signs of Shock

Circulatory shock can be considered as a state of generalized circulatory failure resulting in tissue hypoxia. It is a major cause of organ failure. A diagnosis of shock can be based on a combination of various clinical, hemodynamic, and biochemical signs, which can broadly be summarized into:

1. *Arterial hypotension:* Hypotension is perhaps the hallmark of acute circulatory failure, but may be only moderate, especially in patients with chronic hypertension. Usually the systolic arterial pressure is below 90 mm Hg or the mean arterial pressure below 70 mm Hg.
2. *Signs of tissue hypoperfusion:* These are usually recognized at three levels:
   (a) Cutaneous: The skin is usually vasoconstricted, cold, and clammy.
   (b) Renal: A reduction in renal perfusion is manifested in adults by a fall in urine output below 0.5 mL/kg/h and, in more severe cases, below 20 mL/h.
   (c) Neurologic: This can, of course, be appreciated only in the unanesthetized, unsedated patient. Decreased cerebral perfusion is demonstrated by an altered intellect, with disorientation and confusion, and lack of collaboration; there is often obtundation, but coma develops only in advanced stages of multiple organ failure.
3. *Biologic signs of altered cellular oxygen availability:* The development of anaerobic metabolism is manifest by the development of hyperlactatemia. The normal blood lactate level is around 1 mEq/L (or 1 mmol/L), but is usually increased above 1.5 mEq/L in acute circulatory failure.

Pathophysiologic Classification of Shock

Essentially, shock can be classified according to four pathophysiologic mechanisms[1]: hypovolemic, cardiogenic, obstructive, or distributive. Many patients with acute circulatory failure will have a combination of two or more of the four mechanisms. For example, a patient with severe pancreatitis may have characteristics of hypovolemic, distributive, and even cardiogenic shock. Similarly, patients with severe sepsis or anaphylaxis often have elements of hypovolemic and cardiogenic shock in addition to the baseline distributive mechanism.

Whatever the specific type of acute circulatory failure, the result is an imbalance between the oxygen requirements and tissue oxygen availability, resulting in regional tissue hypoxia, an important contributor to the development of organ dysfunction and multiple organ failure. In hypovolemic, cardiogenic, and obstructive types of shock, the primary abnormality is the reduced cardiac output and hence inadequate oxygen transport. However, in septic shock, the main fault is increased oxygen requirements because of the inflammatory response, in addition to altered oxygen extraction capabilities and myocardial contractility. Hence, although cardiac output may be normal or even increased in such patients, it may still be inadequate to provide sufficient oxygen for the cells' increased requirements.

Hypovolemic Shock

This form of shock occurs when the intravascular volume is depleted as a result of internal or external fluid loss. Hypovolemic shock is the most common form of circulatory shock. The most obvious cause of hypovolemic shock is acute hemorrhage, but it can also occur as a result of severe dehydration caused by severe vomiting or diarrhea, particularly in children and the elderly. The hemodynamic pattern is characteristically one of a low cardiac output (because of reduced venous return), associated with decreased cardiac filling pressures and increased systemic vascular resistance (SVR).

Cardiogenic Shock

This form of shock is characterized by primary failure of the cardiac pump. Cardiogenic shock is most commonly the result of acute myocardial infarction, but other causes include severe cardiac valvular disease, severe myocarditis, end-stage cardiomyopathy, and severe cardiac arrhythmia. Cardiogenic shock is associated with mor-

KEY POINTS

1. Early and adequate resuscitation of patients with acute circulatory failure is important to restore a balance between oxygen needs and delivery and can result in improved outcomes.
2. Fluid resuscitation should be guided by repeated fluid challenges.
3. If fluid administration is insufficient to restore an adequate tissue perfusion pressure, vasopressors may be required; currently, dopamine and norepinephrine are considered the best first-line choices.
4. Inotropes or vasodilator drugs may be needed to improve myocardial contractility and cardiac output.
5. Hemodynamic support should be titrated to the individual patient according to global parameters of hemodynamic and oxygenation status, supported by regional parameters when available.

tality rates in the region of 75%, the highest of the four types of shock. Cardiogenic shock is characterized by a low cardiac output, elevated cardiac filling pressures, and a high SVR.

Obstructive Shock

This form of shock is the result of an impediment to the normal flow of blood, either because of an obstruction to the outflow of blood from the heart, such as in massive pulmonary embolism, severe aortic coarctation, or severe aortic stenosis, or because of an increased resistance to cardiac filling during diastole, such as in cardiac tamponade or tension pneumothorax. Obstructive shock is typically characterized by a low cardiac output and high SVR. Right cardiac filling pressures are increased in pulmonary embolism and right and left pressures are increased in tamponade. Pulmonary arterial hypertension is also present in cardiogenic shock associated with pulmonary embolism.

Distributive Shock

This type of shock is characterized by an increase in the vascular capacity. It is most commonly caused by sepsis, secondary to the release of inflammatory mediators. Other causes include anaphylactic shock, neurogenic shock, and acute adrenal insufficiency. The typical hemodynamic pattern is a normal or high cardiac output, reduced SVR (as vascular tone is reduced), and reduced cardiac filling pressures.

RESUSCITATION OF THE PATIENT WITH SHOCK

Intensive, early resuscitation is essential to restore the imbalance between oxygen requirements and supply in the patient with acute circulatory failure, and therapy should be initiated while investigations are ongoing to determine and correct the underlying cause of the shock. Early resuscitation of patients with severe sepsis and septic shock is associated with improved outcomes.[2]

A useful aid to describe the important steps of hemodynamic resuscitation is the VIP (ventilation, infusion, pump) rule introduced by Weil and Shubin in 1969.[3]

Ventilatory Support

Oxygen should be started immediately with the aim of increasing oxygen delivery and reducing pulmonary vasoconstriction as a consequence of hypoxia. Importantly, oxygen should be administered even if the patient is not very hypoxemic. Although prolonged administration of high inspired oxygen fractions (FiO_2) can be toxic, this is not a problem in the acute situation, and once blood gas results are available, oxygen therapy can be adjusted accordingly. If mask ventilation is not possible, for example, because of facial trauma, or provides inadequate oxygenation, mechanical ventilation should be started. In addition to ensuring adequate oxygenation, mechanical ventilation has the additional benefit of reducing left ventricular afterload by increasing intrathoracic pressures, and resting the respiratory muscles, hence reducing oxygen requirements. The aim of oxygen administration should be to maintain Pao_2 above 8 kilopascals (kPa) (60 mm Hg), and arterial oxygen saturation (SaO_2) above 90%. Although hypoxia should be avoided, hyperoxia can also be harmful, causing peripheral vasoconstriction with reduced regional perfusion and oxygenation.

Fluid Resuscitation

Fluid therapy is an essential part of the treatment of any form of shock, the rationale being to improve microvascular blood flow by increasing plasma volume, and to increase cardiac output by the Frank-Starling effect. However, too much fluid also carries risks, principally of pulmonary edema.

There are many fluids available for use in resuscitation, and which, if any, is optimal remains controversial.[4] Crystalloid solutions (e.g., normal saline, Ringer's lactate) are inexpensive and well tolerated but leak more into the interstitial space than colloid solutions, thus causing more tissue edema. Increased edema is associated with compromised lung function, reduced systemic oxygen availability, impaired wound healing, myocardial function, and gut function.[5–7] As colloids persist longer in the intravascular space, less colloid solution (e.g., albumin, gelatin, hydroxyethyl starch [HES]) than crystalloid is needed to achieve the same hemodynamic goal; consequently, colloids have theoretical advantages over crystalloids. However, the clinical relevance of this potential advantage has not been clearly demonstrated, with no study convincingly demonstrating that one fluid type is superior to another. In addition, colloid solutions are more expensive, especially human albumin.

Controversy has surrounded the use of albumin in intensive care patients for many years and was fuelled by a Cochrane review in 1998 that suggested increased mortality rates occurred in critically ill patients who received albumin.[8] A propensity score analysis of 339 patients from a recent database of 3147 patients admitted to European ICUs, showed that patients who received albumin had greater mortality rates than those who did not.[9] However, in the Saline versus Albumin for Fluid Resuscitation in the Critically Ill (SAFE) study,[10] there were no differences in the mortality rates for ICU patients who had received albumin compared to those who had received crystalloid solution as the initial resuscitation fluid. Moreover, hypoalbuminemia is known to be associated with increased morbidity,[11] and a recent meta-analysis of 71 randomized controlled trials indicated that albumin administration may reduce complications in critically ill patients.[12] Clearly further studies assessing the role of albumin, particularly in certain subgroups of patients, for example, those with hypoalbuminemia, are needed to clarify this issue.

HES solutions have been promoted as having particularly beneficial effects on oxygen delivery to the tissues,[7] and potentially reducing endothelial activation and inflammation in critically ill patients.[13] HES solutions may also have beneficial effects on the transcapillary leakage of fluids by properties other than the increase in oncotic pressure.[14]

Further study is necessary to clearly define optimal fluid choices. Until the results of such studies become available, the choice is best made according to the severity of the circulatory failure, the underlying disease, the type of fluid that has been lost, the serum albumin concentration of the patient, and the risk of bleeding.

Having selected the fluid, the physician is then faced with deciding on how much to give. Precise end points for fluid resuscitation are difficult to define as sensitive tools for monitoring the regional microcirculation and oxygenation are not available, and, although systemic parameters appear to have stabilized, regional tissue per-

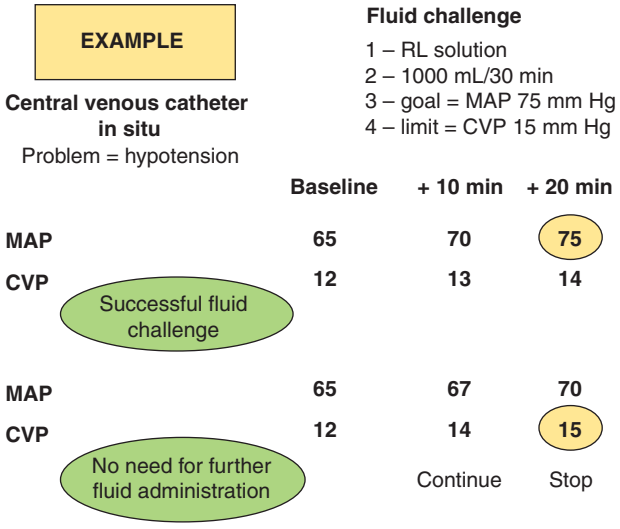

FIGURE 82–1. Example of a fluid challenge in a hypotensive patient. The figure gives an example of orders and two theoretical responses. In the first case, the patient benefited from fluid administration; in the second the patient did not. CVP, central venous pressure; MAP, mean arterial pressure; RL, Ringer's lactate.

fusion may still be inadequate.[15] In addition, the quantity of fluid needed will vary among patients and in the same patient over time. A fluid challenge technique[16] is the best method of determining a patient's ongoing need for fluids. Figure 82–1 is an example of the fluid challenge technique. The fluid challenge approach incorporates four phases:[16]

1. *The type of fluid:* As discussed above, the optimal fluid remains controversial and either crystalloid or colloid can be used, the selection being determined on an individual patient basis.
2. *The rate of fluid administration:* It is important to define the amount of fluid to be administered over a defined interval. The Surviving Sepsis Campaign Guidelines for the management of severe sepsis and septic shock recommend 500–1000 mL of crystalloids or 300–500 mL of colloids over 30 minutes.[17]
3. *The goal to be achieved:* The primary defect(s) that prompts the fluid challenge should be identified and quantitated so that a goal can be determined; most commonly this will be restoration of an adequate mean arterial pressure.
4. *Safety limits:* Pulmonary edema as a consequence of congestive heart failure is the most serious complication of fluid infusion. A safety limit, generally the central venous pressure (CVP), must be set to avoid this complication.

Repeated fluid challenges will enable the physician to continuously reassess a patient's ongoing fluid needs and limit the risks of adverse effects.

Blood Transfusions

Blood transfusions should be given as necessary, although there is again some debate as to what triggers should be used to determine the need for a blood transfusion. The aim of transfusion is to improve oxygen delivery and thereby to limit tissue hypoxia. However, although oxygen delivery is improved, tissue oxygenation or oxygen use do not necessarily improve.[18–20] In addition, there are risks associated with blood transfusions including transmission of microorganisms and prions, transfusion-related acute lung injury (TRALI), transfusion-related immunomodulation (TRIM), which may increase the risk of infections, and administration errors, including wrong type and crossmatch and incorrect patient identification, which can cause hemolytic reactions.

In 1999, Hebert et al.[21] published the results of the Transfusion Requirements in Critical Care (TRICC) trial, which encouraged many to rethink their transfusion practice. This landmark study enrolled 838 critically ill patients with euvolemia who had hemoglobin concentrations of less than 9.0 g/dL and randomly assigned them to a restrictive strategy of transfusion in which red cells were transfused if the hemoglobin concentration decreased below 7.0 g/dL and hemoglobin concentrations were maintained at 7.0–9.0 g/dL, or a liberal strategy in which transfusions were given when the hemoglobin concentration fell below 10.0 g/dL and hemoglobin concentrations were maintained at 10.0–12.0 g/dL. The results suggested that the restrictive strategy, maintaining a hemoglobin of 7–9 g/dL, was adequate for most critically ill patients,[21] with the possible exception of patients with acute myocardial infarcts and unstable angina.[22]

Since that study, several epidemiologic studies have shown that patients who receive blood transfusions in the ICU have increased mortality rates.[23,24] In addition, studies in human volunteers show that isovolemic hemodilution to a hemoglobin of 5 g/dL or less does not result in biochemical evidence of anaerobic metabolism[25] and studies in Jehovah's Witness patients show that survival is possible with markedly decreased hemoglobin concentrations; one case study reported survival of a patient with a hemoglobin concentration of only 1.8 g/dL.[26]

Current recommendations for the management of patients with severe sepsis support a transfusion trigger of 7 g/dL.[17] However, the Sepsis Occurrence in Acutely Ill Patients (SOAP) study, which evaluated data on 3147 patients in 198 ICUs across Europe in May 2002, reported that, unlike earlier studies, blood transfusion was not associated with an increased mortality in multivariate analysis or by propensity case matching.[27] In addition, in a study by Rivers et al.[2] on early goal-directed therapy (EGDT), patients managed according to the EGDT protocol, who had lesser mortality rates than patients receiving standard therapy, received more transfusions, suggesting that at least some patients may benefit from receiving more blood transfusions.

The pendulum therefore seems to be swinging in favor of blood transfusions once again, and this apparent change may be related to the widespread introduction of leukoreduction in recent years. This technique is a process in which the white cells in blood units are intentionally reduced in number using centrifugation or filtration, with the aim of reducing some

of the inflammatory response to transfusion and the transmission of infections. Leukocyte counts can be reduced by more than 99% and the technique is effective in reducing the transmission of cell-associated viruses, especially cytomegalovirus, herpes viruses, and Epstein-Barr virus.[28] It may also reduce parasite and prion transmission, transfusion-related febrile reactions, and TRALI. In a before-and-after cohort study of 14,786 patients who received red blood cell transfusions following cardiac surgery or repair of hip fracture, or who required intensive care following a surgical intervention or multiple trauma, transfusion of leukoreduced blood was associated with fewer febrile reactions and reduced posttransfusion antibiotic use.[29] However, the evidence supporting the benefits of leukoreduction is not yet completely clearcut. In a meta-analysis of 14 randomized controlled trials comparing standard blood with leukoreduced or autologous blood, Vamvakas[30] reported no consistent effect of leukoreduction on long-term mortality, whereas in another meta-analysis of 10 randomized controlled trials, the authors concluded that "patients who were transfused leukoreduced red blood cells might benefit from a decrease in postoperative infections."[31] Many countries have now adopted leukoreduction as routine, although leukoreduced blood is more expensive and it is not clear whether it is necessary in all patients.[32]

In view of the continuing uncertainty about the optimal transfusion trigger, a multicenter European study is currently underway in critically ill patients with euvolemia, comparing a strategy of maintaining hemoglobin concentrations above 9 g/dL with one maintaining hemoglobin concentrations between 7–9 g/dL. This study will essentially revisit the study by Hebert et al.[21] but in conditions of widespread leukoreduction, which was not the case when that study was conducted.

Vasopressors

If hypotension persists despite fluid administration, the use of vasopressors will be required. In severe conditions, a vasopressor could be administered early in combination with fluids, but it should be discontinued as soon as the hypovolemia has been corrected.

Adrenergic agonists represent the first type of drug to be considered because of their potency and their short half-life, which allows easy titration. A range of drugs is available and can be considered for this purpose (Fig. 82–2). The specific effects of the various agonists are largely determined by the extent to which they act on α, β, and dopaminergic receptors (Table 82–1), although the precise action of any catecholamine varies among individuals. In addition, chronic sympathetic stimulation and the presence of inflammatory mediators, such as those that occur in sepsis, can reduce receptor response to stimulation. There are two forms of α receptor: α_1, found primarily on the smooth muscle cells of arterioles and veins, and α_2, found at the presynaptic terminals of adrenergic nerves. Stimulation of α_1 receptors usually causes smooth muscle contraction with vasoconstriction. Stimulation of α_2 receptors decreases the subsequent release of adrenergic transmitter. There are three major forms of β receptor: β_1, found in heart muscle and in the kidney, β_2, found in smooth muscle and metabolic tissue, and β_3, found in adipose tissue. Stimulation of β_1 receptors results in increased heart rate and contractility, whereas β_2 receptor stimulation causes vasodilatation in skeletal and cardiac muscle, bronchodilation, and decreased gastrointestinal motility. β_3 activation stimulates lipolysis. Consequently, stimulation of each group of receptors has potentially beneficial and potentially harmful effects. For example, β-adrenergic stimulation will increase blood flow, but can also increase heart rate and carries a risk of ischemia, whereas α-adrenergic stimulation will increase blood pressure but may decrease cardiac output and cause peripheral vasoconstriction, with decreased renal and hepatosplanchnic blood flow.

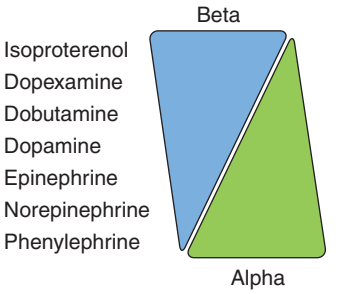

FIGURE 82–2. Various adrenergic agents available today, with schematic representation of their predominant effects on β- and α-adrenergic receptors.

Phenylephrine

Although not a catecholamine, phenylephrine is an almost pure α-adrenergic agent, except at very high doses where some β activity is seen. Phenylephrine is a very powerful vasoconstrictor, but this carries the risk of decreasing blood flow and reducing tissue perfusion. In patients with septic shock, phenylephrine was associated with reduced splanchnic blood flow and oxygen delivery.[33] In the intensive care unit, this drug should be reserved for the occasional management of severe refractory hypotension.

Epinephrine

Epinephrine is an endogenous catecholamine secreted by the adrenal medulla with potent α and β_1 activity and moderate β_2 effects. At lower doses, β effects predominate with α effects becoming more significant at higher doses. In acute hypotension, epinephrine is sometimes preferred to norepinephrine because of its stronger β-adrenergic effects, which are useful for maintaining or increasing cardiac output. It is also the drug of choice in cardiac arrest, where it can be administered via the endotracheal tube if intravenous access is difficult, and in acute

TABLE 82–1.

Effects of the Common Adrenergic Agents on α, β, and Dopaminergic Receptors

	α	β_1	β_2	Dopaminergic

anaphylaxis (0.1–0.5 mg subcutaneously). However, epinephrine is associated with a decrease in splanchnic blood flow or gastric intramucosal pH (pHi).[34–36] Epinephrine treatment is also associated with an increase in cellular metabolism mediated by the increase in intracellular cyclic adenosine monophosphate (cAMP) and leading to increased blood lactate levels;[35] it is probably best avoided in critically ill patients except in the specific circumstances mentioned above.

Norepinephrine

Norepinephrine is an endogenous amine secreted by the adrenal medulla and the terminal endings of postganglionic nerve fibers. Norepinephrine has predominantly α-adrenergic properties, although its weak β-adrenergic effects can help to maintain cardiac output. Norepinephrine administration thus generally results in a clinically significant increase in mean arterial pressure, with little change in heart rate or cardiac output. The normal dose range is 0.05–2 μg/kg/min intravenously. The increased afterload because of the vasoconstriction caused by norepinephrine can increase myocardial workload and norepinephrine can precipitate cardiac failure, myocardial ischemia, and pulmonary edema. Although there are concerns that excessive vasoconstriction with norepinephrine may have negative effects on blood flow, particularly in the hepatosplanchnic and renal circulations, studies suggest that it can successfully increase blood pressure without causing any deterioration in organ function, particularly in the presence of decreased vascular tone, as in septic shock.[36,37]

Dopamine

Dopamine is another naturally occurring compound (the precursor of norepinephrine) that also combines α- and β-adrenergic properties, but has several specific features. First, dopamine also has dopaminergic effects, which predominate at very low doses (<3 μg/kg/min IV), and may dilate the hepatosplanchnic and renal circulations, thereby selectively increasing flow in these important regions. Second, the adrenergic effects of dopamine vary with the dose; at lower doses (3–10 μg/kg/min IV), β-adrenergic effects predominate, so that blood flow may increase together with blood pressure. At higher doses, α-adrenergic effects become increasingly powerful, which may be necessary in more severe cases of hypotension. Importantly, these dose ranges are not cutoff values at which one set of receptors are activated at the expense of another, but are ranges in which the effects of one group of receptors predominate over another. Dopamine increases arterial pressure primarily by increasing cardiac index, as a consequence of an increase in stroke volume and, to a lesser extent, to increased heart rate, with minimal effects on systemic vascular resistance. However, dopamine also has drawbacks. First, it is a relatively weak agent, so that norepinephrine or epinephrine must often be added to control hypotensive states. Second, although dopamine may increase blood flow more effectively than other vasopressors, it also increases heart rate. A study in patients undergoing coronary artery bypass grafting with cardiopulmonary bypass suggests that dopamine, even at low doses, is associated with an increased risk of developing atrial fibrillation.[38] Third, the advantage of the dopaminergic effects may be more theoretical than practical. Thus the routine administration of low-dose dopamine to prevent renal failure is not recommended.[39] Finally, dopaminergic stimulation may have undesired endocrine effects on the hypothalamopituitary gland, resulting in immunosuppressant effects, primarily by a reduction in prolactin release.[40]

There is currently no evidence to suggest that either norepinephrine or dopamine is superior to the other in the resuscitation from shock[41] and both are recommended as first-line treatments.[17,42] Whether one or the other will be shown to be superior in future studies remains to be determined, but that remains academic at present; the most important issue is to reach the desired arterial pressure goal. A multicenter study is currently ongoing in Europe to compare these two drugs and has already enrolled more than 1200 patients. The results from this study should help clarify the optimal choice of vasopressor.

Vasopressin and Terlipressin

Vasopressin is an endogenous stress hormone with a wide range of functions, including effects on blood osmolality and volume, body temperature, insulin release, corticotropin release, memory, and social behavior; as a vasoconstrictor of vascular smooth muscle, it also has an important role in regulating blood pressure.[43,44] Patients with septic shock appear to develop relative vasopressin deficiency, with lower vasopressin levels than patients with cardiogenic shock for the same degree of hypotension.[45] This deficiency may be partly a result of decreased central stores of vasopressin,[46] and administration of low doses of vasopressin to restore normal vasopressin levels can result in substantial increases in arterial pressure and reduced requirements for other catecholamines.[45,47–53] A recent study suggests that vasopressin administration may improve outcome in patients with septic shock of moderate severity.

Vasopressin has also been assessed in patients with other forms of vasodilatory shock, for example, after cardiopulmonary bypass. In such patients, administration of low doses of vasopressin increases arterial blood pressure and reduces vasopressor requirements.[54,55] Interestingly, Morales et al.[56] found that giving vasopressin (0.03 U/min IV) prophylactically before cardiopulmonary bypass to avoid vasopressin deficiency resulted in reduced requirements for norepinephrine and a shorter ICU length of stay, suggesting that early use may be beneficial.

Vasopressin has also been investigated as a potential alternative to epinephrine for use in cardiorespiratory arrest. A randomized controlled study of vasopressin versus epinephrine in in-hospital cardiac arrest reported no advantage of vasopressin over epinephrine,[57] although a later, larger study comparing the two agonists in out-of-hospital cardiac arrest suggested improved outcomes for patients with asystole who received vasopressin,[58] and a cohort study has suggested that using a combination of epinephrine and vasopressin may be better, allowing the beneficial effects of both drugs but avoiding the harmful effects of excessive doses of either.[59] The risk with vasopressin is a reduction in cardiac output because of excessive vasoconstriction and a selective reduction in hepatosplanchnic blood flow. Studies are in progress to further evaluate the role of vasopressin in various shock states.

Terlipressin is an analogue of vasopressin that has been available in Europe for more than 20 years, but is

undergoing phase III clinical trials in the United States at the time of this writing. Terlipressin has a half-life of 6 hours and a duration of action of 2–10 hours, whereas the half-life of vasopressin is 6 minutes and its duration of action is 30–60 minutes. Terlipressin has been compared to norepinephrine in patients with hyperdynamic septic shock. Both drugs increased mean arterial blood pressure and improved renal function, but terlipressin administration was associated with a decrease in cardiac output,[60] and the authors suggested that terlipressin may need to be used with an inotrope such as dobutamine to maintain cardiac output. Terlipressin may also be useful for the treatment of hypotension occurring after induction of anesthesia in patients who have received long-term treatment with renin–angiotensin system inhibitors.[61]

Restoring and Maintaining Cardiac Output

An adequate cardiac output is essential to ensure sufficient tissue perfusion and oxygen delivery. However, a normal cardiac output is difficult to define and the adequacy of cardiac output varies among individuals and in the same individual over time. To increase cardiac output, one must remember its four determinants (Fig. 82–3):

1. *Heart rate:* Bradycardia can limit cardiac output, but only when severe; thus this is easily recognized at the bedside. The management of bradycardia is beyond the scope of this chapter, but the principles of treatment consist primarily of a pacemaker, possibly with isoproterenol as a temporary measure. Outside these extreme situations, increasing heart rate by changing the rate of an in situ pacemaker usually does not increase cardiac output, because stroke volume decreases concurrently. It may even be the opposite: cardiac output may decrease if cardiac filling is impaired by a too short diastolic time, especially in cases of diastolic dysfunction.
2. *Preload:* Fluid administration should be considered in all cases of inadequate cardiac output, and if uncertain of the need for fluid, a fluid challenge technique must be used as described under Fluid Resuscitation above, in which a given amount of fluids is given rapidly under control of cardiac filling pressures.[16]
3. *Contractility:* If the increase in cardiac output is limited by impaired contractility, the use of inotropics may be considered. The major risk is increased oxygen demand as a result of the increased work of the myocardium, which may precipitate myocardial ischemia.
4. *Afterload:* By reducing the factors that oppose ejection of blood by the ventricles, principally using vasodilators, cardiac output may be increased without increasing myocardial oxygen demand. The major limitation of this approach is the risk of decreasing arterial pressure to levels that may compromise tissue perfusion in the peripheral organs as well as in the myocardium, and vasodilators should be avoided in hypotensive states. In addition, all vasodilators may induce some increase in heart rate, especially in the presence of underlying hypovolemia. Such an increase in heart rate should raise the possibility of underlying hypovolemia and suggest the need for a fluid challenge.

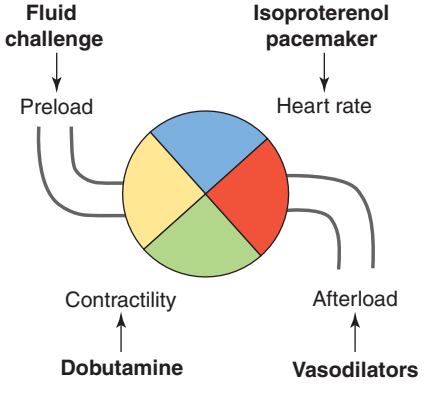

FIGURE 82–3. Various options to increase cardiac output, based on its four determinants.

Dobutamine

Dobutamine is the first-choice inotropic agent for patients with low cardiac output who have received adequate fluid resuscitation. A decrease in arterial pressure during dobutamine administration should raise the possibility of underlying fluid deficits requiring another fluid challenge trial. With predominant β-adrenergic properties, dobutamine also possesses some α-adrenergic effects that limit the increase in heart rate seen with pure β-adrenergic stimulation using isoproterenol. An initial dose of just a few μg/kg/min may increase cardiac output significantly. Doses in excess of 20 μg/kg/min IV are seldom used as they add little benefit and may lead to excessive tachycardia. Dobutamine has limited effects on arterial pressure, although arterial pressure may increase slightly if heart failure is the primary abnormality. Dobutamine formed part of the EGDT protocol used by Rivers et al. in their study of emergency department patients presenting with septic shock.[2] Dobutamine was used in addition to fluids and red cell transfusion to increase superior venacaval oxygen saturation ($ScvO_2$) to more than 70%, and this protocol was associated with improved outcomes compared to standard care.[2] However, dobutamine should not routinely be used to increase oxygen delivery to supranormal levels as this approach is associated with worse outcomes;[62] rather it should be titrated on an individual basis to achieve acceptable oxygenation parameters. Interestingly, in a recent clinical study using orthogonal polarization spectral imaging, De Backer et al. showed that dobutamine improved capillary perfusion in patients with septic shock, independent of its systemic effects,[15] suggesting that it may have additional specific effects on regional blood flow.

Dopexamine

Dopexamine hydrochloride is a newer synthetic catecholamine, structurally similar to dopamine. It has marked β_2-adrenergic agonist activity, some dopaminergic receptor activity, weak β_1-adrenergic activity, and no direct α-adrenergic effects. It also inhibits the neuronal uptake of endogenous catecholamines. Dopexamine's positive inotropic effects combined with its vasodilating effects make it useful in acute exacerbations of chronic heart failure and in heart failure associated with cardiac surgery. However, its use is limited by the development of marked tachycardia, particularly at higher doses. Although it was suggested that because of its dopaminergic effects it may have beneficial effects on renal and splanchnic blood flow, a meta-analysis of 21 randomized controlled studies found no evidence to support the use of dopexamine to improve hepatosplanchnic or renal blood flow in critically ill patients.[63]

Phosphodiesterase Inhibitors

The phosphodiesterases (PDEs) are a group of enzymes that degrade the cy-

clic nucleotides, cAMP and cyclic guanosine monophosphate (cGMP). PDE inhibitors can thus prolong or enhance the effects of physiologic processes mediated by cAMP or cGMP. PDEIII inhibitors, such as enoximone and milrinone, have inotropic and vasodilating properties. These drugs may be poorly tolerated by patients with arterial hypotension and their administration can be difficult because of their long half-life. Intermittent administration may be preferable to continuous infusion. The administration of very small doses of PDEIII inhibitors may reinforce the effects of dobutamine.[64] Short-term administration of PDEIII inhibitors has been associated with a high incidence of complications, including arrhythmias, especially in patients with ischemia cardiac disease, likely related to their effects on cAMP and Ca^{2+} levels. Dobutamine and milrinone provided equally effective inotropic support in patients awaiting cardiac transplantation with no differences in right heart hemodynamics, death, need for additional vasodilator/inotropic therapy, need for mechanical cardiac support before transplantation, or occurrence of ventricular arrhythmias requiring increased antiarrhythmic therapy.[65] In critically ill patients with catecholamine-dependent heart failure, milrinone improved central hemodynamics and was associated with a reduction in dobutamine dose, although there was a tendency for milrinone-treated patients to require higher doses of vasopressors and more fluids.[66] Some studies suggest that milrinone may have additional antiinflammatory effects and beneficial effects on hepatosplanchnic perfusion.[67,68] Clearly, further studies are needed to determine the exact place of these drugs in the management of patients with severe heart failure and shock.

Levosimendan

Levosimendan is a relatively new agent that provides inotropic effects by increasing calcium sensitivity of myocytes by binding to cardiac troponin-C, and vasodilator effects by opening (adenosine triphosphate)-sensitive potassium channels in vascular smooth muscle.[69] Levosimendan has a long half-life that may limit the practicality of its use. Levosimendan may be useful in patients with severe heart failure, where it has been shown to improve hemodynamic performance more effectively than dobutamine and to reduce mortality.[70] It may also be of use for inotropic support after myocardial ischemia, after myocardial stunning during and after cardiac surgery, and in patients with right ventricular dysfunction.[69] However, its place in acutely ill patients has not been well studied and remains poorly defined. In addition, the high costs of the drug limit its use. Several large phase III studies are ongoing to assess the use of levosimendan in various conditions.

Sodium Nitroprusside

Sodium nitroprusside has a direct, short-acting relaxing effect on vascular smooth muscle and has been used primarily to reduce afterload, although by reducing venous return it also reduces preload. It has significant effects on arterial pressure, so that it is also used in the management of hypertensive crises. Sodium nitroprusside has the advantage of a short half-life, allowing easy titration. Administration should start at 20 μg/min IV, and the dose can be progressively increased to 150–200 μg/min. The administration of nitroprusside is complicated by the fact that it is very light sensitive, so that infusion sets must be opaque. Nitroprusside is rapidly metabolized to cyanide and thiocyanate and accumulation of these metabolites can lead to cyanide or thiocyanate toxicity during prolonged administration, especially in patients with renal failure.

Nitrates

Nitrate products include nitroglycerin and isosorbide dinitrate. They cause relaxation of vascular smooth muscle and hence reduce afterload. Low doses (30–40 μg/min IV) predominantly produce venodilation; high doses (150–500 μg/min) lead to arteriolar dilation as well. These drugs are widely used intravenously in the treatment of recurrent ischemia, hypertensive emergencies, and congestive heart failure associated with myocardial infarction (MI). Nitroglycerin is the preferred vasodilator in acute MI, especially when infarction is complicated by congestive heart failure.[71] Nitrates are also indicated in patients with cardiogenic pulmonary edema for their strong relieving effects on venous congestion. Their dose is similar to that of nitroprusside.

Angiotensin-Converting Enzyme Inhibitors

Angiotensin-converting enzyme (ACE) catalyses the conversion of angiotensin I to angiotensin II, a potent vasoconstrictor, and is also involved in the inactivation of bradykinin, a potent vasodilator. Consequently, ACE inhibitors cause reduced formation of angiotensin II and increased levels of bradykinin, thus reducing vascular resistance. ACE inhibitors are widely used in the treatment of chronic heart failure and may be helpful in the acute care setting as well. However, they have two limitations in the acute setting. One is the risk of renal failure that can be precipitated by ACE inhibition, especially in the presence of fluid shifts that may result in relative hypovolemia. The second is the lack of availability of an intravenous preparation. Enalapril was available as the only parenteral preparation in some countries, but its administration resulted in marked decreases in arterial pressure, so that it is no longer used.

Hydralazine

In contrast to nitrates, hydralazine has greater effects on the arteriolar side of the vasculature, and is therefore more likely to increase cardiac output by decreasing SVR. It also increases heart rate, so may be useful in patients with a relatively slow heart rate. Its use requires close cardiovascular monitoring. Long-term administration may be complicated by the development of iatrogenic lupus. Hydralazine is not often prescribed for prolonged therapy of heart failure as there are other drugs with a better benefit-to-risk ratio. However, it can still be considered as an alternative to ACE inhibitors in patients with heart failure.

END POINTS AND GOALS OF HEMODYNAMIC SUPPORT

Indices of Global Perfusion

Mean Arterial Pressure

Arterial hypotension represents a marker of serious disease and a systolic pressure of less than 90 mm Hg (or a mean arterial pressure less than 70 mm Hg) or a decrease in mean arterial pressure of greater than 30 mm Hg are indications of acute circulatory failure. Noninvasive measurement of blood pressure with the sphygmomanometer is perhaps one of the most widely used procedures in clinical medicine. However, in critically ill patients, especially those with significant hypotension, invasive intraarterial moni-

toring of pressure is more accurate and continuous,[72] allowing rapid assessment of response to treatments.

Cardiac Output

A "normal" cardiac output is difficult to define as what is normal or adequate may vary widely among patients and even in the same patient over time. For example, one cardiac output value may be perfectly adequate for an anesthetized, mechanically ventilated patient, but inadequate should that same patient develop severe sepsis with increased oxygen requirements. The measurement of cardiac output provides an assessment of global systemic blood flow but provides no information on regional flow. Cardiac output can be judged inadequate when tissue perfusion is altered, as shown clinically by cutaneous vasoconstriction, decreased urine output attributed to kidney underperfusion, or altered mental status. Biochemical signs of reduced tissue perfusion include decreased mixed venous oxygen saturation (SvO_2) or its surrogate central venous oxygen saturation ($ScvO_2$) or increased blood lactate concentrations (see Blood Lactate Levels).

Cardiac output can be measured using various techniques each of which has its own benefits and drawbacks. For many years, the thermodilution cardiac output measured using a pulmonary artery catheter (PAC) has been the gold standard, but with concerns about the safety and overall benefits with PAC insertion and use,[73] less-invasive techniques, including echocardiography and Doppler measurements, pulse contour analysis, partial carbon dioxide rebreathing, and electrical bioimpedance, are being used more commonly. Nevertheless, although the PAC is not indicated in all patients, it remains valuable in more complex cases, allowing almost continuous measurement, not only of cardiac output, but also of other important parameters including cardiac filling pressures and SvO_2. Accurate absolute measures of cardiac output are perhaps less important than monitoring the trends in cardiac output in response to treatment and time, and if one wants to accurately define the adequacy of cardiac output, measures of SvO_2 are essential.[74] Importantly, targeting predefined cardiac output values for all patients or even for groups of patients is not advisable as adequacy of cardiac output will vary among patients and in the same patient over time.

Mixed Venous Oxygen Saturation

SvO_2 can be measured using a PAC. The normal value is 70–75%. SvO_2 depends on cardiac output, oxygen consumption, hemoglobin, and arterial oxygen saturation. Measurements of SvO_2 are very useful for the correct interpretation of cardiac output (Fig. 82–4). SvO_2 is typically decreased in low flow states, but normal or high in inflammatory conditions.

$ScvO_2$, measured in the superior vena cava using a central venous catheter, may represent a useful surrogate for patients who do not require a PAC. However, it must be remembered that as $ScvO_2$ reflects the oxygenation of the venous blood from the upper half of the body and not of the lower half of the body, it is an estimate of the true SvO_2, which measures whole-body venous oxygen saturation. Physiologically, $ScvO_2$ is slightly less than SvO_2, but in critically ill patients it is often greater. This effect is explained by an increased oxygen extraction in the kidneys (where blood flow is often reduced) and in the gut (where oxygen consumption is often increased), whereas oxygen extraction in the liver is more constant. A recent study has suggested that early therapy in patients with severe sepsis or septic shock targeting an $ScvO_2 \geq 70\%$ may be associated with improved outcomes.[2] As with many other parameters, trends in $ScvO_2$ over time are of more use than individual values, and values must be interpreted in the light of clinical assessment and other hemodynamic and oxygenation parameters.

Blood Lactate Levels

Blood lactate levels provide a useful indication of the presence of anaerobic metabolism caused by hypoperfusion, and, although changes in blood lactate levels occur too slowly to guide therapy, repeating measurements every hour or so can provide useful information on the ongoing adequacy of global tissue oxygenation. In patients with sepsis, the interpretation of blood lactate levels is not always straightforward in that increased lactate levels may result from cellular metabolic failure as well as from global hypoperfusion. However, the prognostic value of increased blood lactate levels is well established in septic shock patients, particularly if the high levels persist.[75]

Indices of Regional Perfusion

Although measurement and monitoring of cardiac output, SvO_2, and blood

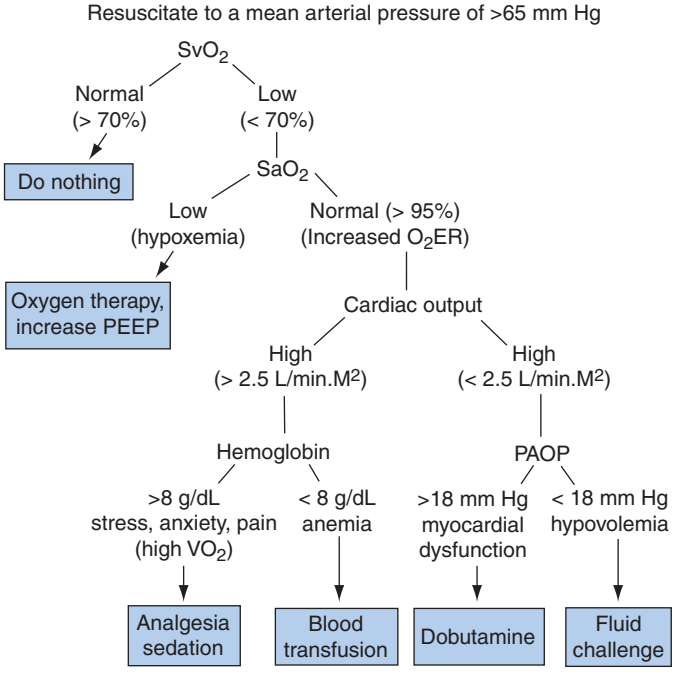

FIGURE 82–4. Diagnostic and therapeutic algorithm based on mixed venous oxygen saturation (SvO_2) measurements: therapeutic options to be considered are presented in the *rectangles*. lactate levels provide valuable information regarding global adequacy or perfusion and oxygenation, they do not provide detail on the adequacy of regional microcirculatory blood flow or oxygen delivery and use, which is believed to be a crucial factor in the development of multiple organ failure in patients with shock. Measuring regional parameters is of particular importance, as they can remain inadequate even when global parameters have returned to normal. However, even though considerable progress is being made in this field, there is as yet no ideal technique that can be used in critically ill patients to assess regional blood flow or oxygenation.

Gut Tonometry

The measurement of regional perfusion initially focused on the splanchnic circulation as the hepatosplanchnic circulation is particularly sensitive to changes in blood flow and oxygenation, and may have a higher critical oxygen delivery threshold than other organs. In addition, a countercurrent exchange mechanism operates in the villus, making the tip particularly sensitive to changes in regional flow and oxygenation. However, gastric tonometry is limited by measurement errors, doubts regarding the validity of pHi calculations, and unreliability of results during patient feeding.[76] Calculations of gastric pHi were replaced by gastric mucosal PCO_2 because this measure is not confounded by arterial bicarbonate, but because gastric mucosal PCO_2 is influenced by systemic arterial PCO_2, the gastric–arterial PCO_2 difference may be of more interest.[77] An early trial suggested that tonometry derived parameters may be useful in guiding therapy,[78] but these findings were not confirmed in a later study,[79] and many investigators have emphasized the limited sensitivity, and especially specificity, of these measurements. Different vasoactive agents have divergent effects on gut PCO_2 and pHi that are neither consistent nor predictable.[80]

Sublingual Capnography

The methodologic limitations of gastric tonometry encouraged researchers to look elsewhere for another easily accessible tissue where local PCO_2 could be measured, and the sublingual circulation has been suggested for this purpose. Several clinical studies have suggested that sublingual PCO_2 ($PslCO_2$) is a reliable marker of tissue hypoperfusion. However, as with gut PCO_2, $PslCO_2$ may also be influenced by arterial CO_2 and the gradient (i.e., gap) between $PslCO_2$ and $PaCO_2$ may be more specific for tissue hypoperfusion.[81] In a recent study, the $PslCO_2$ gap was found to correlate with the alterations in microcirculatory blood flow seen in patients with severe sepsis.[82] Further work is clearly needed to define normal and pathologic $PslCO_2$ levels and to establish whether targeting treatments to restore a normal $PslCO_2$ can improve outcomes.

CONCLUSION: THE GLOBAL PICTURE

Multiple organ failure is a serious problem in intensive care unit patients, resulting in high morbidity and mortality and associated resource use and costs. Multiple organ failure can arise from many causes, but a key factor in its development appears to be an imbalance between tissue oxygen requirements and uptake. Tissue oxygen uptake can be limited by inadequate oxygen delivery and availability, and also by altered oxygen extraction ability. Appropriate hemodynamic support can improve both global and regional blood flow and, hence, oxygen delivery. Early studies suggested that those patients with greater cardiac index and oxygen delivery values were more likely to survive conditions associated with the development of multiple organ failure.[83,84] This observation was the rationale behind several studies in the early 1990s, which assessed the benefits of increasing oxygen delivery to supranormal values using inotropes and fluids. Although this approach was shown to improve outcomes in some groups of critically ill patients, notably surgical and trauma patients,[85,86] routine application to all critically ill patients does not confer a uniform survival benefit and may worsen outcomes in some patients.[62,87] However, a protocol targeting adequate oxygen transport, as reflected by the $ScvO_2$, in patients who are at risk of multiple organ failure, has been shown to result in improved survival[2] and adequate oxygenation clearly remains an important parameter to target. Unfortunately, at present there is no clear marker of adequate tissue oxygenation so we must rely on surrogate markers of tissue perfusion and oxygenation as discussed above. Adequate oxygen delivery is likely to vary among patients and in the same patient over time so that hemodynamic support must be titrated and adjusted carefully based on each individual's response to the therapy.

CHAPTER 83

Mechanical Ventilation for the Surgical Patient

Robert M. Kacmarek, PhD, RRT, and Dean R. Hess, PhD, RRT

The vast majority of surgical patients do not require support of the respiratory system once they are past the immediate postoperative period. However, others with preexistent chronic respiratory diseases, trauma patients, and patients who require extensive surgical procedures may require more lengthy periods of respiratory support. This chapter focuses on mechanical ventilation of the postoperative patient. The chapter primarily discusses invasive ventilation but also reviews selected data for noninvasive respiratory support and the application of noninvasive positive pressure ventilation (NPPV) and continuous positive airway pressure (CPAP) by mask.

INDICATIONS FOR INTUBATION AND MECHANICAL VENTILATION

The main objectives of mechanical ventilation in the postoperative patient are to decrease the work of breathing and the load on the cardiovascular system, and to reverse life-threatening hypoxemia or respiratory acidosis. Table 83–1 summarizes some of the specific indications for mechanical ventilation.[1,2] Esteban et al. reported an international survey of 1638 patients requiring mechanical ventilation. Acute respiratory failure was the indication for mechanical ventilation in the majority of patients (66%), followed by coma (15%), an acute exacerbation of chronic obstructive pulmonary disease (13%), and neuromuscular disorders (5%).[3] Included under the heading of respiratory failure were postoperative respiratory failure, acute respiratory distress syndrome (ARDS), heart failure, pneumonia, sepsis, and complications of trauma.[3]

MECHANICAL VENTILATION TARGETS

Pressure Versus Volume Ventilation

During all forms of mechanical ventilation the ventilator must be programmed to deliver gas to achieve specific target values. The format for gas delivery in most ventilator modes is to either a targeted pressure or volume (Table 83–2).[1] In volume-targeted ventilation (the original approach to ventilatory support), a specific tidal volume is set by the clinician and the ventilator ensures that the volume is delivered regardless of inspiratory pressure (up to a clinician-set limit). In addition to tidal volume, the flow waveform and peak flow or inspiratory time must be set. With this approach to ventilatory support the focus is on ensuring that ventilation is maintained at a targeted level.

Pressure ventilation is essentially an opposite approach to ventilatory gas delivery. A peak airway pressure is set, with the result that the peak alveolar pressure is limited. That is, with each breath pressure increases to the set level before the breath terminates. However, the tidal volume and gas flow are allowed to vary from breath to breath. During pressure ventilation the clinician must set the targeted pressure, and in some modes, the allowed inspiratory time. Flow is provided rapidly at first, then in an exponentially decelerating pattern where the rate of deceleration is dependent upon the patient's inspiratory demand and lung mechanics.[4] Essentially, the ventilator rapidly delivers gas flow to establish the targeted pressure but once the pressure target is met, the flow must decrease to avoid exceeding the set pressure. This approach to ventilatory support focuses on ensuring a targeted pressure is met and never exceeded.

As noted in Table 83–3 pressure and volume ventilation respond differently to changes of the impedance to gas delivery. With volume ventilation pressure increases if the patient becomes more difficult to ventilate, whereas with pressure ventilation the tidal volume is decreased. Most modes of ven-

KEY POINTS

1. Patients require mechanical ventilation because of apnea, acute or impeding acute respiratory failure, or severe refractory hypoxemia.
2. The two basic forms of mechanical ventilation are pressure ventilation (peak airway pressure constant, tidal volume variable) and volume ventilation (tidal volume constant, peak airway pressure variable).
3. Although numerous modes of ventilation exist little data is available to differentiate the benefits of one over the other and no mode has been shown to improve outcome.
4. A major concern during assisted ventilation is patient–ventilator synchrony—the ventilator should be set to match the patients ventilatory demands.
5. Autopositive end-expiratory pressure (PEEP) is a common cause of patient–ventilator dyssynchrony; in patients with obstructive lung disease, properly set applied PEEP improves synchrony and decreases patient effort.
6. It is unnecessary to achieve normal PaO_2 and $PaCO_2$. In most critically ill patients, a PaO_2 ≥60 mm Hg is usually acceptable and permissive hypercapnia may be necessary in some patients.
7. Ventilator-induced lung injury is primarily caused by localized overdistension and the opening and closing of unstable lung units.
8. In the vast majority of patients who are ventilated, the tidal volume should be 5–10 mL/kg predicted body weight (PBW) and the plateau pressure should be <30 cm H_2O, PEEP should be set to avoid collapse of unstable lung units.
9. High-frequency ventilation and airway pressure release ventilation, although useful in managing patients with acute respiratory distress syndrome (ARDS), show no benefit over conventional pressure or volume ventilation.
10. Noninvasive positive pressure ventilation is useful to transition patients who are at high risk of extubation failure from invasive ventilation to spontaneous breathing.

TABLE 83–1.

Indications and Select Specific Clinical Causes for the Need of Mechanical Ventilation

Pathophysiologic Indications	Specific Clinical Cause
Apnea	Anesthesia, head trauma, drug overdose
Acute or impending ventilatory failure; $PaCO_2$ >50 mm Hg and pH <7.30	Anesthesia, asthma, acute exacerbation of chronic obstructive pulmonary disease, flail chest, postoperative respiratory failure
Severe refractory hypoxemia; PaO_2 <60 mm Hg (SaO_2, 90%) with FiO_2 >0.8	Postoperative respiratory failure, acute respiratory distress syndrome, severe pneumonia, sepsis, pulmonary edema

tilation currently available essentially function based on one of these two formats.

Combined Pressure and Volume Targeted Modes

Some of the newer modes of ventilation (see New Modes of Ventilation below) attempt to combine the beneficial effects of volume ventilation (delivering a constant tidal volume) and pressure ventilation (the maximum airway pressure is limited).[4] With these modes both volume and pressure are targeted. Their gas delivery algorithms are designed to ensure on average that the set tidal volume is delivered but also to ensure that the peak airway pressure does not exceed the set level.[4] In other novel ventilatory modes, gas may be delivered initially in a volume ventilation format, but if the patient's demand is increased, the gas delivery mode changes to a pressure format to ensure that ventilatory demand is met.[4]

CLASSIC MODES OF VENTILATION

The classic modes of ventilation include control, assist/control, assist (pressure support), and synchronized intermittent mandatory ventilation (Table 83–4). All of these modes have been available on mechanical ventilators for more than 25 years and generally can provide the basic approaches to ventilatory support for the vast majority of surgical patients.

Control Mode

This is the original mode of mechanical ventilation. Controlled ventilation is available in both pressure and volume ventilation formats (Figs. 83–1 and 83–2). In this mode, the ventilator controls *all* aspects of gas delivery. That is, the patient is assumed to be a passive recipient of mechanical ventilation.[5] With these earliest ventilators, patients were not able to trigger the ventilator to produce an inspiration. However, with today's modern ventilators, even when the airway sensitivity is set at the most insensitive setting, patients with a strong ventilatory drive can still trigger the ventilator. The control mode of ventilation is achieved today by sedating the patient to apnea.

Assist/Control Mode

This mode is essentially the control mode with the sensitivity level set to trigger on a spontaneous negative airway pressure ensuring that the patient initiates his or her own gas delivery (Fig. 83–3). The sensitivity control adjusts the level of patient effort (spontaneous negative airway pressure) required to trigger the mechanical breath. Although the patient determines the ventilatory rate, a "backup" rate is set to insure a minimum rate of ventilation.[5] Worldwide this is the most commonly used mode of ventilation.[3] During volume assist/control the following variables are usually set: tidal volume, flow waveform, backup rate, peak inspiratory flow rate or inspiratory time, inspiratory trigger sensitivity, FiO_2, and positive end-expiratory pres-

sure (PEEP). With the pressure assist/control mode the peak pressure, inspiratory time, backup rate, inspiratory trigger sensitivity, FiO_2, PEEP, and rise time must be set.

Pressure Support

The closest mode to true assist ventilation available on modern ventilators is pressure support (Fig. 83–4). With assist ventilation there is no backup rate. In pressure support, backup safety modes of ventilation take over if patients become apneic for ≥20 seconds but no true backup rate is available.[5] Pressure support is very similar to pressure assist/control.[6] The major feature of gas delivery that differs in this mode is the mechanism that terminates inspiration. With pressure assist/control the inspiration is always terminated by time, whereas with pressure support, inspiration is usually terminated by decreasing gas flow. That is, when tracheal flow decreases to a specific level (usually 25% of the peak flow for that breath) the breath is terminated. There are, however, two alternate methods of terminating inspiration in pressure support: pressure exceeding the set level after about 300 milliseconds of inspiration or the inspiratory time exceeding the manufacturer's set level, usually 2–3 seconds. However, newer ventilators allow the clinician to set the maximum inspiratory time during pressure support ventilation. Both of these secondary termination criteria are valuable for patient safety and prevent lengthy inspiratory times and prolonged elevation of airway pressures which can reduce the cardiac output.

Of the classic modes of ventilation, pressure support allows the patient the greatest control over the process of

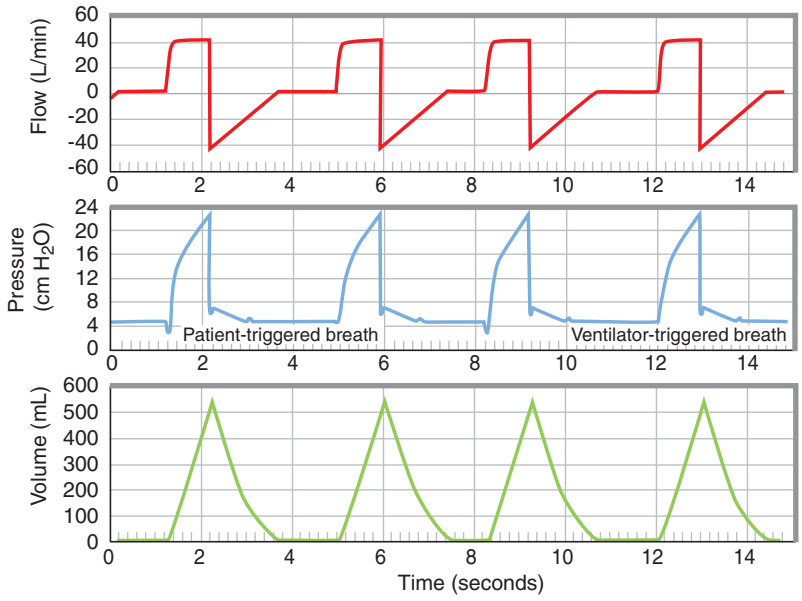

FIGURE 83–3. Volume-targeted assist/control mode ventilation. Note each breath is patient triggered as observed by the deflection in airway pressure at the onset of each breath. (Reprinted from Hess DR, MacIntyre NR, Mishoe SC, et al. Respiratory Care: Principles and Practice. Philadelphia: WB Saunders, 2002:786–791, with permission from Elsevier.)

ventilation. Not only does the patient trigger each breath, but the ending of the breath is based on the patient's demand. As with all pressure-targeted approaches to ventilation, the pressure support mode allows the patient to vary the tidal volume of each delivered breath. The only gas delivery variable set other than sensitivity is the pressure level. Pressure support may be used to ventilate any patient with a stable ventilatory drive.

Inspiratory Termination Criteria

Inspiratory termination criteria, also referred to as E-sens or expiratory sensitivity, is an adjunct to pressure support available on many ventilators as a method of ensuring that the patient and ventilator end their inspiration simultaneously. As Fig. 83–5 illustrates, an increase in pressure at the end of a pressure support breath is abnormal and usually indicates that the patient has begun exhalation before the ventilator has allowed exhalation to occur.[7] When this increase in inspiratory pressure is observed, the patient is contracting the accessory muscles of exhalation during the terminal aspect of the ventilator's inspiratory phase.[8] This results in an increased ventilatory drive and ventilatory rate, and the development of patient–ventilator dyssynchrony. E-sens allows adjustment of the percentage of peak flow terminating the breath. Whenever a spike at the end of a pressure support breath is present, a greater percentage of the peak flow should be set to terminate the breath. Whenever a spike is present the E-sens percentage should be slowly increased until there is a smooth transition from inspiration to expiration.[9]

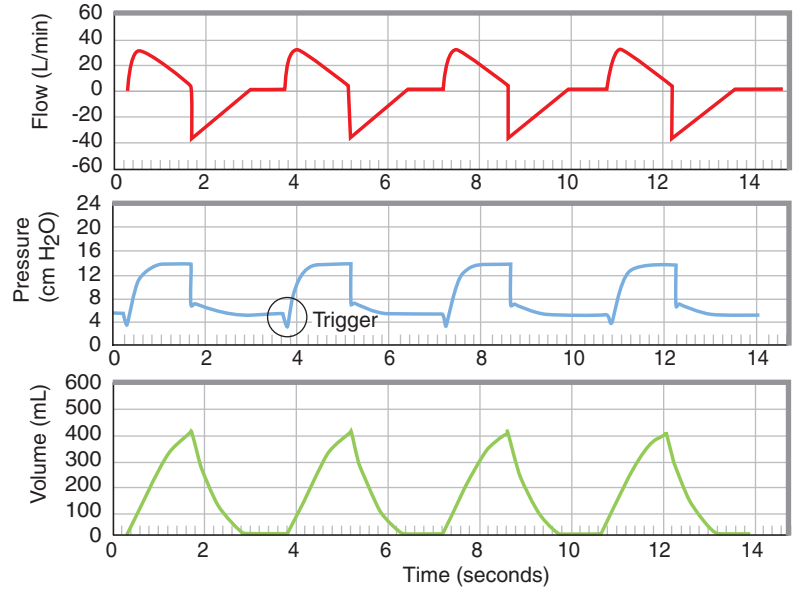

FIGURE 83–4. Pressure support mode ventilation. (Reprinted from Hess DR, MacIntyre NR, Mishoe SC, et al. Respiratory Care: Principles and Practice. Philadelphia: WB Saunders, 2002:786–791, with permission from Elsevier.)

Rise Time

Patient–ventilator synchrony at the onset of a pressure-targeted breath (e.g., pressure assist/control, pressure support, pressure-regulated volume control) can be improved by adjusting the rise time. As noted in Fig. 83–6 the flow rise time varies the slope of the pressure increase at the onset of a breath by varying the time it takes gas flow to increase from zero to peak.[7] Rise time should be adjusted to ensure that airway pressure rises rapidly to the peak level without any concavity during the initial airway pressure waveform. If the airway pressure waveform is concave the rise time should be increased (made more rapid), however, if peak pressure exceeds the set level at the onset of inspiration the rise time should be decreased. An increase in rise time generally results in an increase of peak flow and a decreased inspiratory time (with pressure support ventilation). In most patients with a strong ventilatory drive the rise time should be set between the mid and most rapid level. Proper setting of rise time usually results in a decreased mechanical ventilatory rate.

Synchronized Intermittent Mandatory Ventilation

This mode of ventilation combines spontaneous unsupported breathing with the assist/control mode. As with the assist/control mode, the mandatory positive pressure breaths can be either pressure or volume targeted. Figure 83–7 illustrates the typical volume-targeted synchronized intermittent mandatory ventilation (SIMV). A mandatory respiration rate is set, and

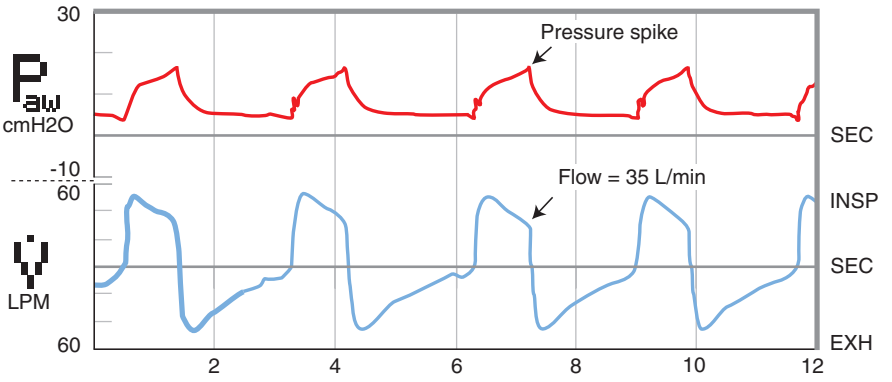

FIGURE 83–5. Pressure and flow tracings during pressure support ventilation with the Nellcor Puritan Bennett 7200ae demonstrating pressure cycling in pressure support. The pressure spike at the end of inspiration indicates the patient desires to end the breath before the ventilator will allow exhalation. (Reproduced with permission from Branson RD, Campbell RS, Davis K, et al. Altering flow rate during maximum pressure support ventilation (PSV_{max}): effects on cardiorespiratory function. Respir Care 1990;35:1056–1064.)

between the mandatory breaths the patient can breath spontaneously.[5] As noted in Fig. 83–8 an assist/control window is open at specific intervals based on the selected mandatory respiration rate.[10] Within each window the patient is able to trigger positive pressure breaths, if the ventilator does not sense a patient's efforts during this time period a controlled positive pressure breath is delivered. Ventilator adjustment is the same as with control mode except that the sensitivity must also be properly set.

Advocates of SIMV emphasize the benefits of spontaneous breathing between mandatory breaths. As shown in Fig. 83–8, spontaneous breathing can improve ventilation–perfusion (V/Q) matching by producing an improved distribution of ventilation to dependent lung regions.[10] In addition, the negative intrathoracic pressure generated during spontaneous breathing decreases the mean intrathoracic pressure, thereby improving cardiac output. However, the work of breathing during SIMV can be excessive. As noted in Fig. 83–9, as the mandatory rate is reduced the work of breathing for both mandatory and spontaneous breaths increases.[11] The surprising reason for this, is that the patient's respiratory center has a difficult time rapidly changing its output based on ventilatory load as the mandatory rate decreases. Essentially, each breath is interpreted as being at the higher load and requiring the higher muscular work output. This is nicely illustrated in Fig. 83–10; note that the electromyelogram (EMG) activity of the diaphragm and the sternocleidomastoid muscles, as well as the esophageal pressure changes, are the same for both mandatory and spontaneous breaths.[12] In other words, the patient's effort is the same regardless of breath type, although the efficiency of gas delivery may be better during the mandatory breaths. Unfortunately, this set of circumstances increases the patient's ventilatory drive and increases the level of patient–ventilatory dyssynchrony.

With most modern ventilators, the pressure support mode can be applied during spontaneous patient breaths, however, this negates the benefits of unassisted spontaneous breathing and increases the complexity of weaning patients from ventilatory support. In general, the lower the mandatory rate

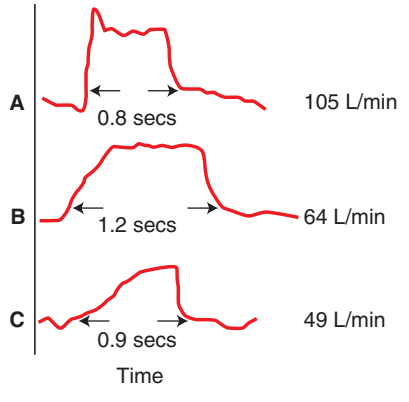

FIGURE 83–6. Effect of changing rise time in a lung model preferring a midrange rise time. **A.** Flow is in excess of demand, and a pressure spike is seen. **B.** As flow rate is decreased, inspiratory time (T_I) lengthens, and the pressure spike is absent—machine output matches patient demand. **C.** When flow rate is further reduced, patient demand exceeds machine flow rate, and T_I decreases. Peak flow is inadequate to establish the expected pressure waveform. (Reproduced with permission from Branson RD, Campbell RS. Pressure support ventilation, patient–ventilator synchrony, and ventilator algorithms. Respir Care 1998; 43:1045.)

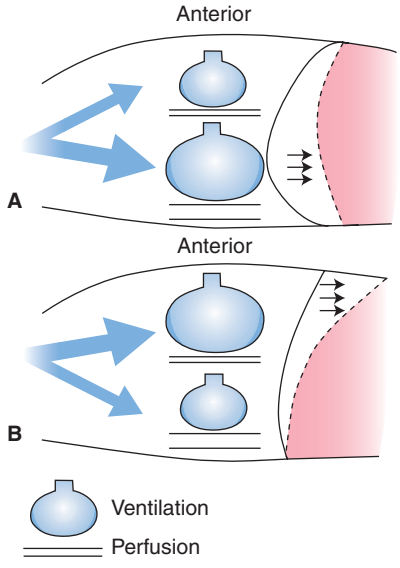

FIGURE 83–8. Effect of spontaneous ventilation and positive-pressure ventilation on gas distribution in a supine subject. During spontaneous ventilation (**A**) diaphragmatic action distributes most ventilation to the dependent zones of the lungs, where perfusion is greatest. The result is good matching of ventilation to perfusion. During positive-pressure ventilation (**B**) because the diaphragm is doing little to no contraction, ventilation is primarily distributed to nondependent lung, increasing the level of ventilation to perfusion mismatch. (Reprinted from Wilkens RL, Stoller JK, Scamlon CC. Egan's Fundamentals of Respiratory Care. 8th ed. St. Louis, MO: Mosby, 2003:972, with permission from Elsevier.)

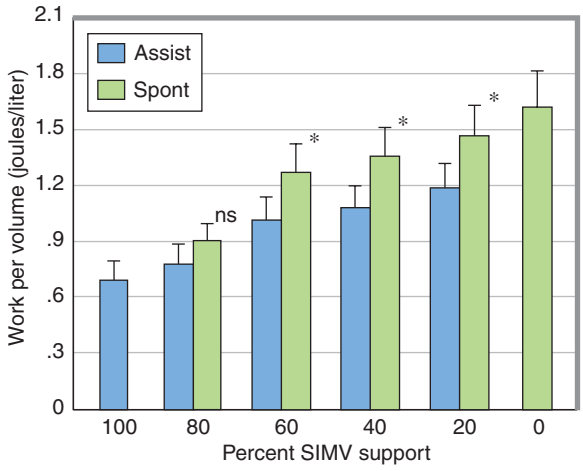

FIGURE 83–9. Inspiratory work per unit volume (work per liter [Wp/L]) done by the patient during assisted cycles (*open bars*) and spontaneous cycles (*reverse cross-hatched bars*). Wp/L increased with decreasing synchronized intermittent mandatory ventilation percentage for both types of breath. Wp/L for spontaneous breaths tended to exceed Wp/L for machine-assisted breaths. (Marini JJ, Smith TC, Lamb VJ. External work output and force generation during synchronized intermittent mechanical ventilation. Am Rev Respir Dis 1988;138:1169. © American Thoracic Society)

during SIMV the greater the likelihood that the patient's effort will be excessive and dyssynchrony will be present.

NEW MODES OF VENTILATION

Table 83–4 lists the latest modes of ventilation currently available on the newest generation of mechanical ventilators. These modes are designed to take advantage of the beneficial aspects of both volume and pressure ventilation. As noted in Table 83–4, they are divided into modes that adjust gas delivery during a given breath and those that adjust gas delivery on the subsequent breath. In this latter group, adjustment is based on the ability of current settings to achieve gas delivery targets.

Pressure-Regulated Volume Control

This mode of ventilatory support targets both a maximum airway pressure and a tidal volume and is a variation of the pressure assist/control mode. This same mode is referred to on some ventilators as autoflow, volume control plus, or possibly another term.[4,5] It accomplishes its goals by varying the pressure applied on the subsequent breath based on the tidal volume achieved on the current breath. All of the ventilators providing this mode of ventilation first deliver a test breath at some low level of pressure and from the volume delivered calculate the pressure required to deliver the targeted tidal volume. The ventilator then automatically adjusts the pressure in 1 or 2 steps to the pressure level needed to deliver the targeted tidal volume. During every subsequent breath, the tidal volume that is delivered is reassessed, and based on this assessment the pressure on the subsequent breath is adjusted ± 3 cm H_2O to ensure that

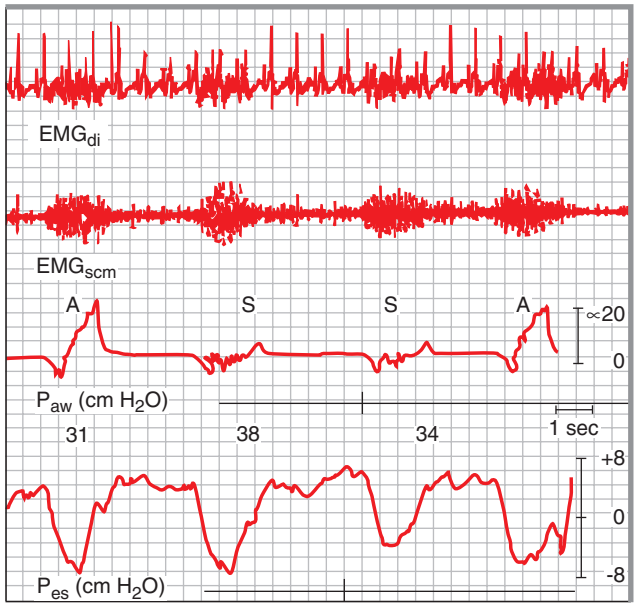

FIGURE 83–10. Electromyograms of the diaphragm (*EMGdt*) and of the sternocleidomastoid muscles (*EMGscm*) in a representative patient, showing similar intensity and the duration of electrical activity in successive assisted (*A*) and spontaneous (*S*) breaths during synchronized intermittent mandatory ventilation. Also, note that esophageal (*Pes*) pressure changes are equal (equal effort) during *A* and *S* breaths. P_{aw}, Airway pressure. (Reproduced with permission from Imsand C, Feihl F, Perret C, et al. Regulation of inspiratory neuromuscular output during synchronized intermittent mechanical ventilation. Anesthesiology 1994;80:13–22.)

the targeted volume is delivered on the next breath.[4,5] Pressure during pressure-regulated volume control (PRVC) can be increased to a maximum level that is selected and can be decreased with some ventilators all the way to the CPAP/PEEP level, thereby allowing unassisted spontaneous breathing. Herein lies our major concern with PRVC: If a patient has a strong ventilatory drive and the additional stimulus of, for example, hypoxemia, fever, or sepsis, the level of ventilatory support could decrease inappropriately to either a very low level or to no support. As a result, be cautious when using this mode with patients who have a strong ventilatory drive.[13] Marked improvement in the operation of this mode could be made by adding a minimum pressure limit. That is, setting a low pressure limit.[4] As a result, this mode is most useful in those patients who are receiving control mode ventilation or for those patients who have limited ventilatory demand. To use PRVC, first set all variables used during pressure assist/control, then add the target tidal volume and maximum pressure limit.

Volume Support

The volume support mode operates similar to PRVC, but is based on a pressure-support mode and not a pressure assist/control format.[4,5] Ventilator software must assess the pressure needed to deliver the tidal volume and provide breath-to-breath pressure adjustment to ensure the targeted tidal volume. The same safety concern regarding a patient with a strong ventilatory demand exists with volume support (as with PRVC). The adjustments made to the ventilator during setup are the same as with pressure support with the addition of setting the target volume and maximum airway pressure.

Two randomized controlled studies of PRVC and/or volume support have been conducted—one in neonates[14] and the other in pediatric patients.[15] In the study of newborns,[14] PRVC was compared to intermittent mandatory ventilation (without synchronization of the mandatory breath). In this study, neonates who were studied weaned faster with PRVC. In the second,[15] volume support was compared to pressure support with and without a protocol for weaning the children from mechanical ventilation. No difference in the rate of weaning was observed regardless of the mode of ventilation. As a result, there is little enthusiasm for the use of either of these new modes of ventilation.

Adaptive Support Ventilation

This is a very unique new mode of ventilatory support. It attempts to adjust ventilator settings to ensure that an ideal ventilatory pattern is achieved,[16] with *ideal* being defined as the pattern requiring the least patient and ventilator work based on the patient's measured mechanical lung characteristics and breathing effort. The goal of adaptive-support ventilation (ASV) is to provide a preset level of minute ventilation while minimizing the total work of breathing expended by both the ventilator and the patient. It can be applied to both patients who require controlled ventilation and to those who are actively breathing.

During set up the clinician must indicate the patient's ideal body weight (males: predicted body weight [PBW] (kg) = 50 + 2.3 [height (inches) (60)]; females: PBW (kg) = 45.5 + 2.3 [height (inches) (60)])[17] and the percentage of minimal minute volume (% min MV) to be delivered. The % min MV can be adjusted between 25% and 350%.[16] From the ideal body weight (IBW) and % min MV the maximum rate is calculated as:

$$22 \times \%\ \text{min MV}/100 \text{ if IBW} > 15\ \text{kg}$$

or

$$45 \times \%\ \text{min MV}/100 \text{ if IBW} < 15\ \text{kg}$$

whereas the maximum tidal volume delivered is the targeted MV/5.[16] With this information the ventilator determines the optimal breathing pattern that will minimize the work of breathing; that is, a ventilatory pattern that results in minimum work of breathing based on the lung and chest wall mechanics of the patient.

With the initial application of ASV the ventilator provides a series of 5 pressure-limited test breaths at a rate of about 10 breaths/min with a maximum pressure of 15 cm H_2O. During these breaths, the ventilator measures dynamic compliance, the respiratory time constant, tidal volume, and the patient's respiratory rate.[16] These measurements are used to determine the initial targets for breathing rate and tidal volume. As ventilation continues the ventilator software recalculates the above variables from each breath and determines the new rate and tidal volume targets. Targets are based on the original work by Otis for estimating the patients' minimal ventilatory work.[18]

This mode of ventilation is designed to ensure an ideal ventilatory pattern is maintained and can be used in all phases of ventilatory support. It continually adjusts mechanical ventilation characteristics as the patient's status changes because it monitors the patient's lung mechanics on a breath-to-breath basis.

Automatic Tube Compensation

This mode of ventilation has been referred to as electronic extubation. Automatic tube compensation (ATC) is designed to provide sufficient mechanical ventilatory support during inspiration and sufficient decompression of the ventilatory circuit during expiration to maintain the tracheal pressure equal to the set PEEP level. The ventilator software accomplishes this by having the resistance properties of various endotracheal and tracheostomy tube sizes programmed into its memory and continually measuring gas flow. From this data, the pressure needed to overcome the resistance (resistance = change in pressure divided by flow) of the endotracheal tube is continually calculated and applied.[19]

Upon activation of the ATC mode, the clinician must indicate the type and size of artificial airway and the desired percentage of automatic tube compensation (20–100% on most ventilators).[4,5] In addition, some ventilators only apply the ATC correction during inspiration, others during both inspiration and expiration. The precise clinical indications for ATC are still unclear. Because this mode responds only to the patient's demand, if demand is low, ventilatory support is low; that is, if the patient generates a low inspiratory effort then little pressure is applied, whereas if the patient generates great effort, the applied pressure is greater.[20] ATC, like proportional-assist ventilation, does not force a ventilatory pattern, but is only designed to unload the flow resistive properties of the artificial airway. Its use is recommended for patients ready to wean from the ventilator. If the ATC pressure level is stable and

remains at a low pressure (5–7 cm H_2O), then extubation is indicated.

The use of expiratory ATC does raise some concerns when used in patient's with airways obstruction. The decompression of the airway during early exhalation may precipitate greater airways collapse and obstruction. As with many of these newer modes of ventilation, additional research is required before clinical indications and contraindications can be clearly defined.

Proportional-Assist Ventilation

This mode of ventilation is similar to ATC but the software weighs both the mechanics of the total respiratory system plus the resistive properties of the artificial airway; that is, the ventilator delivers a pressure assist in proportion to the patient's desired tidal volume (volume assist) and to the patient's instantaneous inspired flow (flow assist).[21] The level of these two aspects of ventilatory assistance are automatically adjusted to meet changes in the patient's ongoing ventilatory demand. This algorithm is based on the law of motion as it applies to the respiratory system:

$$P_{mus} + P_{appl} = (\text{volume} \times E) + (\text{flow} \times R)$$

where P_{mus} is pressure generated by the respiratory muscles,[21] P_{appl} is pressure applied by the ventilator, and E and R are elastic and resistance properties of the respiratory system. Assuming that E and R are linear during inspiration, the instantaneous flow and volume to be delivered are proportional to the resistive and elastic work of breathing respectively. The ventilator measures the instantaneous flow and volume, whereas the clinician must measure and set values for E and R. Ideally, the ventilator should be able to measure on a breath-by-breath basis E and R, and software should adjust gas delivery accordingly by estimating P_{mus} and assisting P_{mus} in a proportional manner.[22] Thus the patient is the determinant of the ventilatory pattern. Patients are given the freedom to select a ventilatory pattern that is rapid and shallow or slow and deep.[22] The ventilator does not force any control variable except the unloading of E and R in a proportional manner.

Proportional-assist ventilation (PAV) is only useful in patients with a stable ventilatory drive who choose an acceptable ventilatory pattern. Of concern is the inability of most mechanical ventilators to reassess E and R on an ongoing basis. As a result, the level of unloading may be inappropriate if respiratory system mechanics are dynamically changing. There are a number of clinical reports that compare the effects of PAV with those of pressure support, and PAV functions equivalently.[23,24] In addition, the PAV mode has been shown to be useful during noninvasive ventilation.[25,26]

Airway Pressure Release Ventilation

This mode of ventilation is a combination of pressure-targeted SIMV and inverse-ratio pressure-control ventilation.[27] As illustrated in Fig. 83–11, airway pressure release ventilation (APRV) applies two levels of CPAP and allows spontaneous unassisted breathing at each CPAP level. There are two approaches to setting APRV based upon the belief that spontaneous breathing should only occur at the high CPAP level,[28] or at both CPAP levels.[29] If the clinician desires spontaneous breaths only at the high CPAP level, the time spent at the low CPAP level is kept brief to prevent complete exhalation, hence an inverse ratio between high and low CPAP levels. In this setting, the high CPAP level is set to maintain oxygenation and the lower level assists ventilation by periodically decreasing the lung volume.

The alternate approach is to set the low CPAP level to maintain oxygenation (as if setting a PEEP level) and the high CPAP level to provide ventilatory assistance, as in SIMV.[29] In this latter approach, the time spent at low CPAP levels is sufficient to allow complete exhalation and spontaneous breathing at the lower CPAP levels. Proponents of APRV cite the salutary benefits of spontaneous unsupported breathing to improve ventilation–perfusion matching, increase cardiac output and reduce the need for sedation.[27–29] However, as noted in Fig. 83–12, the effort associated with spontaneous breathing under these conditions can result in very high esophageal pressure swings and a high work of breathing for the patient. Accounting in part for the greater cardiac output.[30] In addition, dyssynchrony is common with APRV. Dyssynchrony occurs at the mandatory transition from high-to-low or low-to-high CPAP

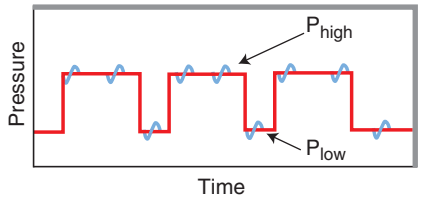

FIGURE 83–11. Airway pressure release ventilation (APRV). P_{high}, high continuous positive airway pressure (CPAP) level; P_{low}, low CPAP level. Note spontaneous breaths at both levels of CPAP. (Reprinted from Kacmarek RM, Dimas S, Mack C. Essentials of Respiratory Care. 4th ed. St. Louis, MO: Elsevier, 2005: 690–714, with permission from Elsevier.)

levels. If the patient is exhaling when the ventilator increases airway pressure, or inhaling when the ventilator decreases airway pressure, dyssynchrony results. Although this mode of ventilation is most commonly used in the management of acute lung injury or the acute respiratory distress syndrome, it has not been shown to be more beneficial than the assist/control mode.[29]

Bilevel Pressure Ventilation

This is a modification of APRV. As noted in Fig. 83–13, pressure support can be added to spontaneous breaths at either the high or low CPAP level or both.[4] This reduces the patient's effort and esophageal pressure swings but it also increases the mean intrathoracic pressure, negating somewhat the increased cardiac output and beneficial augmentation of ventilation to perfusion matching. In addition, the transition from high-to-low and low-to-high CPAP levels is coordinated with the patient's muscular effort (as in SIMV), markedly decreasing dyssynchrony. Like APRV, the bilevel ventilation mode is primarily employed in the management of acute lung injury and the acute respiratory distress syndrome.

VENTILATOR SETTINGS AND PATIENT–VENTILATOR SYNCHRONY

Patient–ventilator synchrony is a critical issue for every patient triggering the ventilator for a mechanically supported inspiration. A lack of synchrony increases ventilatory effort, respiratory rate, and the patient's work of breathing as the ventilator is not providing flow to match the patient's inspiratory demand. Pressure-targeted modes of ventilation are generally better than

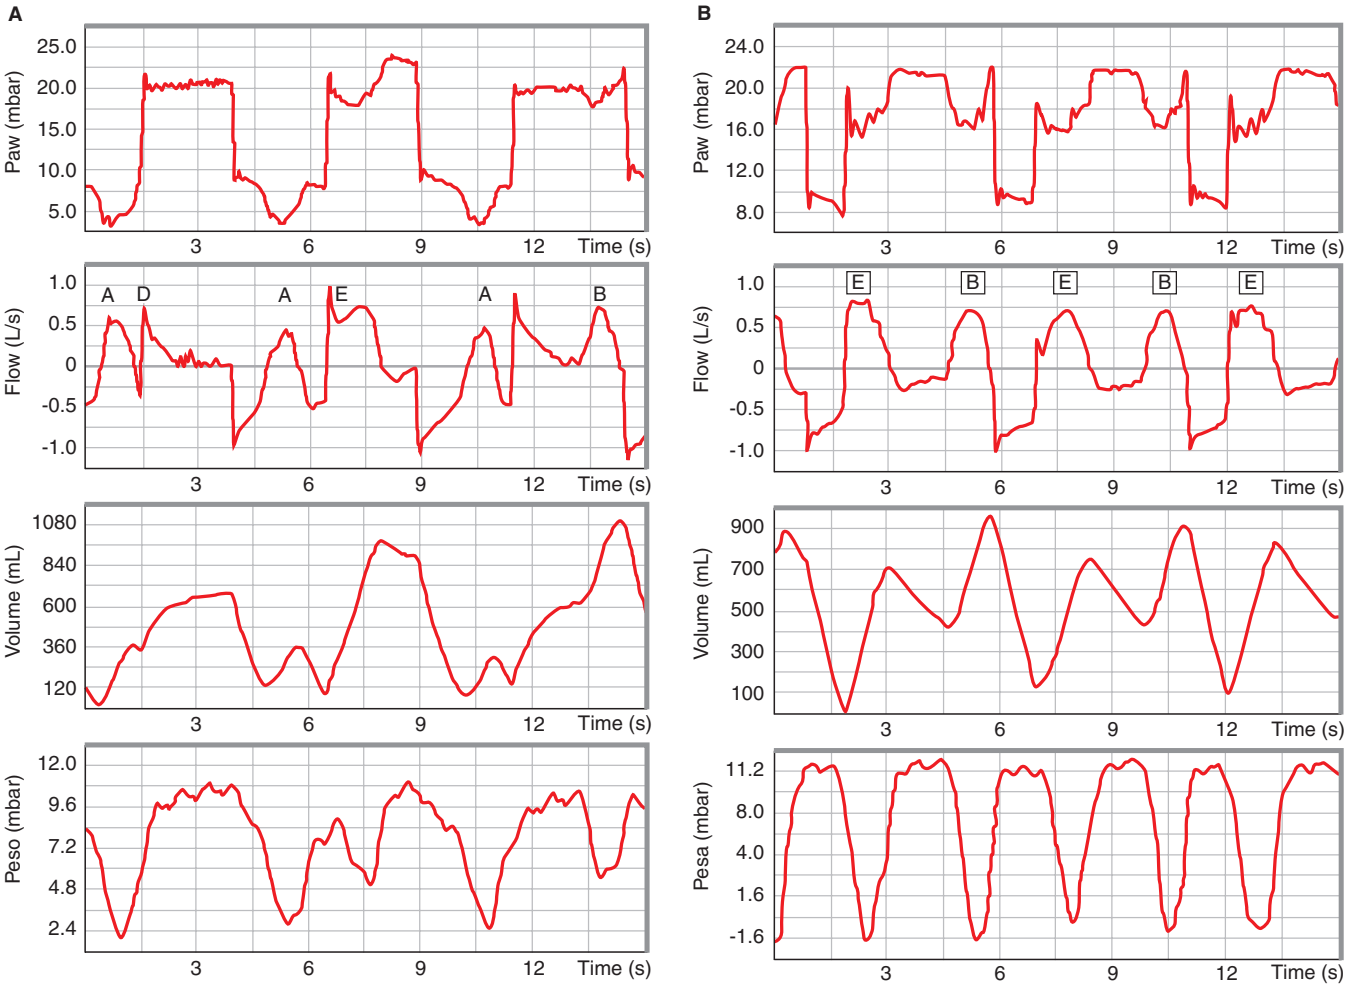

FIGURE 83–12. Airway pressure release ventilation actual patient tracings. A synopsis of airway pressure (P_{aw}), flow, volume, and esophageal pressure (P_{es}) is shown. **A.** Time intervals of the upper (P_{high}) and lower airway pressure (P_{low}) set to 2.5 seconds each. **B.** Time intervals of P_{high} = 4.0 seconds and P_{low} = 1.0 second in the same patient. Note that spontaneous breathing occurs on the upper and lower CPAP levels in A and that tidal volumes varied considerably, depending on the pressure level from which an inspiration started. When P_{low} was decreased to 1.0 second, as shown in B, spontaneous breaths occurred almost exclusively during P_{high}. This results in a more regular breathing pattern as compared with A. Note, however, the large esophageal pressure swings (10–12 mbar or cm H_2O) per breath, indicating high patient effort on each spontaneous breath. Breaths are classified as type A, spontaneous breath at the lower CPAP level; type B, spontaneous breath on the upper CPAP level; type C, the pressure increase from the lower to the upper CPAP level triggered by an inspiratory effort of the patient; type D, mechanical breath; and type E, combined mechanical and spontaneous inspiration without a triggered pressure increase from P_{low} to P_{high}. (Newman P, Golisch J, Strohmeyer A, et al. Influence of different release times on spontaneous breathing pattern during airway pressure release ventilation. Intensive Care Med 2002;28:1742, with kind permission of Springer Science and Business Media.)

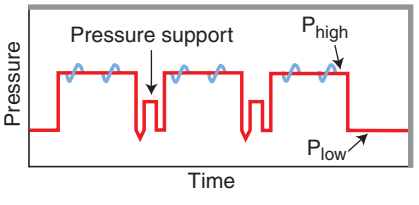

FIGURE 83–13. Bilevel ventilation upper airway pressure (P_{high}). High continuous positive airway pressure (CPAP) level and lower airway pressure (P_{low}) low CPAP level. Note spontaneous breaths at both levels of CPAP, but in this case pressure support is applied to the breaths at the P_{low}. Pressure support could also be applied to P_{high}. (Reprinted from Kacmarek RM, Dimas S, Mack C. Essentials of Respiratory Care. 4th ed. St. Louis, MO: Elsevier, 2005: 690–714, with permission from Elsevier.)

volume-targeted modes at reducing the likelihood of dyssynchrony, as pressure ventilation allows the ventilator to deliver a variable flow with each breath based on the patient's inspiratory demand.[31] In addition, most ventilators now allow adjusting the slope of the increase of flow delivery (rise time) to ensure gas delivery is matched to patient's inspiratory flow demand.[5,32] Patient–ventilator synchrony is also affected by the inspiratory time. The ventilator's inspiratory time and the patient's inspiratory time should be equal. Trigger sensitivity should always be set to be as sensitive as possible without causing spontaneous autotriggering. In general, flow triggering is to be recommended over pressure triggering.[33] A final factor affecting patient–ventilator synchrony is auto-PEEP,[34] which normally is only a problem in patients with airways obstruction, although it is a potential concern in all patients. If the patient's inspiratory efforts fail to trigger the ventilator, the problem is usually auto-PEEP.[35]

Peak Flow and Flow Waveform

If a patient is spontaneously triggering the ventilator, peak flow delivery during volume ventilation should match the patient's inspiratory flow demand.[36] Most adult patients with moderate to strong ventilatory demands require a peak flow of ≥ 80 L/min. As

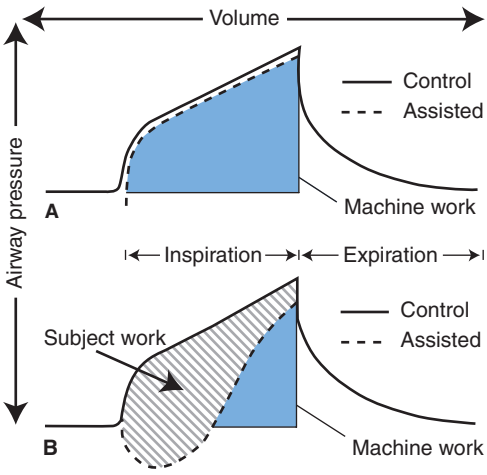

FIGURE 83–14. **A.** Depiction of an actual pressure-time curve (*dotted line*) during volume control ventilation superimposed on the ideal curve reflecting total work of breathing (*solid line*). **B.** Note the scooped-out actual pressure waveform when patient demand increases. The *hatched area* reflects the work performed by the patient during assisted volume-targeted ventilation. (Marini JJ, Rodrigues RM, Lamb V. The inspiratory workload of patient-initiated mechanical ventilation. Am Rev Respir Dis 1986;134:902–909. © American Thoracic Society.)

clearly demonstrated by Marini et al. (Fig. 83–14), if the peak flow does not meet the patient's inspiratory demand the work of breathing performed by the patient increases. The efficiency of the work may be greater than during spontaneous breathing but the overall patient work may be similar.[36]

It is important to remember that if the patient is triggering the positive-pressure breaths, the work of breathing is shared between the patient and the ventilator. It is for this reason that patients originally receiving assisted ventilation demonstrate altered gas-delivery patterns after they are sedated to apnea. With the transition to controlled ventilation, the peak airway and plateau pressures usually increase during volume ventilation, and tidal volumes decrease in the pressure ventilation mode.[37] Because the patient is no longer performing a portion of the work of breathing, the work performed by the ventilator must increase.

Most ventilators during volume ventilation mode can deliver gas flow in a decelerating or square wave flow pattern. If the patient is triggering inspiration, we recommend a decelerating flow pattern, especially when a small tidal volume (V_T) is being delivered.[4,37] A decelerating flow pattern allows a high peak flow to be delivered, but also ensures that the inspiratory time can be adequately set.

In patients who are sedated and who are not triggering the ventilator, the choice of flow waveform is unimportant, and the setting of peak flow is dependent on the predetermined inspiratory time and tidal volume.

Inspiratory Time

In patients self-triggering every breath, the set inspiratory time should equal the patients neuroinspiratory time.[38] As illustrated in Fig. 83–15, when the inspiratory time is decreased to equal the patient's desired inspiratory time and peak flow is increased to match the patient's demand, then the patient's work of breathing and effort correspondingly decrease. It is rare that a patient with a moderate to high ventilatory demand desires an inspiratory time less than 1 second.[38] In fact, many adults with moderate or high ventilatory demands desire an inspiratory time of between 0.6 and 0.9 seconds.[37] Carefully matching the patient's inspiratory time with the ventilator's inspiratory time generally markedly improves patient–ventilator synchrony.

In patients who are receiving controlled mechanical ventilation, inspiratory time is set based on the tidal volume and the clinician's perceived optimal time of inspiration. In most settings, an inspiratory time of about 1.0 second is ideal. Some clinicians prefer to lengthen the inspiratory time in ARDS/acute lung injury (ALI), thereby inversing the usual inspiratory-to-expiratory (I:E) time ratio; however, there are no data to indicate that longer inspiratory times result in better oxygenation or better outcomes in these syndromes than an appropriately set PEEP level.[39,40] Prolongation of the inspiratory time can have a minor positive effect of increasing CO_2 elimination by allowing time for inspired gas

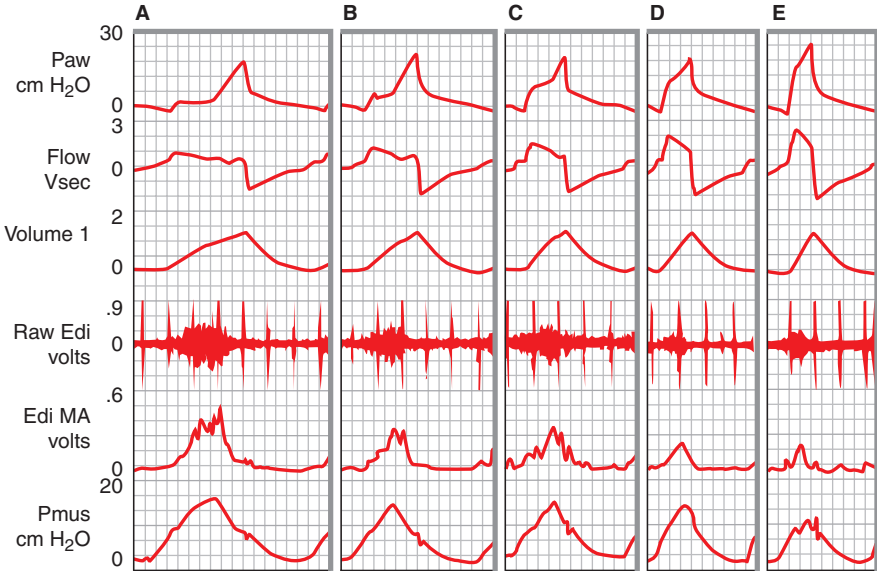

FIGURE 83–15. Representative example of the effect of alternations in peak flow and inspiratory time on airway pressure (P_{aw}), the raw diaphragmatic electromyography (EMG) signal (R_{aw} Edi), the diaphragmatic EMG signal after removal of the electrocardiographic interference and rectification, and the calculated pressure output of the inspiratory muscles (P_{mus}). Note the reduction in EMG activity and muscle output as flow increases. (Fernandez R, Mendez M, Younes M. Effect of ventilatory flow rates on respiratory timing in normal humans. Am J Respir Crit Care Med 1999;159:710–719. © American Thoracic Society.)

to transfer from fast time constant lung units to adjacent slower time constant units ("pendelluft"). In patients with severe asthma, the inspiratory time may need to be increased to 1.2–1.5 seconds to ensure ventilation passes beyond markedly obstructed airways.[37] Note that in asthma the airways resistance is not only increased during exhalation but also during inspiration.

Tidal Volume

Over the past 10 years, emphasis has been placed on the relationship between elevated tidal volumes and ventilator-induced lung injury (VILI; see Ventilator-Induced Lung Injury below).[41] Recent epidemiologic studies indicate that the most common tidal volume used to manage patients in acute respiratory failure is about 10 mL/kg PBW.[42] However, it is also important to emphasize that normal healthy relaxed mammals breathe at a tidal volume of about 6–7 mL/kg of PBW.[43] There is no evidence indicating that tidal volumes >10 mL/kg PBW are useful in the management of critically ill patients. In fact, evidence from a recent retrospective review indicates that the development of ALI is linked to large tidal volume ventilation (>10 mL/kg PBW).[44,52] As a general rule, all critically ill patients should be ventilated with ≤10 mL/kg PBW of V_T regardless of the cause of their acute ventilatory failure. Patients with ALI/ARDS ideally should be ventilated with a V_T 4–8 mL/kg of PBW.[45]

Plateau Pressure

The plateau pressure (end-inspiratory equilibration pressure) is a function of the mean peak alveolar pressure and is a reflection of the transpulmonary pressure. Similar to V_T, it is unknown if there is a specific plateau pressure that is safe. Because of the high shear forces associated with the ventilation of heterogeneously diseased lung, mechanical lung injury is theoretically possible, even with transpulmonary pressures below 30 cm H_2O. However, most clinicians would agree that a plateau pressure less than 25 cm H_2O is unlikely to produce an injurious level of alveolar overdistension, and that a plateau pressure in this range and a tidal volume ≤10 mL/kg PBW will not produce VILI regardless of the cause of respiratory failure. However, as plateau pressure increases, the delivered tidal volume should be decreased, regardless of the cause of respiratory failure. V_T should be kept ≤8 mL/kg PBW if the plateau pressure is 25–30 cm H_2O and V_T should be ≤6 mL/kg PBW if plateau pressures are >30 cm H_2O. Ideally, all patients should be managed with a plateau pressure of <30 cm H_2O unless there is a marked decrease of their chest wall compliance (e.g., burns, abdominal distension). If the chest wall compliance is decreased, the transpulmonary pressure is decreased and the risk of overdistension is reduced. In patients with stiff noncompliant chest walls and abdomens because of sepsis, abdominal distension, fluid resuscitation, and the like, a plateau pressure >30 cm H_2O may be required and would not be associated with an increased risk of VILI.[46] However, in all patients the plateau pressure should ideally be maintained below 40 cm H_2O. Alternatively, some have advocated the use of an esophageal balloon to estimate pleural pressure and guide mechanical ventilation strategies to limit transpulmonary pressure.

Auto-PEEP

Auto-PEEP, also known as *occult PEEP*, is defined as an alveolar pressure above the airway opening pressure. Auto-PEEP can be caused by flow limitation, dynamic hyperinflation, a high minute ventilation, expiratory muscle activity, and/or a high intraabdominal pressure (Fig. 83–16).[34,47] *Occult auto-PEEP* is a term that is used to describe those lung units with trapped gas that do not communicate with the airway following a prolonged end expiratory pause.[48] Occult auto-PEEP is likely a function of airway closure or occlusion secondary to mucus plugging, and can be difficult to clinically diagnose. The performance of an end-expiratory occlusion maneuver can be helpful in estimating auto PEEP levels if the patient is not making expiratory muscle efforts (passive-controlled ventilation). However, the absence of auto-PEEP by this technique should not be completely reassuring, because occult auto-PEEP may still be present. In severe asthma, it is frequently better to monitor the level of plateau pressure, as the plateau pressure will increase or decrease as total auto-PEEP increases or decreases.[48]

Auto-PEEP is a major cause of dyssynchrony. As noted in Fig. 83–17, when auto-PEEP is present, patients frequently cannot generate a sufficient inspiratory effort to decompress the auto-PEEP and trigger a breath.[35,49] Whenever, the patient's respiratory rate exceeds the ventilator's response rate, this problem is almost always caused by auto-PEEP.

When auto-PEEP is caused by dynamic airflow limitation of exhalation volume as in chronic obstructive pulmonary disease, the application of applied PEEP reduces the patient's effort to trigger the ventilator;[35] that is, applied PEEP can be titrated up to approximately 80% of the measured auto-PEEP without increasing the overall level of air trapping. Applying PEEP in the presence of auto-PEEP caused by dynamic airflow limitation increases central airway pressure without increasing auto-PEEP, so that the pressure change needed to trigger the ventilator is reduced, thereby increasing patient–ventilator synchrony; that is, decreasing the pressure difference across the obstruction. From a practical perspective because auto-PEEP is difficult to measure in the spontaneously breathing patient, the applied PEEP is increased in 1–2 cm H_2O steps until every inspiratory effort made by the patient triggers the ventilator. In some patients, this may require more than 10 cm H_2O of applied PEEP. During controlled ventilation, a controversy exists over the benefit of applying PEEP to balance the auto-PEEP, because no spontaneous ventilatory efforts are present.

GAS EXCHANGE TARGETS

Target blood gas tensions during mechanical ventilation are theoretically the normal range for the individual patient. This is usually a $PaCO_2$ of about 35–45 mm Hg for all patients except those with chronic CO_2 retention. In patients with chronically elevated CO_2 levels, the $PaCO_2$ should be maintained at the patient's normal level up to 90 mm Hg.[1] If the arterial pH and PCO_2 are reset in these patients to "normal" values, the patients may become impossible to wean from ventilatory support, because during spontaneous unassisted breathing they will maintain CO_2 levels at their baseline, which now results in an acute acidosis. In patients with ARDS, permissive hypercapnia may be unavoidable, as the effect of increasing the

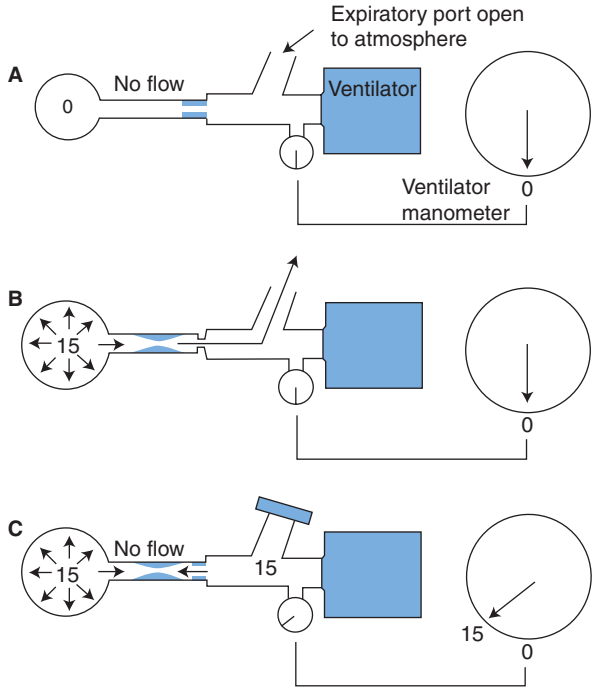

FIGURE 83–16. Relationship between alveolar, central airway, and ventilator circuit pressure under (**A**) normal conditions and (**B** and **C**) in the presence of severe dynamic airway obstruction, (**B**) with expiratory port open, and (**C**) with expiratory port occluded. Autopositive end-expiratory pressure (PEEP) level is identified by creating an end-expiratory hold, allowing alveolar, central airway, and ventilator circuit pressure to equilibrate. Note that during equilibration, auto-PEEP level can be read on the system manometer. (Pepe PE, Marini JJ. Occult positive end-expiratory pressure in mechanically ventilated patients with airflow obstruction: the auto-PEEP effect. Am Rev Respir Dis 1982;126:166–170. © American Thoracic Society.)

level of ventilation to reduce CO_2 levels may produce lung injury.

One factor limiting an increase in $PaCO_2$ with a permissive hypercapnic ventilatory strategy is the acidosis induced by the elevated CO_2.[50] Most healthy young adults can tolerate a pH as low as 7.20 without adverse effect.[51] In fact, in acute lung injury or asthma, the increased cardiac output induced by the acidosis may be beneficial. Some clinicians have proposed that the acidosis associated with permissive hypercapnia protects the cell from hypoxemic injury.[52] In older or cardiovascularly unstable patients, the level of acceptable acidosis must be individually gauged based on the response of the patient's cardiovascular system. In all patients the more gradual the permissive hypercapnia is allowed to develop, the greater the likelihood it will be well tolerated.

Tissue oxygenation is dependent on appropriate blood levels of oxygen and cardiac output. Assuming a normal cardiac output, Pao_2 values in critically ill patients need only to be maintained >60 mm Hg, whereas for some patients, because of a lack of alternatives, a PO_2 of >50 mm Hg may be acceptable.[1] There is no value in the vast majority of patients to maintaining a Pao_2 of ≥100 mm Hg.

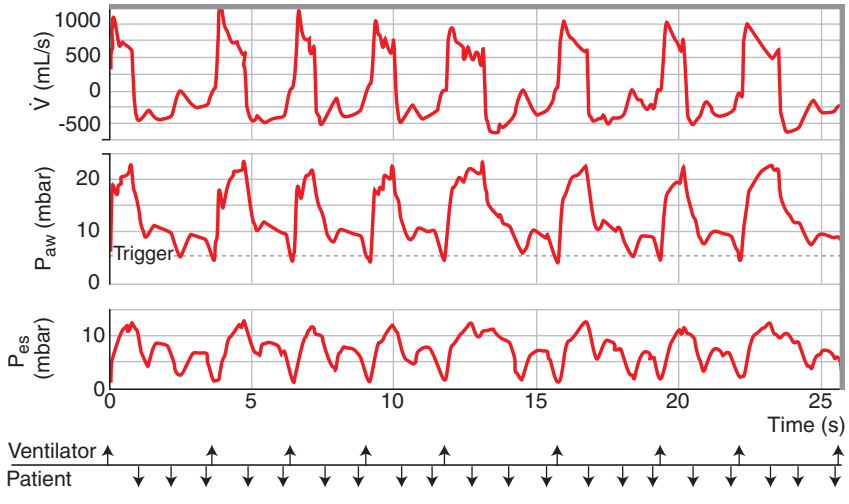

FIGURE 83–17. Gas flow, airway pressure, and esophageal pressure during pressure-supported ventilation with marked patient–ventilator dyssynchrony. Pressure spikes at the onset and termination of the breath indicate dyssynchrony, as well as the difference between patient inspiratory efforts (*arrows*) and the ventilator response (*arrows*). Chest 1995;107:1387–1384.)

VENTILATOR-INDUCED LUNG INJURY

Although the application of mechanical ventilation can be lifesaving, it has become increasingly clear that the mechanical ventilator can induce lung injury. Laboratory data have defined two primary settings in which the mechanical ventilator can induce lung injury, by producing overdistension of the lung at end inspiration and by collapse and reexpansion of unstable lung regions during ventilation.

Overdistension

Figure 83–18 depicts the impact of a large tidal volume without PEEP on a rat lung as compared to a rat lung ventilated with a small tidal volume and one with 10 cm H_2O PEEP and a large tidal volume.[53] One hour of ventilation with a large tidal volume at zero PEEP caused marked hemorrhagic edema of the lung. This type of injury was termed *volutrauma* by Dreyfuss and Saumon because it is believed that the injury is primarily caused by an excessive tidal volume.[54] However, as described above, an excessive tidal volume is accompanied by an excessive transpulmonary pressure, making the distinctions between pressure and volume injury somewhat semantic. VILI is defined as an increase in the permeability of the alveolar capillary membrane, the development of pulmonary edema, the accumulation of neutrophils and protein within the

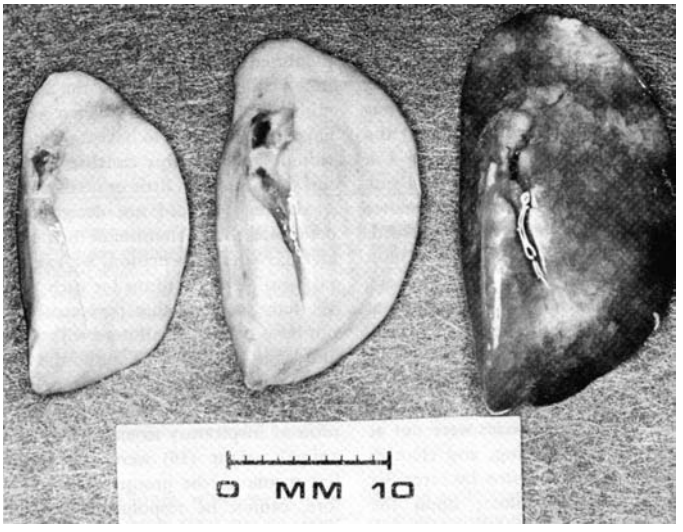

FIGURE 83–18. Comparison of lungs excised from rats ventilated with peak pressure of 14 cm H_2O, zero positive end-expiratory pressure (PEEP); peak pressure 45 cm H_2O, 10 cm H_2O PEEP; and peak pressure 45 cm H_2O, zero PEEP (left to right). The perivascular groove is distended with edema in the lungs from rats ventilated with peak pressures of 45 cm H_2O, 10 cm H_2O PEEP. The lung ventilated at 45 cm H_2O peak pressure zero PEEP is grossly hemorrhaged. (Webb HH, Tierney D. Experimental pulmonary edema due to intermittent positive pressure ventilation, with high inflation pressure protection by positive end expiratory pressure. Am Rev Respir Dis 1974;110: 556–565. © American Thoracic Society.)

lung parenchyma and airway, the disruption of surfactant production, and a decreased lung compliance.[54] VILI is indistinguishable from human ARDS and can be produced in rats within minutes by large tidal volume ventilation.[55] Indeed, VILI caused by inflation with large tidal volumes has been demonstrated in many small- and large-animal models. Parker et al.,[56] in isolated perfused dog lungs, demonstrated that ventilatory pressures greater than 30 cm H_2O peak alveolar pressure resulted in VILI. Hernandez et al.,[57] Egan,[58] and Kolobow et al.[59] also demonstrated similar injuries in large-animal models. Ventilation of many species with large tidal volumes results in the development of VILI and an increase in the severity of preexisting lung injury.

The single factor most responsible for the development of VILI appears to be the transpulmonary pressure (pressure inside minus pressure outside the lung or alveolar minus pleural pressure).[55] In a now classic experiment, Dreyfuss et al.[55] demonstrated that rats with strapped chest walls were protected from VILI as compared with those ventilated with the same peak pressure but without chest wall binding. In fact the lung injury was similar regardless of the use of positive or negative pressure ventilation provided high transpulmonary pressures were established. As a result, we reason higher ventilating pressures can be used in the presence of a decreased chest wall compliance without the development of VILI, as the reduced chest wall compliance decreases transpulmonary pressure at peak airway pressure and results in a lower delivered tidal volume.

Recruitment/Derecruitment Injury: "Atelectrauma"

As noted in Fig. 83–18, the application of 10 cm H_2O PEEP in spite of a peak airway pressure of 45 cm H_2O decreased the level of VILI as compared with similar animals ventilated with the same peak pressure but at zero PEEP.[61] Only mild interstitial edema developed in animals ventilated at 10 cm H_2O PEEP. Similar findings have been reported by Corbridge et al. in dogs with hydrochloric acid-induced lung injury.[60] Dogs ventilated with 12.5 cm H_2O PEEP and a V_T of 15 mL/kg after lung injury had far less pulmonary edema at autopsy than dogs ventilated with 3.2 cm H_2O PEEP and 30 mL/kg tidal volumes, in spite of the fact that peak alveolar pressure (33 cm H_2O) was the same for both groups during the 5 hours of ventilation.

Biotrauma

Slutsky et al.[61] has referred to the activation of pulmonary and systemic inflammatory mediators by an inappropriate ventilatory pattern as *biotrauma*. Increasing data from both animal and clinical studies indicate that a traumatic ventilatory strategy can augment the level of the pulmonary and systemic inflammatory response. Tremblay et al.,[62] in an ex vivo healthy and injured rat lung model, demonstrated that both pro- and antiinflammatory mediators are activated by ventilatory patterns associated with high peak alveolar pressure and zero PEEP. For ventilated animals in which PEEP was set greater than P_{flex} (lower inflection point on the respiratory system pressure-volume curve) and overdistension was avoided, minimal mediator activation was observed. Similar data were reported by Bethmann et al. in an ex vivo perfused mouse lung model.[63] Hyperventilation at 2.5 times the normal transpulmonary pressure using either positive or negative pressure ventilation resulted in a 1.75-fold increased expression of tumor necrosis factor α (TNF-α) and interleukin-6 messenger RNA (mRNA). Imai et al.[64] and Takata et al.,[65] studying rats, noted greater TNF-α mRNA expression with conventional ventilation at low peak pressure (30 cm H_2O) and low PEEP (5 cm H_2O) as compared to high-frequency oscillation at a mean airway pressure of 15 cm H_2O (same as with conventional ventilation). Ranieri et al. showed the same effect of ventilatory pattern on pulmonary lavage and plasma TNF-α level in ARDS patients.[66] In a randomized comparison, patients ventilated with PEEP set greater than P_{flex} and peak alveolar pressure kept below the upper inflection point of the pressure-volume curve had reduced TNF-α levels in both plasma and lung lavage fluid after 36 hours. Patients randomized to PEEP based on oxygenation with V_T set to produce eucapnia increased their TNF-α levels after 36 hours. In addition the ARDSnet[45] demonstrated a lower systemic proinflammatory mediator response in a low tidal volume group of patients as compared to a high tidal volume group. Most recently, Chu et al.[67] demonstrated that lung maintained at a high lung volume either by CPAP or ventilated at the same high peak pressure resulted in the same marked activation of inflammatory mediators.

Based on these data both Slutsky and Tremblay[61] and Dreyfuss and Saumon[68] proposed that the lung was the "engine" that drives the development of multisystem organ failure in

ARDS patients. The additional lung injury resulting from inappropriate mechanical ventilation causes the movement of inflammatory mediators into the systemic circulation increasing the systemic production of mediators influencing and damaging the function of distal organs and tissues.

As a result, it seems reasonable to conclude, as discussed by Marini,[46] that "excessive mechanical forces produce lung damage by at least three mechanisms: (a) the signaling of proinflammatory mediator release by mechanical stress, (b) trauma to the epithelium of the lung parenchyma by repetitive opening at high pressures and subsequent closing with each breath, and (c) physical stress on the parenchyma by high peak alveolar pressures." Marini also points out that there is some evidence that high ventilatory frequency[69] (higher frequency, greater injury), high pre- and postalveolar microvascular pressures,[70] decreased surfactant production,[71] supine body position,[72] high body temperature,[73] and immune suppression[74] all enhance the development and severity of VILI.

LUNG-PROTECTIVE VENTILATION

As already discussed, a primary aim of ventilatory support of the surgical patient is to achieve "lung protection"; that is, to insure that the process of mechanical ventilation does not amplify the extent of lung injury. Care should always be exercised to ensure that the plateau pressure and tidal volume do not result in overdistension. In general, based on current information the tidal volume should be maintained ≤ 10 mL/kg in all acutely ill patients or patients undergoing anesthesia. In ARDS, as presented in the previous section, it is certain that smaller tidal volumes are required. At least three clinical trials have demonstrated a benefit of ventilating at 6–7 mL/kg (PBW) tidal volumes in ARDS.[45,75,76] In conjunction with these small tidal volumes, the plateau pressures should be maintained below 30 cm H_2O unless the chest wall is stiff.[46] However, the lower the plateau pressure, the less likely tidal volumes of 8–9 mL/kg will present concern.

Outside of the clinical setting of ARDS the data are less clear; however, Hubmayr et al. performed a retrospective analysis of data on mechanical ventilation in the ICU[44] and intraoperatively[77] at the Mayo Clinic, and on data from an international ventilation survey[78] that would indicate that small tidal volume (< 10 mL/kg) ventilation should be the norm used in most critically ill patients. In two of these analyses,[44,78] they found that patients in the ICU had a greater probability of developing acute lung injury when ventilated with large tidal volumes (≥ 10 mL/kg). In their most recent review,[77] they demonstrated that patients undergoing pneumonectomy at the Mayo Clinic who were ventilated intraoperatively with larger tidal volumes (median: 8.3 mL/kg) versus smaller tidal volumes (median: 6.7 mL/kg, $p < 0.001$ groups differ) were more likely to develop postoperative respiratory failure and require ventilatory support for longer than 48 hours postoperatively.

In general, rapid respiratory rates (20–40 breaths/min) are needed to maintain gas exchange at low tidal volumes. The smaller the tidal volume and the more severe the lung injury, the greater the probability that patients will require permissive hypercapnia.[54,93,94]

The most appropriate method of setting PEEP in ARDS is still highly controversial.[45,75,76,79] However, there is no question that PEEP is necessary in lung injury to prevent derecruitment. The ARDSnet[45,79] recommends the use of a PEEP/FiO_2 table for setting PEEP, but these tables do not take into consideration the patient's lung mechanics. Incremental PEEP trials have been used for years to provide a reasonable estimate of the necessary PEEP for many patients,[80] but may not be the best approach to setting PEEP in lung injury. Three prospective randomized trials have demonstrated positive outcomes when PEEP was set at P_{flex} + 2 cm H_2O.[66,75,76] In two studies,[75,76] mortality was decreased in the group ventilated with PEEP at P_{flex} + 2 cm H_2O along with a small delivered tidal volume, and in one pulmonary and systemic inflammatory mediators were attenuated when this ventilatory strategy was used.[66]

In lung injury, the method of setting PEEP that appears best is a decremental PEEP trial following a lung recruitment maneuver.[81] That is, PEEP is titrated downward from a level higher than is needed to determine the minimum level that maintains the benefit of the lung recruitment maneuver.

A number of groups have demonstrated the ability of a lung recruitment maneuver to open the lung in ARDS/ALI patients and the ability of a decremental PEEP trial to keep the lung open.[82,83,86] However, no outcome benefit has been attributed to lung recruitment maneuvers. The two lung recruitment approaches that have received the most study are the use of a sustained CPAP level of 40–50 cm H_2O for 30–40 seconds[82,84] and the use of pressure-controlled ventilation at a peak pressure of 40–50 cm H_2O along with PEEP of 20–30 cm H_2O for 1–3 minutes.[83] Lung recruitment maneuvers can open the lung of patients with lung injury and should be applied in the first few days after lung injury but only in patients who are hemodynamically stable with appropriate fluid resuscitation without the presence of, or an increased likelihood of developing barotrauma.

HIGH-FREQUENCY VENTILATION

Various approaches to high-frequency ventilation (HFV) have been employed over the last 30 years to manage patients intraoperatively, as well as to ventilate critically ill ICU patients. Although these techniques have demonstrated their ability to ventilate in both of these setting no beneficial outcome data regarding any of these techniques is available. The three common methods reported are high-frequency jet ventilation (HFJV), high-frequency percussive ventilation (HFPV), and high-frequency oscillatory ventilation (HFO).

High-Frequency Jet Ventilation

HFJV has been the approach to HFV that has been used most commonly intraoperatively.[85,86] With this technique, gas under high pressure is injected via a small-bore nozzle placed within the endotracheal tube or in the airway itself. The velocity of the gas delivery stream creates a "jet drag effect" entraining secondary gases. This technique can provide ventilatory support with or without a sealed or closed airway. As a result, it has been used successfully during upper-airway surgery, tracheal reconstruction, unilateral surgical procedures, and other procedures in which the airway is not sealed.[85,86] In addition, simple HFJV systems have been used to pro-

vide emergency ventilatory support in settings where immediate access to the airway via the pharynx is impossible.[87] This is accomplished by placing the injector through the cricothyroid membrane; however, an escape pathway for injected gases via the upper airway must be present.

High-Frequency Oscillatory Ventilation

HFO is the most commonly used high-frequency technique in the ICU. However, most of the successful applications of this ventilatory mode have been in neonates.[88] Randomized, controlled trials evaluating the use of HFO during ARDS/ALI in pediatric[89] and adult[90] populations have been negative, and HFO is considered equivalent to conventional ventilation in these settings. With HFO a high mean airway pressure is established because gas delivery is achieved by oscillating about the mean airway pressure. Tidal volumes as low as 1 mL/kg are delivered at high frequencies (8–12 Hz) in neonates. In adults, generally larger tidal volumes (2–4 mL/kg) are delivered at lower frequencies of 4–8 Hz. All clinical approaches to HFV require the use of ventilators specially designed to provide HFV.

High-Frequency Percussive Ventilation

HFPV is a unique form of ventilation that combines the effects of conventional mechanical ventilation with HFO.[91] That is, a typical pressure targeted breath is delivered but during the breath, oscillations are provided. Oscillations can also occur during the expiratory phase. The goal is to increase the distribution of ventilation and mobilization of secretions by adding the oscillations to conventional ventilation. Most of the data on HFPV has been accumulated in burn or trauma patients.[91,92] As with HFO this approach to managing critically ill patients is effective but thus far no benefit over conventional mechanical ventilation has been demonstrated.[93]

MECHANICAL VENTILATION OF THE POSTOPERATIVE PATIENT

Normal Preoperative Pulmonary Function

Surgical procedures that require general anesthesia and invade the thorax or abdominal cavity can result in impaired ventilatory function. As a result, well over 50% of cardiac and thoracic surgical patients show postoperative radiographic evidence of atelectasis.[94] In patients with normal preoperative pulmonary function, this normally does not result in any compromise. But in patients with preexisting pulmonary disease, acute respiratory failure is more common.

Initial Management

In patients without prior pulmonary disease, ventilatory management is normally uneventful. Pressure or volume assist/control is preferred with tidal volumes as large as the patient desires (6–10 mL/kg IBW) because lung function is normal and the period of total mechanical ventilation time is usually brief.[37] Five cm H_2O PEEP is applied to maintain the functional residual capacity, and the FiO_2 and rate are adjusted to maintain adequate gas exchange.

Maintenance

Ventilatory management is short-term in most patients. The FiO_2 is titrated to maintain PaO_2 >70 mm Hg and the rate or tidal volume is adjusted to maintain baseline $PaCO_2$. Patients can frequently be rapidly transitioned to pressure support and extubated quickly.

Chronic Obstructive Pulmonary Disease

Pathophysiology

Postoperative chronic obstructive pulmonary disease (COPD) patients are commonly encountered in the ICU and are challenging to ventilate. Of primary concern is patient–ventilator synchrony.[1] The single most significant factor affecting synchrony in these patients is air trapping and auto-PEEP.[47,49] In COPD patients auto-PEEP is caused by dynamic airway compression; that is, unstable airways dilate during positive-pressure inspiration but are compressed by the increased intrathoracic pressure during exhalation. Because auto-PEEP occurs distal to airways obstruction, the airway pressure proximal to the obstruction at end exhalation is normally equal to baseline ventilator circuit pressure. This means during spontaneous inspiration the patient must first decompress the auto-PEEP level, and then trigger the ventilator. This results in a marked increase in patient efforts to trigger the ventilator and dyssynchrony. Many of the patient's inspiratory efforts may not produce sufficient negative force to trigger the ventilator. The patient's actual respiratory rate is then greater than the ventilator's response rate. This increases ventilatory drive, patient respiratory rate, and the patient's overall ventilatory effort. The dyssynchrony associated with auto-PEEP can best be managed at the bedside by applying PEEP as discussed earlier (see Ventilation Settings and Patient–Ventilator Synchrony—Auto-PEEP).[35]

A second major concern is assurance that the ventilator's gas delivery rate meets the patients inspiratory demand. COPD patients who are spontaneously triggering the ventilator have their ventilatory demands best supplied with pressure, as opposed to volume ventilation.[37] However, in either case gas delivery (rise time during pressure ventilation, and peak flow and flow waveform during volume ventilation) should be set to match inspiratory demand. Inspiratory time should coincide with the patient's desired inspiratory time. In assist/control ventilation, the inspiratory time is generally set from 0.6–1.0 seconds, and with pressure-support ventilation, the inspiratory termination criteria should be adjusted to ensure a synchronous ending of inspiration.[38]

COPD patients require ventilatory support because of their inability to perform the work needed to maintain normal ("for them") gas exchange. As a result, the ventilator should ensure adequate rest but should always allow the patient to trigger the ventilator. In general, it is advisable not to use ventilatory modes that do not support every inspiratory effort, because they do not provide sufficient rest for the patient. Thus, synchronized intermittent mandatory ventilation, airway pressure-release ventilation, and bilevel ventilation should not be used in COPD.

Initial Setting

Initially, intubated, mechanically ventilated COPD patients should be managed with pressure support or assist/control (volume or pressure with pressure preferred). The delivered tidal volume should be 6–10 mL/kg PBW, dependent on plateau pressure and patient demand. Most COPD patients can be ventilated with a plateau pressure of ≤25 cm H_2O. The respiratory rate is patient determined; however, in assist/control, a backup rate sufficient to maintain the appropriate $PaCO_2$ should be set. In volume-venti-

lation mode, the peak flow should be set ≥80 L/min with a decelerating waveform. With pressure-ventilation mode, the rise time and inspiratory termination criteria (pressure support only) should be properly set. Inspiratory time is set equal to the patients neuroinspiratory time (0.6–1.0 seconds) and the PEEP level adjusted to ensure that all of the patient's inspiratory efforts trigger the ventilator.[38]

Maintenance

In many COPD patients the key medical management issue is to provide rest for the patient. After 48–72 hours of ventilatory support, many patients are ready for ventilator discontinuation. In all cases, the focus should be on providing a level of ventilatory support consistent with minimal overall ventilatory effort to ensure recovery from ventilatory muscle dysfunction. As patients recover their PEEP level, pressure support or pressure assist/control level and FiO_2 can be decreased, provided that ventilation targets can be met without markedly increasing the patient's work of breathing.

Patients requiring long-term ventilation should be considered for extensive rehabilitation, including generalized muscle retraining. Patients should be weaned with a spontaneous breathing trial and most COPD patients can be extubated after a successful 30–120-minute trial. However, those requiring long-term ventilatory support (>4 weeks) should be given a tracheotomy and will require successful 12–16-hour spontaneous breathing periods before being allowed to breathe without ventilatory support during the night.

For COPD patients who are ventilated for short periods, who meet all the criteria for weaning, and who clinically seem ready for ventilator discontinuation but continue to fail spontaneous breathing trials, carefully consider extubation to NPPV.[95–97] Some COPD patients can be successful transitioned to ventilator independence using NPPV. (See Weaning and Noninvasive Positive Pressure below.)

Acute Respiratory Distress Syndrome

Pathophysiologic Issues

ARDS and ALI are acute lung diseases characterized by atelectasis, edema, decreased compliance, and severe arterial hypoxemia. As a result, a most important issue during mechanical ventilation is to avoid inducing greater lung injury either by end-inspiratory overdistension or by the repetitive opening and closing of unstable lung units. Other important issues are the recruitment of lung, the reversal of atelectasis, and the assurance of adequate systemic oxygenation and CO_2 exchange while avoiding pulmonary oxygen toxicity.

The end-inspiratory plateau pressure should be < 30 cm H_2O to avoid lung injury unless chest wall compliance is decreased. This means for most ARDS/ALI patients the tidal volume should be set to 5–8 mL/kg PBW.[45,75,76] However, if the plateau pressure can be maintained below 25 cm H_2O and the patient desires a tidal volume up to 10 mL/kg PBW, it is more acceptable to meet the patient's demand than to force the patient to accept a low tidal volume (which may require IV sedation to apnea).

Some of the atelectasis in ARDS/ALI patients is recruitable by the use of short-term application of a "high" airway pressure (a recruitment maneuver).[82,83,84] These maneuvers work best on the initial day of identification of ARDS/ALI. The longer the patient has ARDS/ALI the less likely that recruitment maneuvers will succeed and the greater the likelihood of hemodynamic compromise. Following a recruitment maneuver, sufficient levels of PEEP should be applied to maintain the benefits of lung recruitment.

Initial Settings

Assist/control mode (Table 83–5), either pressure or volume, can be used with pressure-targeting recommended if the patient is triggering each breath and has a variable ventilatory demand. A maximum plateau pressure of 30 cm H_2O should be set at a tidal volume of 5–8 mL/kg IBW unless the plateau pressure is less than 25 cm H_2O. The rate should be set to ensure adequate CO_2 elimination. Respiratory rates can be set as high as 40 breaths/min. The rate-limiting factor is the development of auto-PEEP. In most patients, a normal $PaCO_2$ of 35–50 mm Hg can be established by adjusting the rate. In some patients with a low compliance, permissive hypercapnia may be necessary. Tolerance of hypercapnia depends on the pH, it is better to allow the $PaCO_2$ to gradually increase over a day or two to prevent the development of a marked respiratory acidosis.

TABLE 83–5.

Initial Management of ARDS/ALI

- Mode—assist/control (volume or pressure)
- Plateau pressure—<30 cm H_2O
- Tidal volume—5–8 mL/kg ideal body weight
- Inspiratory time—0.7–1.2 sec, if triggering equal to neuroinspiratory time
- Rate—≤40/min to manage $PaCO_2$
- PEEP—10–12 cm H_2O
- FiO_2—1.0 once stabilized
- Lung recruitment—35–45 cm H_2O CPAP for 30–40 sec
- FiO_2—to maintain Pao_2 >60 mm Hg
- PEEP—set by decremental trial to minimal level maintaining benefits of lung recruitment
  - ARDS—usually 12–18 cm H_2O
  - ALI—usually 8–12 cm H_2O

ALI, acute lung injury; ARDS, acute respiratory distress syndrome; CPAP, continuous positive airway pressure; PEEP, positive end-expiratory pressure.

FiO_2 should initially be set at 1.0 and PEEP at 10–12 cm H_2O until hemodynamic stability is achieved. Once the patient is hemodynamically stable a lung recruitment maneuver should be considered, using either a CPAP or pressure-assist/control approach as discussed earlier (in Lung Protective Ventilation). Before recruitment the patient should be stable hemodynamically, sedated to near apnea, and breathing 100% oxygen. Careful monitoring of the hemodynamic response and oxygenation level during the recruitment maneuver should be performed and the maneuver should be stopped if hemodynamic compromise is observed. Following the maneuver, the minimum PEEP level maintaining the oxygenation benefit of the recruitment maneuver should be applied. This is best determined by a decremental PEEP trial.[81] First, the PEEP level is set at 18–20 cm H_2O and the FiO_2 is reduced until the Pao_2 is about 70 mm Hg or the oxygen saturation as measured by pulse oximetry (SpO_2) approximately 92%. The PEEP level is then decreased in 1–2-cm H_2O steps every 10–15 minutes until the Pao_2 drops 10% from the highest level after adjusting the FiO_2 or the

arterial oxygen saturation (SaO_2) decreases below 90%. The PEEP level immediately above that resulting in the critical reduction of PaO_2 or SaO_2 is the minimal PEEP level needed to maintain the benefit of the recruitment maneuver.[82–84] At this point another recruitment maneuver is performed, after which the PEEP and FiO_2 are set at the identified levels or 2 cm H_2O higher. If another method of setting PEEP is used and the oxygenation benefit of the recruitment maneuver is lost over a brief period, the PEEP level is set too low and should be increased. Many ARDS patients will require a PEEP level of 12–18 cm H_2O and ALI patients often require a PEEP level of 8–12 cm H_2O.

Regardless of the use of pressure or volume mode ventilation the inspiratory time should be set about 0.7–1.2 seconds, depending on the patient's ventilatory demand. In patients who are breathing spontaneously, the inspiratory time should be set equal to the patients neuroinspiratory time. In volume ventilation, adequate peak flow should be provided to meet the patient's ventilatory demand (≥80 L/min) using a decelerating waveform.

Maintenance

The FiO_2 should be decreased before PEEP when oxygenation improves. PEEP generally should not be decreased until the FiO_2 is <0.50. If the Pao_2 decreases as PEEP is lowered, the prior PEEP level should be reestablished, and the FiO_2 should not be increased. When this occurs, decreasing PEEP resulted in derecruitment of lung, indicating that the higher PEEP level is needed.

Once the patient's ventilatory drive has normalized and spontaneous triggering of the ventilator can be maintained, patients with ARDS/ALI can usually be maintained with pressure-support ventilation. As with assist/control, the peak pressure should be maintained as low as possible and always <30 cm H_2O.

In patients with reduced chest wall compliances as a result of abdominal sepsis, ascites, obesity, thoracic deformity, or massive fluid resuscitation following trauma, a plateau pressure greater than 30 cm H_2O may be necessary for adequate ventilation. This is acceptable as the transpulmonary pressure is lower with the stiff chest wall preventing overdistension of the lung. However, when the plateau pressure is >30 cm H_2O, the tidal volume should be reduced to ≤6 mL/kg PBW.

In ARDS/ALI, care should be exercised to never disconnect the ventilator circuit. Whenever the circuit is disconnected from the airway, lung derecruitment occurs within seconds. Inline suction catheters should always be used and the use of manual resuscitators (Ambu bags) should be avoided. Suctioning should only occur when the presence of secretions is observed, and when performed, the suction pressure should be regulated to 120 mm Hg and performed gently to avoid lung derecruitment.

If lung recruitment and an appropriate PEEP setting is achieved but the FiO_2 remains ≥0.60 to achieve adequate oxygenation, then consider prone positioning of the patient. Although neither prone positioning nor lung recruitment have been shown to improve survival rates, both can recruit lung and may improve oxygenation. The recruitment of regions of atelectasis reduces the plateau pressure and FiO_2, improves surfactant function, and decreases the risk of pneumonia. At this time, the use of high-frequency oscillation or airway pressure-release ventilation does not appear to improve outcome in ARDS, but both modes can provide adequate management of ARDS/ALI patients. Neither mode has been shown to be superior to conventional assist/control ventilation.

Unilateral Lung Disease

Patients with unilateral lung disease present a particularly difficult challenge for mechanical ventilation. The postoperative patient after single-lung transplantation illustrates these problems. One lung has relatively normal pulmonary mechanics (the transplanted lung), whereas the native lung has mechanics reflecting either obstructive or restrictive disease. In these patients, the ventilator should be set to ensure maximum function of the native lung, as this lung will present the greatest ventilatory challenge. If the native lung has chronic obstruction, ventilate with moderate volume and slow rates. With pulmonary fibrosis of the native lung, a smaller V_T and more rapid rate are indicated. In the case of pulmonary fibrosis, there is less concern about air trapping. However, peak alveolar pressure may be high because of the reduced lung compliance.

The greatest ventilatory challenge is the patient with a single-lung transplant where the native lung is obstructed and the transplanted lung has become stiff (low compliance) as a consequence of infection, rejection, or acute lung injury. In this setting, it is difficult to determine the ideal ventilator settings because of the differing pathology of each lung. Careful attention needs to be paid to two variables as adjustments are made. First, concern about peak alveolar pressure because of ventilator imposed lung injury, damaging the transplanted lung and its bronchial anastomosis, and second, air trapping in the obstructed lung resulting in grossly compromised ventilation/perfusion ratios, overdistension, and the like. In this setting, permissive hypercapnia is often necessary with the final ventilator settings being a compromise between the conflicting needs of each lung.

WEANING

Recent guidelines recommend the use of spontaneous breathing trials for weaning all patients from ventilatory support.[98] These guidelines also recommend that protocols be developed to allow assessment for weaning from the first day of ventilatory support. Table 83–6 lists the criteria for initiation of a spontaneous breathing trial for any patient requiring ventilatory support. Table 83–7 lists guidelines to identify those patients having failed a trial of spontaneous breathing.

If a patient meets the guidelines in Table 83–6 by midnight, sedation should

TABLE 83–6.

Criteria for Conducting a Spontaneous Breathing Trial

- Partial reversal of factors contributing to ventilator dependence
- Assessment of oxygenation
  - PaO_2/FiO_2 ≥150 mm Hg
  - Positive end-expiratory pressure ≤8 cm H_2O
  - FiO_2 ≤0.5
  - pH ≥7.25
- Hemodynamic stability—only low-dose vasopressures required
- Spontaneous inspiratory efforts present

Adapted from Evidence-based guidelines for weaning and discontinuing ventilatory support.[98]

TABLE 83–7.

Criteria Defining Failure of a Spontaneous Breathing Trial

- Respiratory Rate >35 breaths/min
- SaO_2 <90%
- Pulse >140 beats/min or sustained increase of 20%
- Systolic blood pressure >180 mm Hg or diastolic blood pressure >90 mm Hg
- Increased anxiety
- Increased diaphoresis

Adapted from Evidence-based guidelines for weaning and discontinuing ventilatory support.[98]

be adjusted to ensure spontaneous breathing by early morning. A 30–120-minute spontaneous breathing trial is performed, and if the patient does not fail the trial based upon the criteria in Table 83–7, consider the patient for extubation.[98] After short-term ventilatory support most clinicians do not recommend measuring lung mechanics. Even the rapid shallow breathing index has not proven universally useful in identifying those patients who are ready for weaning. All of the current data indicates that the use of other approaches to weaning simply results in prolongation of the ventilatory support period.[95] Patients failing weaning trials should be carefully assessed for the specific factors causing failure. Table 83–8 from Ely lists areas of concern that should be assessed in the patient falling multiple weaning trials.[99] Finally, in some patients, the use of NPPV may facilitate the process of transition to unsupported spontaneous breathing.[95–97]

NONINVASIVE POSITIVE PRESSURE

Over the last 15 years increasing emphasis has been placed on the use of noninvasive (without tracheal intubation) positive-pressure to support patients developing respiratory failure.[100] Although, much of the emphasis in such studies has focused on the patient with COPD in an acute exacerbation,[101] a number of trials over the years have focused on the use of NPPV[102] or CPAP for the management of postoperative patients.[103–107]

The primary mechanism producing arterial hypoxemia after surgery is impaired ventilation-to-perfusion matching as a result of the development of atelectasis.[107] Atelectasis in this setting is a result of recumbent positioning, ventilation with high oxygen concentrations, diaphragmatic dysfunction, and incisional pain producing impaired secretion clearance.[103] Several studies show that mask CPAP ventilation in this setting improves gas exchange, minimizes the development of atelectasis, and increases functional residual capacity.[103–107] Most of these studies were case series;[103–106] the most recent study, however, was a randomized controlled trial.[107] Squadrone et al.[107] demonstrated that mask CPAP at 7.5 cm H_2O at 0.5 FiO_2 for 6 hours in all patients following major elective abdominal surgery with a PO_2/FiO_2 < 300 mm Hg prevented intubation compared to those receiving 50% oxygen by a venturi mask (1% vs. 10% intubation rate; $P < 0.005$). In addition, significant decreases in subsequent pneumonia and sepsis rates were observed.

In postoperative lung resection patients with hypoxemic respiratory failure, Auriant et al.[102] demonstrated that the use of NPPV versus standard care prevented intubation ($P = 0.030$) and decreased hospital mortality ($P = 0.045$). Although CPAP and NPPV are useful in treating postoperative respiratory failure, they should be cautiously applied and tracheal intubation for patients not responding to these therapies should not be delayed.[108] These concerns were recently illustrated by Delclaux et al.[108] They randomized patients with hypoxemic respiratory failure to either CPAP or standard therapy. They found no difference in the subsequent intubation rate or the mortality rate but a greater incidence of cardiac arrest and stress ulcers in those managed with CPAP.

A number of recent studies have focused on the use of NPPV in the weaning process. The most commonly studied patients are those with COPD. At least two groups have shown beneficial results with COPD patients who were failing weaning trials and who were extubated and ventilated with NPPV; that is, NPPV provided a bridge from invasive ventilation to spontaneous breathing in these patients failing weaning trials.[95,96] However, it must be emphasized that these COPD patients were not postoperative patients.

The most encouraging use of NPPV during weaning are the results reported by Nava[109] and Ferrer.[110] In both of these studies patient's passing their weaning trials and who were then extubated but at risk for failing extubation were studied. Those managed postextubation for 24–48 hours with NPPV had a significant decrease in their likelihood of needing reintubation. In these settings, the increased risks were defined as COPD, congestive heart failure, an Acute Physiology and Chronic Health Evaluation (APACHE) score >12, age >65 years, ineffective cough, and excessive secretions, 1 or more weaning failures, upper airway obstruction, or more than 1 comorbid condition. Of note, however, very few of these patients were postoperative patients.

TABLE 83–8.

Factors Contributing to Ventilator Dependence in Difficult-to-Wean Patients

WHEANS NOT

- Wheezes
- Heart disease
- Electrolyte imbalance
- Anxiety, aspiration, alkalosis
- Neuromuscular weakness
- Sepsis, sustained sedation
- Nutritional deficits
- Opiates not reversed, obesity
- Thyroid disease

Adapted from Ely WE.[99]

There is considerable concern over the use of NPPV for the patient developing postextubation hypoxemic respiratory failure. Keenan et al.[111] demonstrated no benefit from the use of NPPV as compared to standard therapy in about 160 randomized patients. No differences were observed in the length of mechanical ventilation, hospital stay or hospital mortality. Of even more concern was the increased mortality reported by Esteban et al.[112] in patients with postextubation hypoxemic respiratory failure who were managed with NPPV. These authors argue that the primary reason for the increased mortality was the delay in intubating those who were treated with NPPV (12 vs. 2 hours).

Based on the current data from these randomized controlled trials, NPPV is best employed for patients passing weaning trials who are at an increased risk of developing respiratory failure as described by Nava[109] and Ferrer.[110]

Cardiopulmonary Resuscitation

Charles W. Otto, MD, FCCM

In the hospital, resuscitation from cardiac arrest depends on the rapid response of a well-trained cardiopulmonary resuscitation (CPR) team that usually includes physicians, nurses, respiratory care providers, and pharmacists. The anesthesiologist is usually a team member and frequently is expected to be the leader. The team must communicate readily and be coordinated. Providing the knowledge base and framework for effective teamwork are the goals of published CPR guidelines and widely taught courses in basic life support (BLS), advanced cardiac life support (ACLS), and pediatric advanced life support (PALS).[1] The anesthesiologist must be thoroughly familiar with ACLS protocols to function within the team. Team leadership requires in-depth, current knowledge of physiology, pharmacology, and alternative CPR techniques. This chapter provides the scientific background on which current CPR practice is based. It focuses exclusively on cardiac arrest. Other circumstances requiring cardiovascular support, such as shock and dysrhythmias, are discussed in other chapters.

Approximately 50% of patients suffering in-hospital cardiac arrest are resuscitated and 18% of adults and 27% of children survive to discharge.[2] The operating room is the location where CPR has the highest rate of success. Cardiac arrest occurs approximately 7 times for every 10,000 anesthesia events.[3] The cause for the arrest is anesthesia-related approximately 4.5 times for every 10,000 anesthesia events but mortality from these arrests is only 0.4 per 10,000 anesthesia events. Resuscitation is successful approximately 90% of the time in anesthesia-related cardiac arrests. Excluding the operating room, the best initial resuscitation rates are found in the intensive care unit (ICU), while the best survival rates are for patients arresting in the emergency department. The in-hospital success is similar to resuscitation and survival rates from out-of-hospital arrest in cities with rapid response emergency medical systems.[4] In out-of-hospital arrests, poor outcomes are associated with (a) long arrest times before CPR is begun, (b) prolonged ventricular fibrillation without definitive therapy, and (c) inadequate coronary and cerebral perfusion during CPR.[5] Optimum survival from ventricular fibrillation is obtained only if basic CPR is started within 4 minutes and defibrillation applied within 8 minutes.[4] A better outcome might be expected for in-hospital arrests because of rapid response times and expert personnel. Intercurrent illnesses of hospitalized patients reduce the likelihood of survival and the arrest victim is more likely to be elderly, a factor that may reduce survival. The cause of arrest associated with the best outcome and the most common cause of out-of-hospital arrest is ventricular fibrillation secondary to myocardial ischemia. This initiating event is less common in hospitalized patients. When applying CPR, attention to the details of effective resuscitation is important. However, CPR is only symptomatic therapy; attention should

KEY POINTS

1. In many resuscitation attempts, both in- and out-of-hospital, chest compressions are performed for less than 50% of the time. Interrupting compressions is detrimental to maintaining myocardial perfusion and, therefore, to the ultimate success of the resuscitation attempt.
2. Fluctuations in intrathoracic pressure play a significant role in blood flow during most resuscitations and the cardiac pump mechanism contributes under some circumstances.
3. Cardiac output is severely depressed during cardiopulmonary resuscitation (CPR), ranging from 10–33% of prearrest values in experimental animals. Nearly all of the cardiac output is directed to organs above the diaphragm.
4. During CPR, measurement of blood gases reveals an arterial respiratory alkalosis and a venous respiratory acidosis because the arterial PCO_2 is reduced and the venous PCO_2 is elevated.
5. The critical myocardial blood flow is associated with aortic "diastolic" pressure exceeding 40 mm Hg.
6. Exhaled end-tidal CO_2 is an excellent noninvasive guide to the effectiveness of standard CPR.
7. Immediate defibrillation is only effective if applied within 4–5 minutes of collapse. Otherwise, a brief period of 2–3 minutes of chest compressions before defibrillation is necessary.
8. Lidocaine and amiodarone are used during cardiac arrest to aid defibrillation when ventricular fibrillation is refractory to electrical countershock therapy or when fibrillation recurs following successful conversion.
9. Of the drugs used during CPR, only vasopressors have been acknowledged to help restore spontaneous circulation.
10. Outcome studies prospectively comparing standard and high-dose epinephrine have not demonstrated conclusively that higher doses will improve survival.
11. Evidence currently suggests that, like other potent vasopressors, vasopressin is equivalent to but not better than epinephrine for use during CPR.
12. Calcium is not indicated for use during cardiac arrest in adults or children. It may be useful for treatment of hyperkalemia, ionized hypocalcemia, hypermagnesemia, or calcium channel blocker toxicity.
13. Sodium bicarbonate should be considered for use during CPR only in arrests associated with hyperkalemia, severe preexisting metabolic acidosis, and tricyclic or phenobarbital overdose. It may be considered for use in protracted resuscitation attempts after other modalities have been instituted.
14. In contrast to pharmacologic therapy, two studies demonstrate improved neurologic outcome when mild therapeutic hypothermia (89.6–93.2°F [32–34°C]) is induced for 12 – 24 hours in cardiac arrest survivors who remained comatose after admission to the hospital.

not be paid to the mechanics of CPR only, but also should include a search for a treatable cause of the arrest.

HISTORY

Discoveries contributing to modern CPR have a long history recorded in many famous works.[6,7] They begin with the Bible story of Elisha breathing life back into the son of a Shunammite woman (II *Kings* 4:34) and continue with Andreas Vesalius' description of tracheotomy and artificial ventilation, William Harvey's manual manipulation of the heart, and the teachings of the Society for the Recovery of Persons Apparently Drowned, founded in London in 1774. Nevertheless, the combined techniques of modern CPR are less than 50 years old. Although there were significant contributions from other centers in the United States and Europe, modern CPR developed primarily from the fortuitous assemblage of innovative clinicians and researchers in Baltimore in the 1950s and early 1960s. In the late 1950s, Elam, Safar, and Gordon established mouth-to-mouth ventilation as the only effective means of artificial ventilation.[8–11] The internal defibrillator was developed in 1933,[12] but not applied successfully until 1947.[13] It was another decade before general use was made possible by the development of external transthoracic defibrillation.[14,15] Despite these advances, widespread resuscitation from cardiac arrest was not possible until Kouwenhoven, Jude, and Knickerbocker described success with closed chest cardiac massage in a series of patients.[16] The final major component of modern CPR was added in 1963 when Redding and Pearson described the improved success obtained by administering epinephrine or other vasopressor drugs.[17]

BASIC LIFE SUPPORT

BLS consists of those elements of resuscitation that can be performed without additional equipment: airway management, ventilation, and chest compressions. Physiologically, the objective of performing CPR is to provide oxygen to the vital organs, especially the heart, and the brain until normal circulation is restored. Common practice is to approach a victim with the ABC (airway, breathing, circulation) sequence although the CAB (circulation, airway, breathing) sequence has been used in some countries with comparable results. Box 84–1 gives the full sequence for initiating CPR in an apparent arrest victim and Fig. 84–1 illustrates the technique of infant chest compressions. If complete resuscitation equipment and expertise in its use is available, the overall priorities of resuscitation may dictate altering this sequence (Box 84–2).

THE IMPORTANCE OF THE TIMING OF INTERVENTIONS DURING CPR

It is now clear that cardiac arrest caused by ventricular fibrillation can be characterized in three phases (Table 84–1).[21] The electrical phase occurs during the first 4–5 minutes of the arrest and early defibrillation is critical for success during this time. The hemodynamic phase follows for the next 10–15 minutes when perfusing the myocardium with oxygenated blood is critical. This is followed by what has been called the metabolic phase when the ischemic injury to the heart is so great that it is not clear what interventions will be successful. What is obvious from this timeline is that early intervention is necessary for resuscitation attempts to be successful. This requires not only rapid response emergency medical systems for out-of-hospital arrests and appropriate code teams for in-hospital arrests, but it requires immediate intervention by bystanders when cardiac arrest victims collapse. Unfortunately, the incidence of bystander CPR has been falling for 3 decades. The reasons for this reluctance to intervene are multiple but seem to be primarily (a) lack of training, (b) the complexity of the task, and (c) fear of harm. Many of these concerns focus on the mouth-to-mouth ventilation part of the CPR intervention and many experts are now stressing the importance of continuous chest compressions, even at the expense of ventilation, by bystanders and early rescuers. There is no doubt that chest compression-only CPR by bystanders is more acceptable for most, easier to learn and retain, and provides better hemodynamic support.

Early studies in anesthetized humans suggested that the airway would not remain open in the unconscious,

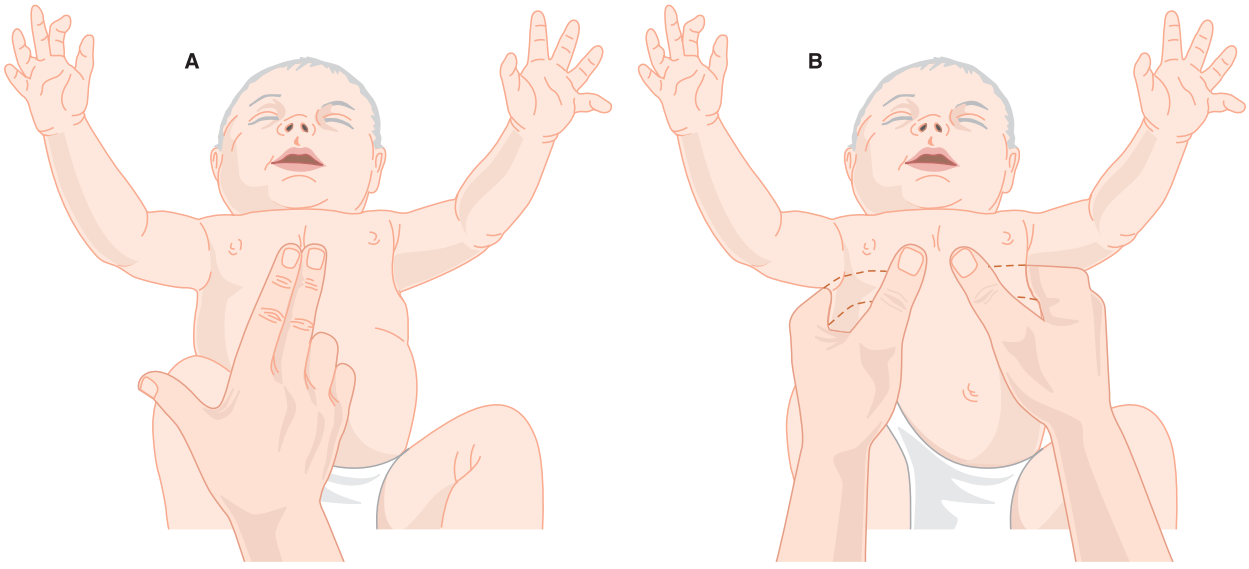

FIGURE 84–1. **A.** Two-finger method of external chest compression in infants. Rescuer places 2 fingers on the sternum and 1 finger-breadth below the line intersecting the nipples and compresses 0.5–1 inch at a rate of 100 compressions per minute. Ventilation is not shown for the sake of clarity. **B.** Encircling method of external chest compression in infants. Rescuer places thumbs over sternum 1 fingerbreadth below the line intersecting the nipples and clasps hands behind infant's back.

leading to the teaching that airway control and artificial ventilation must accompany chest compressions.[8–11] However, there is now considerable data to suggest that eliminating mouth-to-mouth ventilation early in the resuscitation of witnessed fibrillatory cardiac arrest is not detrimental to outcome and may improve survival. Data from the Belgian CPCR Registry demonstrates that 14-day survival and neurologic outcome are the same regardless of whether bystanders initiate full basic life support or only do chest compressions. Both are significantly better than if the bystanders only do mouth-to-mouth ventilation or attempt no CPR.[22,23] The necessity for ventilation during basic life support has been studied in animal models. Multiple studies have been reported by two research groups of 169 swine with up to 5 minutes untreated *fibrillatory* cardiac arrest and 10 minutes of BLS, comparing chest compressions without airway control or ventilation to standard CPR with ventilation.[24–26] Both techniques resulted in approximately 75% neurologically normal 24–48-hour survival. A similar study in an *asphyxial* arrest model showed that assisted ventilation during bystander CPR was critical for survival.[27] The animal studies are supported by a study of telephone dispatcher instructions in CPR techniques to inexperienced bystanders. Instruction in chest compressions only resulted in the same survival as instruction in both compressions and ventilation.[28] These observations suggest that when arrest is witnessed, likely to be of cardiac (rather than respiratory) cause, and intubation will be available within a short time, closed chest compressions alone may be as efficacious as compressions and mouth-to-mouth ventilation. In many venues, basic life support teaching for the lay rescuer is being simplified to eliminate mouth-to-mouth ventilation. Just as importantly, there is renewed interest in importance of not interrupting chest compressions. Compressions are interrupted for repeated patient assessment, ventilations, intubation, central line placement, changing rescuers, and defibrillation (especially with automatic external defibrillators [AEDs]). In many resuscitation attempts both in- and out-of-hospital, chest compressions are performed for less than 50% of the time. Interrupting compressions is significantly detrimental to maintaining myocardial perfusion and, therefore, to the ultimate success of the resuscitation attempt.

BOX 84–2.

Interventional Priorities during CPR If All Necessary Equipment and Expertise Are Available

- Diagnose ventricular fibrillation and defibrillate
- Open airway
- Begin ventilation
- Begin chest compressions
- Administer supplemental oxygen
- Obtain intravenous access
- Administer epinephrine or vasopressin
- Assess adequacy of CPR efforts
- Secure airway
- Additional drug therapy

AIRWAY MANAGEMENT

The goal of airway management during cardiorespiratory arrest is the

TABLE 84–1.

Phases of Cardiac Arrest

Phase	Time from Collapse	Intervention
Electrical	4–5 minutes	Defibrillation
Hemodynamic	15–20 minutes	Myocardial perfusion
Metabolic	>20 minutes	Unknown

same as during general anesthesia: to provide a clear path for respiratory gas exchange while minimizing gastric insufflation and the risk of pulmonary aspiration. Airway maintenance in an unconscious patient is a basic part of anesthesia practice and all the techniques learned for use during anesthesia are applicable to the cardiac arrest victim. Just as in the operating room, the most commonly used technique for opening the airway is the "head tilt–chin lift" method. If this is ineffective, the "jaw thrust" maneuver is frequently helpful. Oropharyngeal and nasopharyngeal airways are useful for helping maintain an open airway in patients that are not intubated. Care must be used to ensure they are correctly inserted and do not worsen airway obstruction. Insertion in the semiconscious can induce vomiting or laryngospasm.

Effective airway management during CPR is a major problem, even for medical professionals. Many individuals cannot manage a self-inflating resuscitation bag and mask effectively. Larger tidal volumes at lower pressures are delivered by mouth-to-mouth or mouth-to-mask ventilation.[18] The bag and mask apparatus is more effective if two individuals manage the airway: one to hold the mask and maintain the airway and one to squeeze the bag.[19] A number of airway devices designed for blind placement have been described for use by individuals who are not skilled laryngoscopists. The combination esophageal-tracheal tube (Combitube) and the laryngeal mask airway (LMA) have been studied for use during CPR. None of these methods allow the degree of airway control that is obtained with an endotracheal tube. However, no method of ventilation has been proven to be superior to the others in promoting successful resuscitation.[20] Intubation may be performed in prolonged resuscitations if a skilled laryngoscopist is available. However, it should not be performed until adequate ventilation by other means (preferably with supplemental oxygen) and circulation by chest compressions have been established and defibrillation performed, if appropriate (Box 84–2). When other methods of establishing an airway are unsuccessful, translaryngeal ventilation or tracheotomy by cricothyroid puncture may be lifesaving (Fig. 84–2).

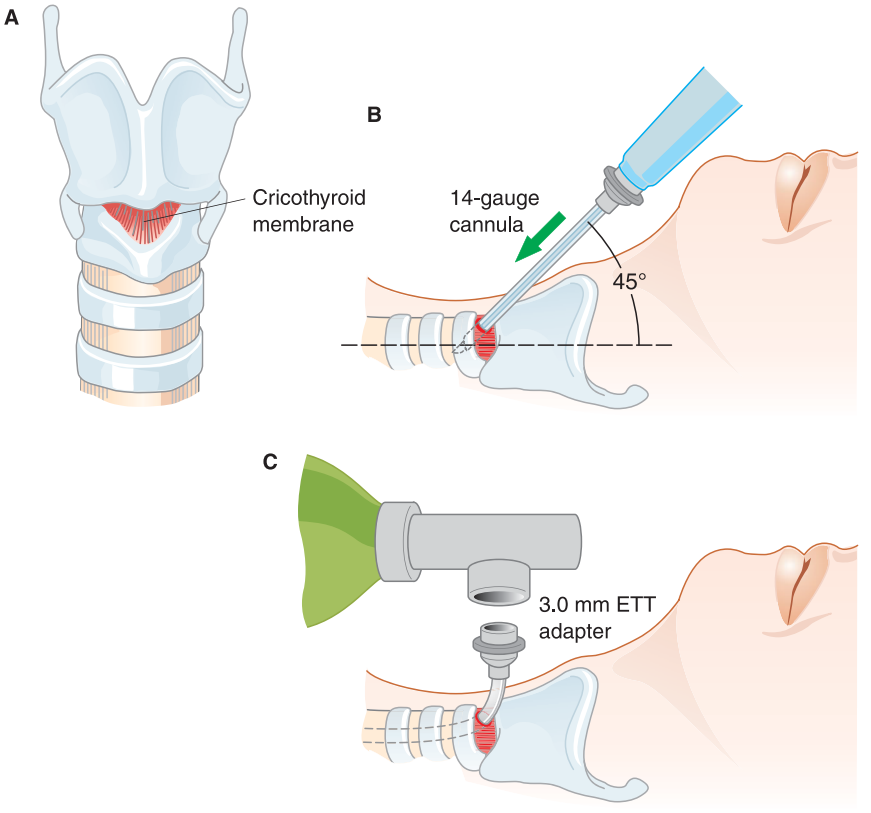

FIGURE 84–2. Cricothyroidotomy. **A**, Anatomic view. **B**, Insertion of 14-gauge IV cannula. **C**, Bag attached to 3.0 endotracheal tube (ETT) adaptor connected to IV cannula.

VENTILATION

Currently, airway management and ventilation remain the standard first steps of CPR. Mouth-to-mouth or mouth-to-nose ventilation is the most expeditious and effective method immediately available. Although inspired gas with this method contains approximately 4% carbon dioxide and only approximately 17% oxygen (composition of exhaled air), it is sufficient to maintain viability. Mouth-to-mask ventilation using a simple anesthesia face mask also is very effective. If the mask is fitted with a nipple adapter, a flow of oxygen can also supplement inspired oxygen concentration. The self-inflating resuscitation bag with mask also can be used with or without supplemental oxygen. Recommendations for ventilation are 2 breaths to 30 chest compressions during basic life support, as summarized in Box 84–3. Once an advanced airway (endotracheal tube, LMA, Combitube) is in place, ventilation should proceed at 8–10 breaths/min without concern for synchronizing ventilation with chest compressions. Do not hyperventilate. Blood flow during CPR slows rapidly when chest compressions are stopped and recovers slowly when they are restarted. Consequently, unless the cause of arrest is hy-

BOX 84–3.

Ventilation during Basic Life Support

A. Healthcare provider(s) without advanced airway
   1. 6–8 breaths/min, each delivered over 1 second
   2. Pause 2.0 seconds for 2 breaths after every 30 chest compressions
   3. Tidal volume adequate to cause chest rise (~0.5–0.6 L)

B. Healthcare provider(s) with advanced airway
   1. 8–10 breaths/min adequate to make chest rise (~0.5–0.6 L)
   2. Do not pause chest compressions for ventilation
   3. Avoid hyperventilation

poxia, emphasis should be on maintaining chest compressions with as little interruption as possible.

Physiology of Ventilation during CPR

In the absence of an endotracheal tube, the distribution of gas between the lungs and stomach during mouth-to-mouth or mask ventilation will be determined by the relative impedance to flow into each; that is, the opening pressure of the esophagus and the lung–thorax compliance. It is likely that esophageal opening pressure during cardiac arrest is no more than that found in anesthetized individuals (~20 cm H_2O) and lung–thorax compliance likely is reduced. To avoid gastric insufflation, inspiratory airway pressures must be kept low.

Insufflation of air into the stomach during resuscitation leads to gastric distension, impeding ventilation and increasing the danger of regurgitation and gastric rupture. If gastric insufflation is to be avoided, inspiratory airway pressures must be kept low. Partial airway obstruction by the tongue and pharyngeal tissues often leads to increased airway pressures and gastric insufflation. A useful aid to minimizing gastric insufflation is the use of cricoid pressure (Sellick maneuver).[29] Pressure applied over the anterior arch of the cricoid cartilage can prevent air from entering the stomach at airway pressures up to 100 cm H_2O.[30] Meticulous attention to maintaining an open airway is necessary during rescue breathing. To cause a rise in the chest of most adults, a tidal volume of 0.5–0.6 L will be needed. Rescue breaths should be given as quickly as possible without causing gastric insufflation.

CIRCULATION

Physiology of Circulation during Closed Chest Compressions

Two mechanisms of blood flow during closed chest compression have been described.[15,31] In the cardiac pump mechanism, the heart is compressed between the sternum and spine, resulting in ejection of blood from the heart into the aorta with the atrioventricular valves preventing backward blood flow. In the thoracic pump mechanism, chest compression raises intrathoracic pressure, forcing blood out of the chest, with venous valves and dynamic venous compression preventing backward flow and the heart acting as a passive conduit. The two mechanisms are not mutually exclusive (Fig. 84–3). Fluctuations in intrathoracic pressure play a significant role in blood flow during most resuscitations and the cardiac pump mechanism contributes under some circumstances. Which mechanism predominates probably varies from victim to victim and even during the resuscitation of the same victim.

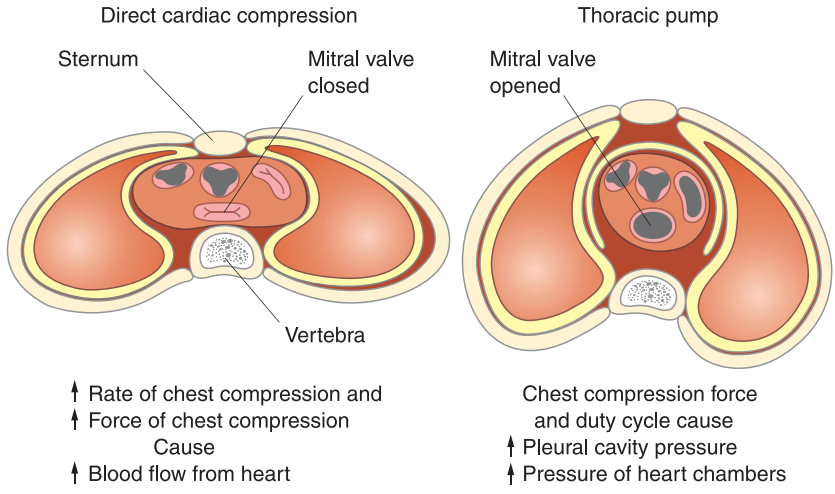

FIGURE 84–3. Possible mechanisms for blood flow during CPR include direct cardiac compression and the thoracic pump. With direct cardiac compression, an increase in chest compression rate causes an increase in blood flow by squeezing the heart between the vertebral column and sternum. With the thoracic pump mechanism, factors that increase pleural pressure cause an increase in pressure within the heart chambers and, ultimately, an increase in blood flow.

Cardiac output is severely depressed during CPR, ranging from 10–33% of prearrest values in experimental animals. Nearly all of the cardiac output is directed to organs above the diaphragm. Brain blood flow is 50–90% of normal and myocardial blood flow 20–50% of normal, while lower extremity and abdominal visceral flow is reduced to less than 5% of normal. Total blood flow tends to decrease with time but the relative distribution of flow does not change. Flow to the brain and heart are improved by the administration of vasopressors, while flow to organs below the diaphragm is unchanged or further reduced.

Physiology of Gas Transport during CPR

During CPR, measurement of blood gases reveals an arterial respiratory alkalosis and a venous respiratory acidosis because the arterial PCO_2 is reduced and the venous PCO_2 is elevated. The cause is not respiratory in origin. Rather, these changes result from decreased cardiac output. During the low-flow condition of CPR, excretion of CO_2 (mL of CO_2/min in exhaled gas) is decreased approximately to the same extent as cardiac output is reduced. This reduced CO_2 excretion is primarily a result of shunting of blood flow away from the lower half of the body. The exhaled CO_2 reflects only the metabolism of the part of the body that is being perfused. In the nonperfused areas, CO_2 accumulates during CPR. When normal circulation is restored, the accumulated CO_2 is washed out and a temporary increase in CO_2 excretion is seen.

Although CO_2 excretion is reduced during CPR, the mixed venous partial pressure of CO_2 (Pv_{CO2}) usually is increased.[32] Two factors account for this elevation. Buffering acid causes a reduction in serum bicarbonate, so that the same blood CO_2 content results in a higher Pv_{CO2}. In addition, the mixed venous CO_2 content is elevated. When flow to a tissue is reduced, not all the produced CO_2 is removed, and CO_2 accumulates, increasing the tissue partial pressure of CO_2. This allows more CO_2 to be carried in each aliquot of blood, and mixed venous CO_2 content increases. If flow remains constant, a new equilibrium is established where all CO_2 produced in the tissue is removed but at a higher venous CO_2

content and partial pressure. In contrast to the venous blood, arterial CO_2 content and partial pressure ($PaCO_2$) are decreased during CPR. This accounts for most of the observed increase in arterial–venous CO_2 content difference. Although venous blood may have an increased CO_2, the marked reduction in cardiac output with maintained ventilation results in very efficient CO_2 removal.

Decreased pulmonary blood flow during CPR causes lack of perfusion to many nondependent alveoli. The alveolar gas of these lung units has no CO_2. Consequently, mixed alveolar CO_2 (i.e., end-tidal CO_2) will be very low and correlate poorly with arterial CO_2. However, end-tidal CO_2 does correlate well with cardiac output during CPR. As flow increases, more alveoli become perfused, there is less alveolar dead space, and end-tidal CO_2 measurements rise.

Technique of Closed Chest Compression

Cardiac arrest should be presumed in the absence of a pulse in the major arteries (carotid, femoral, axillary) of an unconscious patient. After opening the airway and providing two ventilations, search for a pulse should be made before starting chest compressions. If weak circulation exists in a patient with a primary respiratory arrest, pulses may return after adequate ventilation and compressions may not be necessary (Box 84–1).

Standard chest compression technique consists of the rhythmic application of pressure over the lower half of the sternum. For compressions to be effective in providing blood flow to the brain and heart, the patient must be on a firm surface with the head level with the heart. The rescuer should stand or kneel at the side of the patient so that the hips are on a level with the victim's chest. Using the weight of the entire upper body, the compression is delivered straight down with enough force to depress the sternum 3.5–5.0 cm in adults and one-third to one-half the depth of the chest in children and infants. Following maximal compression, pressure is released completely from the chest. Chest compressions should be performed at a rate of 100 per minute. They are most effective if the compression and relaxation phases of the cycle are equal in length. This 50% compression time is easier to achieve at faster compression rates.

Alternative Techniques of Circulatory Support

Better understanding of circulatory physiology during CPR, especially involving the thoracic pump mechanism, has resulted in several proposals for alternative techniques or adjunct devices in recent years. Most are intended to provide better hemodynamics and extend the duration during which CPR can support viability. Unfortunately, none has proven reliably superior to the standard technique, and no improvement in survival from cardiac arrest has been demonstrated consistently. Initial studies suggested hemodynamic advantages for techniques that raised intrathoracic pressure (simultaneous ventilation/compression, abdominal binding with compression, pneumatic antishock garment). Further investigations found that right atrial pressure and intracranial pressure were raised by these techniques, frequently more than aortic pressure. Consequently, there was no improvement in cerebral or myocardial blood flow. Outcome studies with these techniques found no improvement in resuscitation success compared to standard CPR. They are currently not recommended for support of the cardiac arrest victim.

Interposed Abdominal Compression CPR

Interposed abdominal counterpulsation (IAC) CPR consists of a dedicated rescuer providing manual abdominal compression between the xiphoid and umbilicus during the relaxation phase of conventional CPR.[33] IAC-CPR increases venous return and compresses the abdominal aorta to produce retrograde aortic flow, closing the aortic valve and augmenting diastolic pressure. Although initial hemodynamic studies were encouraging, a large randomized study of out-of-hospital arrest found no improvement in survival compared to standard CPR.[34] Two subsequent in-hospital studies using trained providers found improved return of spontaneous circulation (ROSC) and short-term survival with IAC-CPR compared to the standard technique.[35,36] In general, there has not been improvement in long-term survival with the use of this technique. Reports of human studies demonstrate the frequency of complications, including laceration of abdominal viscera or esophageal regurgitation, is not increased with IAC-CPR. During in-hospital resuscitation, IAC-CPR may be considered when there are sufficient personnel trained in its use. Its use for out-of-hospital arrest remains experimental.

Active Compression–Decompression CPR

Active compression–decompression (ACD) CPR developed from the anecdotal report of CPR performed with a plumber's helper applied to the anterior chest wall.[37] This suggested that active decompression of the chest wall might reduce intrathoracic pressure during the relaxation phase of chest compressions, leading to improved venous return, increased stroke volume with compression, and better blood flow. Devices that can be applied to the chest wall in order to enable active compression and decompression have been developed but none is currently approved by the FDA for sale in the United States. Hemodynamic studies in animals and humans show that coronary and cerebral perfusion may be somewhat improved with this method compared to standard CPR, although when epinephrine is used, there is no difference between techniques.[38,39] Clinical trials have found mixed results, with 4 showing improved resuscitation and 5 demonstrating no difference from the standard technique. A meta-analysis of 4162 patients in 10 out-of-hospital trials and 826 patients in 2 in-hospital trials found no difference in early or late survival with ACD-CPR compared to standard CPR.[40]

Impedance Threshold Device

The impedance threshold device (ITD) is a valve that limits the flow of air into the lungs during the relaxation phase of chest compressions, reducing intrathoracic pressure during chest recoil and enhancing venous return.[41] Originally designed for use with an endotracheal tube, it has been adapted for use with a face mask assuming a tight seal with the face is maintained. It has frequently been studied in association with ACD-CPR in the belief that the two techniques would act synergistically to improve venous return. Two randomized trials of the combined techniques found improved ROSC and 24-hour survival compared to the standard technique.[42,43] One randomized trial of adding the ITD to standard CPR found improved admission to the ICU

and 24-hour survival.[44] No studies have demonstrated improved long-term survival.

Pneumatic Vest CPR and Load-Distributing Band CPR

Pneumatic vest CPR is a method of increasing intrathoracic pressure by phasically inflating a bladder around the chest (with or without simultaneous ventilation), without significantly changing the dimensions of the chest.[45,46] Experimental animal studies show excellent hemodynamics and the ability to maintain viability for prolonged periods. The technique continues to be investigated with a number of modifications from the original method. A recent modification is the load-constricting band (LCB) device consisting of a pneumatically or electrically actuated constricting band and backboard. One preliminary report using this device found improved survival to emergency department admission compared to standard CPR in out-of-hospital cardiac arrest.[47]

Invasive Techniques

In contrast to the closed chest techniques, two invasive methods have been able to maintain cardiac and cerebral viability during long periods of cardiac arrest. In animal models, open-chest cardiac massage and cardiopulmonary bypass (through the femoral artery and vein using a membrane oxygenator) can provide better hemodynamics and myocardial and cerebral perfusion than closed chest techniques.[48,49] When performed after 15 minutes of closed-chest CPR, open-chest CPR significantly improves coronary perfusion pressure and the rate of successful resuscitation.[50] When initiated early (probably within 20–30 minutes of arrest) following failure of closed-chest CPR, open-chest CPR may improve resuscitation.[53–55] However, if open chest massage is begun after 30 minutes of ineffective closed chest compressions, there is no better survival even though hemodynamics are improved.[56]

Preliminary trials of percutaneous cardiopulmonary bypass for refractory human cardiac arrest have been reported[51] and this is a technique available in some institutions. Prompt restoration of blood flow and perfusion pressure with cardiopulmonary bypass can provide resuscitation with minimal neurological deficit after 20 minutes of fibrillatory cardiac arrest in canines.[52]

Monitoring during CPR

Assessment of the patient during CPR is similar to other clinical situations; Box 84–4 lists the major points. A basic clinical examination and adherence to basic principles, including inspection, palpation, and auscultation of the patient, are performed. The chest is carefully observed for adequacy of chest expansion with artificial ventilation and for equal and normal breath sounds. In addition, the depth of compression and the position of the rescuer's hands in performing chest compressions should be reevaluated constantly.

Successful resuscitation in experimental models is associated with myocardial blood flows of 15–20 mL/min/100 g (Table 84–2).[57] Obtaining such flows requires that closed chest compressions generate adequate cardiac output and coronary perfusion pressure. During CPR, coronary perfusion occurs primarily during the relaxation phase (diastole) of chest compression. The critical myocardial blood flow is associated with aortic "diastolic" pressure exceeding 40 mm Hg and coronary perfusion pressure (aortic diastolic minus right atrial diastolic pressure) exceeding 25 mm Hg in animal models.[57–67] One report has confirmed similar findings in humans, noting that all patients with successful return of spontaneous circulation had coronary perfusion pressures higher than 15 mm Hg.[67] The use of an indwelling arterial catheter, when available, is an invaluable monitor in assessing the arterial blood pressure and estimating these critical perfusion pressures. In addition, an arterial line allows for determination of arterial blood gases. If pressures are below the critical levels (Table 84–2), adjustments should be made to improve chest compressions and/or additional epinephrine should be administered. Greater pressures do not ensure success. Damage to the myocardium from underlying disease may preclude survival no matter how effective the CPR efforts. However, inadequate vascular pressures consistently result in poor outcomes.

Although invasive pressure monitoring may be the ideal, exhaled end-tidal CO_2 is an excellent noninvasive guide to the effectiveness of standard CPR.[68] Carbon dioxide excretion during CPR with an endotracheal tube in place is dependent primarily on flow rather than ventilation. Since alveolar dead space is large during low-flow conditions, end-tidal CO_2 is very low (frequently <10 mm Hg). If cardiac output increases, more alveoli are perfused and end-tidal CO_2 rises (usually to >20 mm Hg during successful CPR). When spontaneous circulation resumes, the earliest sign is a sudden increase in end-tidal CO_2 to greater than 40 mm Hg. Within a wide range of cardiac outputs, end-tidal CO_2 during CPR correlates with coronary perfusion pressure,[69] cardiac output,[70] initial resuscitation[71,72] and survival.[73] End-tidal CO_2 measured during human CPR has been used to predict outcome. No patient with an end-tidal CO_2 <10 mm Hg could be successfully resuscitated.[73] In the absence of invasive pressure monitoring, end-tidal CO_2 monitoring can be used to judge the effectiveness of chest com-

TABLE 84–2.

Physiological Indicators of Effective Cardiopulmonary Resuscitation

Variables	Amount
Myocardial blood flow	15–20 mL/min/100 g
Arterial diastolic pressure	40 mm Hg
Coronary perfusion pressure	15–25 mm Hg
End-tidal carbon dioxide	>10 mm Hg

pressions. Attempts should be made to maximize the value by alterations in technique or drug therapy. Sodium bicarbonate administration results in the liberation of CO_2 in the venous blood and a temporary rise in end-tidal CO_2. Therefore, end-tidal CO_2 monitoring will not be useful for judging the effectiveness of chest compressions for 3–5 minutes following bicarbonate administration.

ADVANCED LIFE SUPPORT

Advanced life support encompasses all technical skills and cognitive resources required to restore spontaneous circulatory function. In addition to BLS skills, it includes use of adjunctive equipment and techniques for assisting ventilation and circulation, electrocardiogram (ECG) monitoring with arrhythmia recognition and defibrillation, establishment of IV access, and drug therapy.

DEFIBRILLATION

Duration and Electrical Pattern of Fibrillation

Ventricular fibrillation is the most common rhythm disturbance in cardiac arrest; it is caused by reentry impulse generation with multiple circuits with changing pattern. The only consistently effective treatment is electrical defibrillation. The fibrillating heart consumes considerable oxygen, increasing myocardial ischemia, and decreasing the time to irreversible cell damage. The longer fibrillation continues, the more difficult it is to defibrillate and the less likely is successful resuscitation.[5,53,74–77] During the electrical phase of arrest (within 5 minutes of collapse), defibrillation should be the first priority of resuscitation (Box 84–2). Initial resuscitation success following out-of-hospital fibrillation and survival to hospital discharge are improved the earlier that defibrillation is accomplished.[5,76]

The application of defibrillation during the electrical phase has been facilitated by the development of AEDs that recognize ventricular fibrillation, charge automatically, and give a defibrillatory shock. Minimally trained individuals can incorporate defibrillation into BLS skills using an AED, thus improving survival in out-of-hospital arrest by reducing time to delivery of the first shock.[5,77–80] The value of public access defibrillation was dramatically demonstrated by the early results of installing AEDs in Las Vegas casinos where there was a 53% survival to discharge from the hospital[78] and in Chicago airports where there was a 55% one-year neurologically intact survival over the first two years.[79]

Early defibrillation is the paramount intervention during the electrical phase of cardiac arrest. However, in the usual out-of-hospital rescue with EMTs or paramedics doing the defibrillation and in many in-hospital arrests, the first shock frequently is delayed until 6–10 minutes following collapse, well into the hemodynamic phase of arrest. A retrospective analysis in Seattle found that, when response time was greater than 4 minutes, survival was improved if CPR was provided before defibrillation.[81] In a randomized trial of 200 out-of-hospital cardiac arrests in Oslo, there was a highly significant improvement in outcome if CPR was provided before defibrillation when the response time was greater than 5 minutes.[82] Consequently, it now appears that immediate defibrillation is only effective if applied within 4–5 minutes of collapse. Otherwise, a brief period of 2–3 minutes of chest compressions before defibrillation is necessary.

The coarseness of the fibrillatory waves on the ECG may reflect the severity and duration of the myocardial insult and, thus, have prognostic significance.[83] Increasing myocardial ischemia results in less-vigorous fibrillation, reduced amplitude electrical activity, and more difficult defibrillation. Low-*amplitude* and low-*frequency* fibrillatory waveforms are associated with poor outcome and the median frequency of the waveform correlates with myocardial perfusion during CPR and with success of defibrillation.[83,84] Catecholamines with β-adrenergic activity, such as epinephrine, increase the amplitude of the electrical activity but have no influence on the ability to defibrillate.[75,85] Consequently, defibrillation should not be delayed for drug therapy.

Defibrillators

The modern defibrillator is a variable transformer that stores a direct current in a capacitor until discharged through the electrodes. Until recently, the current waveform of most defibrillators used for transthoracic defibrillation was a monophasic (single direction of current flow between paddle electrodes), damped sinusoid, although some delivered truncated exponential waves. Nearly all AEDs and defibrillators sold today deliver a biphasic current (direction of flow reverses during the shock) in either a truncated, exponential, or rectilinear waveform.[86] The output of most defibrillators is indicated in *energy* units (joules or watt-seconds). At a constant stored energy, the energy delivered to the patient will be inversely related to the impedance (resistance) between the paddle electrodes. For consistency, the energy level indicated on most commercially available defibrillators is the output when discharged into a 50-ohm load.

Transthoracic Impedance

Defibrillation is accomplished by the *current* passing through a critical mass of myocardium causing simultaneous depolarization of the myofibrils. Even at a constant delivered energy, delivered current will be reduced as impedance increases. At high impedance and relatively low energy levels, current could be too low for defibrillation.

Transthoracic impedance has been measured at 15–143 ohms in human defibrillation.[87] The major determinants of transthoracic impedance are known, and many are under the control of rescuers (Box 84–5). Impedance decreases with increasing electrode size, but concern has been expressed that a too large a paddle size may diffuse the current over too great an area for effective defibrillation. The most common paddle size remains an 8–10-cm diameter for adults and children and a 4.5-cm diameter for infants. The high impedance between metal electrode and skin requires that carefully applied self-adhesive defibrillation pads or electrode paste/gel pads specifically designed to conduct elec-

BOX 84–5.

Factors Reducing Transthoracic Impedance during Defibrillation

Large paddle size (≥8-cm diameter)
Defibrillation paste
Firm pressure on paddles (≥11 kg)

Successive shocks

tricity in the defibrillation setting be used. When paste or gel is used, it should be applied liberally to the paddle surface to prevent burns and obtain the maximum reduction in impedance. However, it must not form a continuous path from one paddle to the other, allowing the electric circuit to follow the path of least resistance and bypass the heart. Transthoracic impedance decreases with successive shocks, a partial explanation for why an additional shock of the same energy can cause defibrillation when previous shocks have failed. Transthoracic impedance is slightly but significantly higher during inspiration than during exhalation. Air is a poor electrical conductor. Firm paddle pressure of at least 11 kg reduces resistance by improving paddle-skin contact and by expelling air from the lungs.[87]

Optimum success of defibrillation is obtained by keeping impedance as low as possible. The average transthoracic impedance in human defibrillation is 70–80 ohms. Impedance is probably of little clinical significance when reasonably proper technique and high-energy shocks are used. For lower-energy shocks, great care should be taken to minimize resistance. Defibrillators have been developed that measure transthoracic impedance during the charge cycle, allowing the use of low-energy shocks in appropriate patients and identification of victims needing higher energy.[88] Although not clinically available, current-based defibrillation may be a better way describe defibrillation dose.[89]

Energy Requirements and Adverse Effects

The incidence and severity of myocardial damage from defibrillation in humans is not clear. In studies using the traditional monophasic defibrillator, repeated high-level shocks in animals result in dysrhythmias, ECG changes, and myocardial necrosis.[90,91] Whether such injuries occur in humans is unknown. In humans, dysrhythmia frequency and the degree of ST-segment depression is greater with increased energy doses.[92] Although there is no definitive evidence demonstrating myocardial damage within the range of clinically used doses, it would seem prudent to keep energy levels as low as possible during defibrillation attempts. However, if energy is too low, the delivered current may be insufficient for defibrillation, especially when transthoracic impedance is high.

With monophasic defibrillation, there is a general relationship between body size and energy requirements for defibrillation.[93] Children need lower energies than adults, perhaps as low as 0.5 J/kg.[94] However, over the size range of adults, body size does not seem to be a clinically important variable.[95] Multiple studies have demonstrated high rates of successful defibrillation using relatively low levels (160–200 J) of delivered energy. Studies of out-of-hospital and in-hospital arrests have demonstrated equal success when using 200 J or less initial energy compared to administering all shocks at energies of 300 J or greater.[92,96]

Biphasic defibrillators with different waveforms have been demonstrated to be effective over specific dose ranges. AEDs have the shock energy preselected within the defibrillator algorithm. For manual biphasic defibrillation, most manufacturers display the effective dose range on the defibrillator. For biphasic truncated exponential waveforms, initial energies of 150–200 J have been shown to be successful >90% of the time.[1] For rectilinear biphasic waveforms, initial energy of 120 J has had similar success. Escalating doses of biphasic shocks have not been shown to improve success of defibrillation.

Immediate defibrillation is indicated if it can be applied within 4–5 minutes of collapse. Beyond that time, results are likely to be better if a brief (~2 minutes) period of chest compressions is provided before defibrillation. The current recommendation in adult patients using a monophasic defibrillator is to give a single shock of 360 J followed by immediate resumption of CPR for 2 minutes before rechecking rhythm and pulse (Box 84–6).[1] Because most defibrillations result in asystole or pulse electrical activity (PEA), a period of CPR will be necessary; beginning compressions immediately following the shock minimizes interruption of critical blood flow. With an AED or biphasic defibrillator, use the preset or manufacturers recommended energy. If that is unknown or unclear, a dose of 200 J may be selected. In children, with a manual defibrillator (monophasic or biphasic), an initial dose of 2 J/kg is used. As with adults, CPR is immediately restarted after a shock for 2 minutes before repeat rhythm and pulse check. If the first shock is unsuccessful, additional shocks of 4 J/kg are given separated by at least 2 minutes of CPR and appropriate drug and other therapy. If defibrillation attempts are unsuccessful, attention should be directed to the oxygenation, acid–base status, and administration of CPR and drugs such as epinephrine. In addition, factors that may increase transthoracic impedance should be evaluated, including pneumothorax, inadequate paddle–chest wall interface, improper paddle position, excessive distance between paddles, and inadequate paddle pressure on the chest.

Open-chest defibrillation can be used in the operating room when the thorax is already opened during surgery. Appropriate internal paddle sizes are 6-cm diameter for adults, 4-cm for children, and 2-cm for infants. The paddles are applied with saline-soaked pads, one placed behind the left ventricle and the other over the right ventricle. When defibrillation is performed in this manner, 5 J should be used on the first attempt. If unsuccessful, repeated doses can be used with energy levels up to 50 J.

BOX 84–6.

Defibrillation Recommendations

- Adults
  - 2 minutes CPR if >5 minutes since collapse
  - Countershock:
    - Monophasic: 360 J
    - AED: Preset
    - Biphasic: Device recommended (if unknown, 200 J)
  - Immediately restart CPR for 2 minutes
  - Recheck rhythm and pulse
  - Repeat countershock
  - Immediately restart CPR, oxygen, drugs
  - Repeat sequence
- Children
  - 2 minutes CPR if >5 minutes since collapse
  - First countershock: 2.0 J/kg monophasic or biphasic
  - Immediately restart CPR for 2 minutes
  - Recheck rhythm and pulse
  - Repeat countershock with 4.0 J/kg
  - Immediately restart CPR, oxygen, drugs
  - Repeat sequence, all subsequent shocks: 4.0 J/kg

Supplemental Therapy

Lidocaine and amiodarone are used during cardiac arrest to aid defibrillation when ventricular fibrillation is refractory to electrical countershock therapy or when fibrillation recurs following successful conversion. However, no antiarrhythmic agent has been shown superior to electrical defibrillation or more effective than placebo in the treatment of ventricular fibrillation. Consequently, defibrillation should not be withheld or delayed for drug therapy, but should be applied at the earliest possible time when treating ventricular fibrillation (Box 84–2).

Lidocaine and Amiodarone

Lidocaine is primarily an antiectopic agent with few hemodynamic effects. It depresses automaticity by reducing the slope of phase 4 depolarization and reducing the heterogeneity of ventricular refractoriness. It tends to restore the ventricular fibrillation threshold decreased by ischemia or infarction. It has no effect on conduction times through the atrioventricular node or on intraventricular conduction time. Amiodarone is a pharmacologically complex drug with sodium, potassium, calcium, and α- and β-adrenergic blocking properties that is useful for treatment of atrial and ventricular arrhythmias. Amiodarone can cause hypotension and bradycardia when infused too rapidly in patients with an intact circulation. This can usually be prevented by slowing the rate of drug infusion, or treated with fluids, vasopressors, chronotropic agents, or temporary pacing.

Lidocaine is effective in terminating ventricular premature beats (VPBs) and ventricular tachycardia associated with cardiac surgery, acute myocardial infarction, and digitalis intoxication. It is also effective in preventing and treating ventricular dysrhythmias during cardiac catheterization. Lidocaine is not effective in the treatment of atrial or atrioventricular junctional dysrhythmias (Box 84–7). In contrast, amiodarone is effective in treating multiple types of supraventricular and ventricular dysrhythmias.

In cardiac arrest, intravenous lidocaine and/or amiodarone are administered following return of spontaneous circulation for prophylaxis or when ventricular tachycardia or ventricular fibrillation have not responded to or have recurred following epinephrine and defibrillation. There are two randomized, blinded, clinical trials in shock-resistant cardiac arrest victims demonstrating improved admission alive to hospital with amiodarone treatment compared to placebo or lidocaine, although there was no difference in survival to discharge.[97,98] Amiodarone is initially administered as a 300-mg rapid infusion. Supplemental infusions of 150 mg can be repeated as necessary for recurrent or resistant arrhythmias to a maximum total daily dose of 2 g. Lidocaine is an alternative therapy in refractory fibrillation. To rapidly achieve and maintain therapeutic blood levels during CPR, relatively large doses are necessary. An initial bolus of 1–1.5 mg/kg should be given and additional boluses of 0.5–0.75 mg/kg can be given every 5–10 minutes during CPR up to a total dose of 3 mg/kg. Only bolus dosing should be used during CPR but an infusion of 2–4 mg/min can be started after successful resuscitation.

BOX 84–7.

Indications for Use of Lidocaine

- Frequent ventricular premature beats (>10 beats/min)
- Coupled VPBs
- Multiform VPBs
- Ventricular tachycardia
- Prophylaxis during cardiac catheterization
- Prophylaxis following resuscitation

Temporary Pacemaker Therapy

When emergency pacing is indicated, intravenous or transthoracic pacing can be initiated. Temporary pacing can usually be quickly instituted using external, noninvasive, temporary pacemakers that use large, high-impedance electrodes, allowing relatively nonpainful stimuli.[99]

Temporary pacing is indicated for patients with preserved myocardial function whose primary problem is impulse formation or conduction, such as patients with severe bradycardia or high-grade heart block who have a palpable pulse. Studies of temporary pacing during cardiac arrest (out-of-hospital or in the emergency department) have found no improvement in admission to hospital or survival. Consequently, withholding chest compressions in patients with asystole to attempt pacing is not recommended.[1]

PULSELESS ELECTRICAL ACTIVITY AND ASYSTOLE

Although ventricular fibrillation is the most common ECG rhythm seen in cardiac arrest, PEA and asystole do occur as either the presenting rhythm or following defibrillation. They are seen more often in children and are associated with a poor outcome. PEA is the circumstance where no palpable pulse is present but an ECG rhythm is detectable. This includes a number of different rhythms, most commonly electromechanical dissociation (EMD; Box 84–8). Asystole is the absence of electrical activity on the ECG. Fine ventricular fibrillation can masquerade as asystole if the ECG lead being monitored is located at right angles to the fibrillatory wave.[100] For this reason, the trace from a second lead or from a different position of paddle electrodes should always be inspected before a decision is made not to defibrillate.

The predominant cause of primary PEA and asystole is severe myocardial ischemia. These rhythms may represent a failure of myocardial contractility caused by a depletion of intracellular energy stores and carry a very poor prognosis. These ECG patterns also may be secondary, caused by a variety of noncardiac mechanisms that are amenable to treatment (Boxes 84–9 and 84–10). Therapy directed at the underlying disorder may result in a successful outcome. Consequently, consideration of a noncardiac cause for arrest should always be part of the resuscitation sequence when these rhythms are detected (Box 84–11).

DRUG THERAPY

During cardiac arrest, drug therapy is secondary to more fundamental inter-

BOX 84–8.

Pulseless Electrical Activity

Pulseless electrical activity (PEA) includes:

Noncardiac (secondary)
- Hypovolemia
- Tension pneumothorax
- Cardiac tamponade
- Massive pulmonary embolism
- Hypothermia
- Drug overdose
- Hypoxia
- Hyperkalemia
- Acidosis

ventions (Box 84–2). Chest compressions, defibrillation (if appropriate), and ventilation should take precedence over medications. Establishing IV access and administering drugs, although important, should not interrupt sustained chest compressions and ventilation. Of the drugs used during CPR, only vasopressors are acknowledged to help restore spontaneous circulation.[1]

Oxygen

Patients in cardiac arrest or low cardiac output states should receive 100% oxygen as soon as possible. Oxygen will increase arterial oxygen tension and hemoglobin saturation if ventilation is supported and improve tissue oxygenation when circulation is supported.

Vasopressor Agents

Mechanism of Action

Epinephrine has been used in resuscitation since the 1890s and has been the vasopressor of choice in modern CPR since the studies of Redding and Pearson in the 1960s.[17,101] Its efficacy lies entirely in its α-adrenergic properties.[64] When epinephrine is administered during CPR, peripheral vasoconstriction results in higher aortic pressure causing an increase in coronary and cerebral perfusion pressures and myocardial and brain blood flows.[63,102,103] Flow to other organs either does not improve or diminishes further when epinephrine is given, despite the increase in aortic pressure. Animal studies demonstrate that all strong α-adrenergic drugs (epinephrine, phenylephrine, methoxamine, dopamine, norepinephrine) and nonadrenergic vasopressors (vasopressin) are equally successful in aiding resuscitation regardless of the β-adrenergic potency. β-Adrenergic agonists without α activity (isoproterenol, dobutamine) are no better than placebo.[17,59,101,104,105] α-Adrenergic blockade precludes resuscitation, whereas β-adrenergic blockade has no effect on the ability to restore spontaneous circulation.[61,62] Although it has been suggested that the ability of epinephrine to increase the amplitude of ventricular fibrillation (a β-adrenergic effect) makes defibrillation easier, animal studies show that epinephrine does not improve the success of or decrease the energy necessary for defibrillation.[75,85] Retrospective clinical studies show no effect of epinephrine on defibrillation success.[83]

β-Adrenergic stimulation during cardiac arrest is potentially deleterious. In the fibrillating heart, epinephrine increases oxygen consumption. Myocardial lactate production in the fibrillating heart is unchanged after epinephrine administration during CPR suggesting that the increased coronary blood flow does not improve the oxygen supply-to-demand ratio.[106] Large doses of epinephrine increased deaths in swine early after resuscitation as a consequence of tachyarrhythmias and hypertension, an effect partially offset by metoprolol treatment.[107] Despite these theoretical considerations, survival and neurologic outcome studies show no difference when epinephrine is compared to a pure α-agonist (methoxamine or phenylephrine) or to a nonadrenergic vasopressor (vasopressin) during CPR in animals or humans.[108–111]

Epinephrine

When added to chest compressions, epinephrine helps to develop the critical coronary perfusion pressure necessary to provide enough myocardial blood flow for restoration of spontaneous circulation. If invasive monitoring is present during CPR, an arterial diastolic pressure of 40 mm Hg or coronary perfusion pressure of 20 mm Hg must be obtained with good chest compression technique and/or epinephrine therapy (Table 84–1). In the absence of such monitoring, the dose of epinephrine must be chosen empirically. The standard dose used in animals and humans for many years has been 0.5–1.0 mg intravenously. On a weight basis, this dose is approximately 0.1 mg/kg in animals but only 0.015 mg/kg in humans. Animal studies in the 1980s suggested that higher doses of epinephrine in human CPR might improve myocardial and cerebral perfusion and improve success of resuscitation. Case reports on a series of children (with historical controls) were published demonstrating return of spontaneous circulation when large doses (0.1–0.2 mg/kg) of epinephrine were given to patients who had failed resuscitation with standard doses.

Outcome studies prospectively comparing standard and high-dose epinephrine do not demonstrate conclusively that higher doses improve survival. Two randomized, blinded animal studies (one with fibrillatory arrest and one with asphyxial arrest) comparing standard and high-dose epinephrine found no difference in 24-hour survival or neurologic outcome but more of the high-dose epinephrine animals died in the early postresuscitation period as a result of a hyperdynamic state.[107,112] Eight adult prospective randomized clinical trials involving more than 9000 cardiac arrest patients have found no improvement in survival to hospital discharge or neurologic outcome, even in subgroups, when initial high-dose epinephrine (5–18 mg) is compared to standard

doses (1–2 mg).[113–120] Some of the studies (and the cumulative data) suggest that there may be an improvement in immediate resuscitation with high-dose epinephrine. None of the studies found improvement in survival to hospital discharge.

Because of the long experience with epinephrine, it remains the vasopressor of choice in CPR. It should be administered whenever resuscitation has not occurred after adequate chest compressions and ventilation have been started and defibrillation attempted, if appropriate (Box 84–2). High doses of epinephrine apparently are not needed as initial therapy for most cardiac arrests and potentially could be deleterious under some circumstances. However, the successful case reports were in patients with prolonged CPR and the high doses were given as "rescue" therapy when standard doses had failed. This may be the appropriate place for higher doses of epinephrine in CPR practice. Current recommendations are to give intravenous epinephrine, 1 mg in the adult or 0.01 mg/kg in children, every 3–5 minutes. Higher doses may be indicated in specific circumstances, or if treatment has been delayed and the standard dose seems ineffective.

Vasopressin

The newest addition to the pharmacologic armamentarium in CPR is arginine vasopressin. It is currently recommended as an alternative to either the first or second dose of epinephrine in a dose of 40 units intravenously. If additional vasopressor doses are needed, epinephrine should be used. Vasopressin is a naturally occurring hormone (antidiuretic hormone) that, when administered in high doses, is a potent nonadrenergic vasoconstrictor, acting by stimulation of smooth muscle V1 receptors. The half-life in the intact circulation is 10–20 minutes, and longer than epinephrine during CPR. Animal studies demonstrate that vasopressin is as effective as, or more effective than, epinephrine in maintaining vital organ blood flow during CPR.[121–123] Repeated doses during prolonged CPR in swine were associated with significantly improved rates of neurologically intact survival compared to epinephrine and placebo.[124] Postresuscitation myocardial depression and splanchnic blood flow reduction are more marked with vasopressin than epinephrine but they are transient and can be treated with low-doses of dopamine.[125] Clinical studies indicate that vasopressin is as effective as epinephrine, but have not definitively shown it to be superior. A small, randomized, blinded study comparing vasopressin and standard-dose epinephrine in 40 patients with out-of-hospital ventricular fibrillation found improved 24-hour survival with vasopressin but no difference in ROSC or survival to hospital discharge.[126] A larger clinical trial of 200 in-patients found no difference between the drugs in survival for 1 hour or to hospital discharge.[127] In this study, response times were short, indicating that CPR outcome achieved with both vasopressin and epinephrine in short-term cardiac arrest may be comparable. The hemodynamic effects of vasopressin, compared to epinephrine, are especially impressive during long cardiac arrests. Thus vasopressin may find most use in CPR during prolonged resuscitation. A multicenter, randomized study of 1186 patients comparing vasopressin 40 U and epinephrine 1 mg for the first two doses of vasopressor during resuscitation from out-of-hospital cardiac arrest found no overall difference in survival to hospital admission (36% vs. 31%) or discharge (10% vs. 10%).[111] However, in subgroup analysis, in patients presenting in asystole, there was a significant improvement in survival to hospital admission (29% vs. 20%) and discharge (4.7% vs. 1.5%). In those patients who did not resuscitate following two doses of study drug, approximately 60% received additional epinephrine. In these difficult-to-resuscitate patients, irrespective of presenting rhythm, those who received vasopressin followed by epinephrine had better outcomes than those who received only epinephrine, suggesting that the combination of the drugs may have advantages. Overall, evidence currently suggests that, like other potent vasopressors, vasopressin is equivalent to, but not better than, epinephrine for use during CPR.

Atropine

Atropine sulfate enhances sinus node automaticity and atrioventricular conduction by its vagolytic effects. Atropine is indicated when bradycardia coexists with hypotension, ventricular ectopy, or symptoms associated with myocardial ischemia. The drug can also be used to treat second-degree and third-degree heart block, and slow idioventricular rates. Although atropine is frequently given during cardiac arrest associated with an ECG pattern of asystole or slow PEA, neither animal nor human studies provide evidence that it actually improves outcome from asystolic or bradysystolic arrest.[127–130] The predominant cause of asystole and EMD is severe myocardial ischemia. Excessive parasympathetic tone probably contributes little to these rhythms during cardiac arrest in adults. Even in children, the significance of autonomic tone during arrest is doubtful. The most effective treatment for asystole or PEA is improvement in coronary perfusion and myocardial oxygenation with chest compressions, ventilation, and epinephrine. However, cardiac arrest with these rhythms has a very poor prognosis. Because atropine has few adverse effects, it can be tried in arrest refractory to epinephrine and oxygenation. The recommended dose for bradycardia in adults is 0.5 mg IV every 3–5 minutes to a total dose of 3.0 mg. The pediatric dose for treating bradycardia is 0.02 mg/kg with a minimum dose of 0.1 mg and a maximum total dose of 1.0 mg in a child and 3.0 mg in an adolescent. The dose may be repeated every 3–5 minutes. When treating pulseless arrest in the adult, the dose is 1.0 mg IV every 3–5 minutes to a total dose of 3.0 mg. Atropine is no longer recommended for use in pulseless arrest in children. Full vagolytic doses may be associated with fixed mydriasis following successful resuscitation confounding neurologic examination. Occasionally, a sinus tachycardia following resuscitation may be caused by use of atropine during CPR.

Calcium Salts

With normal cardiovascular physiology, calcium increases myocardial contractility and enhances ventricular automaticity. Consequently, calcium salts have been administered during attempted resuscitation of asystole and EMD for many years. However, multiple clinical studies have found that calcium is no better than placebo in promoting resuscitation and survival from asystole or EMD.[131,132] Calcium is not indicated for use during cardiac arrest in adults or children. It may be useful for treatment of hyperkalemia, ionized hypocalcemia, hypermagnesemia, or calcium channel blocker toxicity (Box 84–12). If calcium is adminis-

BOX 84–12.

Indications for Use of Calcium

Hypocalcemia, ionized
Hyperkalemia
Calcium channel blocker overdose
Hypermagnesemia

tered, the chloride salt (2–4 mg/kg) is recommended because it produces higher and more consistent levels of ionized calcium than other salts.

Sodium Bicarbonate

Although sodium bicarbonate was used commonly during CPR in the past, there is little evidence to support its efficacy. Its use during resuscitation was predicated on the adverse cardiovascular consequences of acidosis, including impaired myocardial function, decreased catecholamine responsiveness, and peripheral vasodilatation. However, most studies have been unable to demonstrate improvement in success of defibrillation or resuscitation with the use of bicarbonate.[133–135] The observation that metabolic acidosis develops very slowly during CPR may explain the absence of effect of buffer therapy. Acidosis does not become severe until 15–20 minutes of cardiac arrest have passed.[32,136,137]

Sodium bicarbonate use during CPR should be restricted not only because of its lack of efficacy but because of the documented complications from excessive use, including hyperosmolality, hypernatremia, metabolic alkalosis and hypercapnia from CO_2 liberation (Box 84–13).[136,138] These abnormalities are associated with low resuscitation rates and poor survival. However, if sodium bicarbonate is given judiciously according to standard recommendations, no significant metabolic abnormalities should occur.[139]

Theoretically, sodium bicarbonate could cause a paradoxical worsening of intracellular and intracerebral acidosis as the CO_2 liberated during the reaction with acid readily diffuses across cell membranes and the blood–brain barrier whereas bicarbonate diffuses much more slowly. Direct evidence for this effect has not been found. Animal studies have found no change in spinal fluid acid–base status with clinically relevant doses of sodium bicarbonate[140] and no worsening of myocardial intracellular acidosis during bicarbonate administration.[141] Consequently, paradoxical acidosis from sodium bicarbonate remains a concern primarily on theoretical grounds.

BOX 84–13.

Side Effects from Excessive Use of Sodium Bicarbonate

Hyperosmolality
Hypernatremia
Metabolic alkalosis
Hypercapnia
Decreased unloading of oxygen from hemoglobin
Paradoxical intracellular acidosis

Current practice suggests sodium bicarbonate should be considered for use during CPR only in arrests associated with hyperkalemia, severe preexisting metabolic acidosis, and tricyclic or phenobarbital overdose. It may be considered for use in protracted resuscitation attempts after other modalities have been instituted (Box 84–14). These recommendations stem from its unproven efficacy in increasing patient survival and the known side effects. When bicarbonate is used, 1 mEq/kg should be given as the initial dose and no more than half this dose given every 10 minutes thereafter. However, dosing of sodium bicarbonate should be guided by blood gas determination, whenever possible.

Routes of Administration and Vascular Access

The preferred route of administration of all drugs during CPR is intravenous or intraosseous. If one of these routes cannot be established rapidly because of technical difficulties, one of the other alternatives—endotracheal or intracardiac—can be used.

Intravenous Access

The most rapid and highest drug levels occur with administration into a central vein. Therefore, when a central venous catheter is available during CPR, as is often the case in the operating room, it should be used for drug therapy. However, peripheral intravenous administration also is effective. The antecubital or external jugular vein should be the site of first choice for starting an infusion during resuscitation because starting a central line usually necessitates stopping CPR. Sites in the upper extremity and neck are preferred because of the paucity of blood flow below the diaphragm during CPR. Drugs administered in the lower extremity may be extremely delayed or not reach the sites of action. Even in the upper extremity, drugs may require 1–2 minutes to reach the central circulation.[142] Onset of action may be speeded if a peripheral drug bolus is followed by a 20–30-mL bolus of intravenous fluid.

BOX 84–14.

Indications for Sodium Bicarbonate during Cardiopulmonary Resuscitation

Severe preexisting metabolic acidosis
Hyperkalemia
Tricyclic or phenobarbital overdose
Protracted resuscitation

Intraosseous Administration

The intraosseous route of fluid and medication administration, originally described in 1934,[143] has regained popularity recently in the CPR literature. All medications used during CPR and fluids, including whole blood, have been given by the intraosseous route. This technique should be considered a temporary measure during emergencies when other vascular sites are not available.

The technique of placing an intraosseous line is straightforward. A standard 16- or 18-gauge needle, spinal needle with stylet, or bone marrow needle is inserted into the anterior surface of the tibia, 1–3 cm below the tibial tuberosity. The needle is directed to a 90° angle to the medial surface of the bone or slightly inferior to avoid the epiphyseal plate. There is a loss of resistance after the needle passes through the bony cortex of the tibia. Placement is successful if the needle is in the marrow cavity as evidenced by the needle standing upright without support and bone marrow can be aspirated into a syringe connected to the needle. It will lose the upright position if it has slipped into the subcutaneous tissue. Free flow of the drug or fluid infusion without significant subcutaneous infiltration also should be demonstrated (Fig. 84–4).[144] There are a number of reports of successful intraosseous infusions in children with minimal complications. Animal models have demonstrated successful reversal of hemorrhagic shock,[145] effective buffering with sodium bicarbonate,[146] and equal hemodynamic response to epinephrine with intraosseous and central intravenous administration.[147]

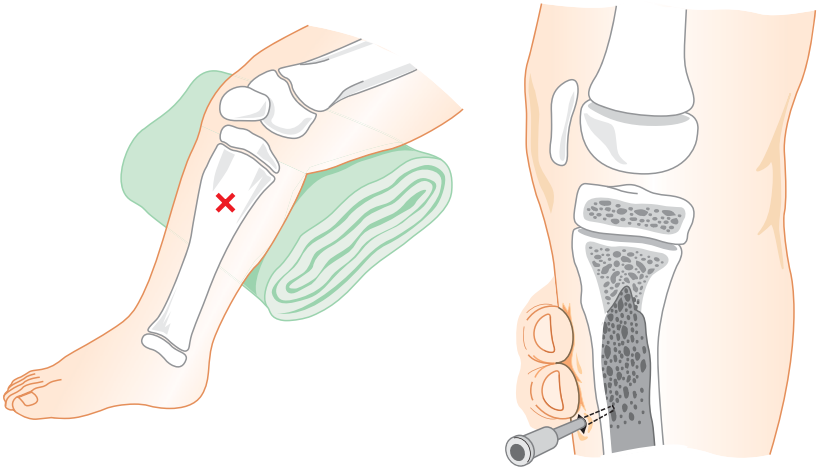

FIGURE 84–4. Intraosseous needle placement. Insert needle at the level of tibial tubercle on the medial portion of the tibia. The needle is aimed carefully and laterally.

Endotracheal Administration

Drugs that can be absorbed from tracheal mucosa include lidocaine, atropine, naloxone, and epinephrine (Box 84–15). During CPR the rapid establishment of an intravenous line can be difficult, especially in the obese or in infants and small children. The endotracheal route can be used as an alternative following intubation in these settings. The time to effect and drug levels achieved are inconsistent using this route during CPR.[148–150] Better results may be obtained by administering 5–10-mL volumes. It is unclear whether deep injection is better than simple instillation into the endotracheal tube.[57] Doses 2–2.5 times higher than the recommended IV dose should be administered when this route is used.

POSTRESUSCITATION CARE

The major factors contributing to mortality following successful resuscitation are progression of the primary disease and cerebral damage suffered as a result of the arrest. There is growing awareness that any cardiac arrest, even of brief duration, causes a generalized decrease in myocardial function similar to the regional hypokinesis seen following periods of regional ischemia. This is usually referred to as global myocardial stunning and can be mitigated with inotropic agents, if necessary. Active management following resuscitation appears to mitigate postischemic brain damage and improve neurologic outcome without increasing the number of patients surviving in a vegetative state.[151] When flow is restored following a period of global brain ischemia, 3 stages of cerebral reperfusion are seen in ensuing 12 hours. There are multifocal areas of the brain with no-reflow immediately following resuscitation. Within an hour there is global hyperemia followed quickly by prolonged global hypoperfusion.

Postresuscitation support is focused on providing stable oxygenation and hemodynamics so as to minimize any further cerebral insult. A comatose patient should be maintained on mechanical ventilation for several hours to ensure adequate oxygenation and ventilation. Restlessness, coughing, or seizure activity should be aggressively treated with appropriate medications including neuromuscular blockers, if necessary. Arterial Pao_2 should be maintained above 100 mm Hg and moderate hypocapnia (Pv_{CO2} 25–35 mm Hg) may be helpful. Blood volume should be maintained normal and moderate hemodilution to a hematocrit of 30–35% may be helpful. A brief 5-minute period of hypertension to mean arterial pressure of 120–140 mm Hg may help overcome the initial cerebral no-reflow. This frequently occurs secondary to the effects of epinephrine given during CPR. However, both prolonged hypertension (>110 mm Hg) and hypotension are associated with a worsened outcome. Hyperglycemia during cerebral ischemia is known to result in increased neurologic damage. Thus, it seems prudent to control glucose in the 100–300 mg/dL range. Specific pharmacologic therapy directed at brain preservation has not been shown to have further benefit. Although animal trials of barbiturates and calcium channel blockers were promising, large, multicenter trials found no improvement in neurologic status when drugs were given following cardiac arrest.[151,152]

In contrast to pharmacologic therapy, two studies have demonstrated improved neurologic outcome when mild therapeutic hypothermia (89.6–93.2°F [32–34°C]) is induced for 12–24 hours in cardiac arrest survivors who remained comatose after admission to the hospital.[153,154] Both investigations studied only patients whose initial rhythm was ventricular fibrillation and the larger of the trials included only witnessed arrests. Nevertheless, these are the first studies to document improved neurological outcome with a specific post-arrest intervention. The International Liaison Committee on Resuscitation (ILCOR) now recommends "unconscious adult patients with return of spontaneous circulation after out-of-hospital cardiac arrest should be cooled to 32–34°C for 12 to 24 hours when the initial rhythm was ventricular fibrillation. Such cooling may also be beneficial for other rhythms or in-hospital cardiac arrest."

PROGNOSIS

For the comatose survivor of CPR, the question of ultimate prognosis is important. One retrospective study demonstrated that the admission neurologic examination of comatose victims is highly correlated with the likelihood of awakening.[155] If there was no pupillary light response and no spontaneous eye movement, and if the motor response to pain was absent or extensor posturing, there was only a 5% chance the patient would ever awaken. A companion study demonstrated

BOX 84–15.

Endotracheal Administration of Drugs

Lidocaine	*Do not administer:*
Atropine	Sodium bicarbonate
Naloxone	Calcium chloride
Epinephrine	

BOX 84–16.

Prognosis of Comatose Survivors of Cardiac Arrest

Signs predicting death or poor neurologic outcome

Absent corneal reflex at 24 hours
Absent pupillary response at 24 hours
Absent withdrawal response to pain at 24 hours
No motor response at 24 hours
No motor response at 72 hours

that the chance of ever awakening fell rapidly in the days following arrest.[156] If the patient was not awake by 4 days following arrest, the chance of ever awakening was less than 20%, and all those awakening had marked neurologic deficits. Most patients who completely recover show rapid improvement in the first 48 hours. A meta-analysis of 11 clinical studies involving 1914 patients identified 5 clinical signs that strongly predict death or poor neurologic outcome (Box 84–16).[157]

PART 7

SPECIAL CONSIDERATIONS IN ANESTHESIA CARE

CHAPTER 85

Blood and Blood Component Therapy

Ian J. Welsby, BSc, MBBS, FRCA, and
Steven J. Bredehoeft, MD

HISTORY OF BLOOD TRANSFUSION

Practical, safe transfusion derives from centuries of experimentation and discovery. Although the first known animal transfusion experiments took place in both England and France in the 17th century, early efforts to translate the technique to humans failed with such spectacular flair that the learned societies on both sides of the English Channel flatly banned the practice.

The first "modern" transfusion is attributed to John Syng Physick in Philadelphia in 1795. English physician James Blundell claimed success for 5 of 10 transfused patients during his professional career (1820–1840).

The 19th century saw rapid expansion of bacteriology and growing understanding of antisera. In 1900, Karl Landsteiner significantly advanced the cause of blood compatibility with his landmark discovery of the ABO blood groups, with O being derived form the German "ohne" or without, for which he received the 1930 Nobel Prize in Medicine and Physiology. Four decades later, in collaboration with Alex Weiner, Philip Levine, and R.E. Stetson, Landsteiner played an instrumental role in the recognition of Rh(D), a major cause of hemolytic disease of the newborn (HDN) and non–ABO-related hemolytic transfusion reactions.

Prior to effective schemes for anticoagulation, Alexis Carrel explored vascular anastomosis as a possible strategy for moving blood from donor to recipient. Although eclipsed by other approaches, this pioneering techniques formed the basis of contemporary vascular anastomoses in solid-organ transplantation and won Carrel the 1912 Nobel Prize.

The use of citrate to anticoagulate stored blood by means of calcium chelation was a landmark, as heparin was unsuitable to transfuse into bleeding patients, and citrate's rapid metabolic elimination in vivo proved ideal for purposes of transfusion. Its adoption paved the way for transition from direct to indirect transfusion. By 1916, Rous and Turner introduced glucose in addition to sodium citrate, extending ex vivo storage by several days.

The first blood depots were established during the First World War by the British and were stocked prior to major campaigns. The Soviets established the first permanent blood bank in a Leningrad hospital in 1932, and 5 years later Bernard Fantus established the first U.S. blood bank at the Cook County Hospital in Chicago.

Although clinical efforts had focused largely on transfusion of whole blood, Professor Edwin Cohn at Harvard explored fractionation of plasma proteins using cold ethanol treatment and centrifugation. By 1940, these techniques yielded concentrated fractions of albumin, immunoglobulins, and fibrinogen. With the outbreak of war in Europe, the U.S. War Department and American Red Cross launched *Plasma for Britain*, under the direction of Dr. Charles Drew.

Despite highly successful initial resuscitation, casualties with significant blood loss treated exclusively with plasma developed "air hunger" from anemia. Improved logistics enabled a shift to use of whole blood. With this transition, volume tolerance emerged as the next constraint to adequate replacement of oxygen-carrying capacity. Large-scale availability of red blood cell concentrates (and more general exploitation of blood component therapy) awaited development of the plastic, integrated, blood-collection systems of the 1950s and 1960s.

Success was tempered by the identification of transfusion borne infections. "Serum" hepatitis followed approximately 10% of transfusions. Worse, in some communities posttransfusion hepatitis reached rates of 30%, an observation that was explained by reliance on monetarily compensated donors. In parallel with these epidemiologic discoveries, advances in virology and radio-immunochemistry brought to market by 1969 limited supplies of tests for detection of hepatitis B surface antigen (HBsAg, the "Australia Antigen"). With transition in the United States to an all-volunteer blood supply, rates of hepatitis B virus (HBV) transmission fell dramatically, and with full deployment of HBsAg testing in 1972, rates of transfusion-transmitted hepatitis B fell to between 0.3% and 0.9%. Although remarkably high by today's standards, this represented risk reduction by an order of magnitude.

Following the emergence of HIV/AIDS, an epidemic that transformed public perceptions of blood safety occurred. Lessons learned for dealing with hepatitis led to rapid progress toward securing the safety of the blood supply. The answer to a patient's question, "Will this transfusion give me AIDS?" is, "No."

KEY POINTS

1. ABO compatibility remains the major safety consideration for blood transfusion. Clerical errors of patient identification and sample labeling remain the primary cause of mistransfusion of ABO-incompatible units.
2. Prestorage leukoreduction of cellular blood products has greatly reduced, but not eliminated, the incidence of febrile reactions, transfusion-related immunosuppression, and cytomegalovirus transmission, and has led to improved outcomes in surgical patients compared to the use of nonleukoreduced products.
3. Rigorous donor screening, serologic testing and nucleic acid amplification testing have proven extremely effective in reducing the risk of transfusion-transmitted infections in developed nations. However, transfusion-transmitted infection remains a serious concern throughout the developing world.
4. International travel and associated exposure to pathogens not addressed by existing screening mechanisms will increasingly limit suitable blood donors. These and other pressures on the blood supply make imperative strategies for blood conservation and promotion of bloodless surgical techniques.

Although infectious risks of blood transfusion have diminished enormously in developed nations, high rates of endemic disease and limited testing resources in developing countries paint a variegated global picture of blood product safety. Today's tools include effective donor screening and testing. Tomorrow holds promise of pathogen inactivation and improved controls of bedside transfusion practice as further steps on the long path toward safe transfusion.

CLINICALLY AVAILABLE BLOOD PRODUCTS

Whole Blood

Despite some clinicians' desires for fresh whole blood, especially for use in pediatric cardiac anesthesiology, the optimal use for a limited resource demands the use of red cells for oxygen-carrying capacity, plasma for coagulation proteins, and platelets for thrombocytopenia or platelet dysfunction. The component therapy approach maximizes the number of recipients benefiting from transfusion and optimally preserves the function of essential blood elements. Colloid replacement can be provided by synthetic colloids, such as gelatins and starches, or albumin products fractionated from plasma. The time required to perform federally mandated testing makes fresh whole blood practically unavailable to most clinicians; consequently, discussion is primarily focused on blood components.

A unit of whole blood is collected in citrate-phosphate-dextrose-adenine 1 (CPDA-1) anticoagulant, giving it a shelf-life of 35 days and a volume of approximately 510 mL (450 mL of blood plus 63 mL of CPDA-1). Within 24 hours of collection, the platelets are dysfunctional,[1] and several plasma coagulation factors are below optimal levels,[2] emphasizing the importance of the component products despite the disadvantage of increased donor exposure.

Red Cell Concentrates

Red cell concentrates, or packed red blood cells (PRBCs), are obtained from CPDA-1-anticoagulated whole blood after centrifugation of most of the plasma and platelets. At most blood centers, the red cells are then mixed with 100 mL of an additive nutrient containing an additional dextrose and adenine (NutriCell or AS-3) or dextrose, adenine, and mannitol (Adsol or AS-1) solution that extends the storage period to 42 days[3] and results in flow properties similar to those of whole blood. PRBCs from CPDA-1-anticoagulated blood are stored for up to 35 days. Loss of viability during storage is caused by cellular adenosine triphosphate (ATP) depletion, which leads to loss of membrane phospholipids, increased rigidity, and reduced life span, with current standards requiring 75% of transfused cells to survive in the circulation for 24 hours.[4] At 35 days, 70% of cells survive in CPDA-1 versus 88% in Adsol, with a pH of 6.7 in both solutions; intracellular ATP is 45% baseline in CPDA-1 versus 75% in Adsol, whereas 2,3-diphosphoglycerate (2,3-DPG) levels are at 10% baseline in both. In vivo, 2,3-DPG levels rapidly normalize over 24 hours and recover to more than 50% within 1 or 2 hours.[5] PRBCs are the product of choice for the correction of an isolated defect in oxygen-carrying capacity, as in chronic anemia, with the advantage of lower volume load in this setting. During acute perioperative blood loss, however, attention must be paid to volume status as well as restoring oxygen-carrying capacity using crystalloid or colloid volume expanders.

Leukocyte-Reduced Red Cells Leukocyte-reduced red cells (LRRCs) can be prepared by a variety of methods, with varying efficiency of white cell removal. The minimum standard, established by the American Association of Blood Banks (AABB), is a leukocyte number in the final component of $< 5 \times 10^{8}$.[6] Early techniques involved centrifugation and washing with saline, repeatedly removing the buffy coat. Next, the "spin-cool-filter" method was introduced, using 1-week-old red cells that were centrifuged and then cooled for 4 hours to enhance microaggregate formation, then passed through a microaggregate filter. Currently, the most widely used method of leukoreduction is filtration, which can be performed either in the laboratory or at the bedside. The various filters on the market result in >99% leukocyte reduction while depleting <10% of the red cells. Most recently, blood bags with in-line filters that allow prestorage leukoreduction have become available. Simple removal of the buffy coat from red cells (a routine procedure during component preparation in Europe) may provide a sufficient degree of leukoreduction.[7] Because component preparation in the United States does not include buffy coat removal and because soluble white cell fragments may be capable of mediating immunosuppression, a prestorage leukoreduction method might be required to abrogate this adverse effect in transfusion recipients in the United States. Introduction of leukoreduction in the United States began around 1998. Confirmation with individual blood banks is necessary to determine their policies, as there are often regional differences.

The major indication for the use of LRRCs has been the prevention of the nonhemolytic febrile transfusion reaction, which is the most common adverse effect of transfusion, particularly in multiply transfused patients or multiparous females. It is believed to be a result of preexisting antihuman leukocyte antigen (anti-HLA) antibodies. Use of LRRCs reduces the incidence of such reactions.[8] Cytokines may cause these reactions, suggesting that prestorage leukodepletion may be more helpful.

A second important indication for LRRCs is the prevention of alloimmunization to HLA antigens that can adversely affect posttransfusion platelet increments.[9] Platelets components also require leukodepletion. The current AABB standards mandate $< 5 \times 10^{6}$ leukocytes for this indication, possibly with third-generation leukoreduction filters for both red cells and platelets.[6] A large, multicenter study (TRAP, Trial to Reduce Alloimmunization to Platelets) confirmed that the use of leukoreduction filters significantly decreased but did not eliminate alloimmunization.[10]

Washed Red Cells Red cells are washed using isotonic saline solutions with some degree of red cell loss with each wash cycle. This open system requires the resulting product to be transfused within 24 hours. The primary aim of washing is to remove plasma proteins (with some leukocytes and platelets also removed) to prevent severe allergic transfusion reactions mediated by recipient antibodies (most likely IgE) to donor plasma proteins or preformed antibodies to IgA in donor plasma, which can cause anaphylaxis in IgA-deficient patients.[11] Washed cells may also be indicated in paroxysmal nocturnal hemoglobinuria.

Frozen Red Cells Red cells can be frozen (with glycerol used as a cryoprotective agent) and stored in liquid nitrogen or mechanical freezers.[12] Thawing and washing away the glycerol using a series of progressively less hypertonic saline solutions allows glycerol to diffuse gradually from the cells to prevent hemolysis before transfusion. This process removes most of the plasma, and any debris and red cells can be frozen for more than 10 years with good viability.[6] As with washed cells, frozen red cells need to be transfused within 24 hours; posttransfusion survival rate is 85–90%.[12] Freezing, ideally using fresh blood, maintains ATP and 2,3-DPG levels, but solutions containing pyruvate, glucose, phosphate, and adenine can restore older blood.[13] The major use of frozen cells is to store units of a rare phenotype. In addition, the military can transport large volumes of frozen units.

Indications for RBC Transfusion

A unit of PRBCs should increase the hemoglobin (Hgb) level by 1 g/dL or the hematocrit level by approximately 3%. However, continued blood loss causes suboptimal response to transfusion. More chronically, hemolysis caused by either immune red cell damage or mechanical trauma shortens the survival of transfused cells, and hypersplenism can lead to sequestration and increased destruction of red cells. Also, transfusion suppresses erythropoiesis; thus sustained results of transfusion may be less than expected.

Chronic Anemia Generally, the signs and symptoms of anemia develop at a Hgb level of <7–8 g/dL. With gradual onset, the body's compensatory mechanisms for maintaining oxygen delivery to the tissues are effective. Cardiac output and intracellular 2,3-DPG are increased; thus oxygen unloads at a lower oxygen saturation of Hgb. When chronic anemia is a result of red cell destruction, the healthy bone marrow can respond by increasing production by up to sixfold, provided sufficient dietary iron, folate, and vitamin B_{12} is ingested. The decision to transfuse depends on how a given individual manifests the signs and symptoms of anemia, determined by underlying health status, cardiorespiratory reserve, and activity level. In the perioperative setting, it is important to cross-match sufficient units to compensate for the lower initial Hgb, particularly in a multiply transfused patient with alloantibodies that may be difficult to match.

Perioperative Period Much of the dogma surrounding perioperative transfusion has few supporting data. One example is the use of 10 g/dL of Hgb as the gold standard for the red cell transfusion trigger during the perioperative period.[14] A rule of thumb is that assuming no preoperative anemia, blood losses of 5–10% of total blood volume require minimal replacement therapy, losses of up to 20% can be replaced exclusively with volume expansion, whereas losses of >25% generally require red cell transfusion to restore oxygen-carrying capacity, along with volume expansion to restore intravascular volume and maintain perfusion. The availability of hemoglobin measurement, acid–base status, and central venous and mixed venous oximetry, combined with tools to assess intravascular volume in most hospital environments, supersedes such rules, allowing more individually tailored, closely monitored transfusion therapy designed to provide sufficient tissue oxygenation. This is still vague and subjective; thus when to transfuse remains a clinical decision. The American Society of Anesthesiologists provides extensive guidelines, available at http://www.asahq.org. Societies, such as the Society for the Advancement of Blood Management (http://www.sabm.org), champion blood conservation techniques and appropriate safe but lower transfusion triggers aimed at minimizing allogeneic blood product usage in the perioperative period. The National Institutes of Health suggest that most surgical patients who are not actively bleeding do not need transfusion unless the Hgb level decreases to <7 g/dL, and such levels of Hgb may not interfere with wound healing or automatically make general anesthesia a risk.[14]

Nonetheless, questions concerning an objective measurement to determine a safe transfusion trigger still arise. Animal models of acute normovolemic anemia can be helpful and describe the whole body oxygen extraction ratio (OER) as an indicator of when to transfuse:[15]

$$OER = ((CaO_2 - CvO_2)/CaO_2) \times 100, \text{ normally } 22–32\%$$

$$CaO_2 = (0.0134 \times Hgb \times SaO_2) + 0.003 \times Pao_2 \text{ mL/dL}$$

$$CvO_2 = (0.0134 \times Hgb \times SvO_2) + 0.003 \times PvO_2 \text{ mL/dL}$$

$$O_2 \text{ consumption} = \text{Cardiac output} \times (CaO_2 - CvO_2) \text{ mL/min}$$

These studies make the seemingly valid assumption that the heart is the major organ at risk. With progressive hemodilution, healthy animals with normal coronary trees were able to maintain normal levels of oxygen consumption (200–250 mL/min) through a moderate increase in cardiac output, an increase in coronary blood flow, and a linear increase in the OER up to a ratio of 50%. As the hematocrit decreased to <10%, however, oxygen consumption began to decrease, and the animals were no longer able to increase the OER. An OER of 50% was the critical point at which the myocardium converted from aerobic to anaerobic metabolism, reflected in net lactate production. At that point, metabolic acidosis developed, resulting in hemodynamic instability. Dogs with critical coronary stenosis converted to anaerobic metabolism and went into congestive heart failure at an OER of >50%, but that an OER of >50% occurred at a hematocrit of 17.0% in the dogs with critical stenosis, compared with a hematocrit of 8.6% in the healthy group, is consistent with the 10% above.[16,17] Dog hearts with normal coronary arteries developed subendocardial ischemia then cardiac failure at a hematocrit <10%; hypertrophied hearts, at higher risk of subendocardial ischemia, may fail at higher hematocrits, although this was not studied.[16] OER can be calculated whenever a pulmonary artery catheter is being used, and therefore mixed venous oximetry can be performed and thus used to help assess transfusion need. An OER of 50% can be used as a red cell transfusion trigger because it appears to be a valid indicator of marginal myocardial oxygen reserve in both healthy people and individuals with coronary artery disease if it is reasonable to directly extrapolate the above animal data to humans. Given the complexity that this adds to clinical practice, most clinicians follow published guidelines based on Hgb levels.

The controversies surrounding transfusion triggers in neonates are beyond the scope of this chapter and are complicated by uncertainties concerning the diagnosis of symptomatic anemia

TABLE 85–1.

Classification of Transfusion Reactions

- Acute
  - Immune mediated
    - Acute hemolytic transfusion reaction (AHTR)
    - Transfusion-related acute lung injury
    - Febrile nonhemolytic transfusion reaction
    - Urticarial reaction
    - Anaphylactic
  - Nonimmune mediated
    - Nonimmune hemolysis
    - Bacterial contamination
    - Volume overload
    - Metabolic
    - Embolic
- Delayed
  - Immune mediated
    - Delayed hemolytic transfusion reaction (DHTR)
    - Posttransfusion purpura
    - Graft-versus-host disease
  - Nonimmune mediated
    - Transfusion-transmitted infection
    - Iron overload

in this group. Similarly, there are fewer data addressing transfusion in pediatric patients compared with adults. Of interest, the humoral and cellular immune systems of the neonate are immature, particularly with prematurity. This introduces a small but real risk of transfusion-induced graft-versus-host disease or thrombocytopenia after transfusion of leukocytes (PRBCs or platelet transfusions) in premature infants or in a fetus undergoing intrauterine transfusion.[18] Irradiated cells are indicated in these settings. Another risk in premature infants is the development of clinical cytomegalovirus (CMV) infection in infants of CMV-seronegative mothers.[19] CMV-seronegative blood is now routinely used in these neonates. The only setting in which there may be some data to support use of CMV seronegative units is in severe combined immune deficiency infants undergoing bone marrow transplantation. Otherwise, contemporary leukoreduced products are considered "CMV safe," equivalent to seronegative products. Leukoreduction by filtration reduces but does not eliminate the risk of these complications.[20]

Safety of Blood Transfusion

Transfusion safety relies on the avoidance of transfusion reactions, as classified in Table 85–1, that have multiple etiologies. Immune-mediated reactions are a result of transfusion of an incompatible blood product, as described below. The single most important contribution to transfusion safety is uncompromising attention to all details of patient, sample, and blood product identification.

Red Blood Cell Compatibility

Compatibility relies on the recipient not recognizing the allogeneic blood transfusion as foreign. Sensitization to alloantigens, with formation of the alloantibodies that determine incompatibility, can occur after transfusion, transplantation, or pregnancy. The most clinically important antibodies, or isohemagglutinins, react with antigens of the ABO system, are naturally occurring, complement-fixing antibodies that require no prior sensitization, and typically result in immediate intravascular hemolysis of transfused erythrocytes and a severe hemolytic transfusion reaction (HTR). The chance of ABO incompatibility with an unmatched transfusion is 1 in 3, leading to a life-threatening HTR with approximately 10% mortality.[21] Anti-A and anti-B antibodies are classically associated with severe HTRs, but reactions to anti-Rh (D, C, E, c, e, f, or ce), Kell, Duffy, or Kidd system antibodies are actually more common.[22] Table 85–2 details ABO compatibility of blood products.

Alloimmunization The likelihood of sensitization to other antigens depends on both the variable immunogenicity of the particular red cell antigen and the immune response of the host; HTRs are three times more common in females.[22] Such alloimmunization is best understood for the Rhesus (Rh) D antigen, studied extensively because of the important role played in hemolytic disease of the newborn. It is a highly immunogenic and clinically important antigen associated with severe HTRs. Up to 80% of RhD-negative individuals, and up to 95% after massive transfusion, produce anti-D antibodies after exposure.[23] Those who generate anti-D after an exposure are more likely to develop other red cell alloantibodies, whereas those not generating anti-D rarely develop other alloantibodies.[24] Other antigen systems are less immunogenic; Kell (K) antigens stimulate anti-K in 10% of cases followed in order of magnitude by Rh c and E, Duffy (Fy^a), and Kidd (Jk^a). Antibodies recognizing antigens from the Kell, Duffy, Kidd, Lutheran, and MNSU systems can cause HTRs, typically delayed, although in many pa-

TABLE 85–2.

ABO Compatibility of Blood Products[a]

Recipient blood group	Recipient alloantibodies	ABO-compatible blood products				
		Whole blood	Packed red cells	FFP	Cryoprecipitate	Platelets
A	Anti-B	A	A or O	A or AB	Any	Any
B	Anti-A	B	B or O	B or AB	Any	Any
AB	Nil	AB	O, A, B, or AB	AB	Any	Any
O	Anti-A and anti-B	O	O	A. B, AB, or O	Any	Any

FFP, fresh-frozen plasma.

[a]Compatibility differs with components, as whole blood contains all components, packed red cells contain minimal plasma and antibodies. Donor antibodies are present in FFP, which is a component of platelet products; cryoprecipitate does not contain donor antibodies. ABO compatibility may, however, increase the life span of transfused platelets, and platelet units with high plasma volume should be ABO matched like FFP to avoid hemolysis of recipient native red cells. Patients with blood group O express the H antigen on the red cell surface but anti-H is very rare.

tients they only result in reduced red cell survival.

In terms of alloantibodies detected by blood banks, the most commonly recognized antigens are in the ABO blood group system followed by anti-D, anti-K, anti-E, anti-K, anti-c, anti-Fy,[a] anti-C, anti-Jk,[a] anti-S, and anti-Jk.[b] The incidence of others is <1%.[25] Studies of alloimmunization after transfusion have focused on chronically transfused patients with hemoglobinopathies (such as thalassemia or sickle cell disease), and an approximate 1% risk of alloimmunization has been attributed to every unit transfused.[26] The incidence of red blood cell (RBC) alloimmunization is up to 50% in adults with sickle cell disease,[27] increasing the likelihood of delayed HTRs, which can present as sickle crises.[28]

HLA Alloimmunization Alloimmunization to antigens in the human leukocyte antigen (HLA) system occurs in multiply transfused or multiparous individuals and can be detected in 30–70% of patients given nonleukoreduced RBC or platelet transfusions.[29] The almost ubiquitous adoption of leukoreduction techniques for RBCs and platelets during the 1990s can reduce the incidence of HLA alloimmunization, which can cause febrile nonhemolytic transfusion reactions, platelet transfusion refractoriness, and increased risk of subsequent transplant rejection.[29] Alloantibodies to the human platelet antigen systems (HPA-1 to HPA-5) cause neonatal alloimmune thrombocytopenia and posttransfusion purpura; they may also lead to platelet transfusion refractoriness but are clinically far less important than HLA alloantibodies.

Hemolytic Transfusion Reactions Immune-mediated HTRs result from recipient alloantibodies reacting to transfused RBC surface alloantigens. HTRs can be classified as acute (within hours of transfusion), delayed (within days or weeks of transfusion), intravascular, and extravascular.

Acute HTRs Acute HTRs are a result of existing, circulating alloantibodies to alloantigens on transfused RBCs. If the alloantibody fixes complement (such as anti-A or anti-B), acute, intravascular, hemolysis occurs, which is a medical emergency. Acute HTRs have an estimated frequency of 1 per 25,000 RBC units.[30] The mortality of 1 in 600,000 RBC units[31] is primarily caused by ABO incompatibility.[32]

Signs and symptoms of an acute HTR can be nonspecific and confounded by the patient's clinical condition; consequently, a high index of suspicion and meticulous identification of patients and blood products is essential. Although chills; infusion site, abdominal, chest, or back pain; nausea; anxiety; and dyspnea may be reported by a conscious patient, fever, hypo- or hypertension, hemoglobinuria, anuria, shock, or coagulopathic bleeding may be the first signs of an acute HTR in anesthetized patients. The etiology of profound shock is the activation of the complement cascade with bradykinin production from factor XII activation, C3a- and C5a-induced histamine and serotonin release from mast cells leading to increased vascular permeability, bronchial and intestinal smooth muscle contraction and neutrophil degranulation, and C5a-mediated capillary vasodilatation. Numerous cytokines (tumor necrosis factor, interleukin [IL]-1, IL-6, IL-8) also play a role.[33] Disseminated intravascular coagulation (DIC) results from complement-mediated activation of factor XII and extrinsic pathway activation by stromal thromboplastins from lyzed erythrocytes.

Free hemoglobin does not appear to have direct toxic effects,[34] and shock-induced renal failure and DIC convey most of the morbidity and mortality.[35] Therefore, prompt supportive therapy with fluids, inotropes, and vasopressors as indicated is crucial, and corticosteroids may be considered in the setting of resistant vasoplegic shock. DIC can be managed with hemostatic blood products as required; the efficacy of heparin or activated protein C in this setting is not established.[36]

Immediate notification of the blood bank is essential, as another patient is likely to erroneously receive the unit intended for the patient experiencing the acute HTR. An anticoagulated ethylenediaminetetraacetic acid (EDTA) and a serum specimen, as well as a posttransfusion urine sample, should be sent with all suspected blood units and infusion tubing. Table 85–3 details laboratory testing for suspected HTRs.

Delayed HTRs Delayed HTRs require a secondary or anamnestic antibody response to a transfused RBC alloantigen in a recipient previously sensitized by transfusion or pregnancy. Detectable antibody levels are not present at the time of pretransfusion serologic testing or transfusion, but appear within days of the transfusion, which is why transfused patients need to have serologic testing repeated after 4–5 days.[37]

The frequency of delayed HTRs is estimated to be 1 per 1500 units. Although fatalities have been associated with delayed HTRs, they were not believed to be causative.[32] Alloantibodies are typically against antigens in the Rhesus, MNS, Kell, Kid, or Duffy systems, but rarer antigens may also be involved.

TABLE 85–3.

Diagnosis of Hemolytic Transfusion Reactions

	Onset	Duration
Plasma free hemoglobin	Immediate	5–12 Hours
Methemalbumin[a]	1 Hour	24 Hours
Direct antiglobulin test (DAT)[b]	Immediate	Hours
Indirect antiglobulin (IAT)	Days	Weeks
Bilirubin[c]	1 Hour	12 Hours
LDH[c]	1 Hour	24 Hours
Haptoglobin[c]	Hours	Days
Urine free hemoglobin	1 Hour	24 Hours

HTR, hemolytic transfusion reaction.
[a]Primarily for acute hemolytic transfusion reactions
[b]The DAT will only be positive until all incompatible cells have been destroyed; frank hemolysis (free hemoglobin › 50 mg/dL) is visible as "pink" plasma. ABO incompatibility causes a positive DAT, whereas other alloantibodies (e.g., anti-Kell) cause a positive IAT.
[c]May be seen in acute HTRs but more useful for confirming delayed hemolysis. When testing urine for free hemoglobin, distinguish from hematuria or myoglobinuria. The time course of urine hemoglobin is dependent on plasma hemolysis and bladder clearance, i.e., urine output.

Opsonized RBCs are cleared by the reticuloendothelial system, resulting in a slower and less severe extravascular hemolysis. A history of fever, anemia, and recent blood transfusion may be the only clue to a delayed HTR, and many pass undetected.[22] Rarely, a delayed HTR causes intravascular hemolysis with the clinical picture described for acute HTRs. Erythrocyte destruction is maximal 4–13 days posttransfusion; a positive direct antiglobulin test is found after 2–3 days, followed by spherocytes in peripheral blood (3–4 days) and antibodies detectable by indirect antiglobulin test, anemia, jaundice, and possible hemoglobinuria (5–7 days).

Pseudo HTRs Poor transfusion practices, such as transfusion of aged, overheated, or frozen cells, osmotic hemolysis by hypotonic solutions, mechanical hemolysis from inappropriate administration equipment, hemolysis from bacterial or parasitic contamination, or coincidental presentation of congenital hemolytic conditions (e.g., sickle trait or glucose-6-phosphate dehydrogenase deficiency) presenting at the time of transfusion (e.g., surgery), all lead to a nonimmune-mediated or "pseudo" HTR. Nonimmune hemolysis can be induced by mishandling of blood, overheating, and mixing with nonisotonic solutions.

Plasma Component Derivatives

Plasma is separated from PRBCs through centrifugation of whole blood at the time of collection, or collected by apheresis as a single product or as a byproduct of platelet or red blood cell apheresis. Plasma can be further processed into its derivatives through the cold ethanol fractionation method of Cohn. This chapter discusses features and uses of fresh-frozen plasma (FFP), cryoprecipitate, and other products derived from pooled plasma.

Fresh-Frozen Plasma Plasma is the fluid compartment of blood and consists of 90% water, 7% protein and colloids, and 2–3% nutrients, crystalloids, hormones, and vitamins. The protein fraction also contains the soluble clotting factors. Plasma frozen at 0.4°F (18°C) or colder within 6 hours of donation is labeled FFP. This product may be stored up to 1 year before use, at which time it is thawed over 20–30 minutes. The activities of the labile coagulation factors (V and VIII) decrease after thawing but remain adequate for at least 24 hours. Plasma that is not immediately frozen as FFP becomes either "liquid plasma" (stored at 33.8–42.8°F [1–6°C]) or "source plasma" (stored at 0.4°F [18°C] or colder) and is used for the preparation of plasma derivatives: albumin, clotting-factor concentrates, and immunoglobulin preparations. When FFP is thawed at 39.2°F (4°C), a precipitate separated by centrifugation forms, resulting in cryoprecipitate and cryo-poor supernatant.

Solvent detergent (SD) plasma is an alternative to FFP. SD plasma is a pooled product (2500 donor units per pool) and subjected to a solvent detergent treatment process combining the organic solvent tri(n-butyl)phosphate with a nonionic detergent, Triton X. This inactivates lipid-enveloped viruses, including human immunodeficiency virus (HIV) types 1 and 2, HBV, hepatitis C virus (HCV), human T-cell lymphotropic virus (HTLV) types 1 and 2, hepatitis G virus (HGV), vesicular stomatitis virus, and Sendai virus, while preserving the structural and functional integrity of most plasma proteins. However, it does not inactivate nonenveloped viruses, such as parvovirus B19 and hepatitis A virus (HAV), or the causative agents of various rare encephalopathies, including Creutzfeldt-Jakob disease. The increased prevalence of parvovirus B19 and HAV makes transmission by transfusion of pooled blood components a potential concern, although pooled SD plasma also contains significant amounts of neutralizing antibody to both parvovirus B19 and HAV. It is unclear what the real value and risk of SD plasma is compared with FFP, but, at present, the cost of SD plasma is much more than FFP.

Indications for FFP Audits of transfusion practices have consistently demonstrated that FFP is commonly used inappropriately.[38] Such inappropriate use includes reconstituting "whole blood" by coadministration with RBCs, volume expansion, and as a source of nutrients. Acceptable indications are discussed below.

Liver Disease and Transplantations Patients with severe liver disease have low levels of the vitamin K-dependent clotting factors (II, VII, IX, and X) in addition to thrombocytopenia associated with hypersplenism and a hyperfibrinolytic state. These patients develop a prolonged prothrombin time (PT) and partial thromboplastin time (PTT). In addition, the thrombin time (TT) may be prolonged, fibrin split products may be elevated, and in later stages, the fibrinogen level decreases. Hemorrhage from portosystemic varices is complicated by this multifactorial coagulopathy.

Infusion of FFP is indicated during bleeding episodes to normalize the PT or PTT. In the absence of anatomic lesions, bleeding does not usually occur until the PT is >16–18 seconds or the PTT is >55–60 seconds and prophylactic FFP (e.g., before a liver biopsy) is not indicated at lower values. The PT and PTT are poor predictors of surgical bleeding, and mild abnormalities in these coagulation tests may not correct despite large volumes of FFP; platelet transfusion, cryoprecipitate, antifibrinolytic drugs, and even recombinant-activated factor VII may be required.[39] This scenario is exaggerated in the setting of orthotopic liver transplantation complicated by an anhepatic stage, massive PRBC transfusion, and DIC. Large volumes of FFP are typically used, ideally guided by clinical assessment of bleeding and coagulation test results.[40]

Massive Transfusion This is the most common situation during which anesthesiologists administer combinations of blood products. FFP is often required after large quantities of PRBC (>1 blood volume in 24 hours) because of the dilutional coagulopathy arising from the PRBC and crystalloid solutions, both of which lack coagulation factors. A predetermined algorithm for FFP transfusion per units of PRBCs is often unreliable, as dilutional thrombocytopenia also complicates the coagulopathy after massive transfusion.[41,42] As recommended in the transfusion guidelines published by the American Society of Anesthesiologists, FFP transfusion should ideally be guided by abnormal PT and PTT results when available as the degree of coagulopathy can be unpredictable.

Disseminated intravascular coagulation may be secondary to sepsis, liver disease, hypotension, perioperative hypoperfusion, trauma, obstetric complications, leukemia, or underlying malignancy. Successful treatment of the underlying cause is paramount. Pa-

tients with DIC leading to coagulopathic bleeding should be given FFP to correct PT and PTT abnormalities, but as in severe liver disease, FFP alone may fail to normalize PT and PTT.[43] The need for cryoprecipitate or platelet transfusion should also be evaluated.

Rapid Reversal of Vitamin K Antagonists Warfarin (Coumadin) inhibits the hepatic synthesis of vitamin K-dependent clotting factors (II, VII, IX, and X), inducing functional deficiencies of these factors that can correct within 48 hours after drug discontinuation if diet and vitamin K absorption are normal. Vitamin K administration corrects the coagulopathy in 12–18 hours. In an emergency, the deficiency of clotting factors can immediately be corrected by FFP transfusion. However, a large volume of FFP may be required, and if unlikely to be tolerated, smaller volumes of FFP can be augmented with a bypassing agent such as prothrombin complex concentrates or more commonly recombinant activated factor VII.[44] In the absence of bleeding, the potential danger of excessively prolonged PTs must be weighed against the risks of FFP infusion, and FFP is rarely indicated.[45]

Thrombotic Thrombocytopenic Purpura and Hemolytic Uremic Syndrome In some patients with thrombotic thrombocytopenic purpura (TTP), hemolytic uremic syndrome (HUS), or the syndrome of hemolysis, elevated liver enzymes, and low platelets associated with preeclampsia (HELLP) syndrome, FFP exchange transfusion has been clinically therapeutic; plasmapheresis is preferred if there is concern for fluid overload.[46,47] The mechanism of the therapeutic effect of FFP is likely to involve transfused anticoagulant proteins such as protein C and antithrombin III, which may restore endothelial prostaglandin I_2 (prostacyclin) production and inhibit the agglutinating activity of the abnormal plasma.[48] Alternatively, it may inhibit the release of large-molecular-weight von Willebrand factor (vWF) multimers or restore their normal processing in the circulation by deficient ADAMTS13 enzyme.[49] The use of cryo-poor supernatant for refractory TTP has been suggested, but the advantage is unestablished.[50]

Dosage One unit of FFP derived from a unit of whole blood contains 200–280 mL; apheresis may contain as much as 800 mL. On average, there are 0.7–1 unit/mL of activity of each coagulation factor per mL of FFP and 1–2 mg/mL fibrinogen. For perioperative use, the FFP dose may be estimated at 8–10 mL/kg and should be ordered as the number of milliliters to be infused for pediatric patients or units for adults. Laboratory measurements and clinical response determine the need for additional doses.

Compatibility and Side Effects Fresh-frozen plasma is screened for unexpected RBC antibodies and should be ABO-type compatible as it contains anti-A (groups O and B) and anti-B (groups O and A). Cross-matching is not performed. The Rh(D) type is not always matched because immunization to Rh(D) antigen has rarely been reported as a result of transfusion of Rh(D)-positive plasma to Rh(D)-negative individuals. Hemolytic reactions as a consequence of infusion of an undetected antibody directed toward recipient RBC antigens are rarely seen, as is alloimmunization to RBC antigens.[51]

Fever, chills, and allergic reactions may occur and are treated symptomatically. Typical urticarial reactions are believed to result from recipient antibodies interacting with donor plasma protein antigens. Rarely, severe allergic reactions occur. Some are believed to be caused by donor antibodies reacting with recipient leukocytes or protein antigens. Anaphylactic reactions may occur after infusion of plasma (containing IgA) into patients with IgA deficiency and antibodies to IgA.[52] IgA-deficient plasma from donors in the national registry can be obtained for these occasional patients. Transmission of infectious disease by FFP has been significantly reduced but not eliminated. Cell-associated CMV is not transmitted by FFP.[53]

Immunoglobulin Preparations Intravenous immunoglobulin (IVIg) is prepared by fractionation of large pools of human plasma. Indications for IVIg use include primary congenital immunodeficiency syndromes, children with HIV infection,[54] chronic lymphocytic leukemia complicated by hypogammaglobulinemia, CMV pneumonia complicating bone marrow transplantation (in combination with ganciclovir),[55] a possible role in preventing severe graft-versus-host disease after bone marrow transplantation, acute and chronic idiopathic thrombocytopenic purpura, and mucocutaneous lymph node syndrome (Kawasaki disease).[56]

Hyperimmune immunoglobulin (HIg) is prepared from large pools of plasma known to contain elevated antibody titers against specific infectious agents. Specifically, CMV HIg is indicated in transplantation recipients seronegative for CMV who receive a seropositive donor organ or in bone marrow transplantation patients with CMV interstitial pneumonia.[55] Hepatitis B HIg is used to provide passive immunity to hepatitis B virus associated with inoculation by or a liver transplantation in HBsAg-positive individuals.

Rhesus HIg is used when fetal Rh(D)-positive RBCs may have entered the maternal circulation of an Rh(D)-negative mother. Rhesus HIg is given to Rh(D)-negative mothers after abortion or amniocentesis as well as before delivery and again postpartum if the child proves to be Rh(D) positive.[57,58] The therapeutic effect is believed to be caused by antibody feedback with T-cell suppression of the B-cell clone responsible for the formation of anti-Rh antibody. Its routine use in obstetrical practice has virtually eliminated alloimmunization of Rh-negative mothers.

Antithymocyte globulin (ATG) is purified from the hyperimmune serum of horses immunized with human T lymphocytes. ATG is used in transplant patients as an adjunct therapy in the treatment of graft rejection.

Cryoprecipitate Cryoprecipitate is prepared from 1 unit of FFP thawed at 39.2°F (4°C). The precipitate is then refrozen in 10–15 mL of plasma and stored at 0.4°F (18°C) or colder for up to 1 year. Cryoprecipitate contains 80–100 units of factor VIII, 100–250 mg of fibrinogen, 50–60 mg of fibronectin, 40–70% of normal vWF levels, and anti-A and anti-B antibodies.

Cryoprecipitate is effectively the blood component containing the highest concentration of factor VIII, vWF, factor XIII, fibrinogen, and fibronectin. Cryoprecipitate may be used to treat bleeding associated with hypo- or dysfibrinogenemia or factor XIII deficiency states, although an equivalent amount of fibrinogen to the usual adult dose of 100 mL is also found in 4 units of FFP. Its use in vWF and factor VIII deficien-

cy has been superseded by individual factor replacement therapy.

Indications: Fibrinogen Deficiency Fibrinogen deficiency may be a result of rare congenital afibrinogenemias or dysfibrinogenemias or more commonly as a result of severe liver disease, DIC, or massive transfusion.[45] These patients often have multifactorial coagulopathies and may require the coadministration of FFP, platelets, and antifibrinolytic agents. Fibrinogen measurements are an important component of a coagulation screen because levels < 100 mg/dL can cause prolongation of both the PT and PTT despite adequate levels of other clotting factors. Low levels of fibrinogen occur during liver transplantation, necessitating cryoprecipitate transfusion.[40]

von Willebrand Disease Initial platelet adhesion to disrupted endothelium is mediated by von Willebrand factor (vWF) interacting with the platelet surface GP1b complex; vWF is low or dysfunctional in the various types of von Willebrand disease. DDAVP (desmopressin acetate; 1-deamino-8-D-arginine vasopressin), which releases stored vWF from platelet granules and endothelial cells, is the initial treatment, but severe bleeding requires cryoprecipitate or vWF concentrate.[59]

Fibrin Glue Fibrin glue results from the mixture of a fibrinogen source (FFP, platelet-rich plasma, heterologous, or more recently autologous, cryoprecipitate) with bovine thrombin, which leads to fibrin formation and enhanced local hemostasis. It has been used for diffuse local bleeding during cardiac surgery[60] and to reduce blood loss and the factor concentrate requirement in surgical patients with von Willebrand disease.[61] Other uses include meniscal tear repair and sealing postoperative neonatal chylothorax.[62] Autologous cryoprecipitate avoids any infectious risks; bovine thrombin can cause anaphylaxis, formation of antibodies to factor V, or activation of coagulation.[63]

Uremic Bleeding Uremia causes coagulopathy, and historically, cryoprecipitate or DDAVP has been used to treat bleeding associated with this.[64] There are no data to support this, although cryoprecipitate could be considered if unresponsive to other therapies.[65]

Dosage The dosage of cryoprecipitate is calculated on the basis of the amount of fibrinogen present in 1 unit of cryoprecipitate, the plasma volume, and the desired increment. The fibrinogen content of cryoprecipitate is variable but, even if relatively low, sufficient response is seen with transfusion of 2–4 units/10 kg. In practice, most adults are given a pooled 10-unit or 100-mL dose that is repeated if the desired response is not seen.

Compatibility and Side Effects Cryoprecipitate can contain anti-A or anti-B antibodies; thus infused units should be ABO plasma compatible. The risks of fevers, chills, allergic reactions, and infectious disease transmission are similar to those of FFP.

Factor Concentrates In the 1940s, Dr. Edwin Cohn developed an ethanol fractionation procedure (the Cohn fractionation procedure) that allowed the fractionation of human plasma into various components, greatly expanding this limited resource by deriving more products from each unit of donated plasma. Sufficient amounts of factor concentrates, however, require pooling of plasma. Present pathogen inactivation technologies have virtually eliminated infectious risks associated with plasma derivatives.

Development of recombinant products has been fueled by concerns of infectious disease risks, but recombinant expression processes are complex and expensive. Mammalian cell culture is most commonly used to optimize posttranslational modifications required for biologic activity, with transgenic recombinant technology being developed to decrease or eliminate reliance on donated human plasma resources or mammalian cell-culture-based recombinant production methods. Recombinant transgenic human antithrombin expressed in goat milk and human α_1-antitrypsin produced in sheep's milk are currently clinically available.

The most common congenital deficiencies of coagulation proteins are hemophilia A (classic hemophilia or factor VIII deficiency) or hemophilia B (Christmas disease or factor IX deficiency). The genes for these coagulation factors are located in close proximity on the long arm of the X chromosome. Limited to males, hemophilia A affects 1 in 10,000 males, whereas hemophilia B affects 1 in 30,000. Familial cases predominate, but more than 30% of cases arise from spontaneous mutations.

Arthropathy is the major morbidity of the hemophiliac secondary to recurrent spontaneous joint bleeding, and such patients are frequently encountered for orthopedic surgery. The major cause of mortality (other than transfusion-related infection) is bleeding, with central nervous system (CNS) hemorrhage occurring in 3–14% of patients, conferring a mortality of 20–50%. CNS hemorrhage occurs predominantly in patients with severe disease (< 1% factor level).

Citrated plasma was first used in 1923 for the treatment of hemophilia by Feissly in Paris, and the development of modern blood banking in the 1930s and expansion of transfusion during and after World War II allowed for more widespread use of whole blood and, subsequently, frozen plasma in the treatment of these fatal hemophilias. The advent of cryoprecipitate revolutionized hemophilia therapy. Cryoprecipitate derived from a single whole-blood collection contains approximately 125 U of factor VIII, and it quickly replaced frozen plasma to treat hemophilia.

The fractionation of plasma using ethanol, glycine, polyethylene glycol, or a combination of glycine and polyethylene glycol, and calcium or barium to precipitate plasma proteins led to the production of factor VIII and factor IX concentrates for clinical use.[66] This enabled high concentration, low volume, intensive infusion therapy for serious and life-threatening bleeding complications, such as intracranial, retroperitoneal, and retropharyngeal hemorrhages, and major surgery. From an infectious standpoint, these large pools of > 1000 donations were universally contaminated with viral pathogens, such as hepatitis B or C, and between 1978 and 1985 most hemophiliacs were tragically infected with HIV from concentrates. Pasteurization and dry heat inactivate HIV and limit hepatitis B transmission; other strategies to limit infection include screening of potential donors for risk factors, surveillance of the blood supply for new pathogens, screening for markers of infectious agents, and other purification steps, including physical and chemical viral inactivation methods.

After cloning of the genes factor VIII and factor IX, recombinant factor VIII and factor IX products were made available that are effective and free from pathogens.[67]

Treatment Regimens The use of prophylactic regimens to maintain trough factor levels at more than 1% of normal reduces the incidence of arthropathy and CNS hemorrhage but requires dosing every 2–3 days with attendant problems and complications associated with long-term venous access.[68]

For the treatment of bleeding, the goal of therapy is to achieve a plasma factor VIII or IX level of between 30% and 50% for non–life-threatening bleeding episodes and a level of 100% for life-threatening bleeds or prophylaxis for surgical procedures using repeated boluses or continuous infusion for a duration of 10–14 days or longer, depending on the severity of the bleed or surgical intervention.

Adjunctive therapy includes DDAVP, a vasopressin analogue used for treatment of patients with mild or moderate hemophilia A. This synthetic octapeptide causes a release of factor VIII (and von Willebrand factor) from endothelial cells, raising plasma factor VIII by approximately 3-fold (range, 2–12-fold) in patients with hemophilia in whom the disease is caused by decreased production or secretion of a functional protein or a protein that has decreased activity. Patients with severe hemophilia do not benefit from its use, as the mutation results in no synthesis, secretion, or a protein with no activity. The DDAVP response is unpredictable but reproducible in a given individual and should be documented by measuring factor VIII levels. The recommended intravenous dose is 0.3 μg/kg infused slowly, as vasodilatation may occur. There have been reports of myocardial infarction and cerebral thrombosis with its use in patients at risk of arterial thrombosis, therefore it should only be used in the setting of a documented coagulopathy.[69]

Dosing of factor VIII concentrates assumes an increase in plasma factor VIII activity of 2% for every 1 IU/kg infused. Cryoprecipitate replacement assumes approximately 80–150 IU per bag of factor VIII per bag of cryoprecipitate (derived from a 450-mL single whole-blood donor collection unit). Thus, a typical 1750-IU dose (50% correction for a 70-kg patient) requires between 10 and 21 units.

Highly purified plasma-derived factor VIII concentrates or recombinant factor VIII concentrates have been available in North America, Europe, and Japan since 1992. These are either full-length or B-domain deleted molecules (the B domain is not required for activity in coagulation) that are expressed in mammalian cell culture (Chinese hamster ovary or baby hamster kidney cell lines) and are purified using immunoaffinity techniques. These products are formulated with added albumin as a stabilizer, but some have been developed that stabilize the factor VIII molecule with nonprotein molecules; despite no reliance on donated blood, the supply of these products is not abundant because of the complex manufacturing process.

Factor IX Concentrates Intermediate- and high-purity plasma products and a recombinant factor IX product are available for the treatment of hemophilia B, all of which undergo at least one viral inactivation or exclusion step in manufacture. Recovery of factor IX after infusion is therefore approximately 1%/IU/kg. The recovery observed with recombinant factor IX is approximately 20% lower than that observed with plasma-derived factor IX, likely because of differences in posttranslational modifications between the recombinant and plasma-derived factor proteins.

Intermediate-purity factor IX products use anion exchange chromatography-selecting proteins containing highly negatively charged epitopes such as the vitamin K-dependent coagulation factors with γ-carboxyglutamic acid-rich domains. Therefore, the other vitamin K-dependent coagulation factors, factor VII, factor X, and prothrombin, are copurified with factor IX and referred to as "prothrombin complex concentrates" (PCCs). PCCs are contaminated with trace amounts of activated forms of these factors, which is the likely explanation for thromboses complicating their use.[70] To minimize the risk of thrombosis with the use of PCCs, it is advisable to achieve a peak factor IX level no higher than 50%; some manufacturers have formulated PCCs with heparin or antithrombin III.[71]

High-purity factor IX products are produced from plasma using techniques of ligand affinity or immunoaffinity chromatography and typically have specific activities greater than 150 IU/mg. A single high-purity recombinant factor IX product has been marketed. Thrombotic complications have not been reported with these high-purity products.

Hemophilia with Circulating Inhibitors Replacement therapy may be complicated by the development of inhibitory antibodies against the infused factors that interfere with factor activity. The incidence of factor VIII inhibitors is approximately 30%, although titers and inhibitory activity vary.[72]

Treatment of acute bleeding episodes can be accomplished by two methods. For patients with low titer inhibitors, hemostasis can be accomplished with large doses of factor VIII or factor IX (e.g., as high as 200 IU/kg given at frequent intervals) in an effort to neutralize, or "override," the circulating inhibitor. Porcine factor VIII can be used to treat an actively bleeding patient with inhibitors to human replacement factors, but problems include inhibitors cross-reacting with porcine factor VIII, allergic reactions, anaphylaxis, and thrombocytopenia caused by binding of porcine von Willebrand factor present in the concentrate to human platelets.

Alternatively, a bypassing agent is required. These bypass agents include PCCs in which contaminant-activated forms of these proteins, factors VIIa, Xa, IXa, and IIa (thrombin), likely enhance the production of a fibrin clot by activating the coagulation pathway later than the level of action of factors VIII and IX. Activated PCCs (aPCCs) have been treated to increase the levels of these activated factors and may be more effective in the treatment of bleeding episodes in patients with inhibitors. They were used as first-line therapy for patients with inhibitors but because of the risk of thrombotic complications with aPCCs,[70] recombinant activated factor VII (rFVIIa) has been licensed as an alternative bypass agent in the treatment of hemophiliacs with inhibitors.[73] The dosage of rFVIIa is 90 μg/kg every 2 hours as necessary, compared with 50–75 IU/kg every 8–12 hours for PCCs or aPCCs. Thrombosis has also been reported with the use of rFVIIa.[74] Coadministration of antifibrinolytic agents, such as ε-aminocaproic acid, is often used as an adjunct to replacement or bypass therapy.

von Willebrand Disease von Willebrand disease (vWD) is an autosomal dominant mucosal, platelet-type bleeding disorder first described by Erik von Willebrand in 1926, which has a prevalence of up to 2% of the general population. The penetrance and severity of the disease vary depending on the type of vWD (type 1, 2, or 3), the specific mutation, the number of affected genes, the patient's blood type, and numerous drug, hormonal, and other parameters. The type of vWD and the patient's response to DDAVP influence the recommended treatment for acute bleeding episodes or for prophylaxis against bleeding.[66] DDAVP releases stored vWF as well as factor VIII from platelets and endothelium, and is often effective for type 1 disease and may be useful in certain patients with type 2 disease. It is not appropriate for use in patients with type 3 disease in whom no stores of vWF exist.

As described for hemophilia A, antifibrinolytic agents are useful adjuncts for replacement therapy for vWD such as in the setting of dental surgery to inhibit fibrinolysis. Estrogens upregulate vWF synthesis and may be useful, especially in women, and may ameliorate menorrhagia.

Plasma-Protein Based Therapy: Factor VIII Concentrates Some intermediate-purity factor VIII concentrates are manufactured from plasma using methods that copurify significant amounts of vWF, but no product has the pattern of multimers that is present in normal plasma.

von Willebrand Factor Concentrates (Plasma-Derived and Recombinant) Several chromatography-purified plasma-derived concentrates enriched in vWF have been studied and may be effective and amenable to viral inactivation steps. Recombinant vWF has been successfully isolated and partially characterized; it is being developed clinically.

Cryoprecipitate was the mainstay of plasma-based therapy for bleeding in patients with vWD until the availability of virally inactivated intermediate-purity factor VIII concentrates that retained functional vWF protein. The factor VIII concentrates are the products of choice for the treatment of bleeding in patients with types 1 and 2 vWD that are unresponsive to DDAVP, and for bleeding in patients with type 3 vWD, as they have a lower risk of transfusion-associated infection than cryoprecipitate.

Acquired Disease Antibodies that inhibit the activity of factor VIII can develop in previously normal patients. Most of these patients have no underlying disease; however, factor VIII antibodies can arise in the setting of autoimmune disorders or in the postpartum period. One-third of these inhibitors resolve spontaneously, but supportive therapy is required while they persist.

Acquired vWD is a rare autoimmune disorder that can occur in association with other autoimmune disorders or lymphoproliferative disease. Antibodies may interact with functional epitopes, and the immune complexes increase the clearance of vWF. Plasmapheresis or immunoadsorption can reduce the circulating levels of inhibitors. Immunosuppressive agents and intravenous immunoglobulin (IgG) are useful adjuncts to abrogate production of the autoantibody. Otherwise, the treatment of these conditions is as for congenital disease with associated circulating inhibitors.

Other Factor Deficiencies Approximately 15% of inherited bleeding disorders are caused by deficiencies of fibrinogen and factors II, V, VII, X, XI, and XIII.[66] As the genes for these factors are not located on the X chromosome, homozygous defects are typically required for symptomatic disease. Hereditary deficiencies of factor XII, prekallikrein, and high-molecular-weight kininogen do not result in bleeding diatheses. The mainstays of therapy for these disorders are cryoprecipitate (for fibrinogen and factor XIII deficiencies) and plasma. Bypass therapy with PCCs, aPCCs, or rFVIIa can be considered for refractory bleeding, and adjunctive therapy with antifibrinolytics may be useful.

Anticoagulant Proteins Plasma-derived concentrates enriched in protein C and antithrombin III are available for treatment of congenital deficiencies that result in thrombosis, and FFP contains normal levels of these circulating anticoagulants. Recombinant-activated protein C (Xigris, Eli Lilly and Company, Indianapolis, IN) is now licensed for the treatment of severe sepsis, and recombinant, transgenic antithrombin III is also available for the treatment of venoocclusive disease in patients who are undergoing bone marrow transplantation, heparin resistance in patients who are undergoing cardiopulmonary bypass, and sepsis.[75]

Platelets

Preparations In 1910, W.W. Duke described the Duke bleeding time, the importance of platelets in hemorrhagic disease, and the value of platelet transfusion. However, it was not until the 1970s before certain specialized centers could reliably offer platelet transfusions because of the preparation and storage problems resulting in loss of platelet viability. Platelets are prepared by centrifuging whole blood, then separating the buffy coat (in Europe) or platelet-rich plasma (United States) for a second centrifugation to produce platelet concentrates (~50 mL per unit). A typical adult dose pools units from 6 donors. Apheresis platelets are collected from single donors using various pheresis devices and reduce donor exposure and thus infection risk. Leukocyte counts are less in apheresis or buffy coat-derived units than in U.S. concentrates (10^6 rather than 10^8), but the introduction of leukoreduction techniques makes this distinction obsolete. Similarly, the risk of alloimmunization to HLA antigens is equal for concentrates or apheresis platelets undergoing leukoreduction.[10] Platelets are stored at room temperature in plastic containers porous to the atmosphere to avoid anaerobic metabolism and acidosis and are licensed for only 5 days of storage.[76] Beyond this time, a storage lesion develops that limits platelet viability.

Platelet preparations contain appreciable volumes of plasma. If inventory constraints or HLA compatibility considerations lead to transfusion of plasma-incompatible products, mild recipient hemolysis may result. This is rarely clinically important unless large volumes are transfused in small patients. Crystalloid-based preservation solutions may allow removal of plasma; such processes could also facilitate viral inactivation by photosensitive dyes. Cryopreserved and lyophilized platelets are areas of future development, with lyophilized platelets close to clinical trials.[77]

Transfusion Triggers Anesthesiologists encounter the need for platelet

transfusions in intensive care and operative settings. The majority (86%) of platelets are given to patients with hematologic malignancies; 68% are given prophylactically, and 32% to treat bleeding episode.[78] Other indications include dilutional thrombocytopenia after massive transfusion-, autoimmune-, or drug-induced thrombocytopenia. Use may be relatively contraindicated in microangiopathic platelet destruction because of TTP, HUS, or DIC. Certain qualitative platelet disorders, either rare congenital conditions (Glanzmann thrombasthenia, Bernard-Soulier) or drug-induced dysfunction (aspirin, clopidogrel, Persantine, abciximab), respond to platelet transfusion. In contrast, high circulating plasma levels of eptifibatide or clopidogrel also render transfused platelets dysfunctional.

The current transfusion trigger for the most common indication of prophylaxis in oncology patients is 10,000/mm^3;[79] in patients who are bleeding or undergoing invasive procedures the trigger is typically higher.[80] A platelet count < 50,000/mm^3 is quoted from the American Society of Anesthesiologists' guidelines. The use of recombinant activated factor VII has been used to augment or replace platelet transfusion, especially in patients refractory to transfusion.[81,82]

Refractoriness to Platelet Transfusion Refractoriness to platelet transfusion can be caused by immune or nonimmune mechanisms.[83] In immune mechanisms, alloantibodies, autoantibodies, drug-associated antibodies, or immune complexes can be responsible. Platelet membrane-associated anti-class I HLA-A and B antibodies are responsible for the majority of platelet refractoriness, and matching of so-called "public" HLA antigens, such as Bw4 or Bw6, forms the mainstay of compatibility testing. Importantly, ABO incompatibility can reduce platelet survival by up to 20%. Other rarer antibodies are HPA or human platelet antigens (polymorphic platelet surface glycoproteins) or platelet surface glycoproteins absent in the recipient (such as GP1b in Bernard-Soulier syndrome or GPIIb/IIIa in Glanzmann thrombasthenia). An antibody does not guarantee refractoriness, and underlying disease processes or immunosuppressive therapy may modulate the clinical picture.[10] Nonimmune mechanisms include microangiopathic destruction (HUS or TTP), sepsis, or fever, especially in the presence of DIC, splenic sequestration, hepatic dysfunction, and certain drugs (such as vancomycin and amphotericin).

Posttransfusion purpura is a rare complication occurring 7–10 days after an immunogenic blood transfusion. It most often affects previously nontransfused, multiparous women. As with neonatal alloimmune thrombocytopenia, the risk for developing posttransfusion purpura is increased among HLA-DR3-positive individuals, and HPA-1a is the antigen most often implicated (in Western populations). At this time, there is no clear understanding of the exact pathology of posttransfusion purpura.

COMPATIBILITY TESTING

Human error is the root cause of almost all fatal acute HTRs, with transfusion of a unit into the wrong patient occurring in 50% of cases. Mislabeling of patient specimens sent to the blood bank and clerical errors in the blood bank occur more often than serologic testing errors, thus attention to design and implementation of safe transfusion practice is of paramount importance, more so than technological advances in serotyping. The aim of compatibility testing is to avoid immune-mediated HTRs resulting from recipient alloantibodies reacting to transfused RBC surface alloantigens. The direct (Fig. 85–1) and indirect (Fig. 85–2) agglutination tests are the mainstay of laboratory compatibility testing.

Pretransfusion testing assures ABO and Rh(D) compatibility and screens recipient plasma for antibodies to less common but clinically important antigens. Figure 85–3 describes the laboratory testing involved in grouping, typing, and crossmatching blood prior to transfusion. When performed in the setting of appropriate controls to prevent clerical error, compatibility determination effectively eliminates risk of acute intravascular hemolytic transfusion reactions. However, it does not eliminate the risk of alloimmunization to non-ABO/Rh antigens, nor does it afford complete protection against delayed hemolytic reactions.

Bacterial Contamination

Bacterial contamination of blood components can be asymptomatic or induce sepsis with a high mortality. It occurs in random donor-pooled platelets (5–30 in 10,000 units) and apheresis platelets (0.5–23 in 10,000 units) stored at room temperature, PRBCs (0.25 in 10,000 units) stored at 39.2°F (4°C), and, rarely, in FFP or cryoprecipitate contaminated during thawing in water baths.[84] Bacterial contamination of platelet products is acknowledged as the most frequent infectious risk from transfusion, occurring in approximately 1 of 2000–3000 platelet

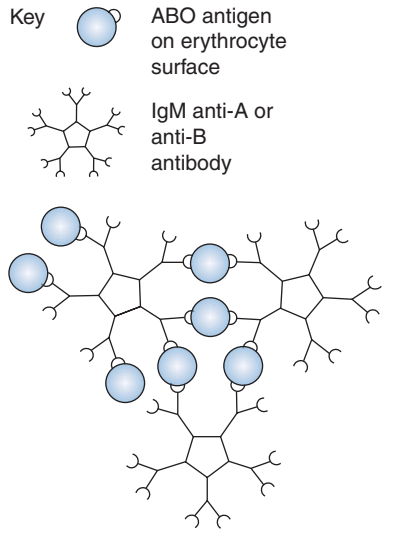

FIGURE 85–1. IgM alloantibodies cross link via surface antigens leading to direct agglutination. Occasionally, IgG antibodies will cause a positive DAT if there is high antigen density.

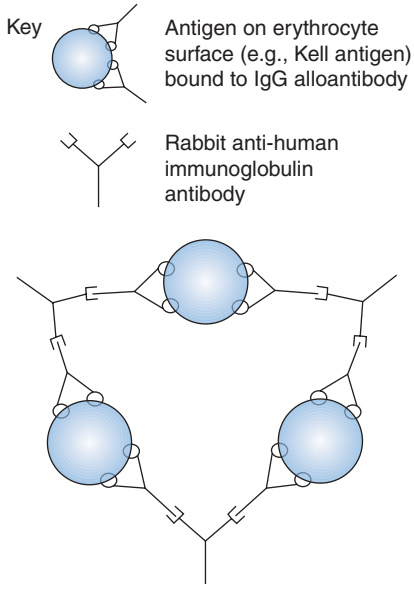

FIGURE 85–2. Antibodies only cross link after addition of rabbit antihuman IgG, causing indirect agglutination.

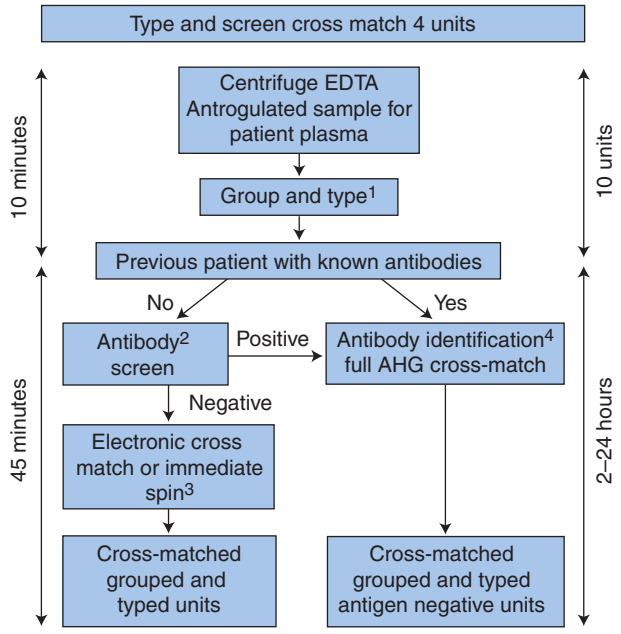

FIGURE 85–3. This schematic depicts the steps taken to type, screen, and crossmatch blood.
1. To determine ABO group and rhesus type, commercial anti-A, anti-B, anti-Rh(D) agglutinate patient cells. This direct agglutination test and hemolysis is visible.
2. "Antibody Screening Test." A panel of commercial red cells of known antigen type (each cell carries numerous antigens) are incubated with patient plasma. In North America, a typical panel of 3 cells (e.g., Immunor Gamma, Immunocor Inc., Norcross, GA) will detect alloantibodies to rhesus (C, c, E, e, f, V, C^W) Kell (K, k, Kp,^{a} Kp,^{b} Js,^{a} Js^b), Kidd (Jk,^{a} Jk^b), Duffy (Fy,^{a} Fy^b), Lewis (Le^a, Le^b) MN (M, N, S, s), Lutheran (Lu,^{a} Lu^b), P_1, and Xg^a antigens The mostly IgG alloantibodies that bind cells then need rabbit antihuman IgG (antiglobulin reagent or Coombs serum) to agglutinate (indirect agglutination test).
3. Electronic or computer crossmatch requires no history of a positive antibody screen, a previous group, type and negative antibody screen from blood bank records, a current group, type and negative antibody screen. An immediate spin is a final check ABO compatibility, looking for direct agglutination (visible clumping or hemolysis) on mixing patient plasma with donor cells.
4. "Antibody identification." A more extensive panel of up to eight commercial red cells of known antigen type (e.g., Ortho Clinical Diagnostics Inc., Raritan, NJ) are tested against patient plasma to identify which antigens are responsible for the agglutination This process may need to be extended to panels expressing rarer antigens not listed above (such as anti-U seen in some sickle cell patients) to identify alloantibodies. Occasionally, this process may take days for multiply transfused patients such as those with sickle cell disease. However, current U.S. practice is to antigen-match patients needing repeat transfusions for all rhesus and Kell antigens to prevent common alloantibody formation, and to reduce the development of subsequent "rarer" alloantibodies and the need for difficult crossmatching.

units, and is considered the second most common cause of death overall from transfusion (after clerical errors) with mortality rates ranging from 1:20,000 to 1:85,000 donor exposures.[85] The incidence of severe septic episodes has not been clearly established but is probably approximately 1 per 50,000 platelet units transfused.[86]

Bacteria can enter the blood bag during venipuncture as a result of inadequate skin preparation; during component preparation, transient bacteremia concurrent with the blood donation, or a break in technique during pooling or sealing; or through disruption of container integrity. Bacterial proliferation occurs more rapidly in platelet concentrates stored for up to 5 days at room temperature than in red cells refrigerated for up to 42 days.

The clinical response may include fever, rigors, skin flushing, abdominal cramps, myalgia, DIC, renal failure, cardiovascular collapse, and cardiac arrest; reactions may be immediate or delayed by several hours. This may be clinically indistinguishable from a febrile nonhemolytic transfusion reaction (FNHTR). If this picture presents, blood samples must be sent to rule out incompatible transfusion, and simultaneously the blood unit must be sent for culture. Patient evaluation includes blood culture; treatment includes stopping the transfusion, supportive measures for developing shock, and broad-spectrum antibiotics.

Although bacterial contamination rate estimates vary, they are generally approximately 0.2–0.3%.[87,88] Clinically recognized septic reactions have been reported at a rate of 1:2,500 to 1:11,400 for whole-blood-derived platelet concentrate pools and 1:15,400 for apheresis platelets. Symptoms occurred after 17–42% of contaminated platelet transfusions, with a 17% mortality rate.[88]

Gram-negative bacteria, including *Pseudomonas*, *Yersinia*, *Enterobacter*, and *Flavobacterium*, are organisms commonly associated with a contaminated unit of refrigerated blood. In contrast, platelet concentrates contaminated with *Bacillus*, *Escherichia coli*, *Klebsiella*, *Staphylococcus aureus*, *Staphylococcus epidermidis*, *Serratia marcescens*, and *Streptococcus* account for 85% of fatal reactions.[87,89] Bacterial contamination may be masked clinically by concomitant antibiotic administration.

Syphilis

Screening for syphilis was mandated in 1958, but the last reported case of transfusion-related disease was in 1966. Any risk of transmission is reduced by sensitivity to most penicillin or cephalosporin antibiotics. *Treponema pallidum* is not currently a threat to the U.S. blood supply.

Viral Contamination

The risk for infection by HIV and hepatitis C viruses is extremely rare in the United States (less than 1 case per 2 million units transfused) after implementation of nucleic acid testing (NAT) in 1999.[90,91] Contrast this blood safety record to the risk of morbidity or mortality in people with indications for transfusion for which blood products are withheld, and HIV or HCV should not affect transfusion decisions. However, a rare but real risk exists, so inappropriate transfusion should be avoided.

Other Viral Pathogens

The HAV, a nonenveloped RNA virus in the *Picornaviridae* family, is transmitted predominantly through the fecal–oral route. Because acute HAV infection is generally symptomatic, infected prospective donors are typically eliminated before donation.

Hepatitis B

The HBV is a DNA virus in the *Hepadnaviridae* family. The infective virion

is known as the Dane particle and has surface and core components: HBsAg and hepatitis B core antigen (HBcAg). Among blood donors, the prevalence of new HBV infections declined from 1.97 per 100,000 *person years* to 1.27 between 1998 and 2001. Most current HBV transfusion transmission cases correspond to blood donations by asymptomatic donors during acute infections before HBsAg appearance and therefore detection (a "window period" of 37–87 days). With current screening, the risk of HBV transmission per unit is approximately 1:205,000 units, with likely reduction in risk with the introduction of NAT testing.[90,91]

Hepatitis C

The HCV is an RNA virus in the *Flaviviridae* family that has 6 genotypes. In the United States, genotypes 1, 2, and 3 cause 75%, 10%, and 10% of infections, respectively, and have similar replication and transmission rates and natural history. The risk of HCV transmission by transfusion declined after the introduction of serologic testing for HCV antibody in May 1990, and NAT testing for the HCV viral genome in 1999 reduced the test negative window period to 40 days. Combined NAT and serologic testing reduced the risk from an estimated 1:276,000 units to 1:1,935,000 units.

Hepatitis D

Originally called the delta agent, hepatitis D virus is a defective RNA-containing passenger virus that requires HBV to act as a "helper" for assembly of envelope proteins. Screening for hepatitis B therefore helps prevent transfusion-associated hepatitis D.

Hepatitis E

The hepatitis E virus (HEV) is an RNA calicivirus associated with fecally contaminated water supplies, which usually causes a self-limited illness; it is not a known transfusion-related pathogen.

Human Immunodeficiency Virus-1

The Centers for Disease Control and Prevention (CDC) report 9352 AIDS cases in the United States linked to transfusion through December 31, 2001, including 41 adults or adolescents and 2 children who received blood from HIV-seronegative donors. In addition, during the 1980s, 4799 hemophiliacs and other patients with coagulation deficiencies acquired AIDS as a result of therapy with plasma derivatives.

Among 37 million donations screened for HIV-1 RNA by NAT between 1999 and 2002, only 12 were NAT positive and antibody negative.[91] The risk with plasma derivatives, such as coagulation factor concentrates and albumin and immunoglobulin preparations, can be expected to be even lower because of additional viral inactivation processes, including heat (pasteurization), physicochemical processes (SD treatment), and nanofiltration, that have been implemented since the mid-1980s; since then, no new HIV infections have been attributed to manufactured blood products.

Human Immunodeficiency Virus-2

Human immunodeficiency virus-2, a retrovirus linked more closely to the simian immunodeficiency virus than to HIV-l, was recognized initially in West Africa. In 1998, the CDC reported 79 cases of HIV-2 infection in the United States, mostly in natives of West African countries. Transmissibility of HIV-2 appears to be lower, the course of infection milder, and the interval between infection and AIDS and disease longer than associated with HIV-1, presenting a lower risk for HIV-2 transmission by transfusion.

Human T-Lymphotropic Virus-I and –II

HTLV-I and -II are closely related retroviruses in the *Oncovirinae* group. In contrast with HIV, HTLV is rarely present in cell-free plasma and shows little active replication in infected humans. HTLV is found around the globe, with endemic foci in southern Japan, the Caribbean, South America, and the Middle East. A sensitive HTLV-I/II combination assay was introduced in 1998, and the threat of acquiring HTLV infection from screened blood is currently minimal.

Human Herpesvirus

Human herpesviruses (HHVs) are enveloped, structurally complex, double-stranded DNA viruses that cause common infectious diseases, usually associated with lifelong carrier states and the possibility of recurrent reactivation infections. However, the common alpha herpesviruses, herpes simplex and varicella zoster, are not linked to transfusion-transmitted infections.

Cytomegalovirus Infection

CMV, a beta herpesvirus (HHV-5), can infect a wide range of cell types, primarily leukocytes; cell-depleted blood components (plasma, cryoprecipitate) do not transmit CMV. In immunocompetent people, this community-acquired infection is either asymptomatic or associated with a mild, self-limited infectious mononucleosis-like syndrome. However, latent virus persists permanently intracellularly, allowing lifelong potential for reactivation of infections or viral transmission by transfusion of cellular blood products or transplanted donor organs.

In immunosuppressed patients, CMV infection leads to morbid and occasionally lethal pneumonitis, hepatitis, gastroenteritis, retinitis, and other inflammatory conditions requiring treatment with ganciclovir and other antiviral agents. Primary infection in pregnancy may be associated with severe fetal malformations and congenital infections complicated by jaundice, hepatosplenomegaly, microencephaly, and thrombocytopenia with significant mortality. Screening for CMV status is essential for neonates, bone marrow transplant recipients, and transplant recipients. A CMV-seronegative transplant recipient is not denied an organ from a seropositive donor but is treated prophylactically and tested for infection. If leukoreduced blood components are not available, transfusion from CMV seropositive donors is avoided to reduce viral load.

At least 50% of blood donors have antibodies against CMV, thereby indicating previous CMV infection. CMV infection develops in 2% of CMV-seronegative transplant recipients given CMV-seronegative blood, compared with 30–60% historically seen after infusion of CMV-unscreened blood components.[66] Additional safety is conferred by pre-storage leukocyte reduction and apheresis platelet collection.

Epstein-Barr Virus

Epstein-Barr virus (EBV), a gamma herpesvirus (HHV-4), causes infectious mononucleosis and is closely associated with Burkitt lymphoma, nasopharyngeal carcinoma, and posttransplantation lymphoproliferative disease. More than 90% of the adult population has evidence of previous exposure, and virus-specific cytotoxic T lymphocytes lyse EBV-infected B lymphocytes, so transfusion-transmitted EBV infection

is rare in both immunocompetent and immunosuppressed recipients.

Parvovirus

Patients with sickle cell anemia, thalassemia, and other conditions associated with shortened red blood cell survival are at risk for developing acute aplastic or hypoplastic anemia after infection. Others at risk for aplasia after parvovirus infection include immunodeficient patients, HIV-infected patients, solid-organ transplant recipients, and children with malignancies. Persistent parvovirus infection may cause severe chronic anemia in immunocompromised patients. Acute parvovirus infection during pregnancy may result in fetal loss, neurologic abnormalities, and congenital infection. Red blood cell aplasia and chronic anemia caused by parvovirus infection often respond to infusion with immunoglobulin preparations.

Parvovirus can be expected to be present in 1:20,000 to 1:50,000 blood donors or a higher incidence during epidemic periods. Reactive antibodies may be present in the donor or the recipient, and only three cases of transfusion-related transmission have been reported. Pooled plasma products theoretically pose a greater threat, and factor VIII concentrates demonstrated a 40% risk of parvovirus infection.[92] The pasteurization process inactivates virus in albumin-based products.

West Nile Virus

West Nile virus (WNV) is a member of the *Flaviviridae* family, the genus *Flavivirus*, and the Japanese encephalitis virus serocomplex that includes Japanese encephalitis virus and St. Louis encephalitis virus. Viruses in this complex are arthropod-borne viruses, or arboviruses (i.e., transmitted by mosquitoes and other arthropod vectors), with the potential to cause meningoencephalitis. WNV was first isolated in 1937 in the West Nile district of northern Uganda and derives its name from that region. The natural life cycle of the virus includes female mosquitoes as vectors, with birds serving as the primary vertebrate hosts. Humans are incidental hosts, with transmission occurring through bites of infected mosquitoes. Peak transmission occurs in the late summer and early fall.

Since 1999, there have been sporadic outbreaks in the United States, with more than 4000 cases—277 attributed to a 2002 epidemic. In 2002, 23 cases of transfusion (any blood component) or transplant-related transmission were reported; 12 patients developed meningoencephalitis and more severe outcomes were seen in immunocompromised patients.[93]

Currently, donors are asked about fevers or exposure to endemic areas, and recommendations exclude donors with suspected or confirmed diagnosis of WNV within 120 days of donation. Since June 2003, NAT was instituted on pooled donor samples, and 800 of 6 million U.S. blood donations were WNV NAT positive. Despite this, 6 cases of transfusion-transmitted WNV infection occurred in susceptible individuals.[94] The risk of WNV infection depends on the immune status of the recipient, presence of donor antibodies, and the rate of endemic disease prevalence.

Lyme Disease and Other Tick-Borne Illnesses

Borrelia burgdorferi, the agent responsible for Lyme disease, is transmitted to humans by deer tick bites. Spirochetemia probably occurs after infection and may be present in asymptomatic individuals, but again, only rarely documented transfusion-related transmissions have been reported for this or other tick-borne pathogens: *Babesia* species (babesiosis) and *Rickettsia rickettsii* (Rocky Mountain spotted fever).

Malaria

Malaria in the United States is typically limited to travelers, military personnel, and immigrants from endemic countries. Prevention of transfusion-transmitted malaria relies on deferral of blood donors immigrating or returning from malaria-endemic regions; there are no available screening tests. Approximately 3 transfusion-associated malaria cases occur per year in the United States, with a reported incidence of 0–0.2 cases per million units.

Babesiosis

Babesiosis is a malaria-like zoonosis in which humans are infected incidentally, usually through the bite of an infected tick. Babesia infections are usually asymptomatic or cause mild flu-like symptoms but can be fatal in the immunocompromised. Endemic throughout the United States, more than 40 cases of cellular transfusion-transmitted babesiosis have occurred since 1980. A history of babesiosis precludes blood donation, but no screening test is available.

Toxoplasmosis

Toxoplasmosis is caused by the intracellular protozoal parasite *Toxoplasma gondii*, whose usual host is the domestic cat. Transmission is via cats or from undercooked pork, goat, lamb, beef, or wild game. There is evidence of infection in 20–25% of the U.S. population, but transfusion-associated disease has only been described in immunocompromised patients.

Chagas Disease

The flagellate protozoal parasite *Trypanosoma cruzi* causes Chagas disease. The disorder is widespread in Latin America. Severe complications include myocarditis, meningoencephalitis, cardiomyopathy, megacolon, or achalasia. Infection is not endemic in the United States, but 50,000 to 100,000 infected Latin American immigrants reside in the United States. Transfusion-associated cases of Chagas disease are rarely reported in immunocompromised patients in North America, and even testing of donors with risk factors or those from endemic areas has not been implemented.

Creutzfeldt-Jakob Disease

Variant Creutzfeldt-Jakob disease (vCJD) is a fatal, degenerative neurologic disease occurring in a younger age group than the rarer Creutzfeldt-Jakob disease (CJD). The United Kingdom first reported vCJD in 1996, and the etiologic agent of vCJD (a prion) is the same agent that causes bovine spongiform encephalopathy (BSE or "mad cow disease"). Transmission of the BSE prions to humans occurs by consuming products containing reticular endothelial or neural tissue from infected cattle, and 158 cases of vCJD had been diagnosed in the United Kingdom and other countries by 2004. A potentially long incubation period increases the theoretical possibility of transfusion-related transmission. For example, 15 patients with vCJD had donated blood while asymptomatic, and 2 (4% overall) recipients of these blood components developed the disease.[66] In the United States, blood donors who spent more than 6 months in the United Kingdom from 1980 to 1996 or 5 years in Europe since 1980 are deferred.

New molecular assays, such as NAT, can enhance safety but at a high cost compared with the serologic screening that was effective for virtually negating the HBV, HIV, and HCV risk of transfusion. The advent of newer infectious agents, such as vCJD, WNV, severe acute respiratory syndrome (SARS), and potentially Avian influenza A (H5N1) virus, may lead to deferral of increasing numbers of potential blood donors, with implications for blood supply.

The discussion of infectious agents is mostly based on North American data, but additional challenges exist for ensuring a safe blood supply in developing countries. With global travel and immigration, proactive and collaborative surveillance on an international level is essential to protect any country's blood supply.[95]

FEBRILE NONHEMOLYTIC TRANSFUSION REACTIONS

A FNHTR occurs when temperature increases >33.8°F (1°C) during or after transfusion when no other cause can be found. These reactions are either caused by cytotoxic or agglutinating antibodies in the patient's plasma reacting against antigens present on transfused donor lymphocytes, granulocytes, or platelets or by donor plasma containing antibodies against the recipient's cellular antigens. These antigens are typically, but not always, HLA antigens.[96] The febrile reaction results from antibody–leukocyte or antibody–platelet interactions leading to the release of inflammatory cytokines and pyrogens.

These cytokines are released from recipient leukocytes or donor leukocytes in response to antigen–antibody interaction but could also be in the supernatant of the transfused unit, derived from the donor leukocytes during storage before transfusion.[97] Such generation of cytokines, mostly from mononuclear leukocytes, occurs during storage and is proportional to the leukocyte count of the unit and the duration of storage.[98] Febrile reactions to platelet transfusions are more likely caused by proinflammatory cytokines in the supernatant than to cellular elements.[99] Use of prestorage, leukocyte reduction lowers the incidence of febrile reactions, as leukoreduction filters do not remove cytokines.[100]

The frequency of febrile reactions is approximately 0.5% per unit transfused, most commonly in recipients exposed to multiple white cell or platelet antigens such as oncology patients or multiparous women.[30] Previous alloimmunization leads to anti-HLA, granulocyte, or platelet-specific antibodies that react with white cells or platelets on subsequent exposure.

Clinically, an FNHTR is characterized by fever and chills occurring shortly after the transfusion begins. FNHTRs are usually self-limited, with fever persisting for no more than 8–10 hours. Elderly patients with a tenuous cardiovascular status and critically ill patients may develop respiratory complications, hypotension, or shock. With any transfusion reaction, the transfusion must be stopped, antipyretics and supportive measures instituted as necessary, and laboratory evaluation initiated.

A febrile reaction may be the first sign of an acute hemolytic reaction or infusion of a unit of red cells or platelets contaminated with bacteria. Repeat crossmatching is performed to confirm patient–donor ABO compatibility, examining the results of pre- and posttransfusion direct antiglobulin tests (DATs), evaluating the serum for hemolysis, and confirming the accuracy of paperwork. The posttransfusion DAT should yield negative findings, as an FNHTR does not involve red cell alloantibodies. Sending blood cultures from the patient and the blood product and administration of broad spectrum antibiotics can be considered depending on the severity of the reaction.

The diagnosis of FNHTR is one of exclusion after ruling out a hemolytic reaction, a septic transfusion, or other miscellaneous causes of fever. Routine premedication is not indicated, but antipyretics and corticosteroids can be reserved for patients with a prior history of FNHTR. The use of leukocyte-depleted blood components is not universal, but as discussed earlier, this practice reduces the incidence of FNHTRs and should be mandated for patients with a previous history of FNHTRs.[101]

ALLERGIC TRANSFUSION REACTIONS

Allergic transfusion reactions are most commonly caused by infusion of plasma proteins. Manifestations include skin erythema with associated mild urticaria and pruritus, a confluent rash that is intensely pruritic, extensive urticaria, severe vasomotor instability, bronchospasm, and anaphylaxis. The severity of these reactions may not be dose related, so a patient developing hives or a mild allergic reaction during a blood transfusion may not necessarily progress to severe anaphylaxis by completing the transfusion.

Causative antibodies have not been conclusively demonstrated, but milder allergic reactions are usually IgG or IgE mediated; anaphylactic reactions are most often IgG mediated. Allergic transfusion reactions are quite common, occurring in approximately 1% of all transfusions and typically leading to pruritus followed by hives. Treatment involves holding the transfusion, administering antihistamines, and assessing the wisdom of continuing the transfusion based on improvement of symptoms and no progression to more serious symptoms such as fever, chills, bronchospasm, dyspnea, or hemodynamic instability.

Such mild urticarial reactions rarely progress to serious reactions and often do not recur with subsequent transfusions. The pathogenesis is believed to be recipient antibody directed against donor plasma proteins, although the etiologic antibody is rarely detected, making the diagnosis of an allergic transfusion reaction a diagnosis of exclusion. Leukocyte depletion filters do not remove plasma proteins, so washed red cells are required to prevent reactions.[102] However, washed cells are reserved for patients with severe or recurrent reactions.

Anaphylactic Reactions

Other anaphylactic reactions can occur when plasma containing IgA is transfused to patients with IgG anti-IgA antibodies or after transfusion of red cells or, more commonly, platelets administered through certain bedside leukoreduction filters.[103] The latter scenario is believed to be a consequence of contact activation by the negatively charged surface of the filter converting prekallikrein to kallikrein, in turn converting high-molecular-weight kininogen to bradykinin. Bradykinin causes pain, cutaneous flushing, and hypotension without fever or chills, and its effects are exaggerated in patients taking angiotensin-converting enzyme (ACE) inhibitors, as ACE is identical to kininase

II, which is responsible for degrading bradykinin. A common theme throughout this chapter is that prestorage leukoreduction avoids this problem.

OTHER ADVERSE EFFECTS OF TRANSFUSION

Microaggregate Debris and Adult Respiratory Distress Syndrome

Microaggregate debris consists of dead platelets, granulocytes, and fibrin strands that form in blood during storage. Theoretically, this debris (20–120 μm) passes through standard 170-μm pore filters, infusing these microaggregates into the pulmonary vasculature, obstructing pulmonary capillaries, and causing pulmonary failure. Microaggregate filters have been suggested to prevent adult respiratory distress syndrome (ARDS) after massive transfusion, but they may reduce transfusion flow rates and do not appear to alter the onset of ARDS.[104] Hypotension and sepsis are postulated to trigger ARDS rather than microaggregate debris, and improvements in general care of the critically ill treating shock and sepsis have likely decreased the incidence of postperfusion respiratory distress syndrome more than the use of microaggregate filters.

Circulatory Overload (Hypervolemia)

It is obvious to any practicing anesthesiologist that rapidly transfusing a patient who is euvolemic and not actively bleeding is unlikely to be of benefit and may cause harm. Infants, patients with cardiovascular disease, and the elderly are especially at risk. Importantly, transfusion-induced hypervolemia may be initially difficult to distinguish from hemolytic transfusion reaction, a febrile nonhemolytic transfusion reaction, or allergic reactions. Hypervolemia results in headache, dyspnea, tachycardia, tachypnea, and congestive heart failure. The absence of hemoglobinuria and hemoglobinemia or a positive posttransfusion DAT distinguishes hypervolemia from immune hemolysis, and the absence of fever, chills, or urticaria from febrile or allergic reactions.

Treatment involves stopping transfusion until the diagnosis is determined, administering diuretics and supportive therapy as indicated, and resuming the transfusion at a slower rate while monitoring for recurrence of symptoms and signs of hypervolemia.

Transfusion-Related Acute Lung Injury (Noncardiogenic Pulmonary Edema)

Transfusion of red cells or platelets may cause noncardiac pulmonary edema (with low intravascular pressures) within 4 hours of administration.[105] Such transfusion-related acute lung injury (TRALI) may cause fever, chills, cyanosis, dyspnea, tachypnea, or hypotension and copious amounts of pulmonary edema fluid, characteristic of hypervolemia but after infusion of volumes of blood too small to produce fluid overload or without the development of elevated left-sided cardiac pressures. The pathophysiology is believed to be a reaction between donor anti-HLA or antileukocyte antibodies and recipient leukocytes (or vice versa) with complement activation and leukocyte aggregation. As a result of the HLA/anti-HLA reaction, the activated leukocytes generate adhesive molecules on their surfaces (CD11/CD18). These proteins permit the activated leukocytes to attach to the pulmonary endothelial cells by a CD11/CD18-dependent mechanism, enter the interstitial space by diapedesis, and degranulate leading to pulmonary edema as a result of microvascular leukostasis/occlusion and capillary leakage. TRALI is estimated to occur in 1 in 4500 transfusions.[106]

When a patient shows signs of pulmonary insufficiency, as with all other reactions, transfusion should be stopped, diagnosis sought, and supportive measures (including mechanical ventilation) initiated as indicated. These HLA/leukocyte antigen–antibody reactions are idiosyncratic and may not recur; again, leukoreduced blood components remove donor antigens, but washed cells may be required to remove donor antibodies. Multiparous women or multiply transfused donors should not be used as plasma donors, as his or her serum may contain high titers of leukoagglutinating antibodies.

Hypothermia

Hypothermia can occur with rapid infusion of large quantities of cold blood. Rapid infusion of cold blood (~5 minutes per unit) may lower the temperature of the sinoatrial node to <86°F (30°C), leading to serious arrhythmias. Numerous inline, blood-warming devices are available for clinically indicated rapid transfusion, as in major trauma, and may reduce the incidence of hypothermia-induced coagulopathy and platelet dysfunction that occurs with temperatures <95°F (35°C). Only approved blood warmers should be used for this purpose. Such devices monitor and regulate temperature to <107.6°F (42°C) to avoid causing hemolysis. The use of hot water or microwave devices is unacceptable, as hot spots develop that can cause hemolysis.

Electrolyte Toxicity

Citrate is used for anticoagulation during storage, acting by chelating calcium and interfering with the coagulation cascade. Rapid transfusion of citrated blood thus can be associated with a decrease in ionized calcium levels. Typically, citrate is rapidly metabolized in the liver to bicarbonate, but mild to severe citrate toxicity can be seen after infusion of large volumes of citrated products or in the setting of transient or established liver dysfunction.

The effects of hypocalcemia range from mild circumoral paresthesia to frank tetany. If prolonged Q-T intervals or signs of tetany are seen, calcium can be administered. In practice, the routine availability of arterial blood gas analysis with ionized calcium measurement allows close monitoring and guided treatment of developing hypocalcemia. Calcium should never be added to a unit of blood, as it recalcifies the unit and leads to clot formation; similarly, the use of calcium containing solutions, such as Ringer lactate, should not be coadministered with blood products.

Hypomagnesemia, presumably caused by chelation of magnesium by citrate, has also been reported, but its clinical relevance has not been determined. In practice, administration of magnesium can accompany calcium administration in response to a large citrate load.

Hyperkalemia caused by infusion of stored blood is rare, and hypokalemia may be more common. With storage, leakage of potassium from red cells to the extracellular fluid occurs. However, after infusion into a recipient, the red cells reverse the biochemical storage lesion, and intracellular potassium levels are restored. In addition, citrate is metabolized to bicarbonate, causing

alkalosis contributing to hypokalemia. In massive transfusion, this may not uncommonly result in the need for administration of potassium. Extracellular potassium increases at the rate of approximately 1 mEq/d during the first few weeks of storage. However, hyperkalemia is still a concern for neonates or patients with renal failure, and washed or fresher units can be requested. Potassium leakage from red cells is increased after exposure to 25-Gy irradiation to prevent posttransfusion graft-versus-host disease; the shelf-life of irradiated units is a maximum of 28 days.

Plasticizers

Plasticizers are chemicals used to make the rigid polyvinyl chloride plastic used in blood bags more malleable; traditionally, diethylhexyl phthalate (DEHP) is used. After concerns about carcinogenic properties and the possible production of peroxisomes by the metabolite monoethylhexyl phthalate, DEHP is being replaced with a citrate-based plasticizer.[107]

Graft-Versus-Host Disease

Graft-versus-host disease (GVHD) occurs when immunologically competent lymphocytes are introduced into an immunoincompetent host who cannot destroy the donor lymphocytes. The immunocompetent donor lymphocytes engraft, recognize the host as foreign, and then attack host tissues. GVHD occurs after allogeneic bone marrow transplantation and less often after transfusion of nonirradiated cellular blood components, especially when the blood donor and recipient share some HLA antigens. There is an increased danger from posttransfusion GVHD in part because of the frequent failure of physicians to recognize and treat the reaction promptly. Another major factor, however, is the propensity of the donor's lymphocytes to attack and produce recipient bone marrow aplasia in contrast to after bone marrow transplantation GVHD, in which the bone marrow is of donor origin, and bone marrow aplasia does not occur.

Posttransfusion GVHD is fatal in >90% of cases, primarily because of aplasia of the recipient's bone marrow. Reports have shown that haploidentical-directed donor units of blood may produce fatal posttransfusion GVHD even in immunocompetent recipients. The use of irradiated blood (>2500 cGy) is now recommended in clinical situations in which transfusion poses risk of GVHD such as when patients receive blood transfusions from their relatives or HLA-matched donors. Leukocyte reduction is not adequate prophylaxis against GVHD, as the exact number of leukocytes needed to produce the disease is unknown.[108]

Hemosiderosis

A unit of red cells contains approximately 250 mg iron and 1 g iron is roughly the amount stored in the bone marrow; men and nonmenstruating women lose only approximately 1 mg iron per day. Consequently, repeated transfusion in individuals with an extravascular hemolytic anemia, such as thalassemia or sickle cell anemia, in which iron is recycled rather than excreted, can result in the accumulation of excessive tissue stores of iron. Chronically, iron stored in parenchymal cells results in cell death and eventual organ failure. Iron chelation therapy, such as deferoxamine, is the mainstay of therapy to avoid predictable iron overload and maintain patients with chronic hemolytic anemias in negative iron balance.

Air Emboli

Air is currently expelled from plastic blood bags but still may be pumped into patients by pressurized transfusion devices, especially after apheresis and intraoperative salvage. All such devices currently manufactured, however, contain air in-line sensors. Regardless, clinicians must remain alert to the potential risk of air embolization at all times while the patient is being treated. Patients suffering large air emboli (boluses of 3–8 mL/kg) can experience acute cyanosis, pain, cough, arrhythmia, acute right ventricular outflow obstruction, cardiogenic shock, and circulatory arrest. Infusions should be stopped and checked for air, and the patient should be placed head down on the left side. This usually displaces the air bubble from the pulmonary valve and may be amenable to aspiration via a central venous catheter.

Transfusion-Related Immunomodulation

Deleterious effects of transfusion can be caused by a reaction to or incompatibility with a component of the transfused blood product or by the more subtle transfusion-related immunomodulation (TRIM) believed to predispose patients to infectious complications. TRIM has a number of postulated immunosuppressive mechanisms related to leukocytes and cytokines present in blood components limiting the potential effect to transfused red cell concentrates and platelets. Leukocytes and leukocyte-derived bioactive substances, such as histamine, myeloperoxidase (MPO), eosinophil cationic protein (ECP), eosinophil protein X, plasminogen activator inhibitor 1 (PAI-1), and IL-6, are known to contaminate PRBCs[109] and platelet units,[110] accumulating in a storage time-dependent manner. Suppression of lymphocyte proliferation has been induced by these mediators, and PRBC supernatant inhibits in vitro proinflammatory cytokine release in a storage time-dependent manner. Length of storage of transfused allogeneic PRBCs, but not plasma, is associated with pneumonia after coronary artery bypass graft surgery.[111]

In addition, phosphatidylserine is expressed on the surface of apoptotic leukocytes in PRBCs and platelets and erythrocytes, mediating phagocytosis of apoptotic cells. This induces transforming growth factor secretion, resulting in an antiinflammatory effect and suppression of proinflammatory mediators;[112] enhanced production of the antiinflammatory cytokines IL-4, IL-10, and transforming growth factor is observed after blood transfusion. Antiinflammatory cytokine release and decreased cellular immune function occur after allogeneic, but not autologous, transfusions.

Prestorage leukofiltration appears to reduce storage time-dependent immunosuppression after blood transfusion and the incidence of febrile transfusion reactions.[113] Indeed, leukoreducing PRBCs decreases postoperative mortality after cardiac surgery and the incidence of multiorgan failure after major surgery.[114] However, leukoreduction is not a panacea, as leukocytes are not eliminated. Leukoreduced PRBCs can still cause hypotensive transfusion reactions, HLA alloimmunization, and express surface phospholipids. It may be that a greater volume of leukoreduced products are required to produce the deleterious effects of transfusion compared with nonleukoreduced products.

CONCLUSION

In summary, the safety of the U.S. blood supply is exemplary, with the chance of a fatal reaction to transfusion in the realm of 1 in every 100,000 patients transfused. Such risk is acceptable should there be definite benefit, which emphasizes the responsibility placed on the physician to use appropriate triggers for blood component therapy with physiologic evidence of a deficiency in oxygen-carrying capacity for red cell transfusion and an accurately defined coagulopathy for hemostatic blood product transfusion. Second only to hematology nurses, anesthesiologists transfuse more blood products than any physician group, and it is incumbent on them to lead blood conservation strategies, including research into safe and effective blood substitutes, and reinforce surgical philosophies that avoid unnecessary blood loss at all costs. Such approaches provide the best possible care for patients and prepare anesthesiologists well for practice in areas with less safe blood supplies or during unforeseen safety concerns with the U.S. blood supply.

CHAPTER 86

Cognitive Dysfunction after Anesthesia and Surgery

Mark F. Newman, MD, and
Joseph P. Mathew, MD

The brain is often a window to early changes in blood flow, tissue perfusion, and early neural damage manifested by decline in higher cortical functions, including recall memory and cognitive processing. In particular, the elderly population is at risk for cognitive deterioration as a consequence of reduced cognitive reserve seen with aging-related cognitive decline. These changes in cognitive function are associated with reduced activities of daily living that substantially reduce the quality of life of the elderly, and can be magnified by physical or emotional stress in high-risk individuals.

The safety of anesthesia and surgery has progressed over several decades to the point that elderly and debilitated patients may safely undergo increasingly complex procedures with low risk of major morbidity or mortality. However, anesthesia and surgery appear to be associated with changes in cognitive functioning that outlast the effects of anesthesia or pain medications, inflammation and the healing response. Several excellent studies have investigated changes in cognitive functioning associated with cardiac and noncardiac surgery.[1–3] Understanding this decline and its etiology is complicated by the realization that anesthesia and surgery are rarely separated, indicating that the differences may be caused by either the stress response associated with surgery or the administration of anesthetics. This chapter discusses the complex field of cognitive neurosciences in the elderly population and the intricate process of measuring and defining change in the perioperative period. Different types of surgery, implications for quality of life, as well as etiologic factors and how they relate to treatment, are outlined.

COGNITIVE FUNCTION

Cognition is an expanding field with increasing research to define the key elements of intellectual functioning, that allow us to learn, reason, and plan. The increasing body of literature typically defines cognition as a processing of information applying both knowledge and preference. The processes include such dimensions as memory, attention, perception, problem solving, and mental imagery. Cognitive functioning is key to the activities of daily living and quality of life; cognitive dysfunction is thus an impairment of these processes that lead to a decline in the activities of the individual.[4,5] The patient or the family often define a decline in activity as the inability to perform or a delayed ability to perform cognitive tasks. In many cases, the changes are more notable to family members than to patients. Thus, studies describing the importance of cognitive change to quality of life are essential in defining the importance of further investigation. Studies show significant associations between quality of life and perioperative cognitive decline even when other physical or emotional factors are taken into consideration.[4,6]

In addition to aging and surgery, many disease entities alter cognitive function, especially in high-risk elderly populations.[7,8] Figure 86–1 shows the complex interaction proposed for the development of mild cognitive impairment.[9]

Diabetes is associated with an increased incidence of mild cognitive dysfunction.[7] Increasing literature points to the impact of chronic elevations in blood sugar on the brain; however, it is difficult to differentiate this effect from the increased probability of atherosclerosis that is also associated with progression of aging-related cognitive decline.[10,11] Even at ages at which atherosclerosis is less likely, diabetes is associated with acceleration in cognitive decline (Fig. 86–2).[7]

Understanding susceptibility to aging-related decline has been a key area of investigation, and overlaps substantially with the investigation of Alzheimer disease development and progression. Although the association between the occurrence of apolipoprotein E ε-4 (Apo E4) and the development of late-onset Alzheimer disease has been clearly demonstrated,[12,13] the association between the presence of the E4 allele and the progression of aging-related cognitive decline in the

KEY POINTS

1. Cognition represents key processes of memory, attention, perception, problem-solving, and mental imagery that define who we are as individuals.
2. Cognitive functioning is key to the activities of daily living and our overall quality of life.
3. Cognitive assessment occurs by a number of well-validated measurements outlined from the field of neuropsychology. Assessment of cognitive functioning in the perioperative period is often less complete than normal; however, understanding what is measured by each individual test and how they change over time is essential in understanding the implications of perioperative cognitive decline to our patients.
4. Incidence of perioperative cognitive dysfunction varies based on the sensitivity of the tests used and the timeframe for evaluation. Correlation with appropriate control groups gives the best idea of the relative impact of surgery and anesthesia on changes in cognition and quality of life.
5. The etiology of cognitive function and/or cognitive dysfunction is complex and associated with disease severity including atherosclerosis and diabetes, as well as surgery and anesthesia. The effect of anesthetic agents on short- and long-term cognition is controversial.
6. New studies indicate an association between patient factors including disease severity and genetic predisposition with perioperative cognitive decline.
7. Understanding risk for perioperative cognitive decline will enhance the probability of developing interventions to reduce cognitive decline and provide a level of persistent improvement and quality of life that can be provided by surgery overall.

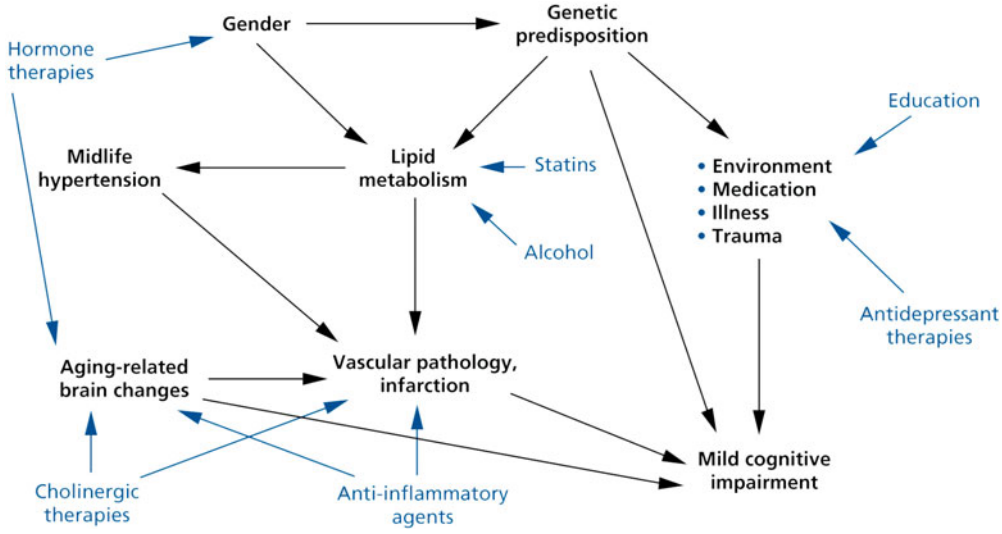

FIGURE 86–1. Hypothetical etiological model of mild cognitive impairment (MCI) in black, and possible treatment or lifestyle intervention points in blue. (Adapted from Ritchie[9] with permission.)

normal aging population is more controversial. The preponderance of data points to poorer learning and memory and other impairments in cognitive functioning associated with the presence of the allele.[14–20] Furthermore, while initial association between presence of Apo E4 and perioperative decline in cognitive decline has been seen, larger trials have been unable to relate this association with acute perioperative changes.[21]

As has been noted in most investigations of biologic function, both genetic and environmental factors alter the progression of cognitive decline outlined in the previous sections. Atherosclerosis and associated vascular disease are highly correlated factors associated with cognitive decline in some works.[22] The influence of cardiovascular diseases and their risk factors on cognitive decline is of substantial importance in the search for prevention of cognitive deterioration and dementia. Haan et al., as well as Slooter et al. in the Rotterdam study, assessed these interactions by measuring cognitive function using the Mini Mental Status Examination (MMSE) and other cognitive measures.[23,24] Following a group of 5888 randomly selected Medicare-eligible patients for 5–7 years, Haan et al. demonstrated that 70% of the population showed no significant cognitive decline.[23] However, in the 30% of patients who did, the severity of atherosclerosis, diabetes, and peripheral vascular disease was associated with cognitive decline. The rate of this environmentally or disease-related cognitive decline was increased by the presence of the Apo E4 allele.[23] The authors note that although many elderly individuals did not experience cognitive decline over the longitudinal study, cardiovascular disease and the presence of the Apo E4 allele increased both the likelihood and severity of cognitive function decline (Fig. 86–3).[23]

Slooter et al.'s results, although from a smaller sample size of 838 patients, are similar.[24] Slooter et al. investigated the association of atherosclerosis, Apo E4, and their interaction on cognitive change over 3 years in a group of patients 55 years of age and older. The main effects of the two predictors approach, but do not reach, statistical significance independently. However, the interaction of the two predictors show a statistically significant correlation with cognitive decline over time. Slooter et al. suggest that the effects of Apo E4 and atherosclerosis are not independent, and that Apo E4 carriers with atherosclerosis are at increased risk for progressive cognitive decline.[24] Despite this association, no studies define whether treatment of coronary atherosclerosis, either coronary artery bypass graft (CABG) or angioplasty, alters the progression of cognitive function in an appreciable way, or if the risk factors are unable to be adjusted.

Cognitive enrichment is a broad term that defines tasks or practices that when undertaken appear to enhance measures of crystallized intelli-

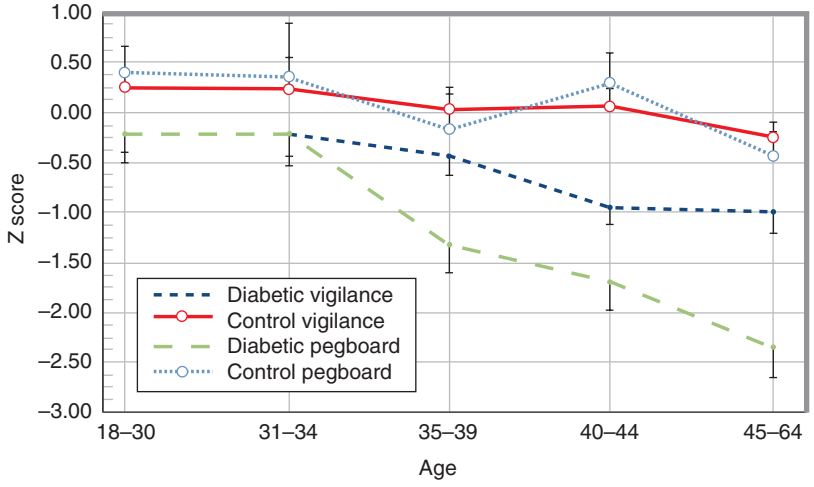

FIGURE 86–2. Performance (mean ± stand error of mean [SEM]) of diabetic and nondiabetic adults, stratified into five age bands, on two measures of psychomotor efficiency: the mean time taken by the dominant and nondominant hand to complete the Grooved Pegboard, and the total time taken to complete two pages of the Digit Vigilance Test. FIGURE 86–3. Change in modified Mini Mental State Examination scores by presence of Apo EApo E4 alleles and the quartile of carotid atherosclerosis.[23]

gence and cognitive reserve. Cognitive enrichment is often broadly defined as the amount of education or the complexity of the work environment or leisure activities. Several studies show the value of education and an increased intensity of cognitive activity at work as significant factors in the delay of aging-related cognitive decline and dementia.[25] This protection against decline has also been demonstrated in multiple perioperative studies defining educational level as a protective factor in perioperative cognitive decline.[3,26] Education differs from intelligence level, which does not appear to provide protection from perioperative cognitive decline.

ASSESSMENT OF COGNITIVE FUNCTIONING

The measurement of cognitive dysfunction occurs via a large group of well-validated tests occurring over a broad range of cognitive domains. One of the difficulties in interpreting the results of studies to date is that different tests with different scales or criteria are often used within the same populations to try and define outcome.[27,28] Several consensus statements and reviews have described these issues and put forward recommendations to allow consistent comparisons and sharing of data that would help us to draw accurate conclusions. The consensus statements[29–31] suggest minimal batteries of tests, as well as the use of individual change scores versus group mean, to define postoperative cognitive dysfunction. The difficulty arises in that the "cut-off," the number of tests employed and the domains assessed can change the overall incidence of decline.[27,28] Furthermore, recent reviews strongly suggest the use of age-matched controls to define the significance of this change to a similar population.[28] This is especially true when conclusions are to be drawn relative to the incidence of decline compared to a similar population. The value of this control or repeated control groups when interventions are compared is lessened.

Cognitive dysfunction is often identified by the family's recognition of a patient's inability to perform what would have previously been normal activities. These include complex tasks, memory, and other daily activities that are often part of a patient's overall enjoyment. Many problems exist in detecting changes in cognitive function in the perioperative period, including a lack of suitable control groups to define practice effects, tests with variable degrees of sensitivity to detect change, lack of adequate time for assessment, and the lack of potential disease-matched controls to understand the importance of disease, as well as the anesthesia and surgery.

In addition to the difficulties defined in the different types of tests utilized and the definition of decline,[1] other difficulties include lack of correlation between cognitive testing and the patient's assessment and the family's assessment of the patient's status. This may indicate other behavioral factors that could define a patient's assessment of their current state or quality of life, such as anxiety, depression or other factors that must be taken into account in the assessment of perioperative cognitive decline.

INCIDENCE AND SIGNIFICANCE OF PERIOPERATIVE COGNITIVE DYSFUNCTION

Many factors outlined in the previous sections alter the measured incidence of cognitive decline. Our group investigated the effect of different definitions of cognitive decline on incidence of postoperative cognitive decline and found large differences in event rates based on the definition.[27] The relative rates as previously defined vary based on the sensitivity of the test used and the degree of representation of the more sensitive and time specific domains assessed.[2,27] Concern has been expressed that early dysfunction within the immediate perioperative period may be related to the use of narcotics, benzodiazepines, or other related anesthetics. Therefore, many individuals have reduced the degree of testing occurring early postoperatively. However, this practice is criticized by some investigators, as later decline may be associated with factors other than perioperative neurologic injuries, such as sleep deprivation, depression, or other issues that may not indicate neurologic injury associated with cardiac surgery.

Defining decline based on different cognitive domains begins to sort out the areas of function more sensitive to perioperative neurologic injury. Visuospatial orientation and other aspects of visual construction seem to be some of the hardest hit domains, as well as aspects of executive function requiring multitasking or involving multiple areas of the brain for completion of an overall task. Although assessment of different domains may point to an area of the brain most affected, logistical limitations in the perioperative period and patient burden at a stressful time limit the ability to investigate decline as thoroughly as most neuropsychologists would like.

Although few would question the significance of a stroke in the perioperative period, the importance of cognitive decline after surgery has long been debated. Despite the many studies showing cognitive decline after cardiac surgery, it is frequently minimized or dismissed because of its

transient nature in most patients. To address the importance of perioperative cognitive dysfunction, we investigated a broad range of quality of life measures in tandem with cognition at 5 years' followup.[4]

Using a number of standardized, validated assessments[4] in patients undergoing cardiac surgery, significant univariate and multivariate correlations between cognitive function and multiple quality of life measures were detected. Furthermore, multivariable logistic regression on a two-way classification of employment status adjusted for age, gender, educational level, and diabetes revealed the 5-year overall cognitive function score to be a significant predictor of the likelihood of being productively working (Fig. 86–4). Finally, perception of general health also varied directly with cognitive functioning where patients with lower cognitive function score at 5 years self-reported a lower quality of general health. Postoperative cognitive decline has also been shown to affect daily activities such as driving.[32,33] Cognitive impairment following cardiac surgery clearly has long-term consequences.

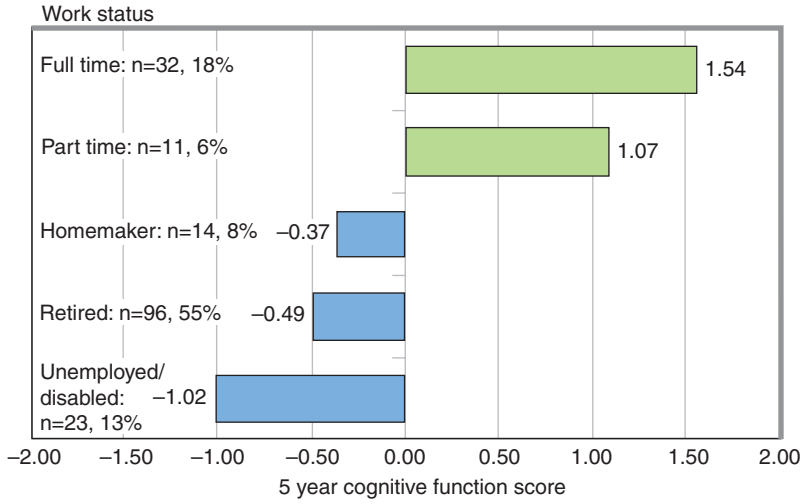

FIGURE 86–4. Patient work status and 5-year composite cognitive index. The 5-year cognitive function score is the sum of the four domain scores, including cognitive decline and learning effects.[4]

CARDIAC SURGERY PERIOPERATIVE COGNITIVE DYSFUNCTION

Stroke and incapacitating central nervous system (CNS) dysfunction after cardiopulmonary bypass (CPB) remain devastating complications, highlighted by significant reduction in overall cardiac morbidity and mortality associated with cardiac surgery.[34] Recent studies suggest that elderly patients with greater comorbidities and advanced cardiovascular disease benefit most from cardiac surgery compared with medical therapy,[35,36] yet they have greater morbidity and mortality after cardiac surgery, specifically neurologic dysfunction.[34,37–39]

Neurologic injury ranges from severely incapacitating or life-ending stroke and coma, to encephalopathy or delirium and cognitive decline. While stroke after cardiac surgery, with or without cardiopulmonary bypass, continues to represent a substantial concern for both short- and long-term disability, more subtle neurologic deficits, such as encephalopathy and cognitive dysfunction, are associated with increased medical costs and decreases in short- and long-term cognitive function and quality of life. In fact, nothing may be more disappointing to the physician team, the patient, and the patient's family than to have an operation that appears successful end with the patient exhibiting substantial neurologic or cognitive deficits that limit the patient's ability to function independently.

We performed neurologic and cognitive testing on 261 patients before they underwent CABG, as well as at discharge, 6 weeks, 6 months, and 5 years. Patients who had a deficit at baseline were excluded. Four domains of cognitive function were identified that accounted for almost 80% of the variability found:

- Verbal memory and language comprehension (short-term and delayed)
- Abstraction and visuospatial orientation
- Attention, psychomotor processing speed, and concentration
- Visual memory

Cognitive outcomes were defined in two ways:

- Cognitive deficit—a decline in performance in any one of the domains by 1 standard deviation or more (a reduction of 1 standard deviation represented an approximately 20% decline in function)
- Composite cognitive deficit—the reduction in the sum of scores of the four domains

Figure 86–5 outlines the pattern of cognitive deficits.

Half of patients showed cognitive deficits at discharge in one or more domains; at 6 weeks, the percentage dropped to 36%; at 6 months, 24%; and at 5 years, 42% of the patients again had a deficit. Therefore, the pattern is one of early improvement followed by later decline. Cognitive deficit at discharge predicted long-term outcome, even if short-term gains occurred in the meantime. At 6 weeks, patients who initially had a deficit improved to a level similar to those who never deviated from baseline levels. But after 5 years, patients who had deficits at discharge had significantly worse outcomes than did those patients without initial deficits. In addition to cognitive deficit at discharge, predictors of cognitive dysfunction at 5 years included baseline cognitive level, age, and years of education. Ejection fraction, history of hypertension, diabetes, and surgical variables were not found to be significant factors. As the population ages, patients have a greater fear of mental disability and loss of independence more so than death, defining the importance of further work to improve perioperative CNS outcomes.

However, some question whether cognitive decline after CABG is related to surgery or only to disease state. A consensus panel from the Outcomes Key West Meeting addressed this issue as a group and responded as outlined below.

1. Many studies have documented that cardiac surgery leads to more serious

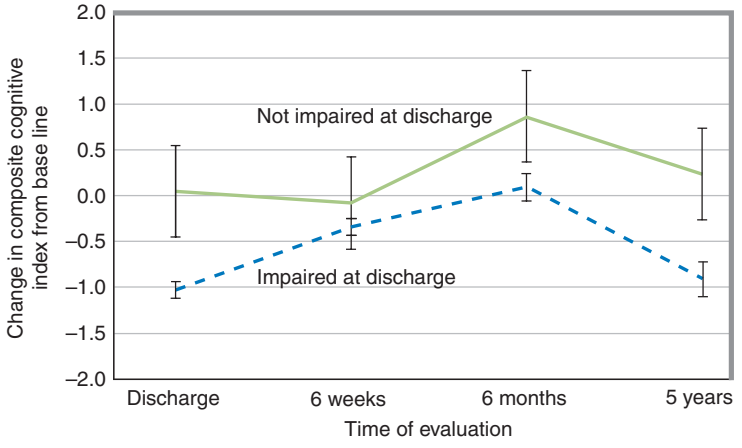

FIGURE 86–5. Change in composite cognitive index from baseline. The composite cognitive index is the sum of the scores for the four domains and includes cognitive decline, as well as increases in scores as a result of learning. Positive change represents an overall improvement (learning), whereas negative values indicate overall decline. Newman MF, Kirchner JL, Phillips-Bute B, et al. Longitudinal assessment of cognitive function after coronary-artery bypass surgery. Neurological Outcome Research Group and CARE Investigators. N Engl J Med 2001;344:395–402. Copyright 2001, Massachusetts Medical Society

consequences in a small but significant proportion of patients. This includes death through neurologic consequences, nonfatal stroke, transient ischemic attacks, coma, or stupor.[40–43] Patients who survive these consequences are subject to significantly increased healthcare costs.

2. A large number of studies have demonstrated cognitive decline after CABG surgery and related procedures, in contrast to the small number of studies that have failed to find a decline. The major difference between these studies is in the patient groups studied, the tools used to assess cognitive function and the methods of analysis used. Where the studies are appropriately designed and the tools of measurement appropriate and appropriately analyzed, there is a consistent finding that cognitive function is impaired.

3. Formal neuropsychological testing prior to and at various times after surgery provides a sensitive measure of cognitive function and has revealed more subtle deficits in 20–70% of patients who are undergoing cardiac surgery.[44] For some patients these changes are transient, with assessments in the days after surgery yielding the highest number of patients with deficits. In some patients, these difficulties persist.[3,45] It is possible that in some patients the longer-term changes are related to effects of aging and the cerebrovascular disease.[46,47]

4. Neuropsychological assessment demonstrates differences in patients according to their biologic characteristics (e.g., EndoCABG[48]) and their postoperative clinical characteristics (e.g. postoperative atrial fibrillation[49]), as well as an association with aspects of the surgical or anesthesia protocols (e.g., postoperative hyperthermia).[50]

5. The clearest evidence for the impact of CABG on the brain and its possible amelioration comes from randomized controlled trials that have contrasted the impact of different surgical or anesthesia procedures on neuropsychological outcome. Evidence of a difference as a result of these types of interventions attests to the fact that CABG surgery can have an impact, and in the case of positive findings, a differential impact, on the brain. For example, various studies show that the pH management by alpha-stat results in less neuropsychological disturbance in comparison to pH-stat,[51,52] neuropsychological outcome improves with the use of arterial line filters,[53] there is an advantage in using leucocyte filtration,[54] and neuroprotective pharmacologic agents do have an impact.[55]

6. Underpinning the findings of the neuropsychological impact of cardiac surgery is the evidence from:
   a. Magnetic resonance imaging (MRI) studies showing that in a proportion of patients new lesions appear after CABG,[56,57] that MRI abnormalities are clearly seen in patients in the hours after CABG surgery,[58] and that there is a relationship between MRI findings and cognitive deficits.[59]
   b. Pathologic evidence of small capillary arteriolar dilations in animals and humans after CABG.[60]
   c. Animal research demonstrating the differential impact of surgical manipulations and the neuroprotective impact of pharmacologic interventions on animals undergoing CABG surgery.[61]

7. The putative causes of the cognitive deterioration following coronary artery bypass surgery include the risk of atheromatous emboli, the risks of air bubbles and thrombotic emboli, the systemic inflammatory response, and disturbances of cerebral perfusion. Dominant amongst these is the occurrence of microemboli. The panel considered it important that some studies demonstrate that the number of microemboli delivered during CPB is correlated with the postoperative cognitive decline seen immediately and 8 weeks after CPB.

8. Changes in surgical practice to reduce embolic load, and so to limit potential for cerebral injury, have been based in part on studies where the primary outcome has been postsurgery cognitive loss.

9. There is some evidence to suggest that these cognitive difficulties are associated with increased hospital stay and poorer quality of life.

10. The panel noted that the American College of Cardiologists/American Heart Association (ACC/AHA) 2004 guidelines include cognitive loss into the ACC/AHA type II neurologic injury category emphasizing, from the perspective of a senior specialist body in the United States, the clinical relevance of this neuropsychological domain as one adverse consequence of cardiac surgery.

Variation in CNS Injury after Cardiac Surgery

The importance of different cardiac surgical procedures on cognitive decline is a controversial topic. Initial studies point to a higher degree of cognitive injury in valve procedure patients; however, more recent trials do not show a substantial difference. Patients who are undergoing com-

bined procedures, CABG and valve, typically have a higher incidence of cognitive decline and overall neurologic injury compared to patients who are undergoing other procedures.[62] Off-pump coronary artery bypass grafting is a procedure with fewer neurologic complications. Cleveland reported data from the Society of Thoracic Surgery database showing a substantial reduction in stroke.[63] However, despite attempts to use control for demographic and perioperative differences, the patient demographics of on- and off-pumps were not similar. In the only large-scale randomized trial to date, the Octopus trial was not able to demonstrate a substantial difference in neurologic or cognitive injury. However, the trial was underpowered for neurologic injury, and likely neurocognition as well, and further investigation is required.

NONCARDIAC SURGERY PERIOPERATIVE COGNITIVE DYSFUNCTION

Postoperative cognitive dysfunction (POCD) is an accepted complication of cardiac surgery, but less appreciated or defined after noncardiac surgery. In 1998, the International Study of Postoperative Cognitive Dysfunction (ISPOCD-1) evaluated cognitive decline in 1218 elderly patients who underwent major noncardiac surgery and found that cognitive dysfunction was present in 25% of patients 1 week after surgery and in 10% of patients 3 months after surgery.[1] Unfortunately, there were significant differences in the incidence of POCD at the 13 hospitals participating in the study. This variability makes generalization of the results to any single medical institution ill advised. In addition, in a letter to the editor, Bonke[64] pointed out numerous errors in the data reported in this manuscript. This combination of poor reliability and errors raises questions about the validity of this study.

To further investigate the findings of the ISPOCD in noncardiac surgery, Monk et al. completed a prospective assessment of 1064 patients undergoing elective noncardiac surgery divided among young (18–39 years of age), middle-aged (40–59 years of age), and elderly (60 years and older) patients. A group of 210 control primary family members were used in order to provide a change score similar to that used in the ISPOCD. Inclusion of criteria for our study included age 18 years and older, major abdominal thoracic or orthopedic surgery, general anesthesia greater than 2 hours, and a MMSE score of 24 or greater at baseline. Exclusion criteria included cardiac or neurosurgical procedures, history of CNS disease with persistent deficits, history of alcoholism or drug dependence, history of major depression requiring treatment, and patients who were not expected to live 3 months or longer.[65]

The patients completed a cognitive battery at baseline (preoperatively), and both 1 week and 3 months postoperatively. To quantify the practice effect, we compared the changes in performance for control subjects in each age group for each measure between baseline and subsequent tests 1 week and 3 months later.

Figure 86–6 presents the incidence of POCD at the hospital discharge and 3-month postoperative neuropsychological evaluations. At hospital discharge, the incidence of POCD was 36.6% in the young, 30.4% in the middle-aged, and 41.4% in the elderly patients. The incidence of cognitive decline was significantly lower in middle-aged patients compared to elderly patients ($p = 0.01$), but was not different for young versus elderly or young versus middle-aged patients. The incidence of cognitive decline was similar for control subjects of all age groups at the first postoperative testing session 4.1% in young, 2.8% in the middle-aged, and 5.1% in the elderly. However, the differences between cognitive decline in age-matched controls and patients were significant for all age groups ($p < 0.001$).

At 3 months after surgery, POCD was identified in 5.7% of young, 5.6% of middle-aged, and 12.7% of elderly patients. POCD was significantly higher in elderly compared to young or middle-aged patients ($p = 0.001$). The incidence of cognitive decline in the control subjects was similar for all age groups at the 3-month testing interval and was 6.3% in young, 4.8% in the middle-aged, and 1.8% in the elderly. At this testing interval, there was no difference in the incidence of POCD between age-matched control subjects and patients in the young and middle-aged groups. However, elderly patients exhibited a significantly greater incidence of cognitive decline at 3 months after surgery compared to elderly control subjects ($p < 0.001$). Of the significant univariate predictive factors for POCD at 3 months after surgery, only increasing age, lower educational level, and POCD at hospital discharge remained significant in the multiple logistic regression analysis.

Postoperative cognitive dysfunction after noncardiac surgery demonstrated a significant increase in the elderly, especially at 3 months postoperatively. This trial indicates that postoperative cognitive dysfunction is common in all age groups at 1 week. However, at 3 months after surgery it is more common in elderly with lower educational achievement.

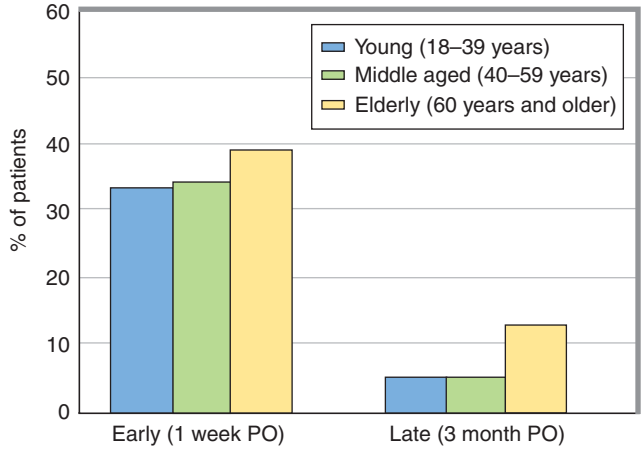

FIGURE 86–6. Incidence of POCD in adult patients after noncardiac surgery: Z score definition. (Modified from data from Monk[65] with permission.)

COMPARISON OF PERIOPERATIVE COGNITIVE DECLINE IN CARDIAC AND NONCARDIAC SURGERY

Much of the work investigating perioperative cognitive decline has centered on cardiac surgery. Historically cardiac surgery was accomplished on more elderly individuals with progressive cardiovascular disease who were at higher risk for cerebrovascular complications, including stroke and cognitive decline, than seen for other surgery. With advances in the safety of anesthesia and surgery, the population now able to receive noncardiac vascular, orthopedic, and general surgery safely is progressively older with increasing comorbidity. The result has been a greater recognition of the presence of cognitive decline after noncardiac surgery as outlined in the previous section. However, little direct comparison with similar testing, same institution, and same age range has occurred to allow direct comparison. After Institutional Review Board approval and patient informed consent, we investigated 675 patients who were undergoing cardiac surgery and 342 patients who were undergoing noncardiac surgery during a 5-year period from 2000 to 2005.

Cognitive testing was accomplished at baseline (before surgery), as well as 6 weeks and 1 year postoperatively. We used a previously published neuropsychologic battery, with cognitive decline defined as a standard deviation decline on any of four independent domains established in a factor analysis of the nine measures used.[3,27] Factor analysis provided for no substantial overlap between domains and, therefore, a standard deviation decline in any one of four unique domains was identified as cognitive decline. To allow comparison of the two groups, a single factor analysis was used for comparison of the two groups.

Although demographic composition of the two groups was similar, the cardiac surgical population had lower cognitive scores at baseline, possibly because of the risk of cerebrovascular disease. Despite expectations for a higher incidence of cognitive decline after cardiac versus noncardiac surgery, the results were actually reversed: 49.1% of noncardiac surgical patients experienced cognitive decline at 6 weeks compared to 36.6% of cardiac patients. This trend continued through 1-year testing, with 42.0% of noncardiac patients showing decline compared to only 32.2% of cardiac surgical patients.

Contrary to our previous assumptions the incidence of cognitive decline after noncardiac surgery appears to occur at similar rates to that seen after cardiac surgery, potentially a result of the fact that our samples were normalized for age. Because baseline scores were different in the two groups, the implications of a similar change may be different and requires further investigation to define the relative importance of the measured change to quality of life (Fig. 86–7).

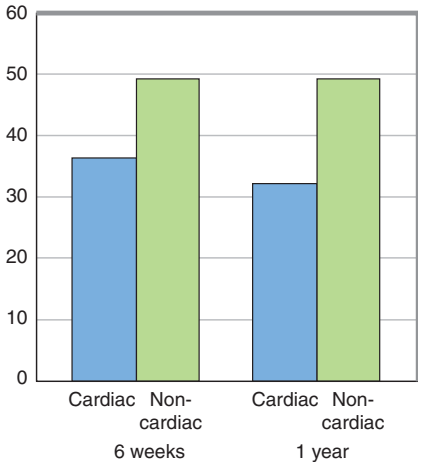

FIGURE 86–7. Comparison of the incidence of cognitive decline between cardiac and noncardiac surgery at 6 weeks and 1 year. (Data from personal communication between M.F. Newman and colleagues.)

ETIOLOGY OF NEUROLOGIC DYSFUNCTION INCLUDING PERIOPERATIVE COGNITIVE DYSFUNCTION

Understanding patient risk factors associated with perioperative CNS injury is an important first step in understanding the etiology of this disease continuum.

Aortic Atherosclerosis and Cerebral Embolization

Multiple investigators have identified proximal aortic atherosclerosis, as identified by cardiac surgical palpation or, more importantly, by transesophageal and epiaortic scanning, as a risk factor associated with a manyfold increase in stroke risk.[41,66,67] There is little doubt that embolization of aortic atheroma or other debris from the surgical field is an important etiologic factor in stroke and major neurologic injury after cardiac surgery. In studies by Roach and others before the widespread use of transesophageal echocardiography, those patients with surgical palpated aortic atherosclerosis were found to have a 5-times greater risk of overall stroke.[41] Further pathologic diagnoses have also defined small capillary arterial dilatations in the brains of patients or animals having recently undergone cardiac surgery with CPB.[57] Most of these presumed embolic changes disappear over time, and they are not typically seen in patients or animals who are investigated or who die weeks to months after the surgery. A number of investigators with the use of transesophageal echocardiography, as well as epiaortic scanning, have defined an association between neurologic injury and the degree of aortic atherosclerosis, especially in the ascending and transverse aorta, whereas the descending aorta has been used more as a factor predictive of a need to use epiaortic scanning. Further support for embolization as a major factor in neurologic injury comes from the use of transcranial Doppler and carotid ultrasound studies that show substantial numbers of cerebral emboli occurring, especially during aortic interventions such as cannulation, aortic cross-clamping or unclamping, partial side-biting clamps, and other cardiac nonaortic manipulations. However, as might be expected, the correlation with neurologic injury and the number of emboli is not as robust as the correlation that we previously defined for transesophageal or epiaortic determined aortic atherosclerosis. This differentiation probably relates to our inability to differentiate between air and particulate emboli, and thus demonstrates the importance of these factors in defining overall injury.

The last and most defining evidence for embolization, an important part in neurologic injury, are recent studies with the use of new diffusion-weighted imaging (DWI) and perfusion-weighted imaging (PWI) techniques that have defined that after coronary artery bypass or aortic valve surgery, up to 45% of patients have new DWI lesions on postoperative imaging.[68] This demonstrates that ongoing neurologic injury is occurring, but the clinical implica-

tion for stroke or cognitive decline may relate to the injury location in defining the expression. A small injury occurring in the internal capsule may produce a profound stroke, in comparison to large frontal or cerebellar infarcts that may appear silent without extensive functional investigation.

Despite the significant correlation between aortic atherosclerosis and stroke, the association with POCD has been tenuous at best. Our group and others have failed to demonstrate a clear relationship between the severity of aortic atherosclerosis and the incidence of POCD.[69] However, several investigators have associated increased cerebral emboli with degree of cognitive decline.[53]

Hypoperfusion

Since the time of Gilman's classic study in 1965, the presence of nonpulsatile perfusion and lower pressure during cardiac surgery has been blamed for much of the neurologic injury that we have previously described.[70] Watershed infarcts in older individuals, especially those with carotid disease have been an important factor in this association.[70] Furthermore, Caplan determined that lower pressure may be associated with a reduced washout of smaller emboli from the watershed areas, thus increasing the probability that hypoperfusion would play a role in causing watershed infarcts that we may see in cardiac surgery.[71]

Gold et al. performed a randomized prospective trial of high (mean arterial pressure [MAP]: 80–100 mm Hg) versus lower perfusion pressure (50–70 mm Hg) during CPB for patients undergoing CABG.[72] This trial of 240 patients, comparing myocardial and neurologic outcomes between the two CABG groups, was unable to reach statistical significance when the individual outcomes were assessed. The combined cardiovascular outcome (myocardial and neurologic) shows a benefit for higher pressure, indicating that at least in part, cardiovascular injury was increased with lower perfusion pressure.[72] However, looking at a subset of 188 of these patients and comparing transesophageal assessment of aortic atherosclerosis severity, Hartman shows that the primary driving factor for neurologic injury was aortic atherosclerosis.[73,74] He further determined that for individuals with severe aortic atherosclerosis, higher perfusion pressure is associated with a reduced incidence of neurologic injury. This indicates that in individuals who are at high risk for embolization, perfusion pressure may determine the extent of measurable injury of the severity of that injury.[73] While the relationship between stroke and MAP appears present in situations of severe aortic atherosclerosis, the association between reduced perfusion pressure and cognitive decline has not been well defined. We examined the relationship between MAP during hypothermic CPB and postoperative cognitive function using new and more sophisticated recordings of blood pressure than previously used. Moreover, because advanced age is an important predisposing variable,[74,75] we analyzed the interaction of age with MAP.

After institutional review board approval and written, informed consent, 260 patients requiring elective cardiac surgery with CPB were enrolled. All patients were 21 years of age or older without a history of cerebral vascular disease (previous stroke, symptomatic carotid bruit, or documented transient ischemic attacks), alcohol or substance abuse, psychiatric illness (previous hospitalization or requirement for medication at the present hospitalization), uncontrolled hypertension (diastolic pressure >110 mm Hg or requiring interventions while hospitalized to reduce blood pressure), renal disease (creatinine >1.8), active liver disease (abnormal liver function tests if they were performed), or literacy at the seventh grade level or above. A neuropsychologic test battery, including mood and cognitive function, was administered the day prior to surgery and the day prior to hospital discharge (approximately 7–10 days after surgery).[76]

Of the 260 patients enrolled, 237 completed pre- and postoperative neuropsychologic tests and had MAP and temperature data to allow analysis (19 patients refused postoperative testing, and data retrieval for intraoperative MAP and temperature was inadequate for analysis in 4 patients). The charts of the 237 patients were reviewed for temperature and MAP data at 1-minute resolution. A total of 26,642 minute points were evaluated, with 0.5% of the points (136 points) discarded as artifactual. MAP and temperature data including initial MAP, MAPavg, AREA50, T5AREA50, minimum temperature, maximum temperature, maximum rate of rewarming over 5 minutes, and temperature area >98.6°F (37°C) were measured for all patients.

Multivariable regression analysis for all 7 cognitive measures showed no significant associations between MAP or rewarming rate and cognitive decline. Similar to previously published reports on a portion of this database, consistently significant associations were found between preoperative score (all 7 measures), age (5 of 7), years of education (5 of 7), and maximum $C(a\text{-}v)O_2$, (2 of 7).[76] Despite the lack of primary effects of MAP and rewarming rate on cognitive decline, the interaction of age with these variables showed significant associations ($p < 0.05$) on two tests. With increasing age, AREA50 predicted increased decline in the Digit Symbol Test at discharge ($p = 0.005$). Characterization of MAP based on 5-minute or greater hypotension episodes presented no additional primary effects or interactions. These interactions without significant primary effects would indicate a differential effect of these variables on cognitive function as an effect of age. In elderly individuals who are at increased risk of cognitive decline, hypoperfusion may be associated with an increased risk of cognitive decline.

Systemic Inflammatory Response

Cardiac surgery is known to be associated with a profound systemic inflammatory response, especially when cardiopulmonary bypass is used. Although it is likely that systemic inflammatory response may play a role in the overall severity of injury, there is very little data to support that it alone is the causative factor. Westaby studied a group of patients undergoing CABG and found no significant association between inflammatory markers and cognitive injury, and we also were unable to find this.[77,78] However, it is likely that these factors were contributory and not causal. Thus as we look at and better understand the severity of injury and other susceptibility factors, we may be able to further determine the importance of these factors in neurologic and cognitive injury. Two recent trials evaluating the use of complement inhibitors in cardiac surgery have defined a small but measurable

positive effect on cognitive decline with the use of the C-5 complement inhibitor continued for the surgical period and 24 hours postoperatively. However, in neither case was the overall decline in neurologic or cognitive function statistically altered.

Depression

Our group and others have studied depression as it relates to cardiac surgery and found that depression is an important factor in defining long-term survival after cardiac surgery.[6] However, when we have investigated depression as a factor in short-term cognitive change, we've been unable to demonstrate a significant association between a low-level of depression and acute changes in cognitive function. On the other hand, many groups, including our own, have been able to show an association between depression and long-term cognitive decline.[79] Whether cognitive decline leads to a greater degree of depression, or depression defines cognitive function over time is a phenomenon that requires longitudinal studies to ascertain.

Genetic Factors

An intriguing development in the field of neuroprotection is in the area of genetic predisposition or susceptibility in cardiac surgery-associated cerebral injuries. Expanding discoveries in this relatively new field of perioperative genetics and neurologic outcomes include our recent study of 1635 patients by the PEGASUS investigative group, in which patients undergoing cardiac surgery using cardiopulmonary bypass surgery were studied. DNA was isolated from preoperative blood and analyzed for 26 different single-nucleotide polymorphisms. Multivariable logistic regression modeling was used to determine the association of clinical and genetic characteristics with stroke.

Permutation analysis was used to adjust for multiple comparisons inherent in genetic association studies. Of the 1635 patients, 28 patients (1.7%) suffered stroke and were included in the final genetic model. The combination of the 2 minor alleles of C-reactive protein (CRP; 3'UTR 1846C/T) and interleukin-6 (IL-6; –174G/C) polymorphisms, occurring in 583 (35.7%) patients, was significantly associated with stroke (odds ratio [OR]: 3.3; 95% confidence interval [CI]: 1.4–8.1; p = 0.0023). In a multivariable logistic model adjusting for age, the CRP and IL-6 single-nucleotide polymorphism combination remained significantly associated with stroke (p = 0.0020). Genetic factors associated with inflammation predicted a 3-fold increase in stroke rate over and above other clinical risk factors, defining the possibility of future risk stratification to focus neuroprotective strategies.

The possibility that one's genetic makeup might alter cognitive outcome after cardiac surgery was first delineated in a 1997 study.[21] In that study, the apolipoprotein E hypothesis was born, that is, that patients possessing the Apo E4 allele had worse cognitive outcomes after CPB. Although somewhat controversial,[80] this hypothesis may likely be the beginning of our understanding of the complex role of individual genetic variations, represented by single nucleotide polymorphisms (SNPs), in moderating cerebral responses to surgery. Despite this initial positive association, others have been unable to replicate it in primarily white populations, making these findings "controversial."[80]

Mathew et al.[81] characterized phospholipase A_2 (PLA_2) a polymorphism of the glycoprotein (GP) IIIa constituent of the platelet integrin receptor GP IIb/IIIa, and examined its influence on cognitive outcome after cardiac surgery. In their study, a multivariate analysis revealed that the PLA_2 genotype was significantly associated with greater decline on the Mini Mental State Examination (p = 0.036). The mechanism this association with adverse cerebral outcome may be related to is an increased prothrombotic role, which has been shown in investigations of coronary artery thrombosis and myocardial infarction.[82,83] The progression of genetic predictors of perioperative cognitive decline have mimicked the progression of the field of genetic association moving from the investigation of single candidate genes to multiple candidate genes and then to genome wide scans as technology advances.

Mathew and colleagues have also hypothesized that candidate gene polymorphisms in biological pathways regulating inflammation, cell matrix adhesion/interaction, coagulation-thrombosis, lipid metabolism and vascular reactivity are associated with postoperative cognitive deficit (POCD).[81] In a prospective cohort study of 513 patients (86% European American) undergoing CABG surgery with cardiopulmonary bypass, a panel of 37 SNPs was genotyped by mass spectrometry.[84] Association between these SNPs and cognitive deficit at 6 weeks after surgery was tested using multiple logistic regression accounting for age, level of education, baseline cognition, and population structure. Permutation analysis was used to account for multiple testing.

We found that minor alleles of the *CRP* 1059G/C SNP (OR: 0.37; 95% CI: 0.16–0.78; p = 0.013) and the *SELP* 1087G/A SNP (OR: 0.51; 95% CI: 0.30–0.85; p = 0.011) were associated with a reduction in cognitive deficit in European Americans (n = 443). The absolute risk reduction in the observed incidence of POCD was 20.6% for carriers of the *CRP* 1059C allele and 15.2% for carriers of the *SELP* 1087A allele. This compared to a greater than 40% incidence of decline in those patients who did not possess either allele (Fig. 86–8).[84]

Perioperative serum CRP and degree of platelet activation were also significantly lower in patients with a copy of the minor alleles, providing biologic support for the observed allelic association. These results suggest a contribution of P-selectin and CRP genes in modulating susceptibility to cognitive decline following cardiac surgery, with potential implications for identifying populations at risk who might benefit from targeted perioperative antiinflammatory strategies. Identifying genetic and mechanistic factors associated with lower rates of injury and sequelae define for us pathways to protection, as well as provide the opportunity for preoperative genetic screening to identify patients who are at risk for cerebral injury and who will most likely benefit from interventional strategies for protection.

Anesthesia

Cognitive impairment occurring up to 6 weeks after cardiac surgery has been likened to the cognitive decline seen after noncardiac surgery by the ISPOCD group and Monk et al.[1,85] The incidence in noncardiac surgery originally appeared lower than that seen in cardiac surgery defined by our group and others, and is comparable to a group younger than 60 years old. However, as the noncardiac population has aged, there has been increased recog-

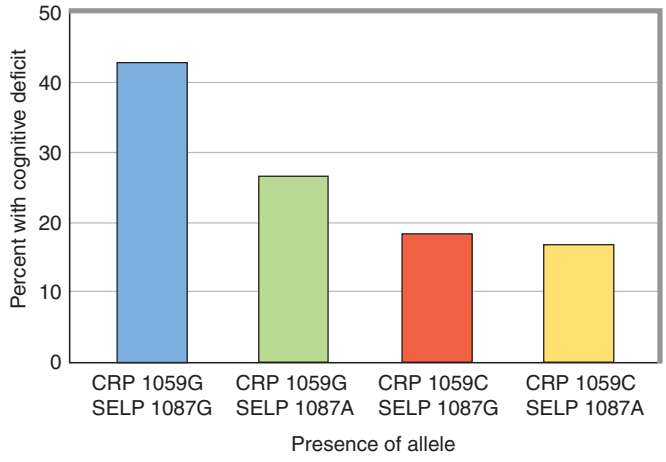

FIGURE 86–8. Incidence of postoperative cognitive deficit by *CRP* 1059G/C and *SELP* 1087G/A genotypes. The incidence of cognitive deficit was 16.7% in carriers of minor alleles at both of these loci, compared to 42.9% in patients homozygous for the major allele (N = 386). Reprinted from Journal of American College of Cardiology, in press, Mathew J, Podgoreanu MD, Grocott GP, et al, Genetic variants in p-selectin and c-reactive protein influence susceptibility to cognitive decline after cardiac surgery, Copyright 2007 American College of Cardiology.

nition of the cognitive decline occurring in elderly surgical patients, demonstrating that cognitive decline is observed in major noncardiac surgery after general anesthesia.[85]

While surgical stress and many of the previously identified etiologic factors likely apply in cardiac as well as noncardiac surgery, anesthesia as a possible etiologic factor has been incriminated by cell culture and whole animals studies.[86,87] General anesthesia agents, especially inhaled agents, may cause amyloid deposition or protein folding differences that could alter either short-term or long-term cognitive function.[86,88–92]

In addition to the described ability of isoflurane to enhance β-amyloid protein (Abeta) oligomerization and generation, and to potentiate the cytotoxicity of Abeta, it has also been shown in a recent investigation to induce apoptosis. Xie et al., in a neuroglioma cell culture model exposed to 2% isoflurane for 6 hours, found that isoflurane induces cellular apoptosis in a dose-dependent manner, and that Congo red inhibits isoflurane-induced apoptosis in H4 human neuroglioma cells.[90] The authors conclude that isoflurane contributes to well-described mechanisms of Alzheimer neuropathogenesis and provides a plausible link between the acute effects of anesthesia, a well-described risk factor for delirium and the more long-term sequelae of dementia.

Despite the cellular evidence, there is little clinical data to support the claim that repeated exposure to general anesthesia markedly alters cognitive function. Further longitudinal trials as well as animal studies are needed to define whether any of the changes that have been identified to date are associated with true clinical sequelae.

Preexisting Cerebrovascular Disease or Documented Brain Abnormalities

A number of investigators have performed investigations on patients scheduled for cardiac surgery preoperatively, including MRI or CT scans in asymptomatic elderly individuals. The presence of silent infarcts in this population is not uncommon and may be associated with later decline in cognition or dementia.[68] Goto et al. have done the largest study. Their study had 421 candidates who were scheduled for coronary artery bypass grafting, of whom 126 (30%) had small brain infarctions preoperatively and 83 (20%) had multiple infarctions.[93] A surprising 50% of the sample had evidence of brain abnormalities before surgery. Thus it is likely that patient characteristics have a significant role in determining the probability of a patient exhibiting neurologic injury after surgery, both by defining the degree of atherosclerotic disease as well as potentially defining individuals with less cognitive or neurologic reserve who will express symptoms of injury to a much greater extent. This association between preoperative MRI lesions and risk of new postoperative lesions was confirmed by Floyd et al.[68] In a small study of 34 patients, they found that 6 patients had evidence of new lesions defined by MRI. The severity of preexisting white matter disease was associated with a higher probability of new lesion occurrence. They defined that preoperative MRI lesions were one of the best predictors of new postoperative lesions.[68]

CONCLUSIONS

Although controversies exist around the incidence and the significance of POCD after cardiac and noncardiac surgery, those patients who experience cognitive decline have measurable reductions in quality of life that offset the benefits provided by surgery. This chapter discusses a number of possible etiologies, including anesthesia and surgery; however, until we have better understanding of how all of these factors interact to define outcome, aggressive intervention is difficult unless the intervention is low-risk. Understanding individuals at risk, intervening in the group at high risk, reproducing the biochemical or physiologic responses in low-risk individuals, and effectively intervening in those who are at risk for long-term decline are measures that hold the greatest potential for benefit with the lowest risk.

CHAPTER 87

Protection of the Central Nervous System in Surgical Patients

W. Andrew Kofke, MD, MBA, FCCM

Neural function is essential to human existence. Loss of any neural element during the course of a critical illness represents a major loss to an individual. Neurons or supporting elements may be lost in a small, virtually unnoticeable manner or manifest as cognitive or behavioral deficit. Widespread selective neuronal loss or tissue infarction may occur with more apparent and disabling deficits. Based on the notion that neural function is the essence of acceptable survival from critical illness, perioperative management must include considerations of neural viability and the effect and interactions of primary diseases and therapeutics on the nervous system.

There are numerous perioperative scenarios wherein a patient may be at risk for neurologic damage. In general, these scenarios involve ischemia, trauma, or neuroexcitation. Each of these conditions, as it progressively worsens, at some point typically involves a period of decreased cerebral perfusion pressure (CPP), either regionally or globally. The latter usually is associated with elevated intracranial pressure (ICP), eventually compromising global cerebral blood flow (CBF) enough to produce permanent neuronal loss, infarction, and possibly brain death. A variety of biochemical pathways play a major role. This chapter reviews the important pathophysiologic factors and ICP considerations and neuroprotective therapeutic options critical to contemporary perioperative care of the surgical patient at risk for central nervous system (CNS) injury.

PERIOPERATIVE STROKE

Types of Stroke

Stroke is the third leading cause of death in the United States. For every patient who dies of stroke, approximately 13 survivors live with the effects of neural tissue loss.[1] The 2-year incidence of stroke is 10 in 1000, and the incidence due to atherothrombotic brain infarction is 4.4 in 1000.[1] Strokes are either ischemic or hemorrhagic. Hemorrhagic strokes are caused by subarachnoid hemorrhage (SAH), intraparenchymal (intracerebral) hemorrhage (ICH), or subdural/epidural hemorrhage. Eighty-four percent of strokes are ischemic, and 16% are hemorrhagic (6% SAH, 10% ICH). Ischemic strokes are caused by embolism, thrombosis, or hemodynamic factors such as anemia or hypotension in the setting of proximal stenosis or brain edema. Atrial fibrillation is a major risk factor for embolic ischemic stroke, comprising approximately 18% of first strokes. Notably, the 3-month mortality of strokes associated with atrial fibrillation is approximately 33% compared with 20% in patients without atrial fibrillation.[2] Genomic polymorphisms are important in the risk of stroke.[3] Another important risk factor in the predisposition to stroke is the cerebrovascular reserve. In the nonsurgical setting, cerebrovascular reserve has been related to increased risk of stroke. In the perioperative context, the inability to compensate for common stresses that require vasodilatation, such as hypotension, anemia, fever, hypoxemia, and hypoglycemia, risks the development of a so-called *hemodynamic stroke.*[4]

Epidemiology of Perioperative Stroke

Perioperative stroke incidence is related to the patient's underlying risk factors (Table 87–1) and the risk factors associated with specific procedures (Table 87–2). Cardiac, thoracic aortic, and vascular neurosurgery have the highest risk of perioperative stroke. An increased risk is reported with procedures on the neck; the lowest risk is associated with general surgery. Cardiac surgery is associated with a 1–5% stroke rate, which increases to ≥ 7% in the elderly. Similar stroke rates are reported with or without the use of cardiopulmonary bypass. Several patient-specific risk factors further increase risk (Table 87–1).[5–7] Stroke rates after thoracic aortic surgery were reported by Goldstein et al.[8] Clearly, the incidence increases when the procedure is performed emergently.

After carotid endarterectomy (CEA), an expected stroke rate is 3–5%.[9,10] Data from the two major multiinstitutional studies examining the efficacy of stroke were reviewed and summarized by Naylor et al.[11] However, Bond et al.[12] report a stroke range that can be larger depending on the degree of carotid stenosis. For unclear reasons, the rate is highest with midrange stenoses. Other factors that increase stroke rate after CEA include female gender,[12–14] age >75 years, global ischemia symptoms (vs. monocular),[12,14] systolic hypertension,[12,14] and peripheral vascular disease.[12,14] Heyer

KEY POINTS

1. The incidence of perioperative stroke without predisposing factors is approximately 0.1%, but specific risk factors and procedures can increase the risk by 10-fold or more.
2. Cerebrovascular reserve refers to the capability of the brain's vasculature to dilate in order to compensate for perioperative physiologic stresses.
3. Attention to maintenance of a normal physiologic milieu is the first principle of brain-oriented perioperative care.
4. Fever kills vulnerable neurons, and hypothermia is protective in cases of cardiac arrest and possibly traumatic brain injury.
5. Glycemic control improves outcome after severe critical illness and probably optimizes neurologic outcome.
6. Some anesthetics are neuroprotective, but some anesthetic drugs may have neurotoxic potential.

TABLE 87–1.

Patient-Specific Risk Factors for Stroke after Cardiac Surgery

Aortic arch atheroma
Renal insufficiency
Recent myocardial infarction
Prior stroke
Carotid disease
Hypertension
Age › 75 years
Left ventricular dysfunction
Low cardiac output
Atrial fibrillation

TABLE 87–2.

Possible Mechanisms of Perioperative Stroke

Intraoperative	Postoperative
Hypotension	Hypotension
Anemia	Emboli: myocardial infarction, subacute bacterial endocarditis, patent foramen ovale
Hypoxemia	Hypercoagulable
Hypocapnia	Atrial fibrillation
Hypercapnia	Anemia
Hypoglycemia	Iatrogenic polycythemia
Hypercoagulable	Hypoxemia
Head position	Hypertension
Hypertension	

et al.[15] reported an association of post-CEA cognitive deficits with apolipoprotein E single nucleotide polymorphism, suggesting a significant role for genetic polymorphisms in ischemic injury after CEA.

From a review of the literature, Thompson et al.[16] reported that surgery on the neck is an important risk factor for stroke, identifying a rate as high as 4.8%. However, they could identify a rate of only 0.2% in their own patients. Nonetheless, these reports of an unexpectedly high perioperative stroke rate after neck surgery have led to the suggestion that extreme turning or extension of the head may introduce a vascular risk factor for perioperative stroke. This is supported by MRI studies of the anatomic consequences of such head positions,[17] transcranial Doppler studies showing the potential for flow decrements with head extension,[18] a brainstem-evoked potential case report,[19] and the beauty parlor stroke syndrome wherein vertebrobasilar ischemic symptoms are associated with head extension during head shampoo in a beauty parlor.[20]

Lanska and Kryscio[21] report a stroke rate of 0.01% in the puerperium. Strokes in this context tend to be due to venous thrombosis. Risk factors include cesarean section, fluid and electrolyte abnormalities, hypertension, and infections.

Ogilvy et al.[22] reported cerebral aneurysm surgery to be associated with a perioperative stroke rate of 5–25% (overall rate 5.2%). However, the rate increases to 38% if intraoperative rupture of the aneurysm occurs. Increases in stroke risk also are associated with longer periods of temporary proximal occlusion of the artery feeding the aneurysm.

General surgery probably is not a high-risk procedure for stroke if the patient does not have any risk factors. Parikh and Cohen[23] reviewed almost 25,000 general surgery procedures reporting a stroke rate of 0.08%. Eighty-four percent of strokes occurred in the 7 days postoperatively, and the mortality associated with a perioperative stroke was 26%. The authors suggest that most of these strokes likely were embolic in origin. They identified preexisting hypertension, prior neurologic symptoms, smoking, and an abnormal rhythm on electrocardiogram, especially atrial fibrillation, as risk factors. Notably, they were unable to identify a relationship between preoperative carotid bruit and the development of perioperative stroke.

The importance of previous neurologic symptoms was underscored by Landercasper et al.[24] and Larsen et al.,[25] both of whom reported an approximately 2% stroke incidence in such patients after general surgery, an approximately 10-fold increase in risk.[24,25] In comparing 61 strokes occurring in patients after general surgery with a group of matched general surgery patients who did not have a perioperative stroke, Limburg and Wijdicks[26] also identified previous neurovascular disease as an important risk factor. These observations underscore the importance of ascertaining the anatomy and circulatory pathology of any patient with a history of stroke or transient ischemic attack. This practice is analogous to that taken in any patient complaining of angina or past evidence of coronary artery disease. In addition, Limburg and Wijdicks identified peripheral vascular disease and chronic obstructive lung disease as other important risk factors. They could not correlate the occurrence of perioperative hypotension with stroke.

Pathophysiology of Perioperative Stroke

The mechanisms of perioperative stroke have not been firmly elucidated in any large prospective studies. Kam and Calcroft[27] suggest that the most likely mechanisms include perioperative hypotension, cardiogenic embolism especially with atrial fibrillation (or cardiac wall-motion abnormalities), in situ atheromatous plaques leading to thrombosis or emboli (or hemodynamic strokes related to impaired cerebrovascular reserve), and increased perioperative coagulability. Perioperative stroke tends to occur in the first week after surgery.[23,27] Presumably, the sequelae of surgical interventions are important in the genesis of stroke. Most ischemic strokes arise from emboli or thrombosis, although some arise from problems with insufficient cerebrovascular reserve in the context of a perioperative physiologic challenge.

A hypercoagulable state is one consequence of the perioperative stress response.[28] This state combines with patient and surgical factors to increase the propensity to create emboli or thromboses that can produce an ischemic stroke. Patients with anatomic pathways from the veins to the great arteries may be at particular risk. Local low-flow conditions may be related to surgical manipulations, inflowing stenotic cerebral or carotid arteries, positioning, or low-output cardiac states with ventricular hypokinesis or dyskinesis that may transiently occur. In particular, head posi-

tion may place the vertebrobasilar system at risk, as described above. Cardiac arrhythmias, most notably atrial fibrillation, are important factors. Atrial fibrillation is relatively common postoperatively and can be another reason for stroke occurrence after surgery. Although unusual, perioperative polycythemia (from endogenous disease, dehydration, or iatrogenic factors) can increase viscosity, adding another low-flow state that can lead to thrombosis. Procedures that entail work on or near the carotid arteries are at particular risk for embolic phenomena. One example from the author's practice is illustrated in Fig. 87–1.

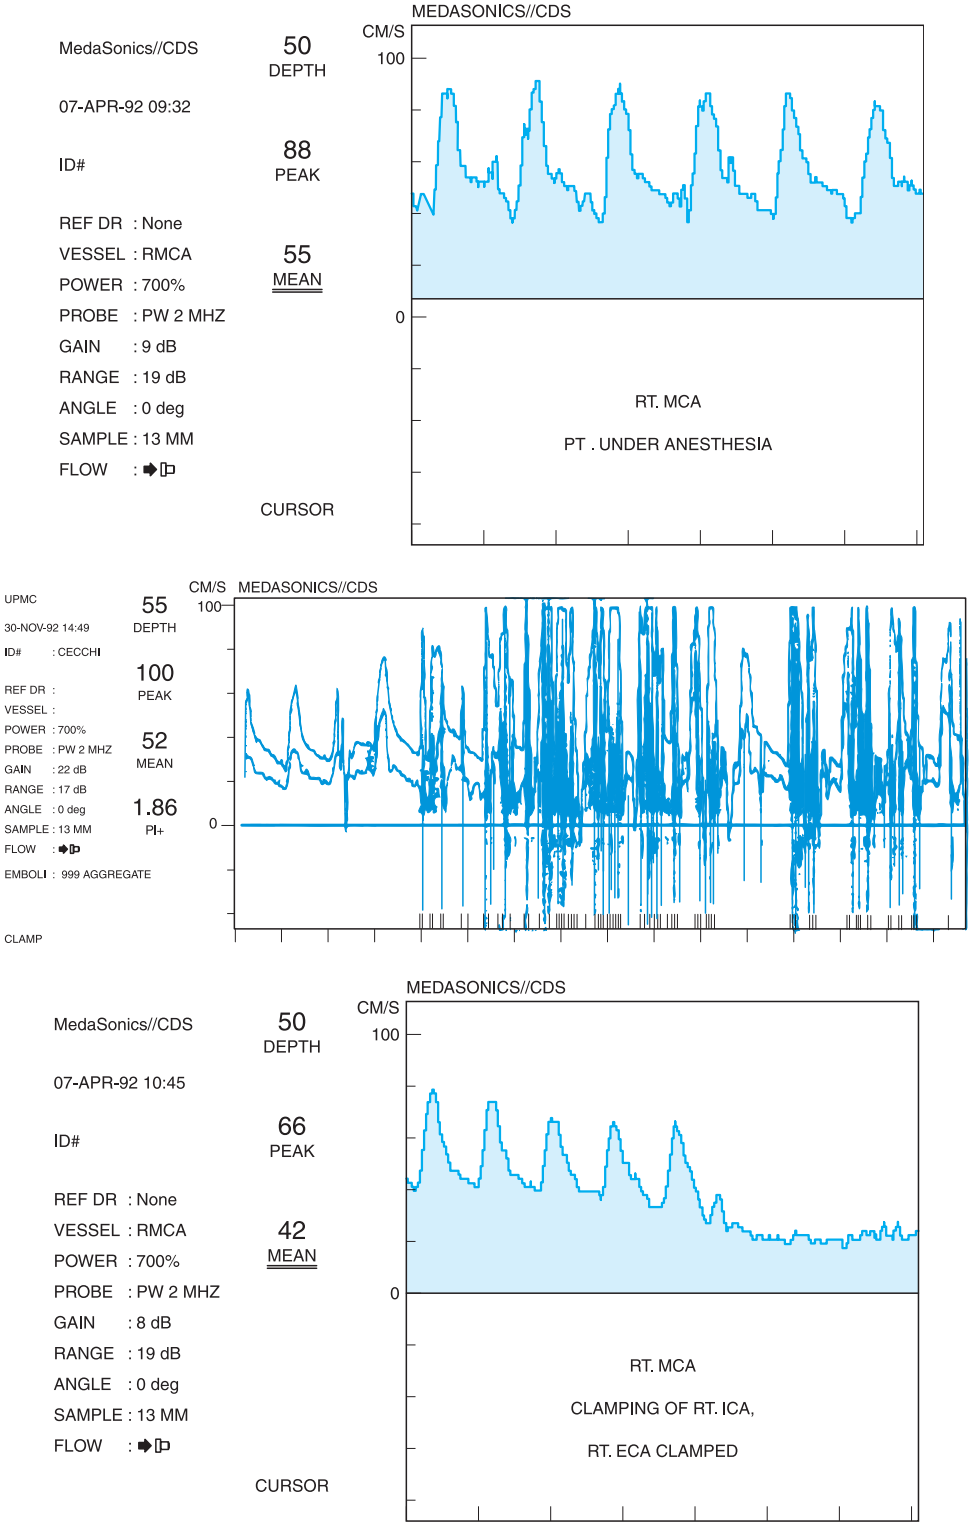

FIGURE 87–1. Transcranial Doppler ultrasonography of the middle cerebral artery during carotid endarterectomy. Flow velocity decrement after internal carotid clamping was transient, with flow restored by a shunt. Unclamping initially was associated with a shower of debris, followed by a transient period of hyperemia. *(continued)*

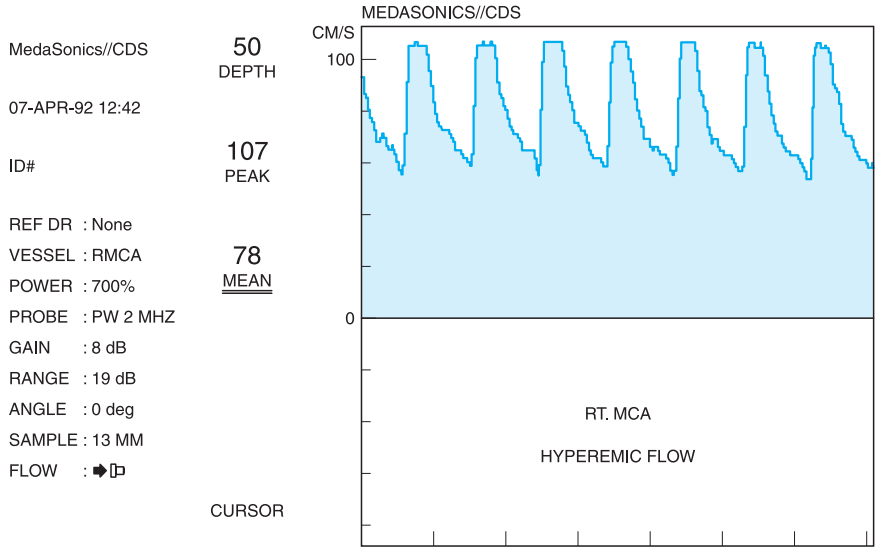

FIGURE 87–1. (Continued)

Cerebrovascular Reserve

Central to physiologic considerations in management of the acutely injured brain are considerations of cerebrovascular reserve. Simply stated, cerebrovascular reserve is the brain's capacity to successfully compensate for physiologic stresses such as hypoglycemia, hypoxemia, hypotension, and anemia. In all of these situations, vasodilatation occurs to provide a compensatory increase in CBF. Inability to sustain vasodilatation in response to such physiologic stresses can result in brain damage.

Animal experiments indicate that it is possible to produce a condition in which cerebrovascular reserve is compromised, with increased tendency to cerebral infarction.[29] For example, occlusion of one carotid artery or production of moderate hypoxemia each by itself does not produce symptoms, as cerebral vasodilatation occurs to compensate. Some investigators contend that arterial hypoxemia occurring with normal cerebral vascular compensatory mechanisms does not cause brain damage. Of course, one contributing factor to this notion is that hypoxic myocardial dysfunction produces organismic death such that isolated neuronal injury cannot occur. However, add hypoxemia to carotid occlusion, or vice versa, and a stroke occurs because compensatory mechanisms, already fully used, cannot accommodate the further decrease in oxygen (O_2) supply.[29] Examples of variants of this situation abound clinically.[30] Examples of attenuated cerebrovascular reserve include cerebral edema, hypoxemia, anemia, carotid stenosis, and peri-infarct penumbra. In each of these situations, although not easy to quantitate, it is clear that added compromise of O_2 supply to the brain risks neuronal injury.[31] The phenomenon is demonstrated in Fig. 87–2.

One way to evaluate the extent of cerebrovascular reserve is through administration of acetazolamide with CBF assessment before and after acetazolamide. An example is shown in Fig. 87–2. Acetazolamide produces a local brain tissue respiratory acidosis that in turn produces local vasodilatation, if this capability is present.[32] If reserve then is impaired even though baseline flow is normal, impaired regional vasodilatation indicates that area of the brain may be susceptible to injury from a perioperative physiologic challenge that requires a vasodilatory response.[33–35] The clinical relevance of this is supported by studies that have associated stroke with hypoxemia,[29] hypotension,[36–39] fever,[40,41] and anemia.[42] This leads to the notion that the practitioner should actively consider the extent of cerebrovascular reserve in every patient. If the patient has arterial stenoses, brain edema, a brain tumor, or other factors that may impair the ability to vasodilate in response to hypoxemia, hypotension, hypoglycemia, fever, or anemia, then a so-called hemodynamic stroke with no emboli or thrombosis may arise.

Role of Head Position

From a review of the literature, Thompson et al.[16] reported that surgery on the neck is an important risk factor for stroke, identifying a rate as high as 4.8%. However, they could identify a rate of only 0.2% in their own patients. Several reviews and reports have led to the suggestion that extreme turning or extension of the head may introduce a vascular risk factor for periop-

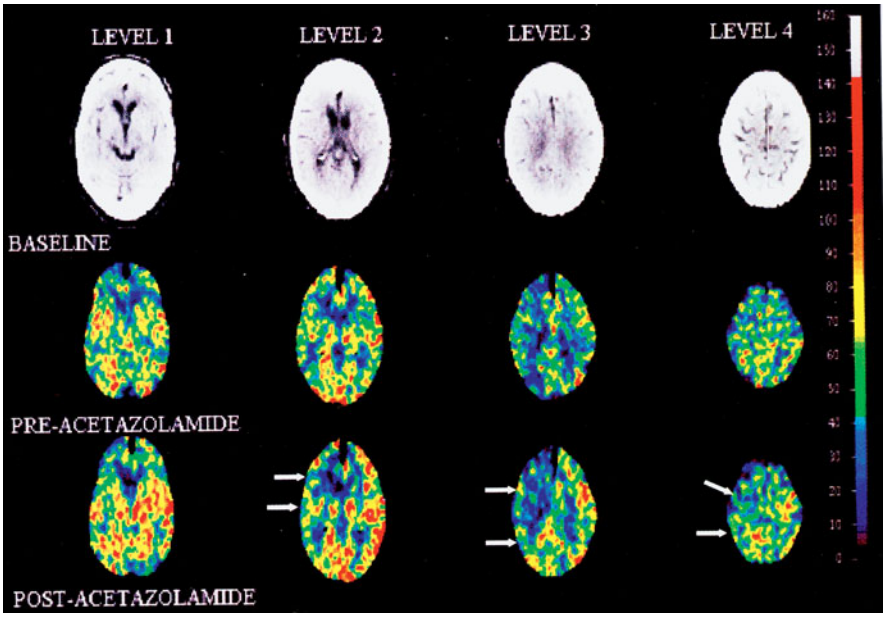

FIGURE 87–2. Stable xenon CT cerebral blood flow was performed before and after administration of intravenous acetazolamide. Areas of the brain with a suboptimal increase in flow in response to the vasodilatory stimulus (*arrows*) have impaired cerebrovascular reserve. (Courtesy of Howard Yonas, MD, University of New Mexico.)

erative stroke. This is supported by MRI studies of the anatomic consequences of such head positions,[17] transcranial Doppler studies showing the potential for flow decrements with head extension,[18] a brainstem-evoked potential case report,[19] and the beauty parlor stroke syndrome wherein vertebrobasilar ischemic symptoms are associated with head extension during head shampoo in a beauty parlor.[20] Another graphic demonstration of this effect was reported by Grundy et al.[19] Her group showed a loss of brainstem-evoked response that clearly was related to head turning for a posterior fossa procedure and was believed to have a vascular cause.

Perioperative Intracranial Hemorrhage

Definitive studies on the pathogenesis of perioperative intracranial hemorrhage have not been published outside of the neurosurgical context. In a retrospective review of >11,000 craniotomy patients, Basali et al.[43] found a 0.77% incidence of ICH postcraniotomy. They evaluated the role of hypertension and determined that systolic blood pressure >160 mm Hg after intracranial surgery is a risk factor for development of ICH.

Eng et al.[44] reported an example of intraoperative rerupture of a previously ruptured cerebral aneurysm during induction of anesthesia. This patient already was intubated, and no significant hemodynamic changes were reported with induction of anesthesia. Nonetheless, aneurysmal rupture was observed and documented with concurrent transcranial Doppler ultrasonography. Temporary transient intracranial circulatory arrest was observed. Although these authors did not observe an association between high blood pressure and this event, there is sufficient correlation of SAH with chronic hypertension as a risk factor to suggest that it similarly is a perioperative risk factor. Ohkuma et al.[45] reported an association between hypertension and early aneurysmal rebleeding. This finding supports the practice of vigorously preventing hypertension in patients with cerebral aneurysms.

Perioperative Stroke Prevention and Treatment

The factors regarding the pathophysiology of perioperative stroke can be used as a guide in preventing perioperative stroke. First and perhaps most important, the anesthesiologist and surgeon should have information regarding previous incidents of cerebral ischemia. Such information should prompt a search for prior evaluations that may include computed tomography, angiography, ultrasound, and other types of assessments of intracranial circulation. This information can be used to decide whether to proceed or to adjust anesthetic management in an attempt to deal with the risk factors.

In the process of making such a determination, assessment of cerebrovascular reserve should be undertaken. Any patient with carotid or intracranial atherosclerotic lesions can be assumed to have impaired cerebrovascular reserve, as can anyone with a history of transient ischemic attack not followed by an evaluation. Any patient with intracranial edema also should be considered to have impaired reserve. Any patient judged to have impaired cerebrovascular reserve requires special attention by the anesthesiologist to ensure that stroke-causing physiologic stresses are avoided, although they may be tolerated in the routine management of healthy patients. Examples of this include hemoglobin (Hgb) concentration <10 g% or mean arterial pressure (MAP) less than the awake baseline. Use of additional monitors, such as electroencephalography (EEG), evoked potentials, or transcranial Doppler, to confirm intraoperative flow should be considered a reasonable course, although no prospective study has proved that such monitoring affects outcome.

Arrhythmias, especially atrial fibrillation, place a patient at particularly high risk for perioperative stroke, perhaps because of an adverse synergistic interaction between the hypercoagulable state and this arrhythmia. It is prudent to consider the possibility that a patient with perioperative atrial fibrillation has an atrial thrombus that is ready to become a perioperative embolus. Atrial fibrillation that arises in the perioperative course must be addressed immediately, with every effort made to produce rapid cardioversion back to sinus rhythm.

Perioperative intracranial hemorrhage most likely is related to hypertensive episodes in the context of individual risk factors. Thus, in patients with known cerebral aneurysm, hypertension (which might otherwise be tolerated) should be aggressively treated. ICH also likely is related to perioperative hypertension. In the context of intracranial surgery, systolic blood pressure >160 mm Hg has been linked to postoperative intracranial hermorrhage[43] and in this specific context is a reasonable limit in the goal to prevent ICH. No other studies like this have been performed in non-neurosurgical settings, but adhering to this guideline seems appropriate in other settings as well.

PRINCIPLES OF BRAIN-ORIENTED PHYSIOLOGIC MANAGEMENT

The essence of satisfactory perioperative neurologic care is to provide a physiologic and biochemical milieu that promotes a good recovery.

Oxygenation

Pao_2 Physiology

Hypoxemia, usually Pao_2 <50–60 mm Hg, is associated with vasodilatation.[46] Conversely, Floyd et al.[47] demonstrated the vasoconstrictive effect of hyperoxia and its accompanying hypocapnia in a group of healthy volunteers. Nakajima et al.[48] evaluated this phenomenon in patients with cerebrovascular disease and found that areas of the brain with impaired cerebrovascular reserve were not adversely affected by hyperoxia.

The optimal Pao_2 in a brain-injured patient is unclear. Some data support hyperoxic therapy, but other data suggest that such an approach is deleterious. In addition, the bedside decision about Pao_2 management is further coupled to cerebrovascular reserve issues previously discussed. Thus, a low Pao_2 that normally is tolerated through vasodilatation may not be so well tolerated if vasodilatory reserve is compromised by carotid occlusion, brain edema, or anemia.

Fiskum et al.[49] reported in laboratory studies that hyperoxic therapy promotes generation of free radicals and that such oxidative stress causes mitochondrial injury that acts to impair neurologic recovery. This notion from in vitro considerations is supported by in vivo studies in rodents and dogs that demonstrated worse neurologic outcome when hyperoxia was used before or after an ischemic insult.[50–52]

Conversely, with the advent of reports supporting the feasibility and reliability of brain tissue PO_2 ($PbrO_2$) monitoring, increased brain tissue oxygen monitoring data are accumulating that normoxemic therapy, in the context of cerebral tissue hypoxia, may promote ischemic injury.[53] Many reports of nonrandomized retrospective and prospective series of both traumatic and SAH patients have described an association between $PbrO_2$ < 20–30 mm Hg and worsened neurologic outcome (Fig. 87–3).[53–58] Notably, however, these studies did not examine for the effects of hyperoxia, which is the situation identified by Fiskum et al. Rather, these studies point out the value of avoiding tissue hypoxia, perhaps at the cost of systemic hyperoxia but not intracranial hyperoxia. However, one side observation from these studies is the effect of avoiding hyperoxia, as brain tissue oxygen monitoring allows the anesthesiologist to provide the minimal fraction of inspired oxygen (FiO_2) that permits the optimal (not too high, not too low) brain tissue oxygen level.

Given these potentially conflicting therapeutic priorities, it seems that the most sensible approach at this time is as follows. If a $PbrO_2$ monitor is available, adjust physiologic parameters to keep $PbrO_2$ >20 mm Hg. This may entail the use of FiO_2 >60% with concomitant risk of pulmonary oxygen toxicity.[59] It seems that this risk can be incurred for 1–2 days, but continued dependence on pulmonary toxic oxygen concentrations should produce a time-dependent increased pressure on caregivers to decrease FiO_2, even if this means use of higher airway pressure or allowing $PbrO_2$ to decrease after a few days.

If a $PbrO_2$ monitor is not available, the clinician must base therapy on assumptions about brain oxygenation. If many brain areas are believed to be well perfused and at risk for hyperoxia, then pulmonary management should aim for Pao_2 just sufficient to produce arterial oxygen saturation (SaO_2) >95%. Conversely, if ICP is elevated and/or areas of brain are hypoperfused, then a reasonable empiric approach is use of FiO_2 = 0.60. This maximizes Pao_2 and $PbrO_2$ but is not associated with significant risk of acute pulmonary injury.

Positive End-Expiratory Pressure

Positive end-expiratory pressure (PEEP) is a modality commonly used to control

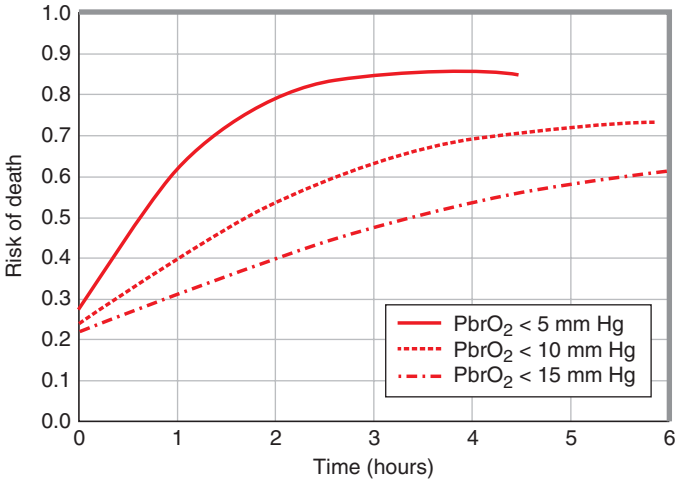

FIGURE 87–3. Relative risk of death as related to initial low brain PO_2 values categorized into groups <5, <10, and <15 mm Hg. Characterization follows from layering the curves, where <5 worse <10 worse <15. Note that the curves stabilize at long durations of hypoxia. (From van den Brink et al.[54] with permission.)

Pao_2, and it is known to have important effects on ICP. The mechanism is cardiovascular and is discussed in greater detail in Cardiovascular Issues below.

Ventilation

$Paco_2$ Physiology

Arterial partial pressure of carbon dioxide ($Paco_2$) is determined by the balance between carbon dioxide (CO_2) production and elimination. CO_2 production is determined by metabolic rate and respiratory quotient (CO_2 production divided by O_2 consumption) and ordinarily is 0.8. Factors that may increase CO_2 production are hyperthyroidism, fever, elevated catecholamine levels, exercise, sepsis, and some pharmacologic stimulants. Respiratory quotient is affected by energy metabolism such that intake of calories in excess of needs results in lipogenesis, which is a CO_2-producing process that leads to more CO_2 produced than oxygen consumed.[60]

CO_2 elimination is determined by minute ventilation and dead space. There is a linear relationship between minute ventilation and $Paco_2$ such that a simple proportion can be described to predict the $Paco_2$ that will result with a given change in minute ventilation. Dead space effects are more complex. There are two types of dead space: anatomic and physiologic. Anatomic dead space is the portion of the airways that does not participate in gas exchange because of no proximity to pulmonary capillaries. Structures include the mouth, trachea, bronchi, and other large airways. Notably, anatomic dead space is roughly halved via endotracheal intubation and halved again by conversion from translaryngeal intubation to tracheostomy. Physiologic dead space is that portion of non–gas-exchanging ventilation that occurs in alveoli that are suboptimally perfused. Thus, physiologic dead space is increased by anything that increases the amount of gas in alveoli without commensurate increase in alveolar perfusion or by anything that may decrease perfusion to alveoli without commensurate decrease in ventilation. Physiologic situations associated with elevated physiologic dead space include use of PEEP in compliant lungs, pulmonary emboli, or shock. A more detailed overview of this physiology is given by West.[60]

In healthy brain, CBF varies linearly with $Paco_2$ between approximately 20 and 60 mm Hg.[61] The mechanism of effect is believed to be related to the effects of $Paco_2$ on the pH of cerebrospinal fluid.[62] Thus, patients who are chronically hypercapnic and sustain pH adjustment in the cerebrospinal fluid may not be hyperemic. These patients may be expected to sustain even more profound decreases in CBF with decrements in $Paco_2$ to equivalent levels.

The $Paco_2$-mediated changes in CBF are generally without any neurologic consequences to health. However, in the context of head injury or other cause of ICP elevation, the effects can be profound, as the changes in CBF induce changes in intracranial blood volume. In the brain with little capaci-

tance for such a change in intracranial contents, the change in $Paco_2$ can have a significant effect on ICP.

For many years, hyperventilation was embraced as the mainstay of treatment of intracranial hypertension.[63] However, such therapy was observed to produce significant cerebral oligemia with the lowered ICP, often developing from a low CBF baseline. Conversely, at times, elevated $Paco_2$ in patients with brain injury was noted to produce both high ICP and high CBF, producing a therapeutic quandary.[64] Moreover, adding to the dilemma were observations from the basic science literature of some neuroprotective side effects associated with hypercapnic cerebral acidosis (Fig. 87–4).[65]

Optimal $Paco_2$

Relatively recent studies debunked the previously accepted verity that hyperventilation is an automatic element in the treatment of head injury. Muizelaar et al.[66] performed a prospective randomized study of the efficacy of hyperventilation in traumatic brain injury. Their outcome data showed a persuasively negative effect of hyperventilation, such that hyperventilation has been abandoned as a routine therapy in traumatic brain injury (Fig. 87–5). However, it still is accepted in some situations. Some authors suggest that brain oxygen monitoring by either jugular oximetry or tissue $PbrO_2$ can be used to guide the use of hyperventiliation.[67] Direct CBF measuring techniques also could be used. Notably, such information can allow the clinician to identify if the patient has an element of hyperemia contributing to the elevated ICP—a situation that logically seems appropriate for hyperventilation therapy, although this notion has not undergone rigorous study.

Temperature

Temperature has a profound effect on the brain. Fever is convincingly associated with worsened outcomes, with greater release and toxicity of neurotoxic amino acids, mismatch between flow and metabolism, oxidative stress, and many other likely unknown processes.[68,69] In normal brain, hypothermia produces a 7% reduction in cerebral metabolic rate for oxygen with every 1°C reduction in brain temperature, thus decreasing consumption of energy metabolites and increasing the time until an hypoxic stress leads to high-energy phosphate depletion and

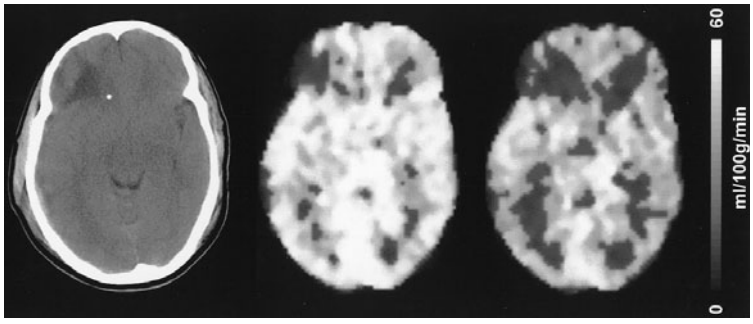

FIGURE 87–4. Effect of hyperventilation on the burden of hypoperfusion. Radiographic computed tomography (*left*) and gray scale positron emission tomographic imaging of cerebral blood flow obtained from a 31-year-old man 7 days after injury at relative normocapnia (*middle*), $Paco_2$ 35 torr (4.7 kPa), and hypocapnia (*right*) 26 torr (3.5 kPa). Voxels with cerebral blood flow ‹10 mL/100 g/min are shaded in black. Note right frontal contusion and small parietal subdural hematoma. Baseline intracranial pressure (ICP) was 21 mm Hg, and baseline cerebral perfusion pressure (CPP) was 74 mm Hg. Baseline jugular venous oxygen saturation ($SjvO_2$) values of 70% and arteriovenous oxygen content difference ($AVDO_2$) of 3.7 mL/dL are consistent with hyperemia and support the use of hyperventilation for ICP control. Hyperventilation resulted in decrease of ICP to 17 mm Hg and increase of CPP to 76 mm Hg, with maintenance of $SjvO_2$ and $AVDO_2$ within desirable ranges (58% and 5.5 mL/dL, respectively). However, despite these values of $SjvO_2$ and $AVDO_2$, baseline critically hypoperfused brain volume was 141 mL and increased to 428 mL with hyperventilation. These increases were observed in both perilesional and normal regions of brain tissue. (From Coles et al.[64] with permission.)

thus increasing the time that the hypoxia can be tolerated.[70] This reduction in cerebral metabolic rate for oxygen cannot explain the neuroprotective effect of mild hypothermia, which must result from the synergism of many physicochemical mechanisms. If the neuroprotective efficacy of hypothermia is compared with that produced by an anesthetic producing an equivalent decrement in cerebral metabolic rate, greater protection by hypothermia is always observed. This is believed to be somehow related to the differential effects of hypothermia and anesthetics on the compartments of brain energy metabolism.[72] Anesthetics decrease metabolic processes related to the work of the neuron—that is, neurotransmitter synthesis and metabolism—whereas hypothermia also affects the compartment responsible for constitutive activities of the cell such as membrane integrity and ionic concentration homeostasis. In addition, other biochemical processes contribute to hypothermic protection. For example, with mild hypothermia, the release of neurotoxic dicarboxylic amino acids such as glutamate and aspartate is blunted substantially.[73] Thus, it is not surprising that countless case reports and basic science studies show the neuroprotective potential of hypothermia across a broad range of neurologic insults. Of interest, clinical studies do not uniformly show comparable efficacy.

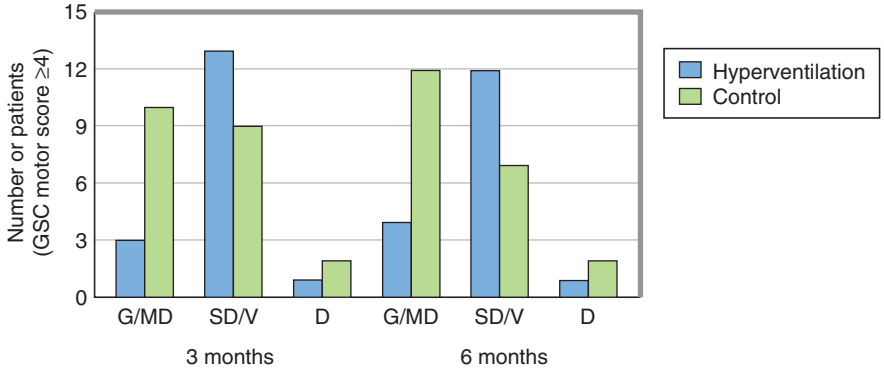

FIGURE 87–5. Head trauma patients were randomized to receive hyperventilation or normoventilation. Outcome was worse in hyperventilated patients. Outcomes: G, good; MD, moderate disability; SD, severe disability; V, vegetative; D, dead. (Data from Muizelaar J, Marmarou A, Ward J, et al. Adverse effects of prolonged hyperventilation in patients with severe head injury: a randomized clinical trial. J Neurosurg 1991;75:731.[66])

Hypothermia has been studied and clinically used for much of the 20th century. This interest arose from anecdotes describing miraculous recovery from drowning and other brain ischemia situations in cold environments. For many years, deep hypothermic conditions have been used for neuroprotection during cardiac surgery and during therapeutically induced deep hypothermic cardiac arrest for a variety of procedures.[74,75] At less extreme levels, hypothermia has been reported to be neuroprotective, although not uniformly so in recent studies. This discussion focuses on moderate hypothermia [86–93°F (30–34°C)].

There are many reports of neuroprotection with hypothermia in traumatic brain injury. However, all these reports are single-institution studies. When hypothermia was examined in multiinstitutional studies, protection could not be demonstrated.[76] However, a study by Clifton et al. reported neuroprotection if the patient arrived already hypothermic, and rapid rewarming may have contributed to some of the negative findings.[77,78] This finding supports the notion that speed of induction and suspension of hypothermia may not have been uniformly applied across the participating institutions in the multiinstitutional studies. Clifton et al.[78] make a persuasive argument in this regard, asserting that significant degradation of the signal-to-noise ratio may have made detection of hypothermic neuroprotection very difficult. The factors contributing to this argument, which they documented, are the extensive practice variations that occur across the United States in the approach to management of head trauma, many of which likely affect outcome, and differences in admission temperature. This latter factor may have important geographic and climactic origins. Moreover, with respect to the hypothermia itself, rapid and safe induction of hypothermia requires an attentive multidisciplinary approach. Hypothermia is associated with coagulopathy, immune suppression, and worse pneumonia, among other factors.

Induction of moderate hypothermia [82–90°F (28°–32°C)] before cardiac arrest has been used successfully since the 1950s to protect the brain against the global ischemia that occurs during some open-heart surgeries. Data from Cheung et al.[79] provide biochemical support for this method, with a safe limit for deep hypothermic arrest identified at approximately 30 minutes neurophysiologically. In other unpublished studies at the University of Pennsylvania, Cheung's group further correlated this 30-minute time limit for deep hypothermic arrest with retrograde perfusion of the brain between evoked potentials and biomarkers for brain injury taken from blood flowing from the ischemic human brain. Induction of hypothermia after return of spontaneous circulation after cardiac arrest has been associated with improved functional recovery and reduced cerebral histologic deficits in various animal models of cardiac arrest.[80–83] These and similar studies led to concurrent publication in the *New England Journal of Medicine* of two studies showing a neuroprotective effect of moderate hypothermia applied to patients sustaining out-of-hospital cardiac arrest.[84,85] These patients sustained a return of spontaneous circulation but on initial examination were not responsive and thus were randomized to the protocol. The protection was found with the target hypothermic temperature successfully achieved up to 6 hours after the return of spontaneous circulation (Fig. 87–6). A summary of these two studies is given in Table 87–3.

On the basis of published evidence, the Advanced Life Support (ALS) Task Force of the International Liaison Committee on Resuscitation (ILCOR) made the following recommendations in October 2002[86]:

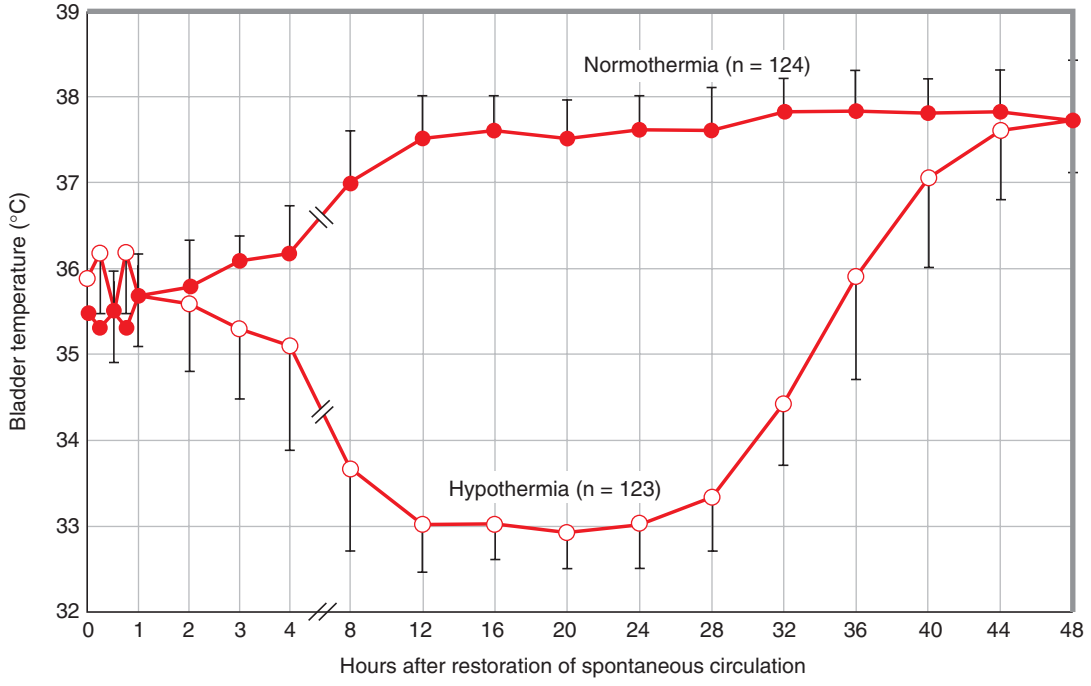

FIGURE 87–6. Time course for temperature in control and hypothermic patients after cardiac arrest. (From Group HaCAS. Mild therapeutic hypothermia to improve the neurological outcome after cardiac arrest. NEJM 2002;346:549–56. Copyright 2002, Massachusetts Medical Society. All rights reserved.)

- "Unconscious adult patients with spontaneous circulation after out-of-hospital cardiac arrest should be cooled to 32°C to 34°C for 12 to 24 hours when the initial rhythm was ventricular fibrillation (VF).
- Such cooling may also be beneficial for other rhythms or in-hospital cardiac arrest."

Although these data supporting the use of hypothermia after global brain ischemia in various contexts seem compelling, some potential issues must be considered when applying these observations to the perioperative situation. These studies were highly selective in their entry criteria. Thus, up to 92% of cardiac arrests were excluded. Moreover, the two studies were not blinded, a practice that is believed to be essential to such investigations but clearly impossible for this specific therapy. In addition, Darby[87] suggests that nonuniform neurologic entry criteria were used. There has been some doubt as to whether these studies investigated normothermia or simply prevention of fever, as the normothermia group had an increase in core temperature of up to 38°C, as is often seen after cardiac arrest. Also important to note is that the therapy is not trivial to implement and is associated with some morbidity. Hypothermia was associated with higher systemic vascular resistance, lower cardiac output, and higher blood glucose level. Twenty-two percent of hypothermic patients had complications, especially pneumonia, although statistical significance was not achieved.

One controversial issue is whether findings from animal experiments and published clinical studies are sufficient to extend the use of therapeutic mild hypothermia to patients who remain comatose after cardiac arrest from any rhythm, after in-hospital or perioperative cardiac arrest, and after cardiac arrest in children. Moreover, many perioperative cardiac arrests have noncardiac causes (e.g., bleeding, anesthesia). Because the use of therapeutic hypothermia has not been studied to a significant extent in this population, its relative risks and benefits are unknown. Kofke[88] suggests that, in cases like this, the value of the benefit—preservation of neural function—is so important as to merit the risk due to uncertainty. Further research is needed to determine optimal duration of therapeutic hypothermia, optimum target temperature, and rates of cooling and rewarming. Animal data suggest that the sooner cooling is initiated after reperfusion from cardiac arrest, the better the outcome, although an impressive therapeutic benefit was seen in clinical studies when cooling was delayed for several hours. One important finding from these studies in traumatic brain injury work is that normothermia should be restored only slowly because rebound hyperthermia is common and should be avoided.

TABLE 87–3.

Summary of Post-Cardiac Arrest Hypothermia Studies

Study	Europe[164]		Australia[165]	
	Cold	Warm	Cold	Warm
Percent dead	41	55	51	68
Percent good neurological outcome	55	39	49	26
Time of assessment	6 months		Discharge	
N	136	137	43	34
Target temperature (°C)	32–34	Normal	33	
How cooled/warmed	Custom cold air mattress; ice	Nothing	Cold packs	
Time to target temperature (h)	4		2	
Duration of cold (h)	24		12	
Mode of rewarm	Passive		Active at 18 h	

Focal ischemia can be categorized as temporary or permanent. Temporary ischemia occurs often during aneurysm clipping surgery when a large cerebral artery may be temporarily occluded to facilitate clipping of the aneurysm. Typically, this lasts only a few minutes but occasionally lasts more than 15 minutes and risks the development of ischemic injury. Ample animal data support the potential value of hypothermia in this context and are the reason why most neuroanesthesiologists in the United States routinely used hypothermia prophylactically in patients undergoing cerebral aneurysm clipping until 2005.[89–91] At that time, the Intraoperative Hypothermia for Aneurysm Surgery Trial (IHAST), another multiinstitutional study of >1000 patients randomized to moderate hypothermia or normothermia, was unable to detect a difference in either stroke rate or cognitive deficits.[92] Thus, moderate hypothermia for this clinical context has been largely abandoned.

However, one critique is that IHAST, by examining all aneurysm patients without measuring the degree of intraoperative ischemia, similar to some of the issues with the traumatic brain study by Clifton et al.,[78] also may have a signal-to-noise problem. Only a small subset of the study group may have actually had a risk of stroke-inducing ischemia. Arguing against this was the scrupulous oversight given to the physiologic support of all the patients at the various sites and the power analysis that was performed on the pilot data patients who presumably were reflective of the entire group. Notably, the pilot data came from a single-institution study that showed a protective effect.[93] Nonetheless, this negative study supports the practice of not using moderate hypothermia in unselected cases.

Therefore, in my opinion, left unresolved is whether hypothermia is useful in a case that is expected to be complex with a high likelihood of significant focal ischemia and whether rapid induction of moderate hypothermia could be of value in the patient in whom significant focal ischemia is actively occurring. I believe that a neuroprotective effect in this situation may have been missed in IHAST. Taking into account the many neuroprotective animal studies and the possible therapeutic gain versus expected outcome and risks of the intervention, this seems a reasonable approach in cases where temporary focal ischemia is believed to be very likely.[88]

Fever is the opposite situation that has been convincingly associated with

exacerbation of neurologic outcome in the injured brain in both animal and clinical studies. Many neuro-ICU patients have recurrent problems with significant fever (>102°F (>39°C) in the absence of identifiable sepsis. In a prospective quantification of 428 consecutive patients admitted to the neurovascular or neurotrauma ICU, 46.7% of patients had at least one febrile episode.[94] This most likely is a sequela of the neurologic process believed by one group of authors to sometimes reflect autonomic dysfunction[95] induced by the neurologic injury.[96] SAH is an independent risk factor for development of fever without identifiable cause.[97] The notion that fever kills neurons is gaining widespread acceptance and is based on many clinical studies that show improvement in neurologic outcome associated with fever prevention.

The mortality rate in patients who had hyperthermia within the first 72 hours after stroke was 15.8% versus 1% in patients who were normothermic during that time. Hyperthermia that occurred within the first 24 hours after stroke—without respect to infectious or noninfectious origin—was independently related to larger infarct volume and worse neurologic deficits and dependency 3 months after injury.[98] Azzimondi et al.[99] reported that a fever ≥ 100.2°F (≥ 37.9°C) proved to be an independent risk factor predicting a worse outcome, and patients with high fever were far more likely to die within the first 10 days than those with lower temperatures. A prospective study by Reith et al.[100] of 390 consecutive cases of acute stroke classified patients into three admission–temperature groups: hypothermic (≤ 97.7°F [36.5°C]), normothermic (97.9–99.5°F [36.6–37.5°C]), and hyperthermic (>99.5°F [>37.5°C]). They showed that admission body temperature was highly correlated with initial stroke severity, infarct size, mortality rate, and poor outcome. For a 1°C difference in body temperature, the relative risk of poor outcome was more than doubled. This finding was supported by Ginsberg and Busto,[101] who reported that fever that occurs soon after the development of stroke in patients is most strongly associated with poor outcome. Body temperature was significantly higher in patients who died within 3 days after admission compared with the rest of the study population. Moreover, in ICH patients who survived the first 72 hours after hospital admission, the duration of fever is associated with poor outcome and seems to be a prognostic factor in these patients.[102] In SAH, fever is associated with vasospasm and poor outcome independent of hemorrhage severity or presence of infection.

Pharmacologic methods can be used to control fever. Drugs include acetaminophen[103] and ibuprofen,[104] although some evidence suggests that ibuprofen is not efficacious in the context of ischemic stroke.[105] The value of acetaminophen can be limited by its hepatotoxicity and the theoretic concern that acetaminophen is an oxidizing agent that, even at subhepatotoxic levels, may decrease glutathione, lessening potentially helpful free radical scavenging processes.[106] Ibuprofen is associated with gastric ulceration and bleeding.[107]

An alternate method is use of a hypothermia blanket or indwelling hypothermia catheters.[108] Both techniques are based on a servocontrolled system in which the cooling bath temperature decreases when the patient temperature starts to increase. In our neuro ICU, we have generated temperature curves indicating that it is possible to virtually eliminate fever from the pathophysiology of severe brain injury. Notably, this has produced a new vital sign, $T_{bathmin}$, which indicates the minimum bath temperature needed to prevent fever in a given patient. Ascertaining $T_{bathmin}$ indicates the need to commence an investigation for the presence of infection.

Glycemic Control

Hyperglycemia has been associated with exacerbation of brain damage with both head trauma and cerebral ischemia.[109–112] However, the issue is not straightforward. Clearly, neuronal damage after global cerebral ischemia is exacerbated by hyperglycemia.[110,113–116] Some studies suggest that a blood glucose level >120 mg% in stroke patients is deleterious.[109] However, subsequent studies suggest a threshold of approximately 180 mg% in subhuman primates subjected to global ischemia.[116] Clearly, a blood glucose level >400 mg% causes striking worsening of neurologic outcome with global ischemia.[110,115] Moreover, the general critical care literature supports prevention of hyperglycemia based on overall mortality, with a suggested goal of 120 mg%.[108,117] This is such a tight control that some worry of diminishing returns due to hypoglycemic complications.[118]

With focal cerebral ischemia, the issue of hyperglycemia is much less clear. Animal and human studies have shown that brain damage is worsened, not affected, or improved with hyperglycemia.[109,119–136] One study of rats by Prado et al.[133] suggests that the discriminating factor in whether brain damage is worsened with hyperglycemia is the presence of collateral flow. Areas of the brain with minimal collaterals were not affected or were improved with hyperglycemia. Brain areas with a continued trickle of flow sustained worsened brain damage. Presumably, the continued substrate supply in oligemic (not ischemic) areas allowed greater accumulation of organic acids in the cells, leading to worsening of brain damage.[111,124] However, these observations are difficult to apply clinically to patients with focal ischemia.

Even if low levels of hyperglycemia were deleterious, the treatment is not straightforward. Aggressive therapy of hyperglycemia imposes a risk of hypoglycemia, which causes deleterious effects.[118] Thus, given the data in the general critical care literature, it seems that a reasonable approach is to aim for a blood glucose level of approximately 120–150 mg% in all acutely ill hyperglycemic patients at risk for cerebral ischemia but to be less stringent in blood glucose control, perhaps aiming for 150–180 mg% in less acutely ill patients who are expected to be in the ICU for <3 days. In any event, blood glucose levels should not be allowed to undergo wide variations; that is, swing between <80 mg% or >400 mg%. Thus, an insulin infusion with frequent glucose assessment should be used in acutely ill patients at risk for cerebral anaerobic metabolism who develop hyperglycemia >150 mg%, with the infusion titrated to keep blood glucose at approximately 120–150 mg%. Once the hyperacute phase has resolved, the intensity of glucose monitoring can be lessened to match the lowered acuity such that a sliding scale insulin paradigm can be used, and somewhat less stringent goals can be used as the patient is readied for discharge from the ICU setting.

Hyperglycemia has not been shown to have deleterious or protective ef-

fects in two animal models of status epilepticus.[137,138] The model used in the report by Swan et al.[138] produced limbic system damage, whereas the report by Kofke et al.[137] used a model that produced substantia nigra damage. Nigral damage in this model is associated with hypermetabolic lactic acidosis,[139] which should be exacerbated with hyperglycemia. The fact that nigral damage was not exacerbated with hyperglycemia suggests that metabolic acidosis may not be an important factor in the development of brain damage after seizure or that the lactic acidosis associated with hyperglycemic exacerbation of ischemic brain damage is not the true pathogenetic culprit but rather is an epiphenomenon.

Cardiovascular Issues

Blood Pressure Effects on ICP–Plateau Waves and Determination of Blood Pressure Optimum

In 1960, Lundberg[140] monitored ICP in hundreds of patients, identifying characteristic pressure waves. One of these waves has been identified as a plateau wave and is known to be associated with increased cerebral blood volume (CBV).[141] Plateau waves occur when the ICP abruptly increases to nearly systemic levels for approximately 15–30 minutes, occasionally accompanied by neurologic deterioration. Rosner and Becker[142] provided data, and a synthesis of the data that convincingly suggests that intracranial blood volume dysautoregulation is responsible for plateau waves. They induced mild head trauma in cats and subsequently intensively monitored the animals after the insult. With normal fluctuations in blood pressure while in the normal range, they observed that mild blood pressure decrements to approximately 70–80 mm Hg preceded the development of plateau waves. CBV in normally autoregulating brain tissue increases due to vasodilatation with decreasing blood pressure, and the increase in CBV is nonlinear. CBV increases exponentially as blood pressure decreases to <80 mm Hg.[143] A small decrease in blood pressure, although in the normotensive range, produces exponential increases in CBV in the setting of abnormal intracranial compliance, with ICP at the elbow of the ICP–intracranial volume relation. Thus, a small decrease in blood pressure introduces an exponential CBV change on an exponential ICP relation such that ICP increases abruptly and significantly. Plateau waves spontaneously resolve with a hypertensive response or with hyperventilation that acts to oppose the increase in CBV. Clearly, development of a plateau wave requires a portion of the brain with normally reactive vasculature in the setting of other brain areas with a mass effect and elevated ICP—a situation of heterogeneous autoregulation. In addition to preventing and treating plateau waves, maintaining MAP in the range from 80–100 mm Hg in patients with high ICP probably is important.

Conversely, hypertension also can increase ICP. Within the normal autoregulatory range and normal ICP, changes in blood pressure have no effect on ICP. However, with brain injury and associated vasoparalysis, blood pressure increases mechanically producing cerebral vasodilatation to increase ICP.[144]

Notably, the Lund group suggests that hypertension-induced exacerbation of brain edema increases ICP.[145] The increase in ICP occludes venous outflow, increasing venous pressure, which in turn worsens the brain edema, constituting a positive feedback cycle initially started by arterial hypertension.[145] Thus it appears that both increasing and decreasing blood pressure can increase ICP, suggesting the presence of a CPP optimum for ICP. In the absence of any patient-specific physiologic information, the value probably is 80–100 mm Hg, although this value has not been definitively determined experimentally. These considerations underlie a current controversy with respect to blood pressure management in the context of elevated ICP. One argument is that blood pressure should be maintained at a high level to ensure adequate CBF and minimize the probability of plateau waves. The contrary argument is for ample fluids and low blood pressure to promote CBF primarily rather than pressure. In my opinion, the preferred approach is to induce the lowest blood pressure that allows sufficient CBF as indicated by repeated (preferably bedside) measurement. However, lacking such technology, it seems best to aim for CPP of approximately 80 mm Hg.

Blood Pressure Management

Blood pressure management is an important issue in most neuro-ICU patients. Concern exists that systemic hypertension may exacerbate cerebral edema or intracranial hemorrhage or have deleterious cardiopulmonary effects, such as pulmonary edema or myocardial ischemia. Conversely, blood pressure decreases can lead to insufficient perfusion even at pressures in the normal range of autoregulation. Moreover, mild blood pressure decreases have been implicated in the genesis of plateau waves. Several important principles apply to management of blood pressure in neuro ICU patients.

Hypertension When blood pressure is high, a central question that must be addressed initially is whether the pressure is elevated as a result of normal homeostatic mechanisms to maintain adequate perfusion. For example, with conditions of inadequate brainstem perfusion, a compensatory hyperadrenergic state may occur, resulting in increased blood pressure and thus maintaining sufficient perfusion to maintain aerobic metabolism in the brainstem. If a decision is made to decrease blood pressure, then brainstem failure and death may ensue.

Animal data from cerebral ischemia models strongly support the notion that sympatholytic drugs should be used to decrease blood pressure if cerebral ischemia is a possibility. Compared with hemorrhagic-induced hypotension, ischemic damage was decreased with ganglionic blockade with hexamethonium,[36] central adrenergic blockade with α_2-agonists,[146] and angiotensin-converting enzyme inhibitors.[38] Hemorrhaged controls were noted to sustain an increase in exogenous catecholamine concentrations. To test the hypothesis that these catecholamines contributed to brain damage, some of the animals treated with hexamethonium also received IV catecholamine infusions. Reversal of the hexamethonium brain protective effect was observed in these animals (Fig. 87–7).[36] Similarly, brain protection has been observed in laboratory studies with preischemic[147] and preseizure[148] treatment with reserpine, a drug that depletes presynaptic catecholamine stores. In a report by Neil-Dwyer et al.,[149] SAH patients received therapy with phentolamine/propranolol compared with no sympatholytic therapy (Fig. 87–8). Subjects who received sympatholytic therapy had significantly better neurologic

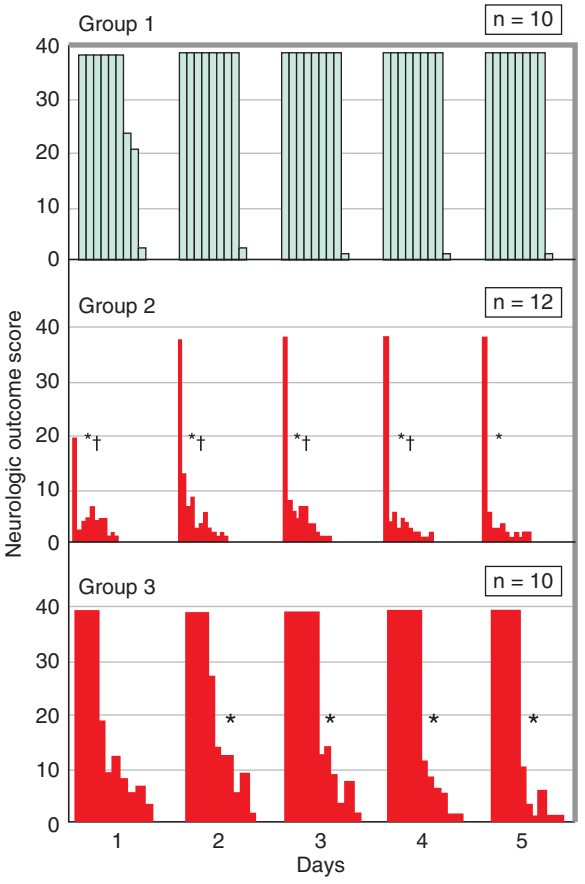

FIGURE 87–7. Neurologic deficit scores after incomplete focal cerebral ischemia in rats over a 5-day examination period. Each bar represents the neurologic score for each rat. *P <0.05 vs group 1; †P <0.05 vs group 3. Rats are ranked according to total outcome score in descending order (o = normal). Cerebral ischemia was induced with occlusion of one carotid artery with hemorrhagic hypotension. Group 1 rats received no vasoactive drugs; group 2 rats received preischemic hexamethonium; group 3 rats received hexamethonium plus intravenous epinephrine and norepinephrine. Protection was conferred by hexamethonium in a catecholamine-reversible manner. (From Werner et al.[35] with permission.)

outcome than did controls. In addition, β-adrenergic blocking drugs have not been reported to produce cerebral vasodilatation or increase ICP.[150–152]

Calcium channel antagonist drugs, which may have brain protective effects, also are available for antihypertensive therapy. Nimodipine and nicardipine, developed specifically for brain protection purposes, have been assessed in numerous studies, with several reports of their conferring protection against vasospasm and ischemic brain damage.[153–159] Thus, they have become reasonable choices for use as antihypertensive drugs based solely on these observations. They are vasodilators and can modestly increase ICP.[160,161] As vasodilators, they may be expected to produce compensatory catecholamine release, which, based on the previous discussion, may obviate some of their protective qualities.[162] Moreover, nimodipine has been observed to decrease $PbrO_2$.[163] Whether this phenomenon can alter outcome is not known.

Peripheral vasodilators (e.g., nitroprusside, nitroglycerin, and hydralazine) have the potential to induce cerebral vasodilatation and thus cause hyperemic intracranial hypertension.[164–167] Moreover, they are associated with compensatory increases in peripheral catecholamines and rennin,[162] factors that theoretically may worsen ischemic brain damage.[36,147] However, the lack of bradycardia and bronchoconstriction associated with their use may make them the optimal choice in some patients with these conditions. If such a drug is chosen and the patient is at risk for neurologic deterioration from ischemia or high ICP, close clinical observation is indicated. Any deterioration mandates discontinuation of the drug. Such concerns are important in deciding from among these three drugs. Although hydralazine is convenient to use, it cannot be reversed at the receptor, and its effects can last hours. Thus, nitroprusside may be preferable in such situations, because adverse effects can be treated quickly simply by discontinuing the infusion. It should be clear that the choice of antihypertensive agent in a patient at risk for cerebral ischemia is not straightforward. Therapeutic urgency, sympatholytic and brain protective side effects, and potential to increase ICP all are important considerations in the choice of antihypertensive drug.

If blood pressure must be decreased very quickly (i.e., within minutes), 100- to 500-μg boluses of nicardipine are very effective and safely titratable. Once the blood pressure is reduced, a maintenance regimen of nicardipine or another drug can be started. Alternatively, sodium nitroprusside can be

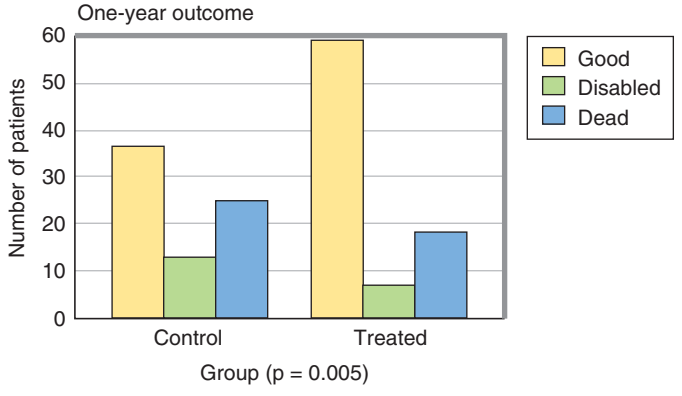

FIGURE 87–8. Subarachnoid hemorrhage patients were randomly treated with propranolol or placebo. Neurologic outcome was better in patients receiving β-blockade. Graph generated from data of Neil-Dwyer et al.[149] (Reprinted from Kofke WA. Critical Neuropathophysiology. In: Fink MP, Abraham E, Vincent J-L, et al., eds. Textbook of Critical Care, 5th ed. Philadelphia: Elsevier, 2005: 285, with permission from Elsevier.)

started. However, nitroprusside has a variety of deleterious side effects (discussed above) that decrease its desirability as an antihypertensive agent in a neurologic patient. However, nitroprusside perhaps is the most potent and reliable antihypertensive drug available.

Plateau waves, which were first reported by Lundberg,[140] are associated with neurologic deterioration and were demonstrated by Risberg et al.[141] to be associated with cerebral vasodilatation. Rosner and Becker[142] reported that mild decreases in blood pressure to the range from 60–80 mm Hg can be associated with plateau waves. Presumably, the decrease in blood pressure prompts vasodilatation in normally autoregulating tissue. The increase in CBV, which is an exponential function versus CPP superimposed on the exponential ICP versus intracranial volume relationship, then is associated with an explosive hyperemic increase in ICP—a plateau wave.[142] This introduces concern with use of any antihypertensive agent (aside from specific, direct cerebrovascular effects) that normal autoregulation may also increase ICP as CPP decreases to approximately 80 mm Hg or less.

Clearly, whenever hypotensive therapy is used in a patient with altered intracranial compliance, edema, or ischemia, close and recurrent observation of the patient is mandatory. Deterioration should prompt consideration of one of the processes that occurs with corrective therapy and reconsideration of the need to decrease blood pressure.

Hypotension and Induced Hypertension In hypotensive patients, low blood pressure should be treated and ongoing efforts made to ascertain the cause of the hypotension. In head trauma patients, consideration must be given to other injuries with hemorrhage or spinal shock. Loss of blood flow to the brainstem can be associated with hypotension, which can be difficult to treat. The usual nonneurologic causes of hypotension in an ICU, such as pneumothorax, sepsis, and cardiogenic causes, also should be considered.

The need for therapy to increase blood pressure, as in the case of vasospasm, must be seriously contemplated. Excessive increases in blood pressure can exacerbate cerebral edema.[168–172] This presumably occurs in brain areas with dysautoregulation and blood brain barrier (BBB) disruption, such that increasing the blood pressure, rather than producing vasoconstriction and no change in regional CBF, causes vascular distension, increased regional CBF, and transudation of fluid across the damaged BBB. In addition, increases in blood pressure risk producing or exacerbating intracranial hemorrhage.

Catecholamines used to increase blood pressure are neurotransmitters or are chemically similar to neurotransmitters. Thus, if catecholamines cross the BBB, neural effects arising secondary to their use are expected. Normally, exogenously administered catecholamines do not cross the BBB and have no effect on CBF and metabolism.[173] However, it has been demonstrated that catecholamine infusion in the presence of BBB disruption leads to increased blood flow and metabolism.[174] In SAH patients, catecholamine infusions produce a variety of disparate and unpredictable effects on CBF,[175] and adrenergic blockade confers neurologic protection.[149] Finally, catecholamines have direct neurotoxic potential, as indicated by data showing neurotoxicity with application directly to the cortex in vivo.[176] However, catecholamines are the only clinically accepted routine pharmacologic means for increasing blood pressure in neuro-ICU patients.

Increasing preload to the heart is one nonpharmacologic method for increasing blood pressure. Crystalloid or colloid infusion is generally associated with hemodilution, and the effects on the patient's status should be considered when use of this method is contemplated. Hemodilution may improve flow to areas with compromised microcirculation. However, it may be associated with increased CBV and hyperemic intracranial hypertension if hematocrit decreases excessively with compensatory vasodilatation.

Whether to use crystalloid or colloid for this purpose remains controversial. The BBB is functionally an osmometer,[177–182] so the added trivial increase in osmolarity with colloid is not a sufficient reason to use colloid. A sensible approach supported by animal studies is use of isoosmolar or slightly hyperosmolar fluids to decrease the possibility of increasing brain edema secondary to fluid administration.

Some advocate the use of induced systemic hypertension with high ICP to prevent plateau waves. As blood pressure increases, incremental increases in vasoconstriction occur in normally reactive tissue to decrease CBV and thus ICP. However, the advantage of this therapy may be offset by increased edema in injured brain regions.

SAH is an entity particularly notable for catecholamine effects, some of which are described here. However, catecholamine effects also occur with other intracranial processes, including increased ICP, stroke, head trauma, and any conditions of compromised midbrain–hindbrain O_2 delivery. Serum catecholamine levels increase dramatically after SAH, notably peaking at the same time as the peak incidence of post-SAH vasospasm with symptom development corresponding to serum catecholamine levels.[183–186] This leads to the notion that hypothalamic injury with excess catecholamine release may be an important factor in the genesis of post-SAH spasm and stroke, observations that may be relevant to other intracranial processes previously elaborated.[184] Several lines of evidence further support this hypothesis:

A. The cerebral vasculature is invested somewhat with adrenergic nerves. With SAH, the adrenergic receptors in cerebral vessels decrease in quantity.[38,187] This suggests that denervation hypersensitivity may be occurring such that the increase in humoral catecholamines with SAH produces spasm in hyperreactive vessels.

B. Catecholamine release after SAH is sufficient to produce electrocardiographic changes[147,183] with ventricular wall-motion abnormalities[148,176] and myocardial injury.[188,189]

C. Treatment with β- and α-adrenergic antagonists of patients with SAH is associated with an improvement in neurologic outcome (Fig. 87–8)[190] and electrocardiographic abnormalities.[148]

D. In animal models, selective destruction of hindbrain adrenergic nuclei with cephalad projections prevents the development of vasospasm.[189] Moreover, laboratory studies indicate an important role for vasopressin in vasospasm, as vasospasm cannot be produced in vasopressin-deficient rats.[191]

E. Animal data with cerebral ischemia models provide strong support for the

notion that catecholamines can exacerbate cerebral ischemia. Compared with hemorrhage-induced hypotension, ischemic damage was decreased with hypotension induced through the use of ganglionic blockade with hexamethonium,[192] central adrenergic blockade with α_2-agonists,[193] and angiotensin-converting enzyme inhibition.[194] Hemorrhaged controls were noted to sustain an increase in exogenous catecholamine concentrations. To test the hypothesis that these catecholamines contributed to brain damage, some of the animals treated with hexamethonium also received IV catecholamine infusions. Reversal of the hexamethonium brain protective effect was observed in these animals (Fig. 87–7).[192]

F. Brain protection has been observed in laboratory studies with preischemic[195] and preseizure[196] treatment using reserpine, a drug that depletes presynaptic catecholamine stores.

G. Application of catecholamines directly to nonischemic cortical tissue has been observed to have neurotoxic potential.[197] In addition, IV administration can exacerbate brain swelling after head trauma, although this most likely is a direct effect of blood pressure on a dysautoregulating brain (Fig. 87–8) rather than a manifestation of biochemical neurotoxicity.[198]

PEEP and Intracranial Hypertension PEEP can increase ICP.[199] Two mechanisms can be posited. The first is through impedance of cerebral venous return to increase cerebral venous pressure and ICP. The second is through decreased blood pressure and reflex increase in CBV to increase ICP. Data by Huseby et al.[200] suggest that cerebral venous effects occur only with very high PEEP.

Shapiro[201] demonstrated ICP increases in head-injured humans with intracranial hypertension upon application of PEEP. Examination of their data indicates that the most profound decreases in CPP occurred in patients with PEEP-induced decrements in MAP consistent with the notion put forth by Rosner and Becker[142] that decreases in blood pressure increase CBV to increase ICP. In studies of cats, Aidinis et al.[202] confirmed these observations in a more controlled setting. In addition, they assessed the role of pulmonary compliance and found that decreased pulmonary compliance with oleic acid injections results in less of an effect of PEEP in increasing ICP. Such observations indicate that in situations where PEEP likely will be needed, often accompanied by decrements in pulmonary compliance, any adverse effects on ICP are less likely to be manifest. This may be related to observations that the hemodynamic effects of PEEP are less apparent with noncompliant lungs such that hypotensive-mediated increases in CBV do not occur.[203]

The intuitive notion that PEEP increases cerebral venous pressure to increase ICP is not as straightforward as some may indicate. For PEEP to increase cerebral venous pressure to levels that will increase ICP, the cerebral venous pressure must equal at least the ICP. Thus, the higher the ICP, the higher the PEEP needed to have such a direct hydraulic effect on ICP. This concept was nicely proven by Huseby et al.[200] in dog studies in which PEEP was increased progressively with different starting levels of ICP (Fig. 87–9). It is important to note that they prevented PEEP-induced decrements in blood pressure, thus avoiding any reflex increases in CBV. They suggested a hydraulic model to better conceptualize this process (Fig. 87–9). For example, if all of a 10-cm H_2O PEEP application was transmitted to the cerebral vasculature, which is unlikely given the decreased pulmonary compliance associated with the need for such PEEP, then ICP is affected only if it is ≤ 10 cm H_2O (7.7 mm Hg) and increases to a level no higher than the applied PEEP. Such observations are consistent with the notion that a Starling resistor regulates cerebral venous outflow.[203]

Optimal Hgb Level

Anemia is generally well tolerated neurologically except at extreme levels. This finding indicates the enormous cerebrovascular reserve that, in health, is in place to compensate for this and similar physiologic stresses. Observations by Borgstrom et al.[206] in rodents indicate that decreasing Hgb levels produce an increase in CBF that initially is primarily due to decreased viscosity, but as Hgb continues to decrease to <10 g%, then active vasodilatation arises (Fig. 87–10). If the brain vasculature already is maximally vasodilated because of other stresses, such as hypoxemia or low CPP, then the anemic stress may not be well tolerated and may produce hypoxic/ischemic brain damage.

Supporting observations of anemia-associated cerebral vasodilatation have been reported in humans after cardiac surgery (Fig. 87–11).[205] Dexter and Hindman modeled these competing issues mathematically using data agreeing with laboratory and empiric observations that Hgb <10 g%, associated with vasodilatation, can be expected to be deleterious in conditions of altered cerebrovascular reserve.[206] Observations of post-GI hemorrhage anemia-associated stroke by Kim and Kang[207] support Dexter and Hindman's calculations. Another supporting point is the observation in brain-injured patients of increased $PbrO_2$ with transfusion to Hgb >10 g%.[208] One approach to managing low $PbrO_2$ is to transfuse to Hgb >10 g%, based on observations that such therapy can significantly improve brain oxygenation in the context of severe brain injury. Notwithstanding reports that 7 g% is optimal in a general critical care population,[209] these observations taken altogether suggest that transfusion to a goal of 10 g% is reasonable in the context of impaired cerebrovascular reserve.

NEUROPROTECTIVE/NEUROTOXIC EFFECTS OF ANESTHETICS

Anesthetics for neuroprotection have been studied at least since the 1960s. Goldstein et al.[210] initially were interested in the potential protective effects of barbiturates for global ischemia. A variety of studies on the efficacy of barbiturates eventually were published. A review of these studies makes clear that the genesis of much of the confusion was related to the timing of barbiturate therapy, the type of ischemia (focal vs. global), and the duration of the ischemia. The studies, all performed in animals, suggest that barbiturates may have a protective effect when given before or shortly after the onset of focal temporary ischemia, as may occur during aneurysm surgery. The studies are conflicting regarding the efficacy of barbiturates in focal permanent ischemia. For global ischemia, there were some initial encouraging canine studies by Goldstein et al.[210] and subhuman pri-

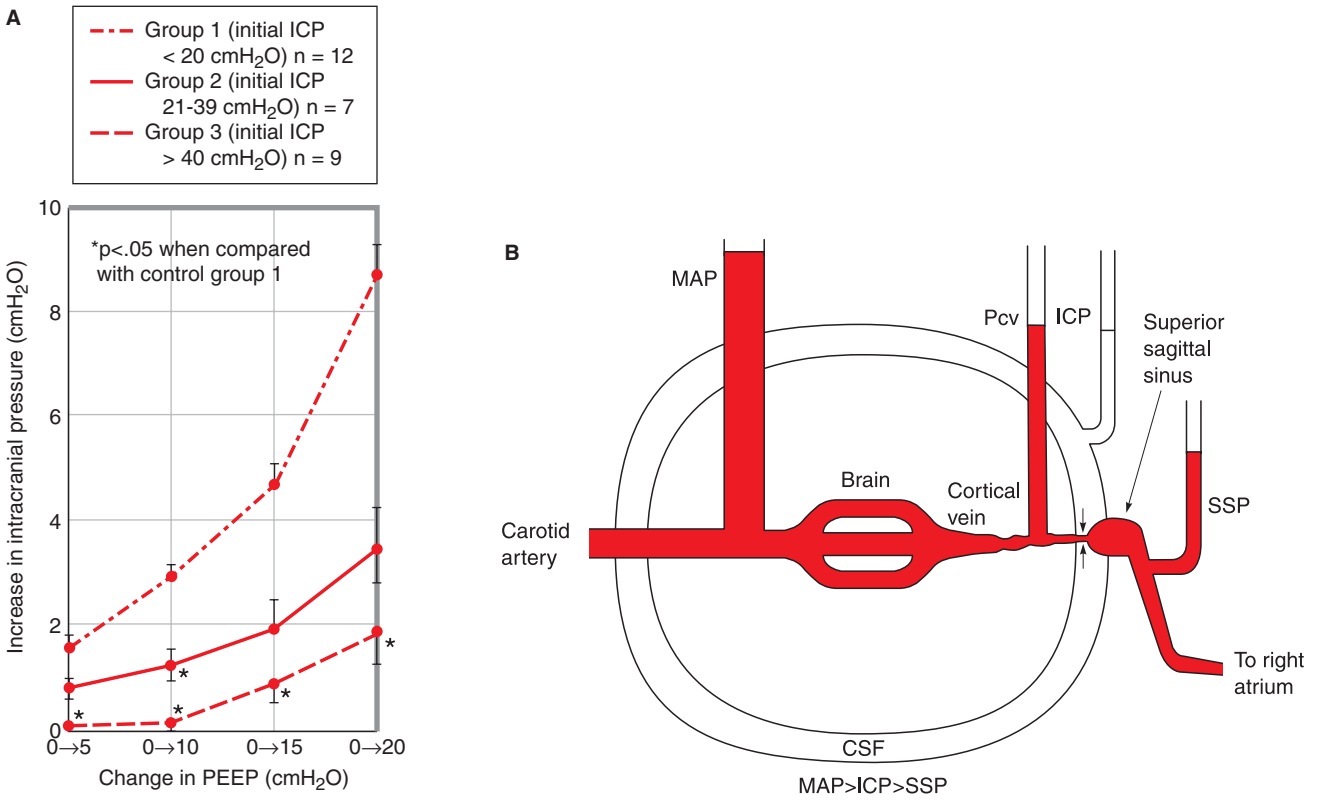

FIGURE 87–9. **A.** Increases in intracranial pressure (ICP) with positive end-expiratory pressure (PEEP) in dogs. Values are given as mean ± SEM. Group 1 included 12 animals with initial ICP ‹20 cm H_2O; group 2 included 7 animals with initial ICP 21–39 cm H_2O; group 3 included 9 animals with initial ICP ›40 cm H_2O. Blood pressure was maintained constant in all animals. Note that when blood pressure was maintained constant, the most significant increases in PEEP occurred in the animals with the lowest starting PEEP level. **B.** Schematic illustration of the intracranial space during increased ICP. Arrows indicate the position of the hypothesized Starling resistor. Here, mean arterial pressure (MAP) is greater than ICP, which is greater than sagittal sinus pressure (SSP). Cortical vein pressure (Pcv) cannot fall below ICP; thus, flow is dependent on MAP ICP and independent of small changes in SSP. (From Huseby et al.[200] with permission.)

mate studies by Bleyaert et al.[211] However, the subhuman primate studies were criticized for the more intense care given to the treated animals that may have accounted for the improved outcome. Indeed, this study was unable to be reproduced by Gisvold et al.[212] Moreover, an attempt some 13 years later to reproduce the original study by Goldstein et al. was similarly unsuccessful.[213] Notably, in the original study by Goldstein et al., the control group had only local anesthetic infiltration for thoracic surgery, with the dog under neuromuscular blockade and ventilated at the time of onset of ischemia, such that the barbiturates were compared to a likely highly sympathetically activated animal.[210] Without such activation in the controls, Steen et al.[213] were unable to reproduce this seminal study. Nonetheless, the Brain Resuscitation Clinical Trial Group evaluated the efficacy of thiopental loading immediately after return of spontaneous circulation after cardiac arrest in humans.[214] They were unable to demonstrate a protective effect in this multiinstitutional study. It was suggested that, in some subsets of patients, a protective effect was lost in the signal to noise inherent in the design of such studies. Nonetheless, at this time, the data do not provide sufficient support for the general use of barbiturates for global brain ischemia.

If barbiturates are to be used, the available data suggest a range of doses. Initial studies examined only high-dose barbiturates, associated with an

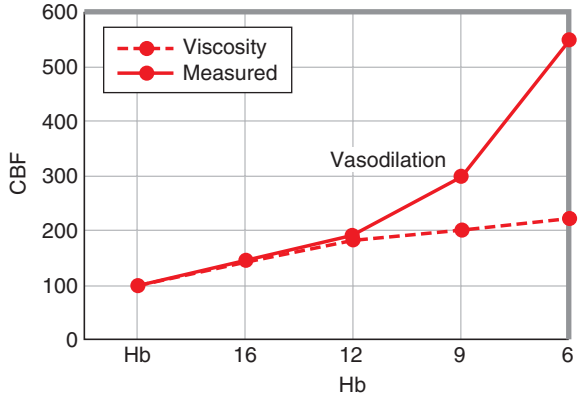

FIGURE 87–10. Rats underwent isovolemic anemia with measurement of per change in global cerebral blood flow (CBF). The theoretic CBF that arises solely from changes in viscosity is indicated by the viscosity curve. Measurement CBF follows this line until the hemoglobin level falls to ‹10, below which active vasodilatation was observed. (Adapted from Borgström L, Jóhannsson H, Siesjö BK. The influence of acute normovolemic anemia on cerebral blood flow and oxygen consumption of anesthetized rats. Acta Physiol Scand 1975;93:505–514.)

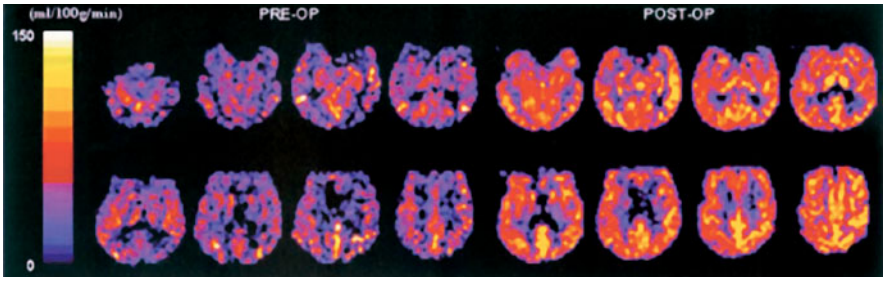

FIGURE 87–11. Preoperative (PRE-OP) and postoperative (POST-OP) (cardiac surgery) continuous arterial spin labeling perfusion magnetic resonance images show cerebral blood flow with color scale for subject 5, an 81-year-old man. Global cerebral blood flow has increased from baseline of 36 to 62 mL/100 g/min on the fifth day after surgery. Multiple regression over all subjects revealed a significant and inverse relationship between cerebral blood flow and hematocrit. (Reprinted from Floyd T, McGarvey M, Ochroch E, et al. Perioperative changes in cerebral blood flow after cardiac surgery: influence of anemia and aging. Ann Thorac Surg 2003;76:2037–2042, with permission from Society of Thoracic Surgeons.[205])

isoelectric EEG. Studies by Selman et al.[215–217] showing neuroprotection for focal temporary ischemia in subhuman primates used very high doses of barbiturates given over at least 24 hours, enough to suppress any edema-mediated ICP elevations. However, Warner et al.[218] found similar protective efficacy for a focal temporary ischemic insult in rats at doses sufficient to produce an isoelectric EEG and doses about half that associated only with significant EEG change and not an isoelectric state.

These data suggest the occasional value of using barbiturates for neuroprotection for focal temporary ischemia. If the amount of ischemic tissue is large and possibly associated with elevated ICP, then higher, isoelectric EEG-producing doses seem appropriate. If the ischemic insult is less severe, then lower doses may be appropriate. These recommendations are not based on randomized human studies but on theoretical gain, which is significant when considering prevention of stroke versus the possible risk of therapy that may or may not be considerable.[88]

Other γ-aminobutyric acid (GABA)-ergic drugs, such as etomidate,[219,220] benzodiazepines,[221–223] and propofol,[223–226] have shown similar results, although the number and breadth of the studies are not at all comparable to those performed with barbiturates. Indeed, in some reports etomidate has been suggested to be deleterious when given for cerebral ischemia,[227] and propofol worsened injury in an in vitro model[221] but not in another in vitro report.[228] In the context of seizure-induced injury, Kofke et al.[229] reported that midazolam reduced substantia nigra injury, whereas thiopental and isoflurane, although they also stopped the seizure, conferred no neuroprotection. Ketamine had an intermediate effect, and an effect may have been missed because of small sample size.

Using isoflurane as a prototype, the volatile anesthetics have been demonstrated to clearly prolong the amount of time that an animal's brain can tolerate an anaerobic condition.[230] Other reports in animals also have reported a capability of volatile anesthetics to confer early histologic protection against a variety of types of ischemic insults.[231–237] However, when the evaluations are extended to 2 weeks after focal ischemia, the protective efficacy can no longer be demonstrated.[238] These data seem to suggest that initial damaging processes can be favorably altered by a volatile anesthetic but that other deleterious postischemic processes, such as apoptosis, are not altered by isoflurane.[239] However, this temporary protection was not observed in a global ischemia model.[240] At this time, the capability of isoflurane and other volatile anesthetics to contribute to permanent perioperative neuroprotection remains unsettled.

Opioids have not been shown to have any neuroprotective effects. Several studies by Kofke et al.[241–244] demonstrated the capability of fentanyl and congeners given in high doses to produce limbic system activation (Fig. 87–12) and damage (Fig. 87–13). Comparable limbic activation was shown when patients were given brief high-dose remifentanil (Fig. 87–14).[244] Cingulate activation was noted with sedative-dose remifentanil in volunteers.[245] Notably, cingulate activation did not occur in patients with the apolipoprotein E (ApoE) genotype, although hippocampal activation did arise with this single nucleotide polymorphism. Moreover, μ opioids in humans have been reported to have proconvulsant properties[246] that are expected to be deleterious in the context of cerebral ischemia, as demonstrated in one laboratory report of opioid use with cerebral ischemia[247] and another on opioid use with traumatic brain injury.[248] These studies investigated isolated opioid use. The negative effects appear to be attenuated with concomitant hypnotic drug administration.[249] Although provoca-

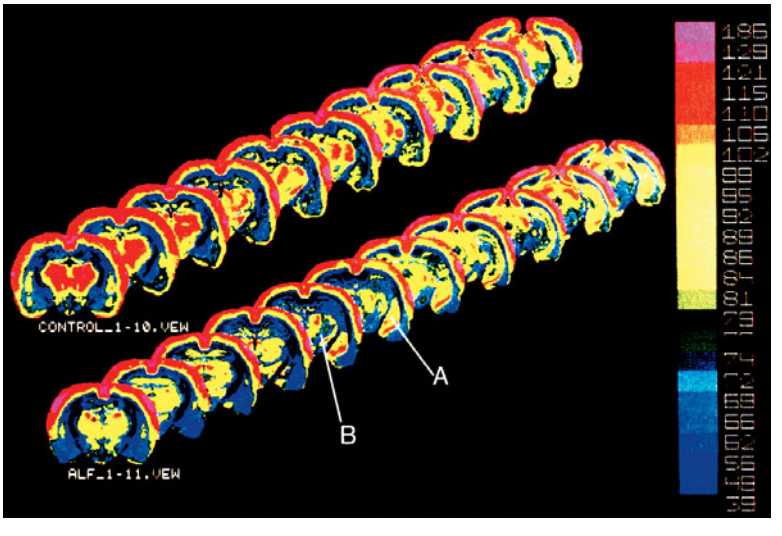

FIGURE 87–12. Glucose autoradiography during administration of high-dose alfentanil with epileptiform activity of paralyzed ventilated rats. Ventral hippocampal (A) activation and thalamic depression (B) were produced by alfentanil. (From Kofke et al.[243] with permission.)

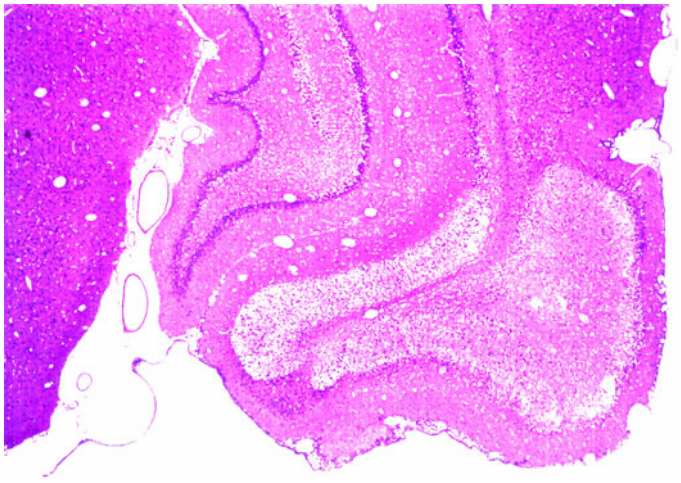

FIGURE 87–13. Histologic slide from a paralyzed ventilated rat that received high-dose alfentanil. Infarction of the amygdala is evident. (Unpublished slide from experiments by Kofke et al.[243])

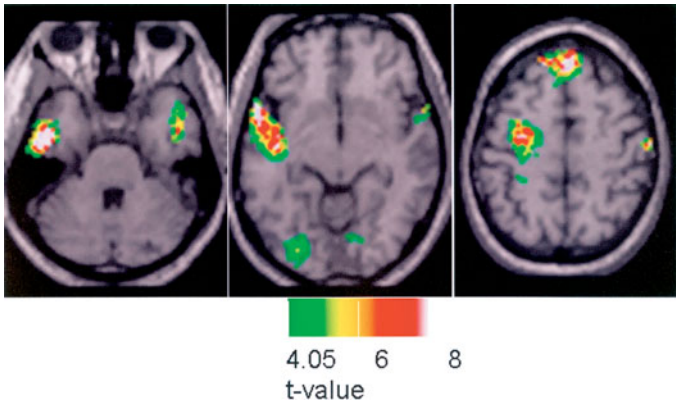

FIGURE 87–14. Fluorodeoxyglucose positron emission tomographic functional brain mapping statistical parametric map images from four ventilated healthy individuals who received brief high-dose remifentanil. Baseline awake scans were subtracted from scans acquired during remifentanil infusion. Areas with significant increases in cerebral metabolic rate for glucose ($t > 4.05$, $P < 0.05$) are displayed in lighter shades overlaid on a normalized magnetic resonance image. Scale for t values also is shown. Hippocampal and cingulate activation occurred. (Adapted from Kofke et al.[244])

tive, the relevance of these observations to clinical practice remains to be established.

CHAPTER 88

Anaphylactic Reactions and Anesthesia

Robert S. Holzman, MD, FAAP

Anaphylaxis is an acute, severe, potentially life-threatening allergic reaction. The word "allergy," introduced by Baron Dr. Clemens von Pirquet in 1906, was meant to describe the uncommitted biologic response that may lead to immunity *or* allergic disease. This concept is very much in keeping with our evolving understanding a century later. Preceding von Pirquet's neologism, Portier and Richet in 1902 reported that the second injection of sea anemone extract into dogs resulted in a fatal systemic reaction after the first injection had no directly observable effect, a finding totally unexpected at the time. Richet fashioned the word "anaphylaxis" by combining the Greek *ana* ("contrary to") and *phylaxis* ("protection") to describe an adverse reaction following repeated exposure to a foreign protein rather than the intended immunization, or prophylaxis.

This chapter takes the view of the anesthesiologist as perioperative specialist, focusing on preoperative evaluation of the patient with a possible history of allergy, diagnosis and intervention in the operating room and perioperative environment, and bridge to the patient's further care and evaluation by primary care physicians and additional specialists.

BIOLOGY OF MAST CELL ACTIVATION

Why are some of us destined for a life of allergy and others not? We now know that our immune systems can choose from two pathways to express reactions to antigens, either a low-grade or high-grade immunologic response (Table 88–1). *Low-grade responders* produce allergen-specific IgG1 and IgG4 antibodies and their T cells respond to the allergen with a moderate proliferation and production of interferon-γ by type 1 T-helper (Th1) cells. *High-grade responders*, however, have an exaggerated response, with increased production of allergen-specific IgE antibodies as well as increased serum levels of IgE-specific antibodies to common allergens. In this group, cytokines produced by Th2 cells, including interleukin (IL)-4, IL-5, and IL-13, are produced rather than cytokines such as interferon-γ and IL-2 from Th1 cells.[1]

IgE-Mediated Mast Cell Activation

Antigenic molecules (usually proteins) capable of stimulating IgE antibody production may cause IgE-mediated anaphylaxis after initial sensitization and subsequent reexposure. Haptens, molecules too small to stimulate immune responses themselves, may bind to endogenous proteins such as albumin and become antigenic. Once produced, IgE antibodies to these antigens become fixed to tissue mast cells and/or circulating basophils, both of which contain high-affinity IgE receptors (Fig. 88–1).[2] Reexposure to antigens or haptens, with subsequent cross-linking of cell surface IgE antibody, induces activation of membrane-associated

KEY POINTS

1. Anaphylaxis is an acute reaction leading to severe physiologic derangements of multiple systems. True anaphylaxis denotes an IgE antibody-mediated reaction.
2. Non–IgE-mediated reactions resembling true anaphylaxis occur and are commonly called anaphylactoid reactions. These reactions can be of identical severity to anaphylactic reactions, may be clinically indistinguishable during the time of occurrence, and should be treated in an identical manner to anaphylactic reactions.
3. Clinical symptoms include urticaria, flushing, nausea, vomiting, abdominal pain, laryngeal edema, bronchospasm, and cardiovascular collapse. Under anesthesia, cardiovascular collapse and respiratory distress are the most common clinical signs.
4. Treatment consists of discontinuing the suspected initiating agent, securing the compromised airway, and establishing intravenous access. Bronchospasm and laryngeal edema are treated with epinephrine. Hypotension and cardiovascular collapse are treated with volume, epinephrine, and cardiopulmonary resuscitation if needed.
5. Evaluation of an anaphylactic reaction starts with a detailed history and may include skin testing, radioallergosorbent testing, and/or provocative challenge. Such efforts should be coordinated in consultation with the primary physician and an allergy specialist. The anesthesiologist's information about the timing and administration of the various medications and the signs and symptoms observed will be invaluable for the ultimate diagnosis of specific allergy.
6. Most serious and fatal allergic reactions to penicillin and β-lactam antibiotics occur in individuals who have never had a previous allergic reaction.
7. Many commonly used anesthetic agents and other drugs administered during anesthesia, including neuromuscular blocking agents, hypnotics, opiates, and antibiotics, lead to nonimmunologic histamine release.
8. True allergic reactions to local anesthetics are exceedingly rare, and cases labeled as such usually are due to other causes (vasovagal response, intravenous injection) or possibly metabolites (para-aminobenzoic acid) preservatives (methylparaben) or antioxidant additives (metabisulfite). If the previous drug is unknown, an amide-type local anesthetic should be chosen.
9. Diabetics exposed to protamine-containing insulin have a 40- to 50-fold increased risk for life-threatening reactions to protamine. Fish-allergic individuals and vasectomized men also may be at increased risk.
10. Healthcare workers regularly exposed to latex have a substantially increased risk of latex-specific IgE positivity (up to 18%), and 28–67% of children with spina bifida have a positive skin test result to latex proteins. Life-threatening anaphylaxis can occur intraoperatively in highly sensitive patients because of mucosal absorption of latex protein allergens from surgical gloves.

TABLE 88–1.

Characteristics of Immunological Responses to Allergens

Low-Grade Responders	High-Grade Responders
Th1 Expression	**Th2 Expression**
Small amount of antigen or low-affinity interaction between T cells and antigen-presenting cells	Large amount of antigen or high-affinity interaction between T cells and antigen-presenting cells
Mediated by IL-12	Mediated by IL-4
Presence of cytidine-phosphate-guanosine (CpG) repeats from bacteria favor Th1 phenotype	Presence of transcription factors such as GATA-3, c-maf, and PGE2 favors Th2 phenotype
	Nitric oxide favors Th2 expression by being less inhibitory to Th2 cells than to Th1 cells
IL-10 and transforming growth factor-β inhibit responses of Th1 and Th2	
	Interferon-γ inhibits Th2 expression
	IL-12 and IL-18 both release Interferon-γ from T cells
IL-4 inhibits expression of Th1 cells	IL-4 promotes expression of Th2 cells
Th2 cells mediate atopy and allergic inflammation. In view of the reciprocity of the relationship, one theory about the rising incidence of allergy in Western countries is the cleanliness of the environment and the ubiquitous presence of antibiotics.	

IL, Interleukin; Th1, type 1 T-helper cells; Th2, type 2 T-helper cells.

enzymes, causing complex biochemical cascades that lead to influx of extracellular calcium and mobilization of intracellular calcium with subsequent release of preformed granule-associated mediators and generation of new mediators from cell membrane phospholipids.

Cytokines are low-molecular-weight chemicals that modulate cell function locally. The cytokines that promote IgE isotype switching (IL-4 and IL-13) are generated by T-lymphocytes with a Th2 cytokine profile. T cells that generate a Th1 cytokine profile—by secreting interferon-γ—inhibit B-cell isotype switching for IgE synthesis. Th1 and Th2 cells reciprocally inhibit each other's development. When IgE production is increased, such as in atopy (from the Greek *atopos* or "out of place"), an imbalance in the Th2/Th1 ratio control is likely. Th2-associated cytokines, such as IL-4, IL-5, IL-9 and IL-13, are associated with many stigmata of chronic allergic inflammation. IL-4 and IL-13 stimulate production of IgE and vascular cell adhesion molecule (VCAM)-1. IL-5 and IL-9 are involved in the development of eosinophils. IL-4 and IL-9 promote the development of mast cells. IL-9 and IL-13 promote airway hyperresponsiveness. IL-4, IL-9, and IL-13 promote overproduction of mucus. In their turn, eosinophils injure mucosal surfaces by releasing toxic basic proteins, cysteinyl leukotrienes, and platelet activating factor. They also damage inhibitory MK2 muscarinic receptors, ultimately leading to airway hyperresponsiveness. IL-5 also releases mature and immature eosinophils from bone marrow.

IgE molecules then bind to high-affinity receptors for IgE [Fc epsilon receptor I (FcεRI)] on circulating basophils and mast cells. This binding itself does not induce the allergic reactions; a second step is required. The allergens, because of their multivalency, express multiple epitopes recognized by specific IgEs and IgGs. *Simultaneous multivalent binding of allergens to several membrane-bound IgEs* induces receptor aggregation,[2] triggering a signaling cascade that leads to production and release of allergic and inflammatory mediators (histamine, leukotrienes, chemokines, and cytokines). Release of these mediators is rapid (in minutes) and produces immediate symptoms.

There is a balance of activating and inhibitory cell-surface receptors, but how is the signaling cascade generated? FcεRI has an IgE binding unit (the α-chain) and a signaling unit (one β-chain and two γ-chains). Aggregation of FcεRI induces activation of a tyrosine kinase bound to the β-chain; the tyrosine kinase then phosphorylates two tyrosine residues in the γ-chains. These tyrosine residues are a central feature of the *immunoreceptor tyrosine-based activation motif* (ITAM), a feature of many receptors throughout the immune system. After phosphorylation, the ITAMs of the γ-chains activate *Syk tyrosine kinase,* which, through activation of downstream pathways, induces release of allergic mediators.

Modulation of these FcεRI pathways occurs via inhibition mediated by the IgG receptor Fcg receptor IIb (FcgRIIb). Allergen-specific IgGs form complexes with allergens that can, in turn, form a bridge between FcεRI and FcgRIIb. This bridge induces aggregation of activating FcεRI with inhibitory FcgRIIb, which inhibits the activation pathways activated by FcεRI. *This delicate balance of IgG counteracting IgE is putatively the central mechanism behind successful allergen desensitization.* In its inhibition of ITAM, FcgRIIb contains an immunoreceptor tyrosine-based inhibitory motif (ITIM), a modified version of ITAM present in FcεRI.

Making use of this membrane architecture, a chimeric molecule designed to bind both FcgRIIb and a specific IgE bound to FcεRI has been shown to create a bridge and inhibit allergic reactions, including allergen-mediated activation of basophils and mast cells in vitro as well as in a mouse model.[3] Such a strategy not only could provide prophylaxis for specific allergic reactions but in addition could displace allergens already bound to IgE, in which case it would help terminate ongoing anaphylactic reactions following initial exposure.

Complement-Mediated Mast Cell Activation

Complement was first identified as a heat-labile "principal" in serum that "complemented" antibodies in the killing of bacteria. Complement consists of a series of plasma and cell membrane proteins that lyse susceptible targets, promote phagocytosis, and generate peptide mediators of the inflammatory response. These anaphylotoxins cause mast cell and basophil mediator release, directly increase vascular permeability, make smooth

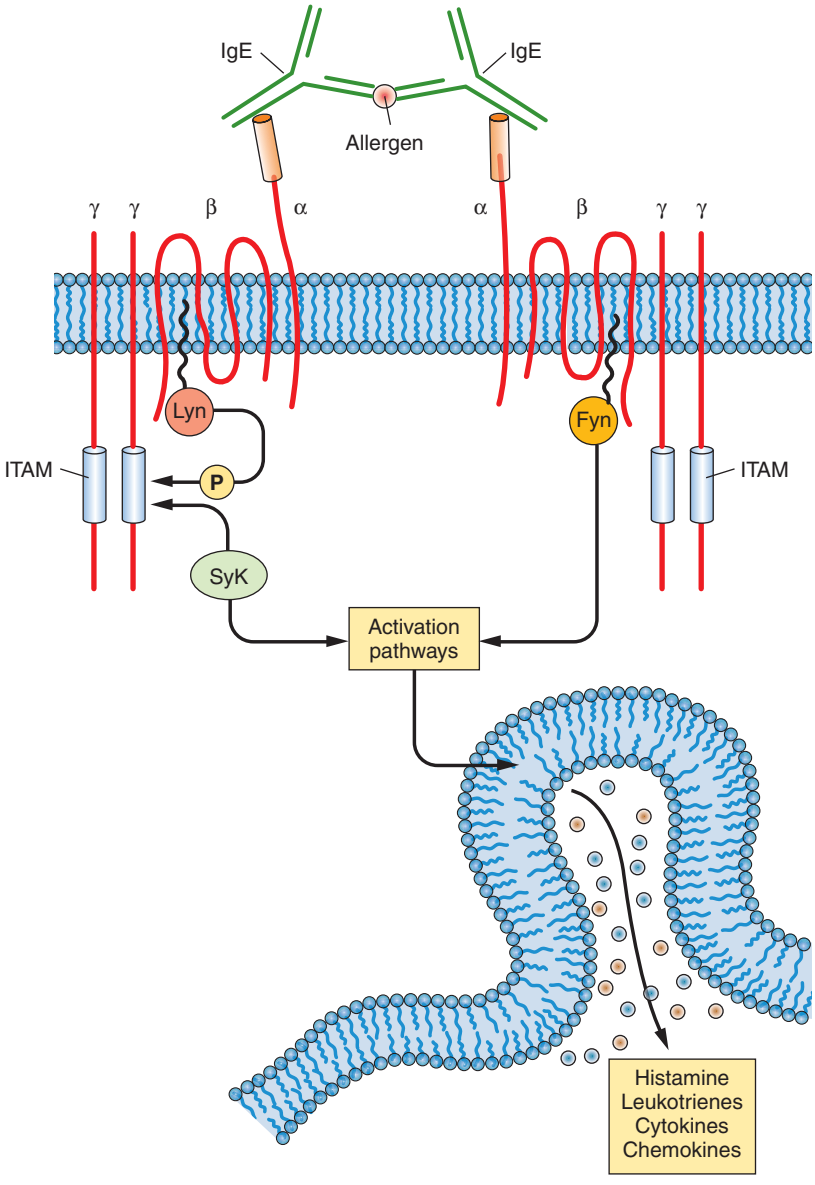

FIGURE 88–1. Mast cell activity. (Kinet J. A new strategy to counter allergy. N Engl J Med 2005;353: 310–312. © 2005 Massachusetts Medical Society. All rights reserved.)

muscles contract, cause platelet activation, and stimulate macrophages to produce thromboxane, effects almost identical to IgE-mediated mast cell activation. The job of the complement system is challenging: it provides host defense through opsonization, chemotaxis and activation of leukocytes, and lysis of bacteria and cells. It also acts to augment the antibody response and enhancement of immunologic memory. Finally, it must dispose of waste through clearance of immune complexes from tissues and clearance of apoptotic cells.

The complement cascade may be activated through either the classic alternative pathway or the mannose-binding lectin pathway (Fig. 88–2). Complement activation through the classic pathway is initiated through IgG or IgM antibody binding to antigens, as in hemolytic ABO-incompatible blood transfusion reactions. Heparin–protamine complexes have been shown in vivo[4] and in vitro[5] to activate complement via the classic pathway. Injection of preformed immune complexes or IgG aggregates can activate complement and mimic clinical anaphylaxis. Patients with selective IgA antibody deficiency may develop IgG anti-IgA antibodies after receiving multiple transfusions, which may result in complement activation and anaphylactic reactions.[6]

Complement activation via the alternative pathway may be stimulated by lipopolysaccharides (endotoxin),[7] althesin,[8] radiocontrast media, and membranes used for cardiopulmonary bypass and dialysis.

The initiators of the mannose binding lectin pathway are microbes with terminal mannose groups. Young children with recurrent infections may have low levels of mannose binding lectin, thus suggesting the importance of the mannose-binding lectin pathway in the loss of passively acquired maternal antibody and the acquisition of a mature immunologic repertoire.[9]

The three pathways converge at the point of cleavage of C3, leading to formation of the membrane attack complex that directly affects the integrity of mast cell and basophil cell membranes. In addition, complement activation has an adjunctive role in amplifying the antibody response.

Nonimmunologic Mast Cell Activation

Certain drugs can cause mast cell mediator release by nonimmunologic means, the exact mechanism of which is poorly understood. Drugs that induce nonimmunologic mast cell activation include opiates (especially morphine and codeine)[10,11] and neuromuscular blocking agents such as atracurium and D-tubocurarine.[12] Evidence suggests that neuromuscular blockers such as atracurium, vecuronium, and succinylcholine also may induce mast cell mediator release via IgE antibodies directed against quaternary or tertiary ammonium ion epitopes.[13–15]

Mediators of Anaphylaxis

Once the mast cell, basophil, or eosinophil is activated by any of the mechanisms, release of mediators results in attraction, accumulation, and activation of other cellular elements. Mediators released include those preformed and stored in granules and those newly generated upon appropriate stimulation. Release of these mediators may cause various pathophysiologic responses that may result in acute or chronic reactions. The complex of allergen, IgE, and high-affinity receptor for IgE on the surface of the mast cell triggers noncytotoxic, energy-dependent release of preformed, granule-associated histamine and tryptase and the membrane-derived lipid mediators leukotrienes, prostaglandins, and platelet-activating factor. Mast cells produce the three cysteinyl leukotrienes C4, D4, and E4, which cause contraction of smooth

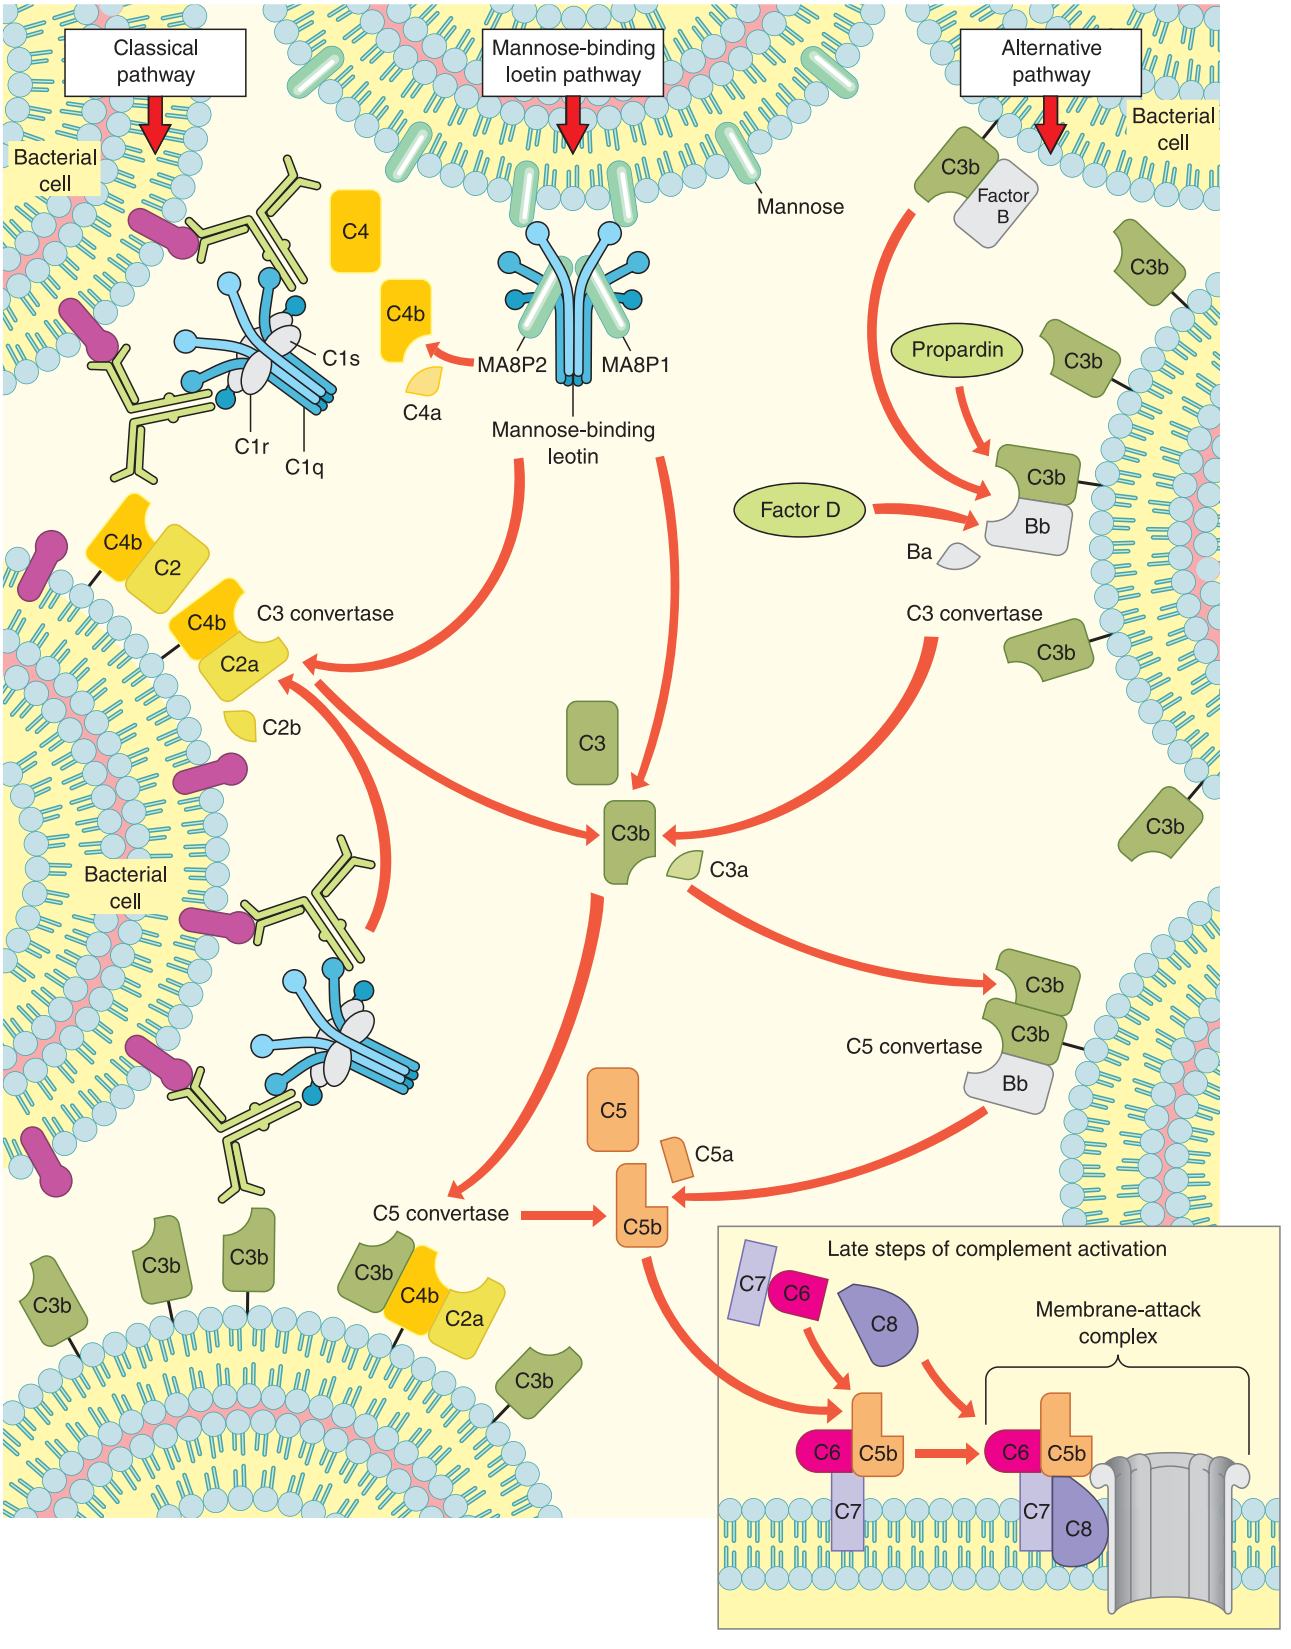

FIGURE 88–2. Activation of the complement pathway. (Walport M. Complement: first of two parts. N Engl J Med. 2001;344(14):1058–1066. © 2001 Massachusetts Medical Society. All rights reserved.)

TABLE 88–2.

Incidence of Anaphylaxis during Anesthesia

Location	Incidence	Mortality	Reference
Australia	0.5–1:10,000	3.4%	20
United States	3.3:10,000		
France, single institution	16.3:10,000		26
France	1–2:10,000		110
Germany	0.5–3:10,000	3–6%	111
Boston Collaborative Drug Program (United States, New Zealand, Scotland)	4.5:10,000	5%	112

muscles, vasodilatation, increased vascular permeability, and hypersecretion of mucus. Collateral sources of cysteinyl leukotrienes are eosinophils, macrophages, and monocytes. Mast cell tryptase activates receptors on endothelial and epithelial cells, which causes upregulation of adhesion molecules that selectively attract eosinophils and basophils.

EPIDEMIOLOGY OF ANAPHYLAXIS DURING ANESTHESIA

Allergic disease is on the increase in western countries. Environment may have a great deal to do with this increase; allergic disease was less common in East Germany than West Germany prior to reunification.[16] This finding supports the intriguing notion that when the developing immune system is deprived of microbial antigens that stimulate Th1 cells, the so-called "hygiene hypothesis," the opportunity to prolong sensitization of Th2 cells ensues. By promoting a Th1 response, infection downregulate the tendency for development of Th2-related disease.[17] Other factors that may favor a greater Th2 response in infants include diet and birth dates during high pollen counts. Additional environmental influences such as viral infections, allergen exposure, tobacco smoke, and air pollutants also may play a role. Epidemiologic data have shown an increased prevalence and severity of pediatric atopic diseases (asthma, eczema, and allergic rhinitis) during the past 15–20 years.[18,19]

Anaphylaxis during anesthesia has a unique epidemiology and subset of etiologic factors. The incidence of anaphylaxis during anesthesia is variable within an order of magnitude but ranges between 0.5:10,000 and 16.3:10,000 (Table 88–2). Anaphylaxis during anesthesia has been attributed primarily to muscle relaxants. A review of 826 patients referred to an anesthetic allergy clinic in Australia over a 17-year period revealed severe immediate anaphylactic reactions in 54%; in 59% a muscle relaxant was involved.[20] Of 452 patients evaluated in an allergy–anesthesia clinic in Nice, France, 62 patients experienced anaphylaxis, 57 due to muscle relaxants, 4 to latex, and 1 to gelatin. By avoiding reexposure and offering alternate methods of anesthesia (e.g., regional block), subsequent allergic reactions were prevented.[21] A 20-year review of the French and English language literature (1964–1984) yielded 975 cases of immediate life-threatening reactions, with the greatest number of cases due to muscle relaxants (51%) and hypnotic drugs (42.3%).[22] In another series, the substances involved were muscle relaxants (70%), latex (12.6%), hypnotics (3.6%), benzodiazepines (2.0%), opioids (1.7%), colloids (4.7%), and antibiotics (2.6%).[23] Once again, these proportions have remained consistent in followup surveys among the collaborating institutions in France, with the most common causes of anaphylaxis remaining muscle relaxants (58.2%), latex (16.7%), and antibiotics (15.1%). Rocuronium (43.1%) and succinylcholine (22.6%) were the most frequently incriminated muscle relaxants (Table 88–3).[24]

Patients who react have a greater incidence of allergy, atopy, asthma, and previous reactions than do nonreactors, suggesting these are significant predictive factors. However, although a history of drug allergy was found in 37% of cases and atopy in 38%,[22] the majority of patients do not have such a history, and the majority of patients with such a history do not react.[25] A multicenter survey carried out in France in 1990 and 1991 revealed in a series of 1585 patients a 3:1 ratio of females to males. The reactions occurred mostly in adults (80%); 9% occurred in children.[26] Cardiovascular collapse has consistently been described as the most common presenting problem, and evidence indicates that this form of shock is substantially different at the cellular level and potentially more harmful than other causes of shock.[27]

Fifty-seven cases of possible allergic reactions in the perioperative period have been reported to the Australian Incident Monitoring Study, representing approximately 3% of the first 2000 incidents. Nineteen were judged as "very likely allergic responses," representing nearly 1% of the first 2000 incidents. Suspected causative agents included "induction drug" (38/57), antibiotic (19/57), nondepolarizing relaxant (14/57), opiate (12/57), blood/plasma/Hemaccel (11/57), and "other" (16/57).[25]

CLINICAL MANIFESTATIONS OF ANAPHYLAXIS

Evaluation and treatment of patients who develop anaphylaxis in the operating room is challenging even for the experienced physician. In the perioperative period, multiple medications frequently are given in close proximity, making causative factors more difficult to interpret. Patients usually are unconscious, draped, and cold, situations that often hide early signs and symptoms of anaphylaxis. Anesthetics themselves alter mediator release, possibly delaying early recognition.[28]

In general, symptoms begin soon (within minutes) after introduction of the causative agent but may be delayed for 1–2 hours. Along with other symptoms, conscious patients frequently describe a sense of impending doom. The primary anaphylactic target organs in humans are the cutaneous, gastrointestinal, respiratory, and cardiovascular systems (Box 88–1). *During general and regional anesthesia or during deep sedation, cardiovascular signs predominate.*[20,29]

TABLE 88–3.

Etiologic Agents of Anaphylaxis

DIFFERENTIAL DIAGNOSIS

In a conscious patient, anaphylaxis is most easily confused with a vasovagal reaction, which may occur when a patient collapses after an injection or painful procedure (Box 88–2). During a vasovagal reaction, the patient looks pale and complains of nausea before syncope but does not report pruritus or become cyanotic. Respiratory difficulty does not occur, and symptoms are relieved almost immediately once the patient is supine. Vasovagal reactions often are accompanied by profuse diaphoresis and bradycardia, without flushing, urticaria, angioedema, pruritus, or wheezing. The differential diagnosis of sudden collapse includes dysrhythmias, myocardial infarction, aspiration of food or foreign body, pulmonary embolism, seizure disorder, hypoglycemia, and stroke. In the presence of laryngeal edema, especially when accompanied by abdominal pain, the diagnosis of hereditary angioedema should be considered. *Globus hystericus* and fictitious asthma must be considered when respiratory symptoms are present. Other conditions that can mimic anaphylaxis are overdose of medication, cold urticaria (especially if generalized), idiopathic urticaria, carcinoid tumors, and systemic mastocytosis.

TREATMENT OF ANAPHYLAXIS

Anaphylactic reactions must be recognized early because death may occur within minutes; the longer initial therapy is delayed, the greater the incidence of fatality.[30,31] Treatment of anaphylactic reactions can be divided into initial and secondary therapies (Box 88–3).

Initial Treatment

When possible, steps should be taken to interrupt further exposure to and absorption of the offending agent. Intravenous infusions of suspected allergens should be stopped immediately. Airway maintenance with 100% oxygen should be administered; adequate oxygenation should be assured by continuous monitoring and arterial blood gas levels. If there is any suggestion of airway compromise due to laryngeal edema, the trachea should be intubated immediately. If laryngeal edema is present, aerosolized epinephrine (three inhalations of 0.16–0.20 mg epinephrine per inhalation from a metered dose inhaler) or epinephrine by nebulizer (8–15 drops of 2.25% epinephrine in 2 mL normal saline) may be useful. If laryngeal edema is refractory to these measures or progresses too rapidly, a needle catheter cricothyrotomy or emergency surgical cricothyrotomy may be necessary.

Upon suspicion of a severe reaction, intravenous access should be established (if not already in place), and intravascular volume should be maintained with administration of isotonic crystalloid (normal saline) or colloidal solutions.

Epinephrine is the cornerstone of initial pharmacologic treatment. In cases of *severe hypotension or airway obstruction*, 0.1-mL (100 μg of a 1:1000 dilution) increments of epinephrine should be given intravenously, usually not exceeding 0.5 mg total. Depending on the patient's condition, however, a lower or higher dosage may be needed. Risks include cardiac dysrhythmias (especially during halothane an-

						22%		15%				

esthesia), myocardial infarction, and stroke. In the rare instance when an intravenous line is not in place, 0.3 mL of 1:1000 epinephrine can be given subcutaneously or intramuscularly, or 10 mL of 1:10,000 epinephrine can be administered through the endotracheal tube. However, when a patient is in shock, absorption of intramuscular or subcutaneous epinephrine is unreliable. For persistent hypotension, catecholamine infusions can be used. Epinephrine also will be useful if both hypotension and bronchospasm persist. Suggested starting doses of epinephrine are given in Box 88–3. If >8–10 μg/min is required, tachycardia may be a significant side effect, and norepinephrine may be more effective. The suggested starting dosage for norepinephrine is 0.05 μg/kg/min (2–4 μg/min) and should be titrated to maintain tissue perfusion. Dopamine can be used to maintain blood pressure. A dosage of 5–20 μg/kg/min may help maintain cardiac output, thereby improving coronary, cerebral, renal, and mesenteric blood flow.

Potent volatile anesthetic agents should be discontinued. Anesthetic agents have negative inotropic properties, may decrease systemic vascular resistance, and may interfere with the reflex compensatory response to hypotension. Halothane specifically sensitizes the heart to circulating catecholamines, which are required for treatment of severe anaphylactic reactions; therefore, change of agents to an ether anesthetic such as isoflurane, sevoflurane, or desflurane may be desirable.

Secondary Treatment

Once the patient's condition begins to stabilize, administration of other pharmacologic agents may be warranted. An antihistamine such as diphenhydramine will be helpful for symptomatic relief of itching. Although no evidence has demonstrated the effectiveness of H_2-receptor antagonists in the treatment of anaphylaxis, ranitidine (1 mg/kg IV) may be useful[32] when hypotension is persistent because peripheral vasodilatation may be exacerbated by the effects of histamine on endothelial H_2 receptors.

Glucocorticoids are useful for preventing potential late-phase reactions and treating persistent bronchospasm, but they have no immediate effects. Hydrocortisone 5 mg/kg (up to 200 mg initial dose) and then 2.5 mg/kg every 6 hours or methylprednisolone 1 mg/kg initially and every 6 hours as indicated can be given.

Treatment with bicarbonate is controversial and probably should be reserved for profound acidosis, preexisting hyperkalemia, or use immediately after intubation following prolonged cardiac arrest.[33] Acid–base status must be monitored using arterial blood gas levels to guide further therapeutic interventions.

The response to therapy usually is prompt, but despite all of the measures mentioned previously, some patients do not respond quickly. Treatment of anaphylaxis may be complicated by increased use of β-adrenergic blocking agents, particularly in older patients.

DETERMINING THE CAUSE OF ANAPHYLACTIC REACTIONS

Patients who have had anaphylactic reactions to drugs administered in the

BOX 88–1.

Target Organs of Anaphylaxis

System	Signs and Symptoms
Cutaneous	Pruritus
	Flushing[a]
	Erythema[a]
	Urticaria/angioedema[a]
Gastrointestinal	Nausea
	Abdominal pain
	Diarrhea
	Vomiting
Respiratory	Laryngeal edema
	Hoarseness
	Dysphonia
	"Lump" in throat
	Chest tightness
	Dyspnea

	Increase in peak airway pressure[a]
	Nasal itching
	Sneezing
	Rhinorrhea
	Nasal obstruction
	Hypersecretion of mucus
Cardiovascular	Light-headedness
	Faintness
	Syncope
	Tachycardia[a]
	Hypotension[a]
	Dysrhythmias[a]

[a]Most likely to occur in patients during anesthesia.

operating room require evaluation to identify the causal agents and to guide selection and use of future medications. The evaluation starts with a detailed history, including concurrent illness and earlier allergic and anesthetic encounters. It is helpful to prepare a flow diagram of the patient's reaction temporally depicting the clinical manifestations of the reaction and the medications received, including indications, when initiated, doses, and duration of therapy. Equally important information includes previous exposure to the same or structurally related medications, effect of drug discontinuation, response to treatment, and any previous diagnostic testing or rechallenge. Medications should be considered with regard to their known propensity for causing anaphylaxis. The proximity of drug administration to the onset of acute reactions should be documented. In general, agents that have been used for long continuous periods before the onset of an acute reaction are less likely to be implicated than are agents recently introduced or reintroduced. However, in the perioperative period, patients commonly receive many medications in close temporal proximity, making a diagnosis by history alone difficult.

Differential Diagnosis of Anaphylaxis

Vasovagal reaction
Dysrhythmia
Myocardial infarction
Overdose of medication or illicit drugs
Pulmonary embolism
Seizure disorder
Cerebral vascular accident
Aspiration
Globus hystericus
Fictitious asthma
Hereditary angioedema
Physical or idiopathic urticaria
Serum sickness
Carcinoid tumors
Systemic mastocytosis

Immunodiagnostic Tests

Skin Testing for Immediate Hypersensitivity Reactions

Although standardized and commonly used by allergists in the diagnosis of immediate hypersensitivity to aeroallergens and Hymenoptera, evaluation of drug allergy is hampered by the unavailability of relevant drug metabolites or appropriate multivalent testing reagents. Intradermal skin tests still are the most readily available and generally useful diagnostic tests for drug allergy. Skin testing clearly has an established role in the evaluation of IgE-mediated penicillin allergy.[34] Skin testing also is useful in the evaluation of allergy to muscle relaxants,[35,36] barbiturates,[35,37] chymopapain,[38] streptokinase,[39] insulin,[40] latex,[41,42] and miscellaneous drugs. Specific protocols for skin testing are well documented. Skin testing must be performed in the absence of medications that will affect the skin test response (especially H_1 antihistamines, tricyclic antidepressants, and sympathomimetic agents). Appropriate positive (histamine) and negative (diluent) controls should be used.

Other In Vivo Tests

Delayed (tuberculin-like) skin tests have little, if any, place in the evaluation of drug allergy. Patch tests may be of value in cases of contact dermatitis.

In Vitro Tests

Total Serum IgE Levels

Although increases in total serum IgE levels have been reported after allergic reactions,[43] the level of antigen-specific IgE is rarely, if ever, helpful in establishing the diagnosis of an allergic drug reaction.

Assays to Measure Complement Activation

Assessment of complement activation includes measurement of the decrease in complement components (C4, C3, or total hemolytic complement [C_H50]) and increases in the generation of products of complement activation (C3a, C4a, C5a, and so on). If positive, these assays may implicate complement activation in specific reactions.

Release of Histamine and Other Mediators

Washed leukocytes containing basophils with IgE antibody on their cell surfaces release histamine and other mediators when incubated with relevant antigens. Although this in vitro basophil–histamine release assay avoids drug exposure to the patient, the assay is clinically impractical because it requires whole blood drawn immediately before the test; presently the test is limited in availability to research laboratories.

During or shortly after allergic reactions, blood can be obtained and analyzed for release of various mediators. Urine also can be analyzed for metabolites of histamine or prostaglandin D_2 (PGD_2). Plasma histamine and PGD_2 levels remain increased only briefly, limiting their clinical use. Measurement of serum tryptase, a protease released specifically from mast cells, appears promising in the clinical assessment of mast cell-mediated allergic reactions.[44–47] Serum tryptase may remain elevated for hours after release from mast cells.

Radioallergosorbent Testing

The radioallergosorbent test (RAST) was first introduced in 1967. It measures circulating allergen-specific IgE antibody. The basic principle of the RAST is simple: the allergen is attached to a solid-phase (carbohydrate

BOX 88–3.

Management of Anaphylaxis

Initial Therapy

1. Stop administration or reduce absorption of offending agent
   If antigen given subcutaneously:
   Venous tourniquet proximal to site
   Epinephrine (dilute solution) infiltrated into antigen site
   If latex is suspected:
   Consider potential routes of administration, including mucosal contact and inhalation
   Remove all latex from surgical field
   Change to nonlatex gloves
2. Maintain airway and administer 100% oxygen
   Aerosolized epinephrine if not already intubated
   Intubation, cricothyrotomy, or tracheostomy
3. Rapid intravascular volume expansion
   25–50 mL/kg (2–4 L) of crystalloid or colloid for hypotension
4. Administer epinephrine
   Initial dose 0.1 μg/kg (0.001 mg/kg) IV
   10 mL of 1:10,000 endotracheal administration in adults
5. Discontinue all anesthetic agents

Secondary Therapy

1. Administer antihistamine
   Diphenhydramine 1 mg/kg IV or IM (maximum dose 50 mg)
   Ranitidine 1 mg/kg IV (maximum dose 50 mg)
2. Administer glucocorticoids
   Hydrocortisone 5 mg/kg IV initially, then 2.5 mg/kg IV q4–6h
   Methylprednisolone 1 mg/kg IV initially, then 0.8 mg/kg IV q4–6h
3. Administer aminophylline

Loading dose 5–6 mg/kg IV

   Continuous infusion 0.4–0.9 mg/kg/h IV (check blood level)
4. Administer inhaled α_2-adrenergic agonists
5. Continuous catecholamine infusion
   Epinephrine 0.02–0.05 μg/kg/min IV (2–4 μg/min)
   Norepinephrine 0.05 μg/kg/min IV (2–4 μg/min)
   Dopamine 5–20 μg/kg/min IV
6. Administer sodium bicarbonate
   0.5–1 mEq/kg initially, then titrate according to arterial blood gas levels

particle, paper disk, or wall of polystyrene test tubes or plastic microtiter wells) and incubated with the serum under study, during which time a specific antibody of all immunoglobulin classes is bound. The particles are washed, and a second incubation is undertaken with a radiolabeled, highly specific anti-IgE antibody. After washes, the bound radioactivity is directly related to the allergen-specific IgE antibody content in the original serum. When performed appropriately, the RAST correlates well with skin test end point titration, basophil–histamine release, and provocation tests. Results from the serum under study are compared with a positive reference serum and a negative control serum. False-positive tests may occur because of high nonspecific binding, high total serum IgE levels, or poor technique. False-negative tests may occur because of interference of high levels of IgG "blocking antibodies" or inability to maximize assay sensitivity.

Anesthesiologists should seek consultation with allergists for such evaluations; they should avoid informal and uncontrolled allergy evaluations using dilute intradermal solutions or patch tests performed without proper controls.

REQUIREMENT OF DRUG IN THE FUTURE AND SPECIFIC IMMUNOTHERAPY

If a patient has experienced an allergic reaction to a medication in the past but must use that medication again, the physician must evaluate the risks and benefits of readministration of the medication in question. If equally effective and non–cross-reacting alternative drugs are available, they should be used. If alternative drugs fail, induce unacceptable side effects, or are clearly less effective, then cautious administration of the drug using a premedication regimen (Box 88–4) or a desensitization protocol (prescribed by an expert allergist) may be considered.

Premedication regimens (Box 88–4) have been tested, validated, and used most often in patients with previous reactions to radiocontrast media who again require administration of radiocontrast.[48] These reactions are not IgE mediated.

Specific immunotherapy, consisting of administration of increasing concentrations of allergen, has three mechanisms of action: downregulation of the cytokines produced by Th2 cells, upregulation of the cytokines produced by Th1 cells, and upregulation of regulatory T cells. As a result, allergic inflammation is inhibited, cytokines that control the production of IgE (interferon-γ and IL-12) are increased, IgG-blocking antibodies are enhanced, and cytokines

BOX 88–4.

Efficacy of Premedication for Patients with Previous Radiocontrast Media Reactions

Premedication with	Repeat Reaction Rate
A. No premedication	A: 33% (range 17–60%)
B. Prednisone (50 mg Po) 13, 7, and 1 h before	
C. Diphenhydramine (50 mg IM or Po) 1 h before	B and C: 9% (mild reactions)
D. Ephedrine (25 mg PO) 1 h before	B, C, and D: 3.1% (historical controls)
E. Low osmolar ionic contrast media	B, C, D, and E: <0.5%

involved in allergen-specific hyporesponsiveness (IL-10 and transforming growth factor-β) are increased. Specific immunotherapy is not without its risks, with anaphylaxis being the most prominent because of the relative crudeness of the allergen extracts. As recombinant technology becomes more available, hypoallergenic isoforms in immunotherapy may minimize the risk of anaphylaxis. Additional strategies include naturally occurring hypoallergenic isoforms, DNA vaccines, blockade of IgE or its synthesis, and interruption of the Th2-dependent allergic cascade. In addition, several ways of inhibiting IL-4 and IL-5 currently are being investigated.[17] This basic understanding informs our targeting of new approaches to treatment.

SPECIFIC ANAPHYLACTIC REACTIONS SEEN IN THE PERIOPERATIVE ENVIRONMENT

Neuromuscular Blocking Agents

Muscle relaxants are a common cause of anaphylactic reactions during anesthesia, although there remains some debate.[24,29,49–52] Evidence supporting an IgE-mediated mechanism includes positive Prausnitz-Kustner tests, basophil–histamine release studies, inhibition of basophil–histamine release after desensitization to anti-IgE, and demonstration of drug-specific IgE antibodies in sera from patients who had adverse reactions to muscle relaxants.[13–15,36]

Extensive in vitro cross-reactivity has been reported between muscle relaxants and other compounds that contain quaternary and tertiary ammonium ions. Insofar as these compounds are found in many drugs, foods, cosmetics, disinfectants, and industrial materials, patients may become sensitized through environmental contact. Sensitization to ammonium ion epitopes in cosmetics has been postulated to explain the predominance of reactions in women.[13] Although the exact incidence of allergic reactions caused by muscle relaxants is unknown, reactions to muscle relaxants are less common in the United States than in France and Australia.

Hypnotics

Acute allergic reactions have been reported after administration of thiobarbiturates, especially thiopental. Proposed mechanisms for thiobarbiturate reactions include nonimmunologically induced mediator release and IgE-mediated reactions. Positive immediate skin tests to thiopental have been reported in patients who had anaphylactic reactions after induction of general anesthesia.[35,37,53] A thiopental RAST has been developed,[54] and mast cell histamine release to thiopental in vitro has been described.[55,56] The predictive value of the RAST to thiopental is uncertain and requires further study, but skin testing appears to be useful.

Anaphylaxis to propofol with subsequent laboratory confirmation has been reported in only two patients,[57,58] without laboratory confirmation (presumptive diagnosis) in an infant with egg and peanut allergy,[59] and in two adult patients, one of whom had a pruritic maculopapular rash around the eyes (for 3 months)[60] and one of whom died from cardiovascular collapse, with increased serum tryptase and methylhistamine levels at postmortem.[61] Although warnings about administration of propofol to patients with egg allergy can be strident, the lecithin in the propofol emulsion containing ethylenediaminetetraacetic acid (EDTA) as a preservative is derived from egg yolk, which is distinct from egg albumin found in egg white. In the majority of patients with egg allergies, egg albumin is the sensitizing protein. In the propofol emulsion using metabisulfite as the preservative, metabisulfite may be the allergenic component. Because the propofol emulsion also contains soybean oil, patients with soybean oil allergy should not receive propofol.

Local Anesthetics

Despite patients commonly reporting "allergic reactions" to local anesthetics, true allergic reactions to injected local anesthetics are exceedingly rare. Adverse reactions to local anesthetics often are the result of vasovagal reactions, toxic reactions (probably caused by accidental intravenous injection), side effects from epinephrine, or psychomotor responses such as hyperventilation. Toxic symptoms often involve the central nervous and cardiovascular systems and may produce slurred speech, euphoria, dizziness, excitement, nausea, nemesis, disorientation, or convulsions.[62] Vasovagal reactions usually are associated with bradycardia, sweating, pallor, and rapid improvement in symptoms when the patient is supine. Sympathetic stimulation, either from epinephrine or anxiety, may result in tremors, diaphoresis, tachycardia, and hypertension. Rarely, symptoms of reactions to local anesthetics are consistent with IgE-mediated reactions, such as urticaria, bronchospasm, and anaphylactic shock.[63] IgE-mediated sensitivity has, on rare occasions, been reported to parabens, preservatives used in local anesthetics.

Local anesthetics are divided into two general chemical classes, the esters and the amide compounds (Box 88–5). Those containing benzoate esters may cross-react with each other but not with the amide compounds. Ester local anesthetics are metabolized to para-aminobenzoic acid (PABA); therefore, ester local anesthetics cross-react and present with allergic or hypersensitivity reactions. In addition, individuals allergic to other drugs metabolized to PABA, such as sunscreens and methylparaben preservatives, may cross-react. In contrast, the amino amide local anesthetics do not substantially cross-react with each other. Epinephrine-containing local anesthetics with the antioxidant metabisulfite may be allergenic because of the metabisulfite component.[64,65]

Evaluation of the patient with a history of adverse reactions to local anesthetics should include a complete history of the episode, skin testing, and incremental drug challenge. The local anesthetic tested should be appropriate for the proposed procedure and not expected to cross-react with the drug implicated in the previous reaction. If the previous drug is unknown, an amide-type local anesthetic should be chosen. In a patient with a history suggestive of an IgE-mediated reaction or possible paraben sensitivity, preparations without paraben should be

BOX 88–5.

Classification of Local Anesthetics

Amino Esters	Amino Amides
Benzocaine	Bupivacaine
Chloroprocaine	Etidocaine
Cocaine	Lidocaine
Procaine	Mepivacaine
Tetracaine	Prilocaine
	Ropivacaine

used for testing, challenge, and treatment. Preparations with epinephrine should not be used for skin testing because they may mask a positive skin test and induce toxic effects.

Narcotics

Narcotics most commonly cause nonimmunologically mediated histamine release from skin mast cells rather than anaphylaxis. In vitro studies suggest that skin mast cells are uniquely sensitive to narcotics, whereas gastrointestinal and lung mast cells and circulating basophils do not release histamine when exposed to narcotics.[10,11,66] Most opiate-induced reactions are self-limited, cutaneous, and restricted to hives and pruritus or mild hypotension treated by fluid administration, although some evidence suggests that IgE antibodies may be induced that bind epitopes contained in opiate narcotics.[67–69] Nonimmunologic release of mediators is a far more common clinical occurrence than are the rare reactions induced by morphine-specific IgE antibody. Because codeine, morphine, and meperidine routinely cause positive skin responses, skin tests must be interpreted cautiously and must be accompanied by skin testing of normal control subjects.

Antibiotics

Penicillin Antibiotics

Outside of the operating room but also within our sphere of responsibility, penicillin antibiotics are the most common medications causing allergic drug reactions (0.7–8% of treatment cases).[70,71] From 0.004–0.015% of treatment courses end in anaphylaxis, resulting in 400–800 deaths per year in the United States. Only 10–20% of patients who claim an allergy to penicillin react to skin testing with the major and minor determinants.

A low-molecular-weight chemical, penicillin must covalently combine with tissue macromolecules to produce multivalent hapten–protein complexes. The β-lactam ring, which opens spontaneously under physiologic conditions, forms the penicilloyl group. Other metabolic pathways result in additional antigenic determinants known as the "minor determinants." Anaphylactic reactions to penicillin usually are mediated by IgE antibodies directed against minor determinants, although some anaphylactic reactions have occurred in patients with only penicilloyl-specific IgE antibodies.

Individuals with a history of penicillin reactions have a 4- to 6-fold increased risk for subsequent reactions to penicillin compared to those without previous reactions.[72] *However, most serious and fatal allergic reactions to penicillin and β-lactam antibiotics occur in individuals who have never had a previous allergic reaction.* Sensitization of these individuals may have occurred from their last therapeutic course of penicillin or (less likely) by occult environmental exposures. Approximately 10–20% of hospitalized patients claim a history of penicillin allergy. However, studies have shown that many of these patients either have been incorrectly labeled as allergic to penicillin or have lost their sensitivity. The most useful single piece of information in assessing an individual's potential for an immediate IgE-mediated reaction is the skin test response to major and minor penicillin determinants.

Penicillin anaphylaxis has not been reported in patients with negative skin tests. Therefore, negative skin tests indicate that penicillin antibiotics can be safely given. A limited number of patients with positive skin tests have been treated with therapeutic doses of penicillin. The risk of an anaphylactic or accelerated allergic reaction ranges from 50–70% in such patients.[34] Therefore, if skin tests are positive, equally effective non–cross-reacting antibiotics should be substituted when available. If alternative drugs fail, induce unacceptable side effects, or clearly are less effective, then administration of penicillin using a desensitization protocol to reduce the risk of anaphylaxis should be considered.

Cephalosporins

Like penicillins, cephalosporins possess a β-lactam ring (Box 88–6). Shortly after cephalosporins came into clinical use, allergic reactions were reported, and the question of cross-reactivity between cephalosporins and penicillins was demonstrated. During the initial clinical trials with first-generation cephalosporins and cefamandole, 8.1% of patients with a history of allergy to penicillin had a possible allergy to a cephalosporin versus 4.5% of patients without a history, so standard teaching was to avoid treatment with cephalosporins for those with a possible penicillin anaphylaxis. Evidence has accumulated that the side chain rather than the β-lactam ring is the antigen in cephalosporin allergic reactions. Among patients with a history of penicillin allergy, the rate of allergic reaction to any other antibiotic

BOX 88–6.

β-Lactam Antibiotics

Penicillins	
β-Lactamase susceptible	
Narrow-spectrum	Penicillin G
Enteric-active	Ampicillin
Enteric-active and antipseudomonal	Ticarcillin
β-Lactamase resistant	
Antistaphylococcal	Methicillin, oxacillin, nafcillin
Combined with β-lactamase inhibitors	Ticarcillin plus clavulanic acid, ampicillin plus sulbactam, piperacillin plus tazobactam
Cephalosporins	
First-generation	Cefazolin, cephalothin, cephapirin
Second-generation	
Hemophils-active	Cefamandole, cefuroxime, cefonicid, ceforanide
Bacteroides-active	Cefoxitin, cefotetan, cefmetazole
Third-generation	
Extended-spectrum	Ceftriaxone, cefotaxime, ceftizoxime
Extended-spectrum and antipseudomonal	Ceftazidime, cefepime
Carbapenems	Imipenem-cilastatin, meropenem, ertapenem
Monobactams	Aztreonam

is three times the rate than among control subjects. Primary cephalosporin allergy in non–penicillin-allergic patients also has been reported, but the exact incidence is not clear. There is evidence for a marked variation in history assessment, requests for penicillin testing, and prescribing practices among physicians, even with patients reporting anaphylaxis to penicillin.[73] In general, patients with positive skin tests to any penicillin reagent or a history compatible with immediate hypersensitivity should not receive first-generation cephalosporin antibiotics unless alternative drugs are clearly less desirable.

Two new classes of β-lactam antibiotics are the carbapenems and monobactams (aztreonam). Cross-reactivity between penicillin and carbapenems would be expected on the basis of the structure of the drugs. There are no published data on allergy to meropenem in patients who are allergic to carbapenem or penicillins. Allergic reactions to the monobactam aztreonam are thought to involve the side chain, so cross-reactivity with other β-lactams should be rare. Investigations suggest weak cross-reactivity between aztreonam and other β-lactam antibiotics and indicate that aztreonam can be administered safely to most, if not all, penicillin-allergic subjects. Cross-reactivity between penicillins and second- or third-generation cephalosporins (excluding cefamandole) probably is no greater than the cross-reactivity between penicillins and other classes of antibiotics.[74] Third-generation cephalosporins have a very low risk of serious allergic reactions. Cross-reactivity between penicillins and cephalosporins with similar side chains appear to be more frequent. In a patient with known allergy to a cephalosporin, substituting another cephalosporin with a different side chain structure usually is safe.

Vancomycin

Hypotension is the most serious immediate adverse effect associated with vancomycin use. Direct myocardial depression[75] and nonimmunologically mediated histamine release[76] have been reported as mechanisms of vancomycin-induced hypotension, and not IgE-mediated anaphylaxis. In patients, hypotension occurs most commonly when the drug is rapidly infused or is administered in a concentrated solution. Vancomycin-associated hypotension that occurs intraoperatively may be exacerbated by concurrent use of other drugs (e.g., anesthetics) that cause vasodilatation and/or have a negative inotropic effect.[75] In addition to hypotension, vancomycin can produce the "red neck" or "red man" syndrome, an intense erythematous discoloration of the upper trunk, arms, and neck that may be associated with pruritus in conscious patients. Vancomycin also has been associated with the sudden development of throbbing pain or spasm in the chest or parasternal muscles without evidence of myocardial ischemia. To minimize the risk of reactions, vancomycin should be infused over a period of at least 60 minutes and in a dilute solution (500 mg/100 mL). Reactions should be treated by discontinuation of vancomycin infusion, administration of an antihistamine for pruritus, and use of medications and other interventions that counteract the hypotension.

Sulfonamides and Trimethoprim

Sulfonamides are generally safe and are often used for chronic prophylaxis. Occasionally, they cause allergic reactions such as minor skin rashes after approximately 1 week of therapy. Life-threatening reactions have been described in HIV-infected infants who were reexposed to sulfamethoxazole-trimethoprim (SMX-TMP). Stevens-Johnson syndrome and toxic epidermal necrolysis have been associated with SMX-TMP treatment, presumably mediated by an immune reaction similar to graft-versus-host disease.[77] Some patients have been acutely desensitized with 10-day or 48-hour regimens.

Other Classes of Antibiotics

Development of a serious allergic reaction to non–β-lactam antibiotics, such as the aminoglycosides, is rare. Nonurticarial rashes can be treated with antihistamines.

Multiple Antibiotic Allergy Syndrome

An evolving entity is the multiple antibiotic allergy syndrome, wherein certain individuals are recognized to make a ìgenericî allergic antibody to unrelated antibiotics[78] Female gender, a history of multiple antibiotic reactions, and reactions to nonsteroidal antiinflammatory drugs appear to be the main risk factors.[79]

Radiocontrast Media

The incidence of reactions induced by radiocontrast media injections is between 5% and 8%.[48] Urticaria, angioedema, wheezing, dyspnea, hypotension, or death occurs in 2–3% of patients receiving intravenous or intra-arterial infusions. Fatal reactions after radiocontrast administration occur in approximately 1:50,000 intravenous procedures, resulting in an estimated 500 deaths per annum. Most reactions begin 1–3 minutes after intravascular administration. Patients with a previous reaction to radiocontrast media have an approximately 33% (range 17–60%) chance of a repeat reaction on reexposure.[80]

The exact mechanism of adverse reactions to radiocontrast media is unknown. Intravascular injection of radiocontrast material activates complement, either by the classic or the alternative pathway.[81] Therefore, production of anaphylatoxins with subsequent mast cell and basophil mediator release has been suggested as the cause of these reactions. However, radiocontrast media are capable of inducing nonimmunologic histamine release from mast cells and basophils in the absence of complement activation. The hypertonicity of these materials has been suggested to result in nonimmunologic mediator activation from mast cells and basophils. There is no evidence that IgE-mediated mechanisms play a role in radiocontrast media reactions.

Pretreatment of high-risk patients with oral prednisone (50 mg) and diphenhydramine (50 mg) 1 hour before radiocontrast administration reduces the risk of reactions to 9%.[82] Almost all reactions in pretreated patients are of no clinical importance (e.g., mild urticaria). The addition of oral ephedrine (25 mg) 1 hour before radiocontrast administration (in patients without angina, dysrhythmias, or other contraindications for ephedrine administration) further reduces the reaction rate to 3.1%.[48] Combining premedication with nonhyperosmolar contrast media may be of additional benefit in preventing reactions in high-risk individuals (Box 88–4).[83]

Protamine

Protamine sulfate is a polycationic protein extracted from salmon milt. It is used to reverse heparin anticoagulation and retard the absorption of cer-

tain insulins (NPH and PZI). Use of intravenous protamine following cardiopulmonary bypass, cardiac catheterization, hemodialysis, or pheresis has resulted in increasing reports of life-threatening adverse reactions.

Diabetic patients receiving daily subcutaneous injections of insulins containing protamine have a 40- to 50-fold increased risk for life-threatening reactions when given protamine intravenously.[84,85] In diabetic patients who had received protamine–insulin injections, the presence of serum antiprotamine IgE antibody is a significant risk factor for acute protamine reactions (relative risk 95).[86] Moreover, patients allergic to protamine also may be allergic to protamine-containing (NPH) insulin.[87] Another group that may be at increased risk for protamine reactions are men who have undergone vasectomies. In addition, because protamine is produced from the matured testis of salmon or related species of fish belonging to the family *Salmonidae* or *Clupeidae,* it has been suggested that individuals allergic to fish may have serum antibodies directed against protamine.[88] Finally, previous exposure to intravenous protamine given for reversal of heparin anticoagulation may increase the risk for a reaction with subsequent protamine administration.[89,90] Following cardiopulmonary bypass, risk factors found to correlate with adverse events following protamine administration included NPH insulin use (odds ratio = 8.18; 95% confidence interval [CI] 2.08–32.2), fish allergy (odds ratio = 24.5; CI 1.24–482.3), and a history of nonprotamine medication allergy (odds ratio = 2.97; CI 1.25–7.07).[91]

The exact mechanisms by which acute protamine reactions occur are incompletely understood. Some protamine reactions may be associated with complement activation, either through protamine–heparin complexes or through the interaction of protamine and complement fixing, antiprotamine IgG antibody, leading to pulmonary artery pressure elevation through generation of thromboxane.[92,93]

Topical Preparations

Cutaneous hypersensitivity and eczema may occur from chronic exposure to topical preparations. Of 50 case reports of chlorhexidine anaphylaxis, one third occurred during surgery.[94] However, the risk of development of type I and type IV allergy to chlorhexidine, even with daily occupational exposure of healthcare workers in Denmark, likely is extremely rare.[95]

Concerns are often expressed about allergy to povidone iodine preparation solutions in patients with a history of seafood allergy. Similar concerns are voiced about patients with allergy to radiocontrast media, because iodine is present in both. The allergen responsible for sensitization probably is the povidone component of povidone iodine, the carrier molecule for iodine atoms. In the first reported case of anaphylaxis to povidone iodine preparation solution, a 32-year-old man had a positive skin prick and intradermal test to Betadine and povidone. A basophil activation test and leukotriene release test also were positive for Betadine and povidone. A 9-year-old child has been confirmed to have eosinophilia, elevated specific IgE level, and positive skin prick test for povidone iodine.[96] Fish allergy is due to protein M, and tropomyosin probably is the cross-reactive allergen in various species of shellfish.[97]

Transfusion-Related Anaphylaxis

Transfusion-related anaphylaxis, a serious, life-threatening condition, is discussed in Chapter 85.

Natural Rubber Latex

Natural rubber latex present in various materials, especially surgical gloves, is responsible for a dramatic change in the etiology of intraoperative anaphylactic shock, increasing in one series from 0.5% in 1989 to 22.3% of cases in 2002 (Table 88–3). Although it is possible that the connection to latex exposure and reactions was never made in the past, it is more likely that the increased general use of latex products for medical and nonmedical applications has resulted in some change in the manufacturing process that has led to increased antigenicity of latex products, particularly gloves.[98,99]

Natural rubber latex is a complex suspension of polyisoprene, lipids, phospholipids, and proteins. The proteins are found in three physical states: water soluble, starch bound, or latex bound, and there are at least 240 potentially allergenic proteins in the processed latex product. The protein content of latex gloves can vary up to 1000-fold among different lots marketed by the same manufacturer and 3000-fold between gloves from different manufacturers.[100] A number of chemicals, including preservatives, accelerators, antioxidants, and vulcanizing compounds, are added during the manufacturing process to yield the final product. Although the chemicals added to latex have long been associated with contact dermatitis and type IV reactions, it was only after the embracing of universal precautions that alarming reports from around the world describing generalized urticaria, angioedema, upper and lower respiratory obstructions, and cardiovascular collapse first appeared. Patients who have suffered severe systemic reactions often have a history of contact urticaria or angioedema to rubber products such as gloves or rubber balloons, or atopy.

Certain populations are at significantly increased risk for latex allergy. These include healthcare workers, who have had increased exposure to latex usually in the form of gloves, patients with prolonged or frequent exposure to latex products such as urinary catheters, and latex factory workers.[101] Patients with meningomyelocele or congenital urologic anomalies seem particularly susceptible, with an estimated incidence of latex allergy averaging 50%.

IgE antibodies play a major role in the immunopathogenesis of latex-induced allergy and anaphylaxis. The diagnosis of latex allergy is made by a combination of medical history, physical examination, and reliable in vivo or in vitro tests. Although skin prick testing is both sensitive (100%) and specific (99%),[102] this method should be restricted to patients with a compelling history and an inconclusive serologic test result because of possible systemic reactions.[103] The RAST for latex-specific IgE is recommended, although it is less sensitive than skin prick testing.[104]

Serum tryptase levels in the immediate postanaphylaxis period may be helpful in confirming the diagnosis following a clinical episode.[29,46,47,49,105–108] The positive predictive value of tryptase for diagnosis of anaphylaxis is 92.6%, and the negative predictive value is 54.3%.[24] A provocative challenge to latex has been described that involves placing a latex glove on a dampened hand for 15 minutes and comparing the response of the contra-

lateral hand wrapped in a vinyl glove. Provocation tests should be avoided if severe systemic reactions have occurred. Multiple allergies are often found in latex allergic patients. Cross-reactivity of latex with tropical fruits is not uncommon,[109–113] and such findings in the history can be used to heighten suspicion about a patient's potential for latex allergy.

Patients who have had serious allergic reactions to latex and patients at high risk (e.g., patients with meningomyeloceles) should avoid contact with latex products. Because prophylactic drug protocols have proven ineffective, a latex-safe environment is advocated. Box 88–7 provides a checklist for dealing with the latex-allergic patient. Moreover, patients in identified high-risk pediatric groups, such as children with urologic birth defects and myelomeningocele, should be offered latex-free exposure in the operating room from birth to avoid subsequent sensitization. The American Society of Anesthesiologists has a brochure available on its website summarizing current recommendations for anesthesiologists caring for latex-allergic patients.

CONCLUSIONS AND THERAPEUTIC IMPLICATIONS

1. **Once an allergen is identified, the most important clinical strategy is avoidance of that allergen.** As perioperative specialists, anesthesiologists have a critical role in understanding the etiology, treatment, and evaluation of patients' allergic reactions.
2. **Epinephrine is the most important medication to have available and to provide in the setting of anaphylaxis**. Early administration of the appropriate dose is crucial for optimum outcome because the outcome of shock due to anaphylaxis may be far worse than other forms of shock. For prophylaxis or attenuation of an anticipated allergic response, effective protocols exist that reduce the risk of anaphylaxis to $<0.5\%$. Following primary treatment, adjunctive, or secondary, treatment (antihistamines, anticholinergics, β- and α-agonists) is important for patient comfort and reduction of symptoms of anaphylaxis.

BOX 88–7.

Checklist for Latex-Allergic Patients

Preoperative

History of chronic care with latex-based products
History of spina bifida, urologic reconstructive surgery
History of multiple surgical procedures (e.g., >9)
History of intolerance to latex-based products: balloons, rubber gloves, condoms, dental dams, rubber urethral catheters
History of allergy to tropical fruits
History of intraoperative anaphylaxis of uncertain etiology
Healthcare workers, especially with a history of atopy or hand eczema
Consider allergy consultation
In vitro testing
In vivo testing
Minimize latex exposure for at-risk patients
Latex alert: Patients with significant risk factors for latex allergy but no overt signs or symptoms
Latex allergy: Patients with or without significant risk factors for latex allergy and positive history, signs, symptoms, and confirmatory laboratory test
Carefully coordinate care among surgical, anesthesia, and nursing teams
Have lists available of non-latex product alternatives
First case of the day is preferable to decrease aeroallergen concentration
Display "Latex Allergy" or "Latex Alert" signs inside and outside the operating room

Intraoperative

Anesthesia equipment
Latex-free gloves, airways, endotracheal tubes
Masks (polyvinylchloride if available, or old, well-washed, black rubber masks)
Rebreathing bags (neoprene if available, or old, well-washed black rubber bags)
Ventilator bellows (neoprene or silicone if available, or old, well-washed black rubber bellows)
Breathing circuit (disposable, polyvinylchloride, packaged separately from latex rebreathing bag)
Beware of latex intravenous injection ports, natural rubber latex tourniquets, and rubber bands; use nontoxic latex glove as tourniquet; tape latex inject ports, or use silicone injection ports or stopcock
Blood pressure cuffs (if new latex, cover with soft cotton)
Ambu-type bag (assure that bag and valve do not have latex components)
Alternative is silicone self-inflating bag
Dilute concentration of epinephrine (0.01 mg/mL or 1:100,000) readily available
Surgical equipment
Avoid latex surgical gloves
Avoid latex drains (e.g., Penrose)
Avoid latex urinary catheters
Avoid latex instrument mats
Avoid rubber-shod clamps
Avoid latex vascular tags
Avoid latex-bulb syringes for irrigation
Avoid rubber bands

Postoperative

Medical Alert tag
Warning sign posted on chart
Warning sign posted on bed

3. **Specific immunotherapy strategies are emerging** for a variety of allergens to which patients and healthcare workers have become exposed. Chronic as well as acute desensitization strategies exist that reorganize an individual's profile from primarily a Th2 to a Th1 type of response. Because of the increasing understanding of the immune response, strategies now can be developed for therapeutically interfering with the interaction of IgE and allergen, inhibiting cytokine function and T-cell activation, or modifying allergy cell responsiveness.
4. There is an important epidemiologic challenge in explicating the reasons for the **increasing incidence of allergic disease**, particularly in western countries.

CHAPTER 89

Malignant Hyperthermia, Thermoregulation, and Perioperative Hypothermia[a]

Sheila Muldoon, MD,
Nyamkhishig Sambuughin, PhD,
Maria Voelkel, BA,
Rolf Bunger, MD, PhD,
Hilary P. Grocott, MD, FRCPC,
and Christopher Sulzer, MD

KEY POINTS

1. Malignant hyperthermia (MH) was first described in the early 1960s in a case report that also suggested an inherited basis for the syndrome.
2. Skeletal muscle is the primary target tissue in MH. A laboratory diagnostic test for MH was derived using the enhanced contracture response of in vitro muscle strips from MH patients. Studies using these tests suggest that the cellular mechanism responsible for MH is a derangement in calcium regulation.
3. No convenient minimally invasive laboratory test for MH susceptibility is yet available. Halothane and caffeine contracture tests are bioassays and remain the most reliable indicators.
4. Molecular genetic tests, for example targeted screening of the RyR1 gene, can confirm the diagnosis of MH susceptibility.
5. A negative screen of the RyR1 gene does not rule out MH susceptibility.
6. The immediate cause of an MH crisis appears to be a sudden increase in the concentration of myoplasmic calcium; this Ca^{2+} overload is thought to follow the actions of inhalational anesthetic agents on the sarcoplasmic reticulum (SR), specifically the Ca^{2+} release channel called the RYR1.
7. All potent anesthetics are capable of triggering an MH reaction, but an MH episode does not always occur with each exposure to an inhalation agent, even in persons known to be MH susceptible. This situation reflects the variable penetrance of the gene.
8. Time of onset of a fulminant episode of MH is unpredictable, varying from within minutes to within several hours of induction; it may even occur in the recovery room.
9. The earliest, most sensitive and most specific sign of an MH episode is an unexpected increase in end-tidal CO_2.
10. Laboratory signs in MH include elevated $PaCO_2$, combined metabolic and respiratory acidosis, hyperkalemia, elevated creatinine kinase, myoglobinemia, and myoglobinuria.
11. In 1979, dantrolene, a drug that inhibits SR Ca^{2+} release in skeletal muscle was approved for clinical use by the Food and Drug Administration; this was a major advance in the treatment and management of MH.
12. A near-zero mortality rate from MH can result from prompt recognition of the clinical situation, ready access to supplies necessary for treatment, and initiation of appropriate therapeutic measures.
13. Adults thermoregulate with their environment by cutaneous vasomotor adjustments, sweating, shivering, and environmental behavioral adaptation (dressing appropriately, modifying environmental temperature).
14. Neonates do not shiver but can generate heat via nonshivering thermogenesis.
15. Heat loss occurs via sweating and cutaneous vasodilatation. Heat conservation results from cutaneous vasoconstriction and behavioral adaptation.
16. Although not precisely defined, core temperature reflects mean temperature of the well-perfused organs (e.g., brain, heart, kidney, and lungs).
17. Hypothermia which develops during general anesthesia typically follows a predictable pattern: (a) an initial rapid decrease in core temperature of between 32.9°F (0.5°C) and 34.7°F (1.5°C) during the first hour after induction, believed to be the result of internal redistribution of heat; (b) a more gradual linear decline in core temperature, usually lasting 2–3 hours that apparently results from cutaneous heat loss exceeding metabolic heat production (typically 0.9°F [0.5°C] to 1.8°F [1°C] per hour); and (c) a plateau phase when core temperature stabilizes after 3–4 hours and which results from thermoregulatory balance.
18. Following redistribution-mediated decreases in temperature, body heat loss occurs via radiation (60% of heat loss) and convection, with <10% occurring via evaporation, and a negligible amount via conduction.
19. Postanesthesia shivering is most likely mediated via normal thermoregulatory response to hypothermia.

Continued

MALIGNANT HYPERTHERMIA[a]

Malignant hyperthermia (MH) is a dominantly inherited disorder of skeletal muscle (myopathy) that predisposes susceptible individuals to a potentially fatal reaction (fulminant episode) upon exposure to potent volatile anesthetics and/or succinylcholine. Fulminant MH episodes apparently result from a rapid, sustained rise in myoplasmic Ca^{2+}. Molecular genetic analysis identified mutations in the ryanodine receptor type 1 (RyR1) that codes for the Ca^{2+} release channel in muscle to be a major cause for MH. However, MH is known to be a heterogeneous disorder and mutations in RyR1 account for approximately 70% of all MH cases. An MH episode constitutes a hypermetabolic state manifesting as tachycardia, mixed respiratory and metabolic acidosis, muscle rigidity, and, ultimately, hyperthermia. Muscle membrane damage leads to release of intracellular muscle constituents, such as creatine kinase (CK), lactate dehydrogenase, myoglobin, and potassium. The formerly high mortality rate (70%) has dropped 5% since the introduction of dantrolene, a drug that inhibits Ca^{2+} release from the sarcoplasmic reticulum (SR), and can usually stop the crisis if administered when early

[a] "Malignant Hyperthermia" was written by Dr. Shelia Muldoon, Dr. Nyamkhishig Samguughin, and Ms. Maria Voelkel, and Dr. Rolf Bunger. "Thermoregulation and Perioperative Hypothermia" was written by Dr. Hilary P. Grocott and Dr. Christopher Sulzer.

Key Points–continued

20. Hypothermia during regional anesthesia is caused by depression of regional thermal afferent input and efferent responses, such as vasoconstriction and shivering, loss of heat to the operating room environment, and redistribution of heat within the body.
21. Hypothermia during anesthesia may be prevented or treated by prewarming, the control of ambient temperature, skin insulation, warm IV solutions, heating and humidifying inspired gases, the application of a forced-air heating system, and the use of new generation circulating-water heating systems.
22. There is an abundance of experimental evidence for the neuroprotective effects of hypothermia; emerging clinical applications include the postcardiac arrest and neonatal asphyxia patients.

symptoms are recognized. Hyperthermia, for which the syndrome is named, is a late clinical sign and is likely of metabolic origin, most probably caused by the maximum turnover of muscle adenosine triphosphate (ATP).[1–3]

For more than 20 years after the MH syndrome was first described the underlying causes were largely speculative, but experimental evidence indicated that alterations in myoplasmic Ca^{2+} were involved. It was only in 1991, after the skeletal muscle RYR1 gene was cloned,[4] that the first report linking MH mutations in the ryanodine receptor type 1 (RYR1) Ca^{2+} channel appeared. These findings propelled an explosion of new knowledge and insights into the genetics and pathophysiology of MH and mechanisms by which MH mutations alter muscle function in human, animal, and cell culture models of MH. Although these new developments have not shown the same dramatic improvements in patient care as the introduction of dantrolene and capnography (end-tidal CO_2) monitoring, our mechanistic understanding of the syndrome and how it relates to calcium control and energy metabolism in muscle has greatly improved.

Despite this impressive progress there are still a number of areas that currently are not well managed or understood. First, fulminant MH remains an unpredictable occurrence and deaths attributable to MH in otherwise healthy persons still occur. Second, there is a lack of a convenient and rapid test to identify MH-susceptible patients prior to surgery; this remains a serious concern to all anesthesiologists and surgeons. Third, estimates of MH prevalence in the general population are at best uncertain; indeed, published estimates range from 1 in 250,000 to as high 1 in 4200, depending on geographic region and types of anesthetics administered.[16] Fourth, the early symptoms of a beginning MH crisis are often not specific for MH and administering dantrolene early abolishes the typical symptoms that would have developed without treatment. Thus, many clinical reports documenting dantrolene use, especially if it was given without the key clinical signs of MH, may be equivocal, yet persons experiencing such treatment are classified as MH susceptible. It is important that such equivocal MH cases are referred for definitive contracture tests, along with genetic analysis, when appropriate. Other people are classified as MH susceptible on the basis of a family history alone, and these "individuals" also should be referred for definitive diagnosis. This is important because the MH-susceptible (MHS) label can be a serious lifelong burden to patients and their families: they are limited in the kinds of anesthesia they can receive, are denied entry into the military and police academies, and they may also be denied surgical care by some anesthesiologists and surgeons.

This chapter discusses current concepts on the pathogenesis of MH, the roles of RYR1, skeletal muscle, and genetics used in diagnostics of MH, and the clinical management of MH.

Historic Perspective

The first link between inhalational anesthetic drugs as etiologic agents and the familial nature of a disorder called malignant hyperpyrexia or malignant hyperthermia was made in 1960. Denborough and Lovell reported a case of a 21-year-old man with a compound fracture of the tibia who was reluctant to undergo surgical repair of his leg.[5] The patient had good reason to be concerned, because 10 members of his family had died without explanation during or shortly after general anesthesia with ether-type anesthetics. In some of the cases, the deaths were preceded by convulsions and fulminant fevers. The patient was reassured that a new anesthetic agent, halothane, a halogenated hydrocarbon, with a different chemical structure than ether, would be safe and it was decided to proceed cautiously with anesthesia using it. However, within 10 minutes of induction of anesthesia with halothane, the patient developed tachycardia, hypotension, cyanosis, and hot sweaty skin. The anesthetic was discontinued, vigorous cooling was begun and the patient survived. When Denborough investigated the patient's family, he correctly surmised that they exhibited an inheritable disorder that caused life-threatening hyperthermia when administered general anesthetic agents and suggested that an underlying skeletal muscle disorder may confer susceptibility.[6]

Identification of a large affected family from Wisconsin in which 20 episodes of MH and 8 fatalities had occurred confirmed the dominant inheritance pattern of the disorder, and was an important step in spreading awareness of the syndrome in North America.[7] Retrospectively, fatal increases in body temperature during general anesthesia that have been described since the beginning of the 20th century may have been malignant hyperthermia cases.

Studies by Kalow and Britt reported that freshly biopsied skeletal muscle from MH-susceptible survivors had abnormally strong muscle contracture responses to caffeine in vitro.[8] Because caffeine in high doses had been previously reported to release Ca^{2+} from the SR, their observations were important in linking MH contracture response to Ca^{2+} released from the SR. Also, the contractile responses to caffeine were potentiated by halothane, which suggested that halothane might also affect Ca^{2+} release and handling in skeletal muscle. Later it was reported that halothane alone could cause abnormal contracture in human MH skeletal muscle. The observations by Kalow and Britt led to the development of a bioassay using freshly excised skeletal muscle samples, which later became the in vitro caffeine contracture test (IVCT) in Europe and the caffeine halothane

contracture test (CHCT) in North America for MH diagnosis.

Susceptibility to MH is not confined to humans but occurs in several animal species, including pigs, dogs, and horses. The porcine model has been studied most extensively, and the pharmacological properties of MH swine muscle appear to be similar to MH human muscle.[9] The breeds of swine (Landrace, Poland, China, and Pietrain) in which MH has been characterized are the same as those in which there is a high incidence of porcine stress syndrome. Porcine stress syndrome is a condition associated with lean, heavily muscled pigs that develop acute shock-like episodes in response to stress, mild exercise, sudden increases in ambient temperature, fighting, coitus, and transportation.

An important milestone in bridging the porcine and human MH syndromes was made when Hall et al.[246] administered halothane to pigs that had porcine stress syndrome and found that the animals experienced an event remarkably similar to human MH.[10]

Subsequently, a single homozygous mutation in the RyR1 gene was identified in all MHS and porcine stress syndrome–prone swine.

In the 1970s, even as progress in understanding the pathophysiology was being made, and human MH was recognized to be an inherited disorder, patient mortality from MH remained high because there was no effective pharmacologic treatment. In 1975, Harrison et al. described the efficacy of dantrolene (later shown to inhibit the release of Ca^{2+} from the SR) in preventing and treating porcine MH.[11] These results were subsequently confirmed in humans, and in 1979 the Food and Drug Administration approved intravenous dantrolene as an antidote in cases of fulminant MH. The advent of dantrolene dramatically decreased the mortality rate from 70% to less than 10%.

Major advances in the past 2 decades involved elucidating the subcellular site of the MH defect in skeletal muscle, standardization of the diagnostic contracture tests, and identification of the SR Ca^{2+} release channel encoded by the RyR1 gene on chromosome 19q as the major candidate gene for MH susceptibility.[12,13] Subsequent studies identified several other genetic loci on other chromosomes with 1 additional candidate gene (CACNL1A3) coding for the α_1 subunit of the dihydropyridine receptor (DHPR) on Chromosome 1q. In 2005, investigators used stem cell technology to create knock-in mice, and reported that mice harboring a specific RyR1 mutation (Tyr522Ser) could be triggered to develop fulminant MH syndrome by exposure to volatile anesthetics or heat exposure.[14] Transgenic knock-in mice will likely permit detailed analysis of how different mutations relate to altered muscle calcium handling plus muscle function alterations, both in vivo and in vitro.

Epidemiology: Prevalence and Incidence

The prevalence of MH susceptibility in the population is unknown and estimates of the frequency of acute fulminant episodes vary widely. In the first extensive study of human MH, published in 1970, the incidence was estimated to be 1 in 15,000.[15] In a later survey of a mixed surgical population of all ages in Denmark, fulminant MH occurred once in 250,000 anesthetics when all types of anesthesia were included and once in 60,000 anesthetics when a combination of potent inhalation agents and succinylcholine was used.[16] Suspicion of MH was raised in 1 in 4500 anesthetics with halothane and succinylcholine. The Danish study further reported that masseter spasm occurred in 1 in 12,000 administrations of succinylcholine.[17]

In 1997, a code specific for MH (995.86) was added to the International Classification of Diseases (ICD-9CM).

Clinical Syndromes

Fulminant Episodes

Box 89–1 contains all currently known potent inhalation anesthetics that are capable of triggering an acute fulminant MH reaction in humans, as well as a list of anesthetic drugs that are safe (non-triggering) for use in MH susceptibility individuals.[3]

The most potent trigger for MH appears to be induction of anesthesia with halothane followed by succinylcholine. This combination can cause an almost immediate onset of fulminant MH in a susceptible individual. However, the clinical presentation of fulminant MH episodes can be highly variable and the initial symptoms can have a slow onset, which makes MH difficult to recognize. This is especially true with newer inhalation anesthetics such as isoflurane, sevoflurane, and desflurane, where the onset of an episode is often delayed.[18] Many cases have been reported in which anesthesia was uncomplicated for an hour or more prior to recognition of MH. Difficulties in diagnosis and in confirmation of susceptible individuals also occur when the anesthetic is terminated immediately after MH is suspected, as there may be insufficient laboratory and clinical abnormalities to confirm or reject the tentative diagnosis of MH.[19–21]

Box 89–2 summarizes the clinical signs of fulminant MH. The underlying events that trigger a fulminant MH episode and determine its severity are poorly understood. While the existing evidence suggests that RyR1 mutations underlie a high proportion of MH cases, there is considerable variation in clinical expression, for example, many MH-susceptible individuals are known to have had uneventful exposure to triggering anesthetics before developing a fulminant MH episode; differing intensities in clinical expression have developed with the same triggering agents in patients from the same family; patients may trigger without a clear family lineage; and patients may trigger with exposure to high environmental temperatures and certain noxious chemicals. This suggests that environmental and genetic factors affect the responsiveness of patients carrying MH mutations. This may be a result of incomplete penetrance of the mutations, the influence of one or more modifying genes, and/or complex interactions between genes and environment.

BOX 89–1.

Malignant Hyperthermia Trigger and Safe Anesthetic Agents

Trigger Agents	Safe Agents
Inhaled Anesthetics	*Inhaled Anesthetics*
Halothane	N_2O
Isoflurane	Xenon
Enflurane	*Intravenous Anesthetics*
Sevoflurane	Barbiturates
Desflurane	Propofol
Intravenous Anesthetics	Ketamine
None	*Muscle Relaxants*
Muscle Relaxants	Nondepolarizing (all)
Depolarizing (succinylcholine)	*Local Anesthetics*
	All
	Narcotics
	Benzodiazepines

BOX 89–2.

Clinical and Laboratory Signs Associated with Malignant Hyperthermia*

Clinical Signs	Laboratory Findings
Increased end-tidal CO_2	Increased $PaCO_2$
Increased minute ventilation (if spontaneously breathing)	Acidosis (mixed respiratory/metabolic)
Tachycardia, hypertension	Increased O_2 consumption
Dysrhythmia	Hyperkalemia
Cyanosis/mottling	Hypercalcemia
Muscle rigidity, masseter spasm, or both	Hyperphospatemia
Hyperthermia‡	Serum lactate elevation
Dark brown urine	Creatine kinase elevation
	Myoglobinuria
	Abnormal coagulation tests

*In known cases of MH, there have been large variations in the intervals between exposure to the triggering agent and development of symptoms. Patients with MH have also demonstrated varying and unpredictable times for the initial signs to develop into a fulminant, life-threatening, crisis.
‡Elevation of body temperature is a late and serious sign of MH and may not be present at the time of the diagnosis. During fulminant acute MH, body temperature may increase at a rate of 1.8–3.6°F (1–2°C) every 5 minutes.

BOX 89–3.

Differential Diagnosis of Increased $ETCO_2$ Concentration in Malignant Hyperthermia

I. Equipment
- A. Machine: leak, disconnect, decreased fresh gas flow
- B. Breathing circuit: leak, disconnect, decreased fresh gas flow, obstruction, valve malfunction, depletion or channeling of CO_2 absorbent, improper attachment of circuit to machine
- C. Ventilator: leak, disconnect, improper settings, malfunction, decreased driving pressure
- D. Monitor: leak, disconnect, inaccurate calibration, moisture, baseline drift

II. Metabolic: increased production of CO_2
- A. Fever: iatrogenic, sepsis, thyrotoxicosis, pheochromocytoma, central nervous system injury
- B. Light anesthesia
- C. Release of aortic cross-clamp
- D. Release of leg tourniquet
- E. Malignant hyperthermia

III. Mechanical: decreased elimination of CO_2
- A. Pulmonary: airway obstruction, bronchial intubation, secretions, aspiration, pulmonary edema, asthma, pneumonia, acute respiratory distress syndrome, pneumothorax, hemothorax
- B. Extrathoracic: pressure on chest, retractors, increased abdominal muscle tone, ascites, Trendelenburg position
- C. Central: decreased ventilatory drive in spontaneously ventilating patients (narcotics or inhalational agents) via non-instrumented airway, laryngeal mask airway or endotracheal tube
- D. CO_2 insufflation for pneumoperitoneum during laparoscopic abdominal surgery

The depolarizing muscle relaxant succinylcholine can trigger or enhance the severity of an MH episode induced by volatile anesthetics. Succinylcholine has several other effects; it can cause muscle contracture in muscle that is myotonic or denervated, and it can increase muscle membrane permeability resulting in an increase in serum K^+, myoglobin, and CK, even in non-MH patients.[1]

In the swine model of MH the severity of muscle rigidity correlates with sustained elevations in intracellular Ca^{2+} concentration in the myoplasm ($[Ca^{2+}]_i$) and it is generally assumed that a similar correlation exists in humans.[22] Fulminant MH episodes in humans apparently occur because the triggering anesthetics cause a rapid and sustained rise in $[Ca^{2+}]_i$ of the skeletal muscle cells. Physiologically, resting $[Ca^{2+}]_i$ is tightly controlled at submicromolar levels (about 100 nM) and during a full contraction–relaxation cycle there is a short transient rise of $[Ca^{2+}]_i$ of up to 1000-fold, which is rapidly reversed by the reuptake of Ca^{2+} via the SR Ca^{2+} pump. In contrast, during an MH crisis, $[Ca^{2+}]_i$ increases massively and is not transient but remains elevated in spite of a functioning SR Ca^{2+} uptake pump. The sustained calcium overload in MH-susceptibile cases stimulates numerous metabolic pathways, including glycogen breakdown, glycolysis, ATP hydrolysis, pyruvate dehydrogenase, oxidative phosphorylation of adenosine diphosphate (ADP), and the ATP-dependent sarcolemmal and SR Ca^{2+} pumps. Under such conditions, the demand for ATP greatly increases, to which the mitochondria respond with increased rates of oxidative phosphorylation as long as oxygen supply remains sufficient. The sustained increase in $[Ca^{2+}]_i$ leads to muscle contraction without relaxation, that is, spasm, which, if prolonged, develops into severe contracture. The muscle contracture greatly increases the extravascular resistance to muscle perfusion resulting in ischemia initially locally and eventually systemically.

The overall higher metabolic activity and ATP consumption is reflected as an increase in CO_2 production, lactate formation, and heat production, as well as increased O_2 consumption, leading to the clinical symptoms of hypercapnia, acidosis, hyperkalemia, and, ultimately, hyperthermia. If the MH syndrome is not treated by withdrawing the anesthetic agents and administration of dantrolene to decrease SR Ca^{2+} release, metabolic exhaustion will occur with resulting skeletal muscle edema, rhabdomyolysis (skeletal muscle breakdown), cerebral edema, and multiorgan failure.

In the typical case, an unexplained rise in end-tidal CO_2 ($ETCO_2$) is the earliest, most sensitive and specific sign of an MH episode. Box 89–3 describes the differential diagnosis for increases in $ETCO_2$. Tachypnea will be present if the patient is breathing spontaneously. If the patient is paralyzed and ventilation is controlled, the need to increase minute ventilation to control acidosis becomes apparent and emphasizes the need for routine, continuous $ETCO_2$ monitoring. Without $ETCO_2$ monitoring, an unexplained increase in heart rate occurring in the first 30 minutes of an anesthetic may be the most important early sign. Multifocal ventricular dysrhythmias frequently occur in conjunction with the

tachycardia. If the syndrome is not recognized and treated, ventricular tachycardia, major conduction defects, and cardiac arrest, probably as a consequence of hyperkalemia, may occur.

Generalized whole-body muscle rigidity can occur in association with masseter muscle rigidity (MMR) following succinylcholine and this combination, particularly when it occurs with an increase in body temperature, usually indicates MH susceptibility.

Muscle rigidity that develops during maintenance of anesthesia with potent inhalational anesthetics is a "sinister feature," as noted by Hopkins.[2] This is because a new and serious pathologic element—muscle ischemia—has been introduced as a result of extravascular compression at a time when myoplasmic $[Ca^{2+}]_i$ and metabolic demand is high. This further stimulates ATP catabolism, intracellular acidosis, and K^+ efflux. Prolonged ischemia has several detrimental effects. It limits oxygen availability to the mitochondrial respiratory chain, greatly impairing oxidative phosphorylation of ADP to ATP, which leads to deenergization[23] of the calcium-overloaded muscle cells; the reduced tissue perfusion also makes it difficult if not impossible to deliver therapeutic agents such as dantrolene to its target organ, the muscle. Dantrolene inhibits calcium channel activity by suppressing $[Ca^{2+}]_i$ release from the SR.[24] Prolonged ischemia also eventually inhibits glycolytic (substrate) level phosphorylation of ADP because of massive cytosolic ($NADH^+$ [reduced form of nicotinamide adenine dinucleotide] + H^+) accumulation, which inhibits glyceraldehydes-phosphate dehydrogenase.[25] With ADP rephosphorylation virtually fully disabled at both the mitochondrial and glycolytic levels, the cytosolic phosphorylation potential will collapse[23,26,27] and a reversal of the MH process, which requires ATP-dependent clearing of the calcium overload from the cells, is practically impossible.

It is now clear that hyperthermia is the result, not the cause, of a metabolic failure in muscle. Therefore, hyperthermia tends to be a relatively late clinical sign. Skeletal muscle heat production may be mainly the consequence of increased cross bridge cycling and ATP-dependent ion pumping.

The maximum temperature attained in fulminant MH episodes is variable. The increase in temperature depends on the rate of rise of the metabolic rates, skin perfusion, patient size, site of surgery, ambient temperature, ongoing infection, and use of other drugs (e.g., atropine). Box 89–4 outlines the differential diagnosis of MH.

High temperature directly induces tissue injury and procedures to cool the body should be instituted quickly. The goal is to reduce muscle metabolism and avoid exposure to a critical temperature, that is, a core temperature of >104°F (40°C).[28] At extreme temperatures of 120.2–122°F (49–50°C), cellular structures are destroyed and necrosis occurs in less than in 5 minutes. At lower temperatures, cell death is largely caused by apoptosis. Survival from fulminant MH has been reported in at least one case with temperatures as high as 111.2–113°F (44–45°C).

Laboratory signs in MH, detailed in Box 89–2, include elevated $PaCO_2$, acidosis, hyperkalemia, hypercalcemia, hyperphosphatemia, elevated CK, elevated lactate dehydrogenase, myoglobinemia, and myoglobinuria. As muscle metabolism increases, CO_2, lactate, and potassium are released into the blood. In the physiologic exercising state the body responds by increasing cardiac output and minute ventilation, but in MH these compensatory mechanisms are soon overpowered, as reflected by continually rising levels of $PaCO_2O_2$ combined with metabolic acidosis. The acidosis is associated with K^+ release into the blood. The permeability of muscle membrane increases, exacerbating the hyperkalemia and leading to further increases in serum levels of inorganic phosphate (Pi), Ca^{2+}, myoglobin, CK, and lactate dehydrogenase. The muscle edema can result in excessive release of myoglobin, next resulting in gross myoglobinuria, which can cause tubular renal failure. In humans, once the skeletal muscle membrane permeability is increased, myoglobin is lost before CK because myoglobin crosses the cell membrane more readily than CK. Thus drawing blood for baseline serum CK and myoglobin levels early in the episode will provide valuable information for monitoring clinical progress. Death early in an MH episode is usually caused by fatal arrhythmias (hyperkalemic cardiac arrest), or due to severe muscle spasms that render endotracheal intubation and ventilation impossible. When the MH episode is prolonged, death occurs from disseminated intravascular coagulopathy, myoglobinuric renal failure, and neurologic damage (Fig. 89–1).[1].

BOX 89–4.

Differential Diagnosis of Malignant Hyperthermia

I. Iatrogenic
  A. Excessive warming measures
  B. Surgical drapes and coverings
II. Fever
  A. Infection
  B. Bacteremia
  C. Sepsis
  D. Transfusion reactions (acute hemolytic and nonhemolytic)
  E. Central nervous system dysfunction
  F. Allergic reactions
III. Endocrine abnormalities
  A. Pheochromocytoma
  B. Thyrotoxicosis (thyroid storm)
IV. Drug induced
  A. Neuroleptic malignant syndrome
  B. Cocaine overdose
  C. Tricyclic antidepressants
  D. Monoamine oxidase inhibitors (MAOIs)
  E. Anticholinergics (atropine, glycopyrrolate)
  F. Amphetamines (methylenedioxymethamphetamine [MDMA])
  G. Alcohol withdrawal
  H. Drug interactions (MAOI and meperidine)
V. Rhabdomyolysis
  A. Dystrophinopathies
  B. Myotonias

Masseter Muscle Rigidity

Masseter muscle rigidity (MMR) is the condition in which the patient's mouth can barely be opened after succinylcholine administration for intubation.[29] MMR has also been called masseter spasm or trismus. MMR may be the first sign of MH, or it can develop during an MH episode. However, it may also occur as an exaggerated response to succinylcholine in normal individuals.

The masseter muscle is a complex muscle containing a high proportion (70%) of type 1, or slow oxidative fibers. The type 2 fibers in the masseter muscle are comprised of 2A, 2B, 2C, and ATPase intermediate (IM) fibers. These ATPase IM fibers, unlike other adult skeletal muscles, express neonatal myosin heavy chain (MHC) isozyme and embryonic chain myosin,

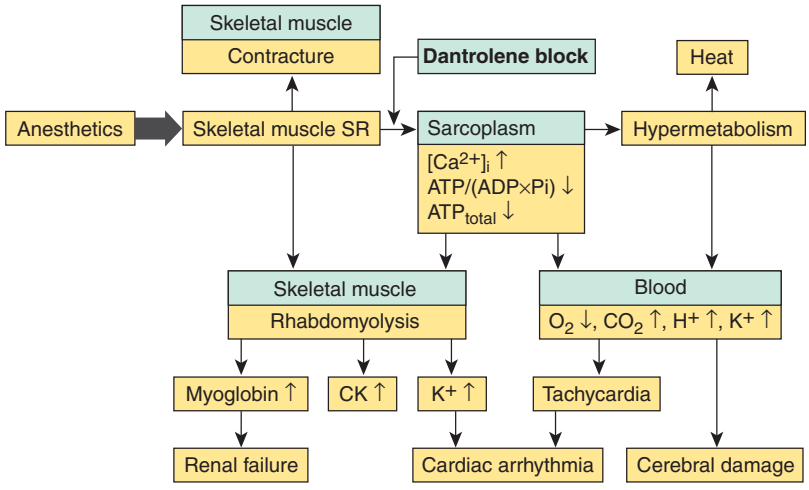

FIGURE 89–1. Current understanding of clinical and cell biologic processes in a malignant hyperthermia crisis. Volatile anesthetics like halothane sensitize skeletal muscle sarcoplasmic reticulum (SR) in MH-susceptible patients, leading to increased open probability of the RYR1 channel protein with simultaneously impaired ability to close the channel; channel closure is required to terminate SR Ca^{2+} release and allow muscle relaxation. Uncontrolled SR Ca^{2+} release produces calcium overload, that is, large increases in $[Ca^{2+}]_i$. The Ca^{2+} pumps at SR and the sarcolemma are activated to reuptake Ca^{2+} into the SR or to transport it into the extracellular space, respectively. The energeric costs to regain cellular calcium control is associated with large decreases in the phosphorylation potential (ATP/(ADP×Pi)). Because ATP/(ADP×Pi) also determines the Na^+-K^+ pump activity, cellular deenergization is associated with myocyte K^+ release (contributing to hyperkalemia) and Na^+ uptake. The muscle spasm greatly increases the extravascular resistance to perfusion resulting in myocyte ischemia, lactate formation, and ATP breakdown, which releases free Mg^{2+} and large amounts of protons (H^+) resulting in acidosis. High $[Ca^{2+}]_i$ stimulates numerous metabolic pathways, enzymes, and oxidative phosphorylation (see text), so long as muscle oxygen supply remains sufficient. This hypermetabolic state produces heat (hyperthermia), increased O_2 uptake and CO_2 production, along with hyperkalemia, and acidosis with hyperlactemia. Severe hyperkalemia is associated with cardiac arrhythmias and, if serum K^+ levels rise significantly, there is a risk of hyperkalemic cardiac arrest. This causes severe hypotension leading to cerebral ischemia and damage, unless hypotension can be controlled resuscitatively. Prolonged muscle ischemia will cause myocyte death due to necrosis resulting in rhabdomyolysis, which exacerbates systemic hyperkalemia and leads to excessive myoglobin and creatine kinase (CK) serum levels. Myoglobinemia can result in renal tubular failure and, ultimately, multiorgan failure. The main drug of choice to date is IV dantrolene, because it can block the uncontrolled SR Ca^{2+} release and, if given early in an episode, it can enable the skeletal muscle cells to regain calcium control. Modified from: Melzer W, Dietze B. Malignant hyperthermia and excitation-contraction coupling. Acta Physiol Scand 2001;171:370, Fig.2.

which are characteristic of developing muscle.[245] In addition, the masseter has a high number of muscle spindles that are larger and more complex than spindles found in limb muscles.

The literature regarding the mechanism of MMR is inconclusive. The myofilaments of type 1 fibers are more sensitive to agents that release SR Ca^{2+} than type 2 fibers. Type 1 fibers from skinned preparations (i.e., fibers in which the sarcolemma has been removed) from the masseter muscle are 2–4 times more sensitive than the type 1 fibers from *vastus lateralis*. This finding was proposed as an explanation as to why some patients develop increased masseter muscle tone after receiving halothane and succinylcholine. However, other studies using intact human masseter muscle bundles did not confirm this result.[247]

A mild case of MMR is a subjective diagnosis, making its clinical significance controversial. Practical guidelines for evaluation and classification of MMR have been proposed by several groups. Most anesthesiologists use the following 3-level general classifications:

1. The most common response to succinylcholine is "jaw stiffness" that is subclinical and can only be detected using special measuring devices.[30] This is a normal response to succinylcholine and is considered to be of no prognostic significance with respect to MH.
2. A greater increase in masseter spasm is called "jaw tightness that interferes with intubation."[1] This group may be quite large (1–2%) in children who are administered halothane and succinylcholine. A small but unknown number of these patients are at risk for MH.
3. The most severe form of masseter muscle spasm has been characterized as "the mouth could not be opened" or "jaws of steel." This group is documented to have an increased incidence of fulminant MH and increased mortality if the triggering agents are continued.[31]

Characteristics of MMR

- Occurrence: anesthesia is induced with a potent inhalational agent and succinylcholine is administered for muscle relaxation.
- It can also occur with thiopental, propofol or other intravenous induction agents in combination with succinylcholine.
- Succinylcholine induces a dose-dependent increase in jaw tension.
- The increase in jaw tone usually lasts between 90 and 120 seconds.
- Tachycardia and dysrhythmias often accompany MMR.
- Only in rare cases does fulminant MH occur immediately after MMR.
- Increases in serum CK, serum myoglobin, and myoglobin concentration in the urine typically follow MMR.

Succinylcholine administration results in an immediate increase in serum myoglobin reaching a maximum at 20–40 minutes, whereas serum CK peaks in 6–12 hours after drug administration.

If serum CK increases to >10,000 IU/L, the response is clearly abnormal and should be treated to prevent renal complications. Such patients should be referred for work up of occult myopathy, including myotonia.[32] If a preexisting myopathy is not identified, it is good practice to assume the patient is MH susceptible, to be confirmed by the CHCT, an MH diagnostic test. If the CHCT is positive, and molecular genetic examination of the RyR1 identifies a mutation believed to be causative, the first-degree relatives can be tested for this mutation and will not need to undergo a muscle biopsy and CHCT for diagnosis of MH susceptibility.

Awake Triggering: Exercise and Heat Illness

In the porcine model of MH, a single homozygous mutation in the RyR1, the Arg615Cys mutation, is causative for the disorder. Pigs homozygous for the disorder reproducibly develop fulmi-

nant MH episodes with each administration of potent inhalation anesthetics. They are also known to develop MH in response to heat, stress, and exercise. Interestingly, pigs that are heterozygous for the disorder have milder reactions to the same drugs and stresses.

In humans, the relationship between MH and exertional heat illness emanates from clinical reports that the acute MH syndrome may occur more readily after the stress of physical exercise. Gronert and colleagues reported the first patient diagnosed as MH susceptible who had a 10–15-year history of febrile episodes that were related to exercise, fatigue, and emotional stress.[33] The patient had a positive CHCT and the episodes were prevented by oral dantrolene. There are a number of reports that relate heat stroke, sudden and unexpected death, unusual stress and fatigue, and myalgia to MH episodes, called *awake episodes* because they occur without anesthesia.[34–36] There is also a subset of patients who survive fulminant MH episodes, but who continue to have muscle pain, often severe and debilitating, with exercise.[37]

Strong evidence for a relationship between heat stroke and MH comes from a case report by Tobin et al.[38] This case concerned a 12-year-old boy who died following exercise. This boy had a previous clinical MH episode and was found to harbor one of the RyR1 mutations established as causative for MH. In addition, Wappler et al. studied 12 young men with exercise-induced rhabdomyolysis.[39] Ten were diagnosed as MH susceptible based on IVCT results and 3 were identified with RyR1 mutations strongly associated with MH susceptibility. The availability of genetic testing will likely help to clarify the relationship between heat illness and MH susceptibility. From a clinical perspective, patients who have a personal or family history of MH have a greater likelihood of developing heat-related illness or rhabdomyolysis; they are advised to avoid exercise in extremes of heat. However, it is unlikely that all cases of rhabdomyolysis or heat-related illness are MH susceptible.[40]

Associated Myopathies

We first discuss myopathies that have genetic mutations in RyR1 (central core disease [CCD], multiminicore diseases [MmDs], and nemaline rod myopathy), followed by King Denborough myopathy in which RyR1 mutations have not been identified, but patients are considered MH susceptible based on clinical presentation and contracture testing results. Separate from this group are the myopathies and myotonias that can exhibit an "MH-type crisis" in response to inhalational anesthetics and/or succinylcholine, but they are genetically distinct from RyR1 defects of MH.

Central Core Disease CCD is a rare, non-progressive congenital myopathy that is histopathologically characterized by central core lesions that extend the length of the type 1 muscle fibers (Figure 89-2). The cores lack subcellular organelles such as mitochondria and, therefore, oxidative enzyme capability.[41]

Clinical presentation of CCD is variable, ranging from asymptomatic cases to those with marked skeletal muscle hypotonia and delayed motor development. CCD is mostly inherited in an autosomal dominant manner, although families with autosomal recessive inheritance and sporadic cases have been reported. Secondary musculoskeletal abnormalities seen in severe CCD cases include congenital hip dislocation, pes cavus, foot deformities, kyphoscolosis, and joint contractures.[42]

Both MH and CCD were linked and subsequently associated with mutations in the RyR1 on chromosome 19q13.1. Analysis suggests that certain mutations in the RyR1 produce both MH and CCD, whereas others result in an MH phenotype only, or in rare cases a CCD phenotype only.[43–46] The majority of RyR1 mutations associated with CCD occur in the C-terminal region of the gene, and many are "private" mutations, meaning that they are unique to individual families. Some mutations that give rise to CCD have also been identified in regions 1 and 2 of the RyR1 gene.

For clinical management, CCD patients are normally treated as MH susceptible, and virtually all CCD patients who have undergone contracture testing for MH have been diagnosed as MH susceptible and have a mutation in the RyR1.[41] The cellular mechanisms by which CCD mutations in RyR1 reduce Ca^{2+} release during excitation–contraction coupling are: enhancement of Ca^{2+} leak and store depletion (leaky channels) and "diminished coupling between the excitation and contraction process," or "excitation–contraction uncoupling."[47,48]

Multiminicore Diseases MmD is a congenital, progressive myopathy associated with multifocal "minicores" of muscle fibers. It is clinically heterogeneous and at least 4 distinct phenotypes have been associated with mutations in either the selenoprotein N (SEPN1) or the RyR1 genes.

Classical multiminicore disease has been described as an early onset autosomal recessive myopathy in which muscle axial weakness may lead to

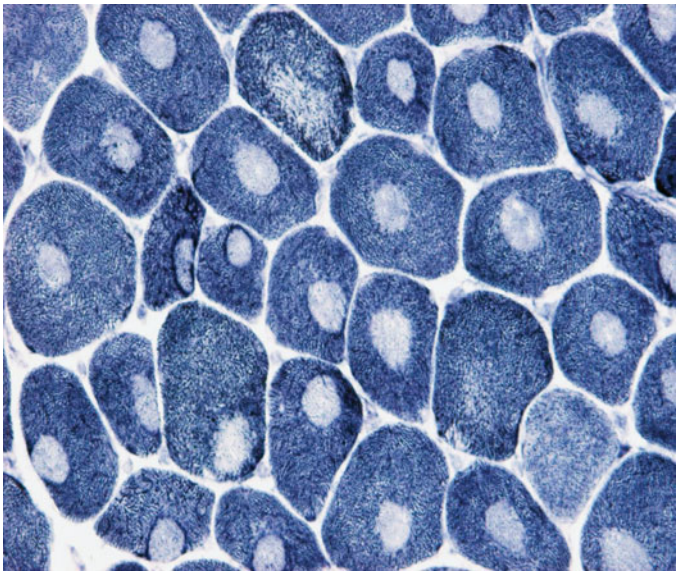

FIGURE 89–2. NADH-TR stain reveals the "central core" in almost all fibers. Note the "rimming" of some cores. Wu S, Ibarra MC, Malicdan MC, et al. Central core disease is due to RYR1 mutations in more than 90% of patients. Brain 2006;129:1476, Fig. 4B. By permission of Oxford University Press.

severe life-threatening respiratory insufficiency and scoliosis in two-thirds of patients. MmD can also be distinguished from CCD by histological examination of muscle specimens. In MmD, mini-cores occur in type 1 and type 2 muscle fibers and do not extend the full length of the fibers. Three other subgroups include a moderate form characterized by generalized muscle weakness that predominantly affects the pelvis and hands; and two classical forms, one including additional feature of ophthalmoplegia, and the other with antenatal onset in addition to arthrogryposis.[42,49]

Nemaline Rod Myopathy Nemaline rod myopathy is a very rare congenital myopathy with autosomal dominant or recessive modes of inheritance. Onset is typically from birth to infancy, and in severe cases, patients suffer from danger of nocturnal hypoxia or hypercarbia, but otherwise have no respiratory symptoms. Severe, intermediate, mild adult and Amish subtypes have been reported. Histologic features include sarcoplasmic rods (nemaline) in type 1 muscle fibers that can vary from <1% to virtually all fibers. Five genes are associated with the disease, namely, α-tropomyosin 3, α-actinin, nebulin, troponin T, and β- tropomyosin. Scacheri et al. reported the presence of an RyR1 mutation in a family affected with nemaline rod myopathy, and we advise that these patients be treated as MH susceptible.[42,50]

King-Denborough Syndrome King-Denborough syndrome is a rare, congenital, progressive myopathy that is characterized by short stature, pectus deformities, low-set ears, mental retardation, and cryptorchism; thus, it resembles the more frequently occurring Noonan syndrome. Most patients are the only individuals in their families with clinical or biochemical evidence of myopathy. Typically, MH crisis and anesthesia-related deaths have been reported. All King-Denborough patients who have been subjected to contracture testing were MH susceptibile, but molecular genetic data is lacking.[51]

Duchenne and Becker Muscular Dystrophies Duchenne muscular dystrophy (DMD) is a chromosome X-linked myopathy characterized by progressive muscle wasting, with early onset and rapid progression. DMD results from the absence or abnormality of a single protein, dystrophin, which is located in the muscle membrane and is also expressed in cardiac and brain tissue. Dystrophin links the muscle cytoskeleton to the extracellular matrix via dystrophin-related proteins (sarcoglycans, dystroglycans, and syntrophins). Patients with DMD can respond to general anesthesia with cardiac arrest or sudden acute rhabdomyolysis. Many reported cardiac arrest cases have occurred after administration of succinylcholine and have been attributed to acute hyperkalemia (> 10mEq/L). Identification of this problem during anesthesia with DMD, and other occult myopathies, led to new guidelines by the FDA (via package insert) for use of succinylcholine in young boys.[52] Even without succinylcholine, cardiac arrest following induction with halothane or isoflurane has been reported in children with DMD or other myopathies. One possible explanation for this, as Klinger et al. reported, is that "muscles lacking dystrophin are more susceptible to stretch-induced muscle damage and take up Ca^{2+} and Na^{+}. Inhalation anesthetics are not recommended because they further increase myoplasmic Ca^{2+} by facilitation of release from intracellular stores."[53] The FDA has published additional guidelines for use of volatile anesthetics in children with myopathic conditions. If there is no hyperkalemia, the cause of death is more likely to be the DMD-associated cardiomyopathy. The same guidelines concerning the use of volatile anesthetics and succinylcholine should be used in patients with Becker dystrophy. Becker dystrophy is an allelic disorder of DMD, and although it has a later onset and less-severe progression, the same perioperative complications as in DMD can occur.[54]

Neuromuscular Disorders: The Myotonias This group of neuromuscular disorders is characterized by delayed muscle relaxation and characteristic abnormalities on electromyography (EMG). Although the exact pathophysiology differs between various myotonic syndromes, common to most of them are defects in sodium and chloride membrane channels. Myotonic dystrophy is a multisystem disease with a genetic locus defect localized to chromosome 19. Myotonia congenita, paramyotonia and hyperkalemic periodic paralysis result from defects on chromosome 17. Some of these disorders are allelic of a genetic locus encoding a sodium channel.[32,54]

We recommend that patients with any form of myotonia should **not** receive succinylcholine. The same recommendations should be applied to patients with hypokalemic period paralysis, paramyotonia, or myotonia fluctuans.[53] Some groups also advocate avoidance of volatile "triggering" anesthetics, but there is insufficient data to support this recommendation.

Animal Models

Animal models that have been used in the study of MH are cats, dogs, horses, pigs, and more recently, genetically engineered mice. The porcine model of MH has been an invaluable tool for linking RyR1 to MH susceptibility. Data from this model showed unambiguously that a single homozygous mutation in the RYR1 gene was responsible for porcine stress syndrome, as well as for anesthetic-induced MH episodes. Also from the studies in the pig came the insight that MH is a derangement of Ca^{2+} handling by the calcium release channel in the SR and that neither the Ca^{2+} pump (SERCA1) or the mitochondria were the source of the primary defect.

Compared to the human MH syndrome, the porcine model has a number of limitations. The Arg615Cys mutation, which accounts for >99% of porcine cases, accounts for only 2–5% of MH susceptibility seen in humans. The inheritance pattern also differs: the porcine model is homozygous for the trait but in man, the disorder is heterozygous with a variable expression and, as a consequence, occurrence is unpredictable. Also, the MH-susceptible swine can develop an MH episode with exposure to heat, stress and exercise. In addition although it is technically possible to create a herd of "knock-in" swine expressing more than one mutation, such studies would be prohibitively expensive. Although the dog model would be heterozygous, maintaining genetically altered canine colonies and performing *in vivo* experimentation in dogs would also be extremely expensive and slow.

"Knock-out" mice homozygous for mutations in the RyR1 do not live because of insufficient muscle func-

tion for respiration. Attempts to produce a heterozygous, RyR1 mutant, transgenic mouse have succeeded. Heterozygous mice, which correspond to the human mutation Tyr522Ser, have been made.[14] These mice experience whole-body contractures and elevated core body temperature in response to the administration of isoflurane or heat stress. They also exhibit increased sensitivity to caffeine, which is an important tool in the clinical CHCT. Yang et al.[250] reported the use of "knock-in" targeting vector to create mice carrying the RyR1 mutation Arg163Cys. Extensive validation of this model was provided, including development of a fulminant MH episode after exposure to halothane, as well as after exposure to an ambient temperature of 42°C. The availability of these new animal models are expected to permit detailed analysis of how mutations causative for MH relate to altered muscle function both *in vivo* and *in vitro*.

Subcellular Sites of Defect in Skeletal Muscle

Because one of the striking features of fulminant MH episodes is that patients exhibit skeletal muscle rigidity and contracture, which are most likely to occur when myoplasmic $[Ca^{2+}]_i$ is significantly elevated, the study of the underlying basis of MH has focused on disturbance in intercellular $[Ca^{2+}]_i$ handling. Initially, it was thought that Ca^{2+} reuptake by SR Ca^{2+} ATPases (SERCAs) was the key defect. However, that mechanism was ruled out as a participant of MH reactions.[55] Early studies showed no difference in Ca^{2+} uptake rates between SR from MH-susceptible and normal pig skeletal muscle, and potent volatile anesthetics increased the calcium uptake rates in both. Comparisons of MH reactions from human or porcine SR suggested that Ca^{2+} release might be abnormal in MH-susceptible individuals. [56]

Similarly, mitochondrial defects had been raised and subsequently largely discarded as the primary mechanism for MH; nevertheless, it is not entirely ruled out that secondary mitochondrial defects develop as a result of the massive calcium overload during a fulminant MH crisis and this may contribute directly or indirectly to the clinical syndrome.

It is now generally accepted that the skeletal muscle cell loses control of Ca^{2+} release during a fulminant MH episode and that the DHPR and the RYR1 receptors are involved. These two receptors are key elements in excitation–contraction coupling in skeletal muscle. A brief review of excitation–contraction coupling as it is relates to MH is presented; for a more in depth review, see Dulhunty et al.[57]

Excitation–contraction coupling is the sequence of events that links membrane depolarization, to the release of intracellular Ca^{2+} from the SR to muscle contraction. Excitation–contraction coupling in skeletal muscle involves bidirectional mechanical interaction between two different types of Ca^{2+} channels, the DHPR or voltage-gated L-type Ca^{2+} channels (L channels) located in the transverse tubular membrane, and the Ca^{2+} release channel (RYR1), located in the SR membrane. Coupling between DHPR and the RYR1 occurs across triad junctions formed between terminal cisternae in the SR and the transverse tubular membrane. The interaction between the DHPR and RYR underlies all voluntary movement including respiration, and is therefore essential for life.[57] Major defects in either DHPR or RYR1 proteins result in poor development in utero and death at or before birth. Mutations in these proteins can lead to MH susceptibility, CCD, multiminicore disease, nemaline rod myopathy, and occasionally exertional rhabdomyolysis. Figure 89–3 is a representation of the membrane systems involved in excitation–contraction coupling.

Properties of DHPR and RyR1

DHPR is major component of the transverse tubular membrane. It contains α_1, α_2/δ, β, and γ subunits, forming an L-type channel protein that is the receptor for certain Ca^{2+} channel blockers such as dihydropyridines. The α_1 subunit forms the Ca^{2+} ion channel, the voltage sensor for channel gating and the DHPR binding site. It is comprised of 4 repeat domains connected by large cytoplasmic loops. The functions of the other subunits are less-well defined, although it is known that the β subunit is required for targeting the DHPR to the tubular membrane.

Although the α_1 subunit mediates slow (L)-type Ca^{2+} inward currents, it has been known since the 1970s that Ca^{2+} entry through the Ca^{2+} channel is a late event in excitation–contraction coupling. This is in marked contrast to heart muscle, which has led to the conclusion that the voltage sensor of the α_1 subunit, not the Ca^{2+} channel function, is the key component in excitation–contraction coupling of skeletal muscle. Although the precise mechanism for excitation–contraction coupling remains unknown, current concepts suggest that membrane depolarization causes a conformational change in the DHPR that opens the SR Ca^{2+} release channel. This precedes the slower opening of the L-type Ca^{2+} channel.[58]

Electron microscope studies reveal that the RYR1 and α_1 subunit of DHPR have a highly specific spatial association in skeletal muscle. Clusters of 4 evenly spaced particles (tetrads) representing DHPRs are positioned in the sarcolemma such that each particle is located immediately above 1 of the four RyR1 subunits.[59] However, DHPR tetrads are associated with only every second subunit of RyR1, suggesting that not all release channels are directly coupled to DHPRs. Release channels that are not opposed by tetrads are most likely activated by Ca^{2+} release channels via Ca^{2+}-induced Ca^{2+} release (CICR) (Fig. 89–4).[1] Available evidence suggests that there is a direct physical coupling between the II and III loops of the α_1 subunit of the DHPR and multiple cytoplasmic regions of the RYR1.[59]

RYR1 belongs to intracellular Ca^{2+} channel superfamily that includes two other RyR isoforms. All three isoforms have tissue-specific expression and share a high degree of homology (70%). The name ryanodine receptor came from its affinity to bind to the plant alkaloid of the same name. RYR1 is expressed predominantly in skeletal muscle, and has also been identified in human B lymphocytes and in immature dendritic immune cells. RYR2 is expressed predominantly in cardiac tissue and RYR3 is expressed in skeletal muscle at relatively low levels and in smooth muscle (Table 89–1).

RYR1 is composed of four identical 560-kDa proteins that assemble into a homotetramer to form functional Ca^{2+} release channels. Each subunit (monomer) of RyR1 is predicted to consist of a cytoplasmic N-terminal region constituting approximately 80% of the protein. The C-terminal which comprises $^1/_5$ of the entire gene, contains a number of important structural features, including transmembrane complex, the Ca^{2+} per-

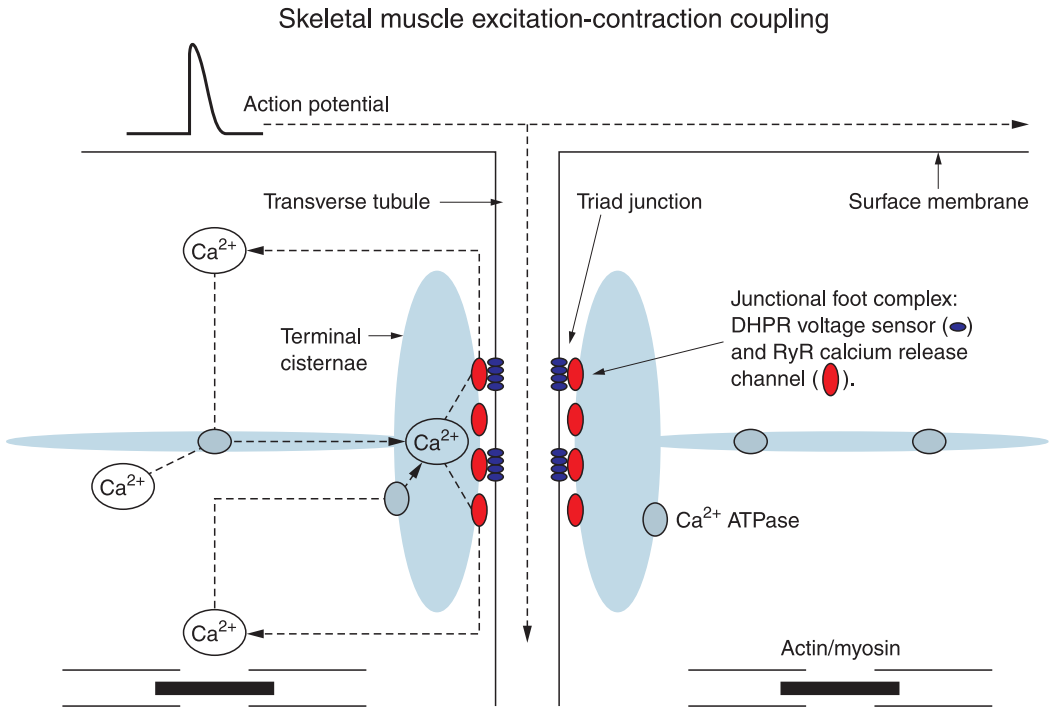

FIGURE 89–3. Membrane systems and membrane proteins involved in excitation–contraction coupling. The action potential propagates along the surface and transverse tubule membranes. The signal resulting from depolarization is transmitted across the triad junction that is formed between the transverse tubule membrane and the terminal cisternae membrane of the sarcoplasmic reticulum Ca^{2+} store. A triad is the usual junction between the transverse tubule membrane and sarcoplasmic reticulum in skeletal muscle, and is named because it consists of a central transverse tubule membrane with a terminal cisternae of the sarcoplasmic reticulum on either side. The voltage sensor for excitation–contraction coupling is the dihydropyridine receptor (DHPR) in the transverse tubule membrane. The Ca^{2+} release channel in the sarcoplasmic reticulum is the ryanodine receptor (RYR). A tetrad of DHPRs oppose every second RYR. The contraction is terminated when Ca^{2+} is actively pumped back into the sarcoplasmic reticulum by the adenosine triphosphate (ATP)-dependant Ca^{2+} pump (Ca^{2+}-ATPase). Dulhunty AF, Haarmann CS, et al. Interactions between dihydropyridine receptors and ryanodine receptors in striated muscle. Prog Biophys Mol Biol 2002;79:47, Fig. 1.

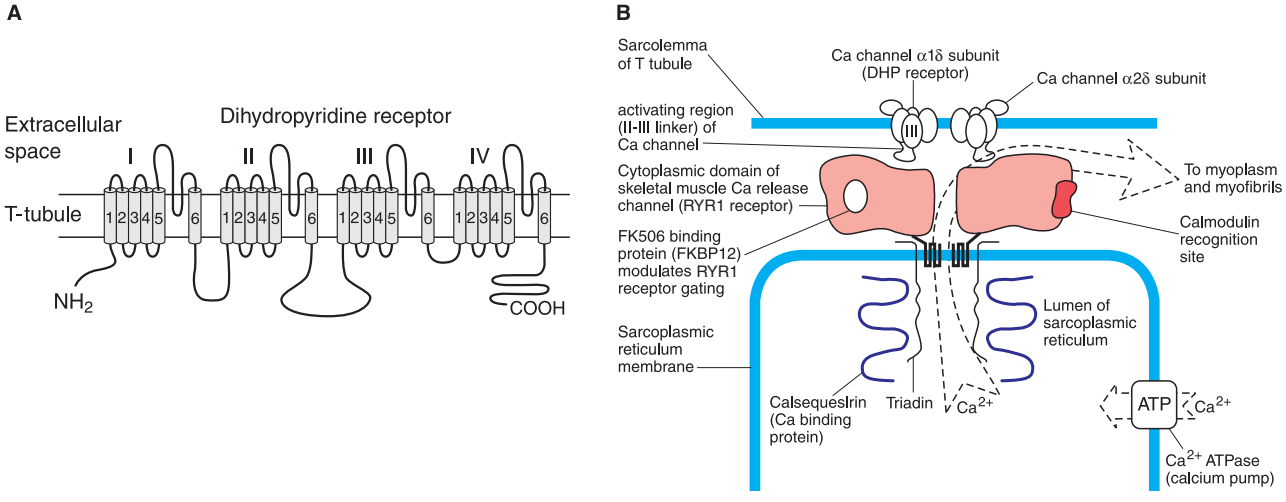

FIGURE 89–4. **A.** Voltage-gated Ca^{2+} channel dihydropyridine receptor (DHPR). The alpha 1 subunit of the DHPR consists of four repeat domains (I-IV), each with six transmembrane segments (1-6). Segment 5-6 loops form the ion channel pore, and the segment 4 segment contains positively charged residues which confer voltage dependence to the protein. The II and III intracellular loop of the DHPR interacts with the ryanodine receptor to mediate excitation contraction coupling, as shown in *B*. Figure and legend adapted from Loke J, MacLennan DH. Malignant hyperthermia and central core disease: disorders of Ca^{2+} release channels. Am J Med 1998;104:472, Fig. 2, and Jurkat-Rott K, McCarthy T, Lehmann-Horn F. Genetics and pathogenesis of malignant hyperthermia. Muscle Nerve 2000;23:10, Fig. 2. **B.** Schematic representation of the triad junction of skeletal muscle shows the junctional foot protein (ryanodine receptor [RYR1]) and its associated proteins. In skeletal muscle, the alpha1s-subunit of the dihydropyridine receptor (DHPR) participates in excitation-contraction coupling. These physical links transmit essential signals across the narrow gap of the triadic junction that activate RYR1 and release Ca^{2+} from the sarcoplasmic reticulum. RyR and its interaction with DHPR are illustrated essentially as Pessah, Lynch, Gronert. Complex pharmacology of malignant hyperthermia. Anesthesiology 1996;84:1276, Fig.1.

TABLE 89–1.

Properties of RYR

Structural
- 500 amino-acids long
- Molecular weight ~560 kD
- Homotetramer
- Associates with structural proteins in muscle, calsequestrin, triadin junction

Functional
- 100 pS single channel conductance to Ca^{2+} in lipid bilayers (50 mM luminal Ca)

Nonprotein regulators
- Adenosine triphosphate, Ca^{2+}, Mg^{2+}, Ph

Protein regulators
- Calmodulin
- FKBP12 (FK506 binding protein)

Pharmacologic regulators
- "Activators": caffeine, 4-CmC, ryanodine at (μM)
- "Blockers": ruthenium red, dantrolene, ryanodine at (μM)

TABLE 89–2.

Three Isoforms of the RYR (similar to the IP3R)[a]

RyR1
- Activated by relatively high Ca^{2+}
- Readily inactivated by Ca^{2+}
- Designed for fast release of larger quantities of Ca^{2+}

RyR2
- More readily activated; less likely to close
- More easily activated by caffeine

RyR3
- Broader sensitivity to Ca^{2+}
- Doesn't necessarily inactivate at high Ca^{2+}
- May be more capable of sustained activity

[a]Each isoform is on a different gene.

meability pore, and interaction sites for Ca^{2+}, caffeine, 4-chloro-*m*-cresol, ATP, and ryanodine (Table 89–2).[60,61]

Regulators of RYR1 Function In addition to activation by the DHPR, RyRs can be triggered to release Ca^{2+} in a number of ways, including an increase in intracellular Ca^{2+} itself, Ca^{2+}-induced Ca^{2+} release. Ca^{2+}-induced Ca^{2+} release is the predominant mechanism of excitation–contraction coupling in cardiac muscle, but not in skeletal muscle. All three RYRs are stably bound to the immunophilin FKBP12 (FKBP506 binding protein) which stabilizes channel function and helps to coordinate gating. In addition to FKBP12, an array of accessory and regulatory proteins such as calmodulin, triadin, junctin, and calsequestrin help to regulate channel activity.

The principal endogenous modulator of RYR1 is Ca^{2+}, which at micromolar levels can activate the RYR1. However, numerous studies indicate that Ca^{2+} has a biphasic effect, as millimolar concentrations of $[Ca^{2+}]_i$ can inhibit channel activity. Other endogenous RYR1 modulators include Mg^{2+} (an inhibitor) and ATP (activators), as well as cellular oxidation–reduction state, which have complex effects on channel activity probably via oxidation–reduction changes in accessible sulfhydryl groups.[61]

In addition, exogenous modulators can alter RYR1 activity, and one of the most extensively used is ryanodine. Ryanodine modulates RYR1 in a biphasic manner (nanomolar concentrations activate, whereas concentrations >100 μM inhibit channel activity), caffeine (mM) is an activator, and ruthenium red (μM) is an inhibitor, all of which are specific pharmacologic tools used to identify intracellular signaling pathways involving RYR1. Caffeine has complex effects on RYR1. Its primary effect is to increase release of Ca^{2+} from the SR, but some of caffeine's effects appear to be Ca^{2+} dependent, thus caffeine-induced Ca^{2+} release can further influence the effect of caffeine itself. One of the most important inhibitors of the RYR1 channel activity is dantrolene, which suppresses intracellular Ca^{2+} release from the SR and is used for prevention and treatment of MH. A binding site for dantrolene has been identified within the N-terminal part of the RYR1,[24] but still requires independent confirmation. Azumolene, a more potent and soluble derivative of dantrolene, is not used clinically but in experimental research studies. Halothane and other volatile anesthetics are activators of the RYR1 channel, but their exact site and mechanism of action is unclear.

Effect of Mutations on Functional RYR1 Activity Mickelson first demonstrated that skeletal muscle samples from MH-susceptible pigs exhibit higher specific ryanodine binding as well as increased sensitivity to activation by micromolar Ca^{2+}.[9] Because specific ryanodine binding is proportional to the open probability of the Ca^{2+} release channels, these results suggest that SR Ca^{2+} release is linked to MH and exhibits a higher open probability. In isolated SR vesicles from pig MH-susceptible muscle, the initial rate of Ca^{2+} release examined over a range of Ca^{2+} concentrations from submicromolar to millimolar levels, showed a 2–3-fold increase in the initial rate of Ca^{2+} release compared to SR vesicles prepared from normal animals (Fig. 89–5).[62] However, Fill et al. reported that the closing of single porcine MH channels at high $[Ca^{2+}]_i$ was inhibited. These investigators reported that inactivation of the open release channel was less sensitive to micromolar Ca^{2+} even though there was no difference in activation of the SR Ca^{2+} release channels (Fig. 89–6).[63] In comparable studies with humans, muscle samples with an increased caffeine sensitivity of the calcium release channel were found.[64] Taken together these results suggest that Ca^{2+} release channels are more likely to open and be unable to close promptly (delayed) with physiologic stimuli (high $[Ca^{2+}]_i$, low pH, and/or high Mg^{2+}), with the net effect of a sustained and large increases in myoplasmic calcium levels (Fig. 89–7).[9,65]

The significance of these functional defects in SR calcium channel became apparent when linkage between MH and the gene coding for the Ca^{2+} release channel in skeletal muscle was independently established by two different groups in 1990.[12,13] Following these discoveries, an important role for ryanodine receptors as causal agent for MH was accepted. Functional studies by a number of investigators confirmed that the Arg614Cys was both necessary and sufficient to alter the biochemical and physiologic properties of the RYR1 from the MH susceptible animal model.[9]

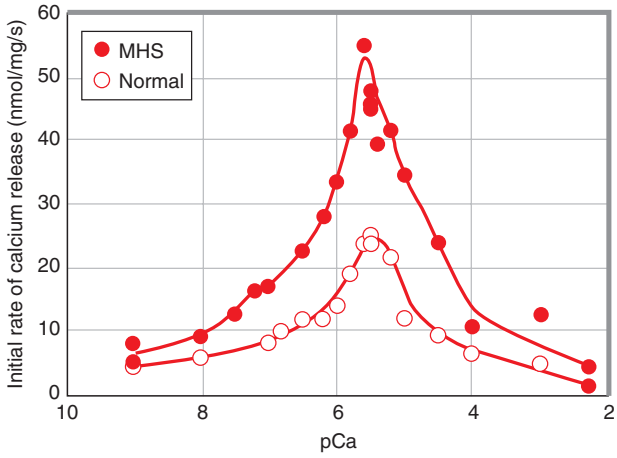

FIGURE 89–5. Ca^{2+} dependence of rate of Ca^{2+}-induced Ca^{2+} release from MH-susceptible and normal pig SR vesicles. SR vesicles were passively loaded with Ca^{2+}, and Ca^{2+} release was initiated by rapid filtration with a solution containing ionized Ca^{2+}. Under these conditions, the rate constant for Ca^{2+} release from MH-susceptible SR was significantly greater than that from normal SR. Carrier L, Villa M, Dupont Y. Malignant hyperthermia: excitation-contraction coupling, Ca2+ release channel, and cell Ca2+ regulation defects. Physiol Rev 1996;76:548, Fig.6.

Molecular Genetics

Inheritance

Absence of apparent clinical symptoms in MH-susceptible individuals and variability in clinical presentations of MH caused by triggering agents are a challenge in assessing the inheritance of this condition in humans. Nevertheless, it is generally accepted that MH in humans is inherited as an autosomal dominant trait with reduced penetrance.[44,45]

MH Candidate Genes

Identification of the homozygous RyR1 mutation causing MH in pigs was a breakthrough in understanding genetics of MH. This discovery directed genetic studies in humans and the first MH susceptibility locus was linked to the RyR1 on chromosome 19q12–13 in the early 1990s.[12,13] Soon after linking the porcine MH syndrome to the Arg615Cys mutation, the first human mutation in the RyR1 (Arg614Cys) was linked to the MH-susceptible phenotype.

The RyR1 was proposed as a candidate gene for MH and numerous RyR1 mutations were found in many affected families. Furthermore, genetic linkage studies revealed that MH susceptibility is characterized by genetic heterogeneity with five other loci (17q21–24, 1q32, 3q13, 7q21–24, and 5p) designated MHS 1–6, respectively (Table 89–3). The only gene other than RyR1 that has been identified is the gene coding for the α_1 subunit of the DHPR, CACNL1A3.[248] Two causative mutations have been identified in the CACNL1A3, but screening studies indicate that these mutations are linked to <1% of MH-susceptible families worldwide.[54,248]

Mutations in the RyR1 are thought to account for approximately 70% of MH susceptible subjects, but are found in almost 100% of families with CCD.[41,42] The RyR1 gene is a complex gene containing 106 exons and encoding an messenger ribonucleic acid molecule of 15 kb that is transcribed mostly in skeletal muscle.[12] More than 100 different mutations have been identified in the RyR1.[41,42] The majority of them are missense mutations in three regions: the N-terminal region between codons 34 and 614; the central region between codons 2163 and 2458; and the C-terminal region between codons 4136 and 4973 (Fig. 89–8).[3,42,43,54,66] This preferential localization raised speculations concerning the specific role of these regions. The central region is proximal to the region where the protein would interact with the regulatory protein, FKBP12 and the α_1 subunit of the DHPR, the voltage sensor of RyR1, and the C-terminal region that corresponds to the transmembrane domain of the protein.[3]

Functional Consequences of the RyR1 Mutations Functional studies by a number of investigators confirmed that RyR1 mutations associated with MH susceptibility were both necessary and sufficient to alter the biochemical and physiologic properties of the protein. The pathogenic character of many RyR1 mutations have been studied experimentally by kinetic measures of intracellular calcium release in response to caffeine, 4-chloro-*m*-cresol, or halothane in different cell lines.[46,68–70] Other methodologies used included analysis of the biophysical properties of channels incorporated into lipid bilayers, ryanodine-binding experiments, and patch-clamp experiments. Expression analysis of a series of RyR1 mutations in HEK-293 kidney cells demonstrated that in Ca^{2+} free media, those cells expressing a mutated protein were more sensitive to caffeine than the wild type.[68] A similar conclusion was reached by Yang et al., who expressed 6 human mutations in dyspeptic mouse myotubes (myotubes lacking

Physiol Rev 1996;76:553, Fig. 12.

RYR1) and demonstrated that all 6 transfected myotubes had increased sensitivity to caffeine, 4-chloro-*m*-cresol, and cell membrane depolarization induced by K^+.[71] Yang et al. demonstrated with radiolabeled ryanodine binding that all 6 mutations were more sensitive to caffeine even at a normal intracellular calcium concentration of 100 nM.[71]

Wehner et al. investigated the functional consequences for calcium homeostasis in primary human myotubes cultured from an individual with MH phenotype and members of two other MH families expressing three RYR1 mutations in exon 44.[70] Exon 44 lies in the cytoplasmic foot region of the RYR1. The sensitivity to RyR1 receptor agonists, 4-chloro-*m*-cresol, caffeine, and halothane was examined with the calcium-sensitive probe Fura 2. In all three mutations examined (Ala2350Thr, Arg2355Trp, and Gly2375Ala), the EC_{50} (median effective concentration) for 4-chloro-*m*-cresol, caffeine, and halothane was reduced approximately 40–50%, which was statistically significant com-

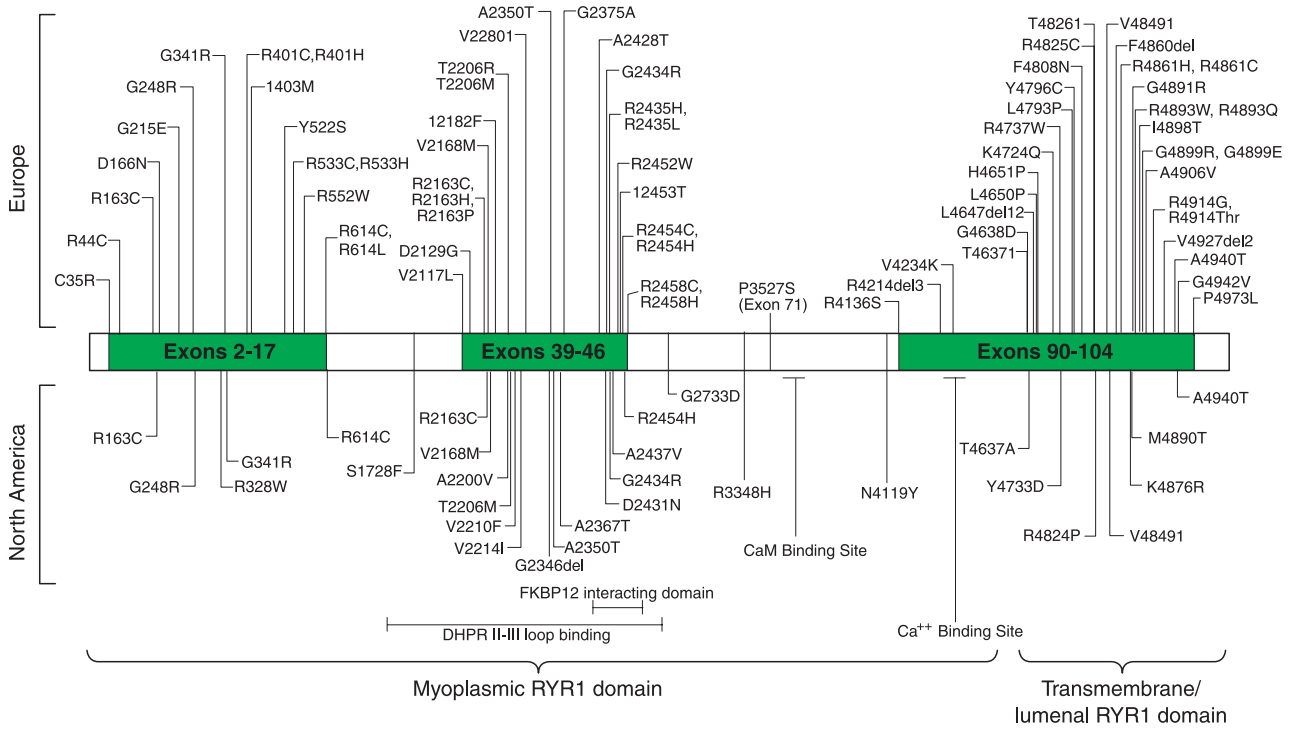

FIGURE 89–8. Location of ryanodine receptor type 1 (RyR1) mutations associated with malignant hyperthermia susceptibility and central core disease. Mutations found in European and Australian malignant hyperthermia-susceptible/central core disease families are shown at the *top*; mutations found in North American malignant hyperthermia-susceptible/central core disease families are shown at the *bottom* of the diagram. The novel mutations identified in this study are shown in *bold*. The three mutational hot spot areas are *shadowed*. CaM, calmodulin; DHPR, dihydropyridine receptor; FKBP12, FK506 binding protein 12. Sambuughin N, Holley H, Muldoon S, et al. Screening of the entire ryanodine receptor type 1 coding region for sequence variants associated with malignant hyperthermia susceptibility in the north american population. Anesthesiology 2005;102:519, Fig. 3.

pared to MH-negative individuals. Sambuughin et al. reported comparable findings with the Ala2350Thr mutation in a North American family.[72]

In a subsequent study Wehner et al. found a similar reduction in EC_{50} for RYR1 agonists in a family with spontaneous occurrence of the Ile2453Thr mutation.[73] Affected individuals were diagnosed as susceptible to MH and CCD. Collectively these results suggest that mutations in the N-terminal and central regions appear to increase ryanodine receptor agonists binding coupled with an increased release of Ca^{2+}. It is as yet unknown whether all mutations induce similar changes in agonist binding and Ca^{2+} release characteristics.

Phenotype–Genotype Correlation

Phenotype–genotype correlations in MH susceptibility are difficult to study because fulminant MH episodes are now rare as a consequence of early dantrolene intervention in suspected cases, the large number of mutations that have been identified, and the variability of CHCT results among diagnostic laboratories. Nevertheless, phenotype and genotype correlation studies show that different phenotypic expressions exist according to the nature of the mutation. Analysis of series of RyR1 gene mutations associated with MH show good correlation with caffeine threshold and tension values.[74] In North America, contracture responses to halothane appear to provide a better correlation.[75] The RyR1 mutations associated with both MH and CCD (Arg163Cys, Arg2163His, and Arg2435His) exhibit more-severe caffeine and halothane responses than those associated with MH alone.[76] The most severe phenotype is found in RyR1 mutations associated with CCD. The Ile4898Thr mutation in the C-terminal part of RyR1 that was described in a large Mexican family is associated with a CCD phenotype with severe clinical expression.[77]

The widespread practice of the contracture test on both parents of MH-susceptible patients has allowed the identification of a significant number of patients homozygous for the MH susceptibility trait.[49] Surprisingly, these patients differ neither from a symptomatic point of view, nor in their response to the contracture test, from patients heterozygous for the same mutations. Another interesting fact is the number of families in which two different mutations (compound heterozygote) were identified.[78] These two observations suggest that the frequency of mutations affecting the RyR1 gene in the general population is probably underestimated.

Global Distribution of Known RyR1 Mutations

Geographic differences in frequencies for common MH susceptibility mutations are observed across Europe. For example, in the United Kingdom population, the most prevalent mutation is Gly2434Arg, accounting for approximately 40% of mutation-positive MH families investigated; in Germany, the Arg614Cys mutation is the most common; whereas in Switzerland, Val2168Met and Ile2336His are more common. In France, the Gly341Arg and the Arg614Cys are the most common. The Arg614Cys accounts for MH in several families in Italy.

In North America, the most frequent mutation is the Gly2434Arg and the second most frequent is the Arg614Cys, which is similar to the MH-susceptible populations of the United Kingdom and Germany. However, the total number of MH-susceptible patients reported in North America is small compared to the European countries, and the current North American data does not include all ethnic groups. In Japan, the

distribution and frequency of RyR1 mutations in MH-susceptible individuals differs from both the North American and European populations, with many mutations being found outside of the "hot spot" regions.[79]

Evaluation of Malignant Hyperthermia Susceptibility

Because MH is often called a "silent disorder," apparent only after exposure to potent volatile anesthetics and/or succinylcholine, identifying MH-susceptible individuals is difficult and is usually made after an adverse response to anesthesia in the individual or in family members. Most MH episodes present as completely unexpected events, and there is no simple screening test that can predict the onset or severity of an MH episode prior to the administration of the triggering anesthetics. A number of diagnostic procedures have been described in the past, and although some of these tests may be useful under restricted conditions, they have not been successful when applied to a larger population of MH patients. Tests that show some promise for the future include genetic analysis of RyR1 and other candidate genes, measurements of Ca^{2+} flux in B cells, ^{31}P NMR (nuclear magnetic resonance) spectroscopy, and microdialysis of muscle in vivo. Although further development of these tests is necessary, they may lead to a less-invasive test than the CHCT in the future.

Evaluation of MH susceptibility starts with history and physical examination of the patient. The history (personal and family) provides the most useful information, particularly if anesthetic or surgical records of an adverse response to anesthetics are available. This information is crucial in deciding what the appropriate testing is for an individual patient and related family. Patients who do not want to undergo diagnostic testing should be counseled about obtaining, for example, MH bracelets and wallet cards (see Resources below).

Physical examination is generally not very helpful in the preoperative diagnosis of MH susceptibility. Nevertheless, examination of the musculoskeletal system can provide some clues that suggest MH susceptibility but their predictive power is weak. In the past, it was suggested that MH-susceptible patients have a higher incidence of: muscle cramps, increased muscle bulk, hyperextensible joints, strabismus, and scoliosis. However, the documented incidence of such muscle skeletal problems in MH-susceptible individuals appears to be no higher than that in the general population.

Diagnostic Testing for MH: In Vitro Testing

Since the mid-1970s, the standard diagnostic test for MH has been the measurement of contracture response of biopsied skeletal muscle to graded concentrations of caffeine and the anesthetic halothane *in vitro*. This test is referred to as either the CHCT or the IVCT. In Japan, MH testing is performed on human skinned muscle fibers using the calcium-induced calcium release test.[80] Muscle histology and histochemistry are not diagnostic for MH susceptibility.[39] As all diagnostic tests must be performed on fresh tissue, it is necessary that the muscle biopsy and diagnostic testing be performed at a center that does both procedures. There are 6 such centers in North America.

Two standardized tests, the North American CHCT and the IVCT, are widely used to diagnose patients as MH susceptible (MHS), or MH negative (MHN). Both tests are highly sensitive (93–97%), but not highly specific (78–93%),[81,82] and are invasive, requiring a surgical biopsy of leg muscle (*vastus lateralis*). In an effort to improve the specificity of the test, particularly for MH-equivocal (MHE) cases, the European MH Group has investigated adding 4-chloro-*m*-cresol and/or ryanodine to the testing procedure to improve accuracy, but neither of these substances has reached general acceptance by MH diagnostic groups. The response of skeletal muscle to halothane still is considered the most specific test for malignant hyperthermia susceptibility, but it is the least sensitive. Caffeine causes contracture in any skeletal muscle, but a contracture response will occur at a lower dosage in MH-susceptible individuals (Fig. 89–9).

Patients requiring muscle biopsy for diagnostic CHCT can be safely anesthetized with general anesthesia using nontriggering agents (see Box 89–1) or with a femoral nerve block or one of its variants. The muscle bundles obtained during the surgical biopsy are exposed to various pharmacologic agents, such as halothane and caffeine, and the change in muscle tension is measured.[83]

The protocols for the performance of the IVCT and CHCT tests are slightly different. The North American and the European protocols both use incremental caffeine concentrations of 0.5, 1, 1.5, 2, 4, 8, and 32 mM, but it is the response to 2 mM caffeine that is used for evaluation of MH susceptibility in both protocols. In testing with halothane, the North American protocol uses a single bolus dose of 3% halothane, whereas the European protocol uses incremental doses of halothane (0.5%, 1%, 2%, and 3%).[83] Additionally, the testing protocols for MH vary slightly in interpretation of the results. The North American protocol only requires that one muscle strip be positive to either caffeine or halothane for the patient to be called MH susceptible; whereas the European MH Group's protocol requires that muscle samples must be positive to both halothane and caffeine for the patient to be called MHS. For the European MH Group protocol, if a patient is only positive to either caffeine or halothane, they are considered MHE. This classification is not used in the North American protocol.

Indications for Muscle Biopsy and CHCT Testing Listed below are the indications for muscle biopsy and CHCT testing.[83]

- *Definite Indications:*
  - Suspicious clinical history of MH.
  - First-degree relative of an index case with a suspicious history of MH if the index case cannot be tested (e.g., too young, too old, MH death, unwilling to undergo the muscle biopsy, no test center available).
  - Severe masseter muscle rigidity during anesthesia with MH-triggering agents.
  - Military service—The military requires determination of MH susceptibility by contracture testing in persons with a suspicion of MH susceptibility, as individuals with MH susceptibility are not eligible for military service.
- *Possible Indications:*
  - Unexplained rhabdomyolysis during or after surgery.
  - Moderate to mild masseter muscle rigidity with evidence of rhabdomyolysis.

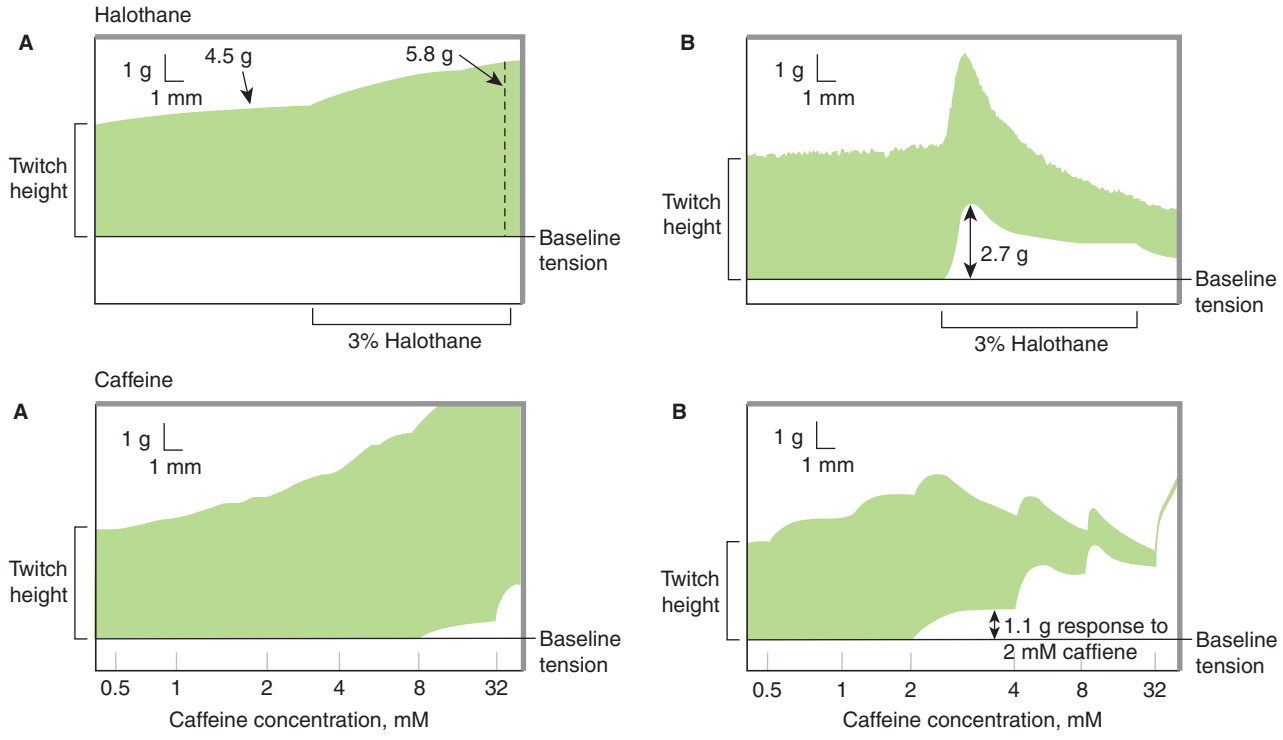

FIGURE 89–9. Halothane response (North American protocol). **A.** Normal halothane response. Halothane potentiates twitch height in all muscle strips similar to caffeine. The twitch height in this strip increases from 4.5–5.8 g of tension. However there is no change in baseline tension in response to 3% halothane. A positive response to 3% halothane is an increase in baseline tension of ≥0.7 g of tension. **B.** Abnormal halothane response. The muscle strip has a 2.7-g increase in baseline tension in response to 3% halothane. Caffeine response (North American protocol). **A.** Normal caffeine response. Caffeine potentiates twitch height in all muscle strips. However, baseline tension remains unaffected until the bath concentration of caffeine is increased to 8 mM (0.6g increase in tension). A caffeine contracture test result is considered positive when the muscle strip exhibits an increase in baseline tension of 0.2g or more in response to a caffeine concentration of 2 mM or less. **B.** Abnormal caffeine response. The muscle strip has a 1.1g increase in baseline tension in response to a caffeine concentration of 2 mM. From: Karan, S, Lojeski E, Muldoon S. Malignant Hyperthermia. In: Tremper K ed. Principles of Anesthetic Techniques and Anesthetic Emergencies. Philadephia: Current Medicine, Inc., 1998;9.10, Fig. 17A,B.

- Severe or recurring exercise-induced rhabdomyolysis.
- *Probably Not Indicated:*
  - Sudden, unexpected cardiac arrest during anesthesia or early postoperative period that is not associated with rhabdomyolysis.
  - Neuroleptic malignant syndrome.

Drawbacks of the CHCT The drawbacks of the CHCT are as follows:

- It is an invasive procedure requiring a surgical biopsy to obtain the muscle specimens.
- The test is not performed on children less than about 40 pounds or 5 years of age.
- The CHCT must be performed within 5 hours of tissue removal. This means the patient has to be at 1 of 6 biopsy center sites in North America.
- The cost of the CHCT is usually $5,000–$6,000 and is only partially covered by insurance.
- Although sensitivity of the CHCT is high, specificity is only 78% and can result in false-positive tests.

Other Tests

Molecular Genetic Testing Molecular genetic analysis has been proposed and incorporated in limited capacity as a diagnostic test for MH, first in Europe and then in North America. In 2002, the North American MH Group developed a consensus on genetic testing in North America along the lines proposed by the European MH Group.[84,85] The MH-susceptible patient or at-risk family members are referred for genetic testing based on CHCT results and clinical assessments. Genetic testing uses a panel of 22 RyR1 mutations that are associated with MH and shown to alter RYR1 channel function in experimental models. If MH susceptibility is diagnosed in a family member or index case by CHCT, then detection of RyR1 mutations becomes valuable for other members of the family, reducing the number of relatives requiring contracture test. However, a muscle biopsy and CHCT is currently recommended for cases in which a familial mutation is not detected because of the genetic heterogeneity of MH and because a negative genetic screen does not yet rule out MH susceptibility.[86] For more information, please contact the Malignant Hyperthermia Association of the United States (MHAUS; see Resources below).

Creatine Kinase Measurement Measurement of resting CK has been considered as a less-invasive test for MH susceptibility. However, CK testing is too insensitive and nonspecific to be recommended. Measurements of serum CK in MH-suspect families is normal or variably elevated, but unrelated to MH diagnosis. An elevated serum CK level in MH susceptible patients in the absence of triggering drugs may suggest the presence of a myopathy.

Nuclear Magnetic Resonance Spectroscopy ^{31}P NMR measures the concentrations of ATP, phosphocreatine,

and other phosphomonoesters, along with pH, both in vivo and noninvasively, in muscle and other tissues. Olgin et al. found that the resting inorganic phosphate to creatine phosphate ratio was increased in unanesthetized, nonexercising, MH-susceptible subjects as compared to control subjects, suggesting a partial cellular deenergization state possibly caused by leaky calcium channels.[87] They also showed delayed recovery of pH, levels of ATP, and of the inorganic phosphate-to-creatine phosphate ratio in MH patients after exercise.[87,88] However, ^{31}P NMR has not translated into a diagnostic tool for MH because changes in high-energy phosphate levels and pH are not specific for MH. Furthermore, the equipment and personnel costs required to establish and maintain a ^{31}P NMR facility are very high compared to existing testing centers.

Two potentially useful diagnostic tests are currently in development. These tests involve microdialysis of in vivo skeletal muscle and measurement of Ca^{2+} levels in human B cells.

Microdialysis of Skeletal Muscle In Vivo Anetseder et al. first described the an application of percutaneous partial pressure of carbon dioxide (PCO_2) probes for the diagnosis of MH susceptibility in dialysates from skeletal muscle in vivo.[89] Results from the European MH center that originally described the technique are promising, but a larger number of patients need to be enrolled, preferably in a multi-center study. Application of muscle microdialysis in vivo in the porcine model of MH reveals distinct differences between MH-susceptible muscle and muscle from normal animals using the lactate–pyruvate system as the end point.[90]

Ca^{2+} in Human B Cells Another approach is the development of intracellular Ca^{2+} assay reflecting RYR1 function using human B lymphocytes. Sei et al. reported that RYR1 is expressed in human lymphocytes (B cells) and initial reports indicated correlation between increased Ca^{2+} responses to caffeine and 4-chloro-*m*-cresol and MH phenotype in a small number of patients.[91] Several other laboratories have independently confirmed Sei's observations and reported that RYR1-mediated intracellular Ca^{2+} release can be used as an end point to distinguish MH susceptible patients from normal controls.[92] Thus, measurements of RYR1-mediated Ca^{2+} release have the potential to diagnose MH susceptibility but require further technical development and diagnostic validation.

Management of Malignant Hyperthermia

Successful treatment of MH relies on prompt recognition of the clinical signs (see Box 89–2), stopping the triggering anesthetics, rapid access to supplies necessary for treatment (Box 89–5), and initiation of appropriate therapeutic measures. This combination can result in a mortality rate near zero. The MH hotline (800–644–9737) is available 24 hours a day and is a valuable resource for all practitioners for the management of suspected MH cases. This section discusses the management of fulminant episodes, patients with a documented history of MH, patients with a questionable history of MH, and MMR. It is assumed that routine noninvasive monitors (i.e., electrocardiography, blood pressure, pulse oximetry, capnography, and electronic temperature monitoring) are in use.

BOX 89–5.

Necessary Supplies for the MH Cart

The MH cart must contain the following supplies:

- Dantrolene, at least 36 vials.
- Sterile water for injection, 3 L (for reconstitution of dantrolene, 60 mL per vial)
- 5–10 syringes (60 mL) and 16-gauge needles to mix the dantrolene
- Lidocaine for bolus and continuous infusion
- Sodium bicarbonate, 10 ampules
- Dextrose 50%, 4 ampules
- Furosemide, 200 mg
- Regular insulin, 100 units/mL × 1 (refrigerated)
- Calcium chloride 10%, two 10-mL vials
- New fresh gas hose, carbon dioxide canister, circuit, ventilator bellows

Plan for rapid access to the following:

- Refrigerated normal saline solution for irrigation
- Ice maker or crushed ice
- Central pressure catheters, transducers, and monitors
- Pulmonary artery catheter
- Blood collection tubes for laboratory processing of samples: blood gas analysis, electrolytes, glucose, and creatine kinase
- Cooling blanket
- Rectal tube and irrigating Foley catheter

Patient with a Fulminant MH Episode

In addition to the measures outlined in Box 89–6, assistance from surgical personnel is a necessity because many of the actions discussed in Box 89–6 should occur simultaneously. Prioritizing tasks is critical in the management

BOX 89–6.

Management of Patient with a Fulminant Episode of Malignant Hyperthermia

I. Discontinue all potent inhalational agents and succinylcholine. Maintain anesthesia with total intravenous nontriggering anesthetics.

II. Increase minute ventilation to lower $ETCO_2$. Administer 100% oxygen.

III. Inform the surgeon to expedite or abort the procedure, if possible, and obtain assistance from MHAUS hotline for acute crisis.

IV. Administer IV dantrolene, 2.5 mg/kg. Be prepared to repeat this dose until the patient responds with a decrease in $ETCO_2$ levels, rigidity, or heart rate.

V. Obtain blood gas analysis to determine if bicarbonate therapy is indicated. Place central or intraarterial catheter for serial measurements.

VI. Begin cooling measures if the patient is hyperthermic. Efforts to cool the patient must correspond with the extent of temperature elevation. Patients can be cooled by decreasing room temperature, surface cooling with ice, or using cold solutions for gastric, bladder, and rectal lavage.

VII. Hyperkalemia is common and is treated with insulin and glucose, 10 units of regular insulin in 1000 mL of $D_{10}W$ (10% aqueous dextrose solution). Serum potassium and glucose levels must be monitored.

VIII. Measure baseline CK and serial CKs every 6 hours until CK plateaus.

of the fulminant MH episode. When anesthesia-trained personnel are unavailable, the professional skills and assistance of the operating room nurse, the operating room technicians, and the surgeon are invaluable. A telephone call to the MH Hotline should be placed. The tasks should be prioritized as outlined in Box 89–6.

The initial dose of dantrolene is 2.5 mg/kg and should be given as an intravenous bolus into a large vein. A decrease in $ETCO_2$ is the first sign that the therapy is effective and is followed by a decrease in heart rate and a reduction in the severity of muscle rigidity. If a decrease in $ETCO_2$ is not seen within minutes, the acid–base status should be monitored and dantrolene administration IV continued until the hypermetabolic state is controlled. 10 mg/kg of dantrolene is recommended on the MHAUS website, but higher doses may be necessary. Heart rate may remain elevated despite a decrease in $ETCO_2$ and temperature; this is usually an indication that more dantrolene may be needed. Continuation of respiratory support is determined on a case-per-case basis. If the patient is ventilated via laryngeal mask airway, conversion to endotracheal intubation should be done. After the episode is controlled, dantrolene should be continued at 1 mg/kg every 4–6 hours, until all signs of hypermetabolic state are resolved. During this time clinical signs and laboratory results should be used to monitor the hypermetabolic state of the patient and to decide whether further dantrolene is necessary. Strict vigilance must be maintained at all times for recrudescence (recurrence of symptoms) of MH signs, which has to be managed with the urgency of a new episode of MH.

Dantrolene is packaged in lyophilized form at 20 mg/vial and is dissolved with 60 mL of sterile water, in which it is relatively insoluble. Sodium hydroxide and 3 g of mannitol are added to the vial to allow the dantrolene to dissolve in 2–3 minutes. The resulting pH of the solution is 9.5, so care must be taken to prevent extravasation and to monitor for thrombophlebitis. Mannitol is an osmotic diuretic and therefore central venous pressure monitoring may be necessary to manage volume status.

Cooling the patient is one of the most important aspects of treatment to decrease core body temperature and thereby lower oxygen consumption. Core cooling is superior to surface cooling and is accomplished by cold gastric and rectal lavage, and cold wound irrigation. Surface cooling can be used effectively if peripheral vasoconstriction is avoided. Ice packs to the groin and axilla can be helpful in lowering core temperature. Decreasing the room temperature or packing the patient in ice may induce shivering and hence increase oxygen consumption which is considered counterproductive. The patient's temperature needs to be continuously monitored to detect hypothermia from overaggressive cooling.

Dysrhythmias result from the by-products of the hypermetabolic state, which include hypoxia, hypercarbia, acidosis, and hyperkalemia in combination with an increased sympathetic tone. Treatment of the primary condition should control the dysrhythmias, but if they persist or become life-threatening, lidocaine, 1–2 mg/kg, should be administered intravenously and repeated as needed. Lidocaine is not a triggering agent and is safe to use in patients with documented MH. If heart rate is unresponsive to the previously described measures, short-acting β-blockers like esmolol should be used instead of calcium channel blockers, which are contraindicated. In both humans and swine, the combination of dantrolene and verapamil resulted in cardiovascular collapse secondary to hyperkalemia.[93,94] The same result has been reported in swine administered dantrolene and diltiazem. Hyperkalemia was not observed when dantrolene and nifedipine were administered, but mild hyperkalemia was noted in 1 case in a human.[93]

The arterial blood gas analysis is the most useful laboratory evaluation to assess the effectiveness of therapy. Capnography does not eliminate the need for arterial blood gas for several reasons. First, rapid ventilation may underestimate the true $ETCO_2$. Second, metabolic acidosis, another marker in assessing the effectiveness of therapy, may still be present even when the $ETCO_2$ has returned to baseline. Furthermore, bicarbonate therapy for the correction of metabolic acidosis cannot be managed effectively without serial arterial blood gas analysis. Empiric bicarbonate therapy risks severe alkalosis and has the potential to exacerbate the intracellular acidosis. Finally, the arterial blood gas assesses the adequacy of oxygen delivery more precisely than pulse oximetry. If central venous access is present, mixed venous oxygen measurements provide additional information to calculate oxygen consumption.

Electrolyte abnormalities include gradual changes in serum potassium, calcium, and glucose; therefore, serial measurements are required. Hyperkalemia is generally considered to result from acidosis that shifts K^+ ions out of the cell in exchange for H^+ ions combined with the leakage of K^+ out of the damaged muscle cells. The most effective therapy for hyperkalemia is treatment of the underlying MH with the muscle SR calcium release inhibitor, dantrolene. If hyperkalemia persists or results in cardiac dysrhythmias, intravenous glucose and insulin (10 units regular insulin in 1000 mL $D_{10}W$), and bicarbonate should be administered slowly. Potassium-binding agents may be useful after cold gastric or rectal lavage has been completed. Calcium therapy is reserved for life-threatening dysrhythmias or inotropic support. Variations in serum calcium levels are reflected on the electrocardiogram (ECG) as a shortening or prolongation of the QT interval. Hypocalcemia is more common and is treated with incremental doses of calcium. Sodium values can be increased as a result of the large sodium load contained in mannitol or decreased because of a dilutional effect from fluid therapy. The risk of hypo- or hyperglycemia increases if insulin and glucose therapy are used to treat hyperkalemia.

Laboratory evaluations should include CK, myoglobin, and coagulation studies, and in cases resistant to therapy, catecholamine levels and thyroid function tests. Serum CK and myoglobin should be followed every 6 hours until the CK reaches a plateau and the myoglobin has been cleared from the urine. CK values may rise to very high levels (>100,000 IU/L or much more). The elevated CK indicates the at-risk period for myoglobinuric renal failure and the need for renal protective measures; it may also signify an increased risk of compartment syndrome and renal failure if the values do not return to baseline within 24 hours. Disseminated intravascular coagulation is not uncommon following a fulminant episode of MH. Factors contributing to disseminated intravascular coagulation include hemolysis, cellular edema with increased release of tissue thromboplastins, and inadequate tissue perfusion. A high level of suspicion com-

bined with serial laboratory evaluation of the coagulation system aids in this diagnosis. There are no special considerations for treating disseminated intravascular coagulation in this setting. If the clinical situation appears to be MH but the patient continues to only partially respond to appropriate therapy, continue current therapy but consider other processes (see Box 89–4). Collecting blood for catecholamine assays and thyroid function (T_4) tests may help to identify thyroid storm or a pheochromocytoma, which may mimic MH. When the episode has been reversed and the patient's status has stabilized, arrangements should be made for ICU care for at least 24 to 48 hours. The major areas of concern include recrudescence of the initial episode, renal protection therapy to prevent myoglobinuric renal failure, the occurrence of disseminated intravascular coagulation, compartment syndrome, delayed awakening possibly related to cerebral edema, and the patient's underlying medical condition that warranted surgical intervention.

Patient with a Documented History of MH

The goal for patients with histories of documented MH susceptibility (positive CHCT or strong evidence of a clinical episode; i.e., a copy of anesthesia records or a letter from the physician who diagnosed and treated the case) is preparation and administration of a safe anesthetic (Box 89–7). Regardless of the surgical procedure or anesthetic technique, additional time is required to prepare the anesthesia machine, check the monitors, and inspect the MH cart. Some departments maintain an anesthesia machine without vaporizers for use only with MH patients. This practice is unnecessary because of the ease of preparing an uncontaminated machine. Although it is impossible to define a background level of inhalation agent that may trigger an MH episode, a practical goal can be defined by adopting the National Institute of Occupational Safety and Health standard for waste gas exposure. The National Institute of Occupational Safety and Health standard is 2 ppm concentration of a halogenated agent and is an acceptable level as this concentration may be present in the operating room or recovery room. It is known from the MH-susceptible swine model that 2 ppm is several-fold lower than the threshold concentration required to trigger an MH crisis.[95] The MH cart should be inspected to ensure that the medications, especially dantrolene, are not past their expiration date.

The North American MH Group recommends scheduling the surgical procedure as the first case of the day to allow time for preparation and to avoid contamination of the operating room by waste anesthetic gases. Extended observation in the recovery room is arranged and the ICU is alerted in anticipation of any signs of an MH episode. Extended postoperative monitoring is required to ensure that late development of MH is diagnosed and treated promptly.

Outpatient surgery is acceptable if the patient can be observed in the recovery room for 4–6 hours and intensive care support is available as needed.

Whether dantrolene should be administered preoperatively is debatable. The infrastructure and the operating support services are major factors in making this decision. Arguments in favor of pretreatment with dantrolene are based on preventing MH through prophylactic measures and in preventing stress-induced MH. If a hospital is in a remote area of the country, or has limited staff and resources, it can be argued that preoperative administration of dantrolene is warranted. Likewise, if the patient is very anxious, pretreatment should be considered. If the surgery is to be performed at a fully equipped surgical facility with additional staff available, pretreatment in most cases is not indicated. Other arguments for not pretreating with dantrolene include depleting a limited supply of the drug and avoiding the risk of morbidity from the drug (muscle weakness that may require ventilatory support). If the patient is given dantrolene in a therapeutic dose, admission to hospital for 24 hours will be required as the patient will have muscular weakness.

If pretreatment is chosen, an intravenous dose of 2.5 mg/kg just before the start of the anesthetic is recommended to achieve therapeutic serum levels. A Foley catheter is also required because of the osmotic diureses

BOX 89–7.

Anesthetic Management of Patient with a Documented History of MH

I. Equipment
- A. A "clean" anesthesia machine should be prepared by removing or sealing the vaporizers, replacing the first gas hose, and using a new disposable circuit. Next, flush the machine with a fresh gas flow of 10 L/min for 5 minutes. Prepare the anesthetic machine even if a regional technique or monitored anesthesia care is planned in case of failed technique or emergency.
- B. Capnography with real-time display, electrocardiogram, blood pressure, and electronic temperature monitoring are required.
- C. MH cart must be checked to make sure medications are current.

II. Scheduling
- A. First case of the day.
- B. Observation in the recovery room for 4–6 hours.
- C. Outpatient surgery is acceptable if the patient can be observed in the recovery room for 4–6 hours and intensive care support is readily available.

III. Premedication
- A. Dantrolene prophylaxis is not routinely recommended.
- B. Check availability of dantrolene in pharmacy.
- C. Sedation is at the discretion of the anesthesiologist.

IV. Technique
- A. Monitored anesthesia care.
- B. Regional anesthesia (peripheral or neuroaxial).
- C. Nontriggering agents for a general anesthesia.

V. Postoperative course
- A. Monitoring: respiratory rate, blood pressure, heart rate, and temperature.
- B. Laboratory: if clinical course remains uneventful, tests are not necessary.
- C. Healthcare providers in the recovery room should be alerted to the patient's MH status.

caused by the mannitol included in the dantrolene formulation. Oral dantrolene is not recommended because of the variable time required to obtain therapeutic plasma levels. Pretreatment with dantrolene does not eliminate the need for a nontriggering anesthetic technique.

Anxiety and stress have been implicated in predisposing a patient to MH.[249] Preoperative sedation is beneficial and can be accomplished by administering appropriate doses of narcotics, benzodiazepines, barbiturates, or antihistamines.

The anesthetic technique depends on the patient, surgical procedure, and anesthesiologist, and may include monitored care, regional anesthesia, or use of a nontriggering total intravenous anesthetic technique for general anesthesia. Administration of a nontriggering anesthetic may be routine in some centers, but it is not always easily applied as highlighted in the following two case histories:

1. A 4-year-old girl with history of MH and severe asthma for bilateral myringotomy tube placement.
2. A 3-year-old boy with acute epiglottis requiring intubation, who has a cousin with a documented history of MH.

In the first case, the usual anesthetic of an inhalation induction with no IV placement is unacceptable. Nitrous oxide and oxygen alone does not provide sufficient analgesia. Intramuscular or intravenous ketamine can be used in combination with nitrous oxide; however, the sympathetic response to ketamine may make interpretation of tachycardia difficult in a situation when capnography may not be reliable (child who is not intubated). Continuous intravenous anesthesia can be maintained with propofol, but requires intravenous access before induction.

The second case contrasts two possibly fatal complications: loss of an airway and a fulminant MH episode. The possibility exists that the patient may not be MH susceptible. In this situation, securing the airway takes precedence and intravenous access must be established for induction with intravenous nontriggering anesthesia. Pretreatment with dantrolene is not recommended because of the possibility of muscle weakness severe enough to precipitate respiratory arrest. After the patient has been intubated, the clinical situation may dictate the use of dantrolene.

No special precautions are necessary for MH-susceptible obstetric patients. The stress of labor has not been shown to predispose patients to MH episodes, and MH susceptibility is not a contraindication for epidural or spinal anesthesia. We do not recommend pretreatment of obstetric patients with dantrolene for emergency cesarean section. However, if an episode is triggered during the anesthetic, dantrolene should be administered immediately. To date, dantrolene appears to have little or no adverse effect on the fetus or newborn.[96]

In the postoperative period, the patient with a documented history of MH should be monitored for signs of MH for at least 4–6 hours. To ensure early detection of postoperative MH, recovery room/ICU staff must be alerted and educated regarding MH. If the procedure was uneventful, no special laboratory analysis is indicated. If dantrolene was given prophylactically, but no signs of MH occurred, it need not be continued.

Patient with a Questionable History of MH

When MH susceptibility is suspected, patients must be treated as though they have MH (see Box 89–7) until either a chart review or a negative contracture test proves otherwise. Elective surgery can proceed as scheduled (follow the guidelines in Box 89–8) without the results of contracture test; however, if CHCT is required it can be scheduled at a MH diagnostic center. Although the goal is to avoid unnecessary or indiscriminate labeling of patients as MH susceptible, all family members must wear an MH identification tag (see Resources below for how to obtain a tag) stating that they are MH susceptible while the review is in progress. When suspicion of MH susceptibility exists in a family member of a patient, the patient should not be given triggering agents.

The North American MH Registry has been established to collect and disseminate information regarding MH and the families involved. The chart review is eliminated if the patient or family member in question has been evaluated and entered into the registry by one of the MH diagnostic centers. If the patient is not registered, a chart review of the initial episode is necessary to rule out alternative explanations for the episode (see Box 89–4). If the diagnosis is still in question, contact the nearest MH diagnostic center available for consultation (see Resources below). Even if the diagnosis is inconsistent with MH susceptibility, provide documentation and counseling to the family regarding the findings; this helps to eliminate confusion for the family and their future healthcare providers.

BOX 89–8.

Patient with a Questionable History of MH

I. Treat the patient as MH susceptible.
II. Elective surgery may proceed as scheduled if provisions for the patient with documented MH are met (see Box 89–7). However, if the workup indicates a need for diagnostic contracture testing, a second anesthetic must be administered.
III. Identify susceptible family members and provide information for entry into the MedicAlert system and MHAUS. If the diagnosis is found to be negative, the MedicAlert tags can be removed.
IV. Verify the diagnosis to rule out mislabeled patients
  A. If a patient or family member in question has been registered, calling the North American MH Registry (888–274–7899) can confirm the history and workup.
  B. Obtain and review records of the event in question
  C. If the diagnosis is still unclear, consult with the nearest MH diagnostic center, which is available through MHAUS (607–674–7901).
V. Provide documentation and counseling for the patient and affected relatives.

Patients with Masseter Muscle Rigidity

Management of a patient with MMR depends on the degree of rigidity (Box 89–9). If a patient develops moderate or severe MMR, surgery should be aborted if it is elective and nonemergency, and the patient should be promptly awakened and closely monitored for other signs of MH. Urine should be tested for myoglobinuria.

BOX 89–9.

Patient with Masseter Muscle Rigidity

When masseter muscle rigidity is diagnosed
Discontinue any potent inhalation agent.
Continue to ventilate by mask with 100% oxygen.
Do not give a second dose of succinylcholine.
Call for assistance and the MH cart.
Continue to monitor $ETCO_2$, minute ventilation, electrocardiogram, blood pressure, and core temperature.
Obtain blood gas and electrolyte analysis if the situation does not rapidly improve.
Is the patient stable?*

Yes	No
In elective surgery, cancel the procedure and observe the patient in the operating room until awake.	In elective surgery, cancel the procedure and treat as fulminant MH.
In emergency surgery, convert to a nontriggering technique and observe for changes in the patient's condition over 15–20 minutes; then proceed with surgery	In emergency surgery, treat as fulminant MH and proceed with surgery using nontriggering anesthetics after the patient is stable.

Postprocedure management
A. Institute ICU/overnight recovery room observation for 24 hours to monitor urine output and signs of increased metabolism (increased heart rate, blood pressure, respiration, acidosis, and temperature).
B. Obtain serial CK measurements every 6 hours for 24 hours or until the CK has plateaued.
C. Test urine for the presence of myoglobin:
1. If positive, maintain alkaline urine output at 1–2 mL/kg/h until clear.
2. If negative, continue to monitor until CK has plateaued.

*If the airway is secure, minute ventilation less than 1.5 times expected produces normal carbon dioxide and circulatory parameters, and core temperature is normal or slightly low, then patient is stable.

Serum CK should be measured at the time and at 6-hour intervals over the next 24 hours. If there is no evidence of myoglobinuria and if the increases in CK are modest, many centers allow the patient to be discharged that day. Surgery may be rescheduled when CK has returned to normal. In light of more recent data, if $ETCO_2$, arterial blood gases, blood pressure, pulse rate, temperature, serum CK, urine color, and muscle tone are monitored and these signs remain stable, then the procedure may be continued. Nontriggering anesthetic agents should be administered.

If the case is an emergency, the surgeon should be informed and the decision should be made to expedite the surgical procedures. All potential triggering agents should be discontinued and replaced by nontriggering agents (propofol, barbiturate/opiates, nitrous oxide, and nondepolarizing muscle relaxants). $ETCO_2$, arterial blood gases, and core temperature should be monitored continuously. Dantrolene should be available in the operating room. Some advocate administering dantrolene prophylactically, but we advise clinicians to wait for some definite signs of MH. Previously it was thought that a positive CHCT should be obtained if perioperative serum CK values exceeded 20,000 IU. More recently, Kaplan et al. found that CK elevations following MMR were not predictive of contracture test outcomes.[97]

THERMOREGULATION AND PERIOPERATIVE HYPOTHERMIA[a]

Hypothermia is a common perioperative occurrence and results in a number of clinical consequences ranging in significance from mild to serious (Table 89–4).[98] With normal body temperature being 98.6°F (37°C), and taking into account a 1.8°F (1°C) diurnal variation and 0.9°F (0.5°C) variation depending on the menstrual cycle, hypothermia can be defined when the core temperature is less than 96.8°F (36°C).[99] As with other mammals, humans require a nearly constant internal body temperature to maintain optimal function. Significant deviation in this internal temperature can result in alterations in numerous metabolic and physiologic functions that, if not reversed, may lead to significant morbidity and eventually, mortality. The human body has evolved a sophisticated thermoregulatory control system by which to maintain core temperature (usually within 0.4°F [0.2°C] of its ideal target temperature). Anesthetics profoundly affect these control mechanisms, and when coupled by adverse environmental conditions (such as a cool operating room) and other heat-losing perioperative events, the risk of developing hypothermia easily becomes apparent. An understanding of both normal and anesthetic-modulated thermoregulation is essential for the prevention and management of perioperative hypothermia.

Normal Thermoregulation

The body produces heat as a direct result of its metabolic activities. The major organs, in particular, the brain, generate the greatest proportion of this heat. In addition, muscle can significantly contribute to this, but usually only during relatively brief periods of intense use.[100,101] Thermal energy within the body is distributed between central (core) and peripheral compartments. The core compartment consists of the trunk (including the major organs) and the head. The skin (including superficial tissues of the trunk) as well as the arms and legs represent the peripheral compartment.[102] Temperature in this peripheral compartment is usually 3.6–7.2°F (2–4°C) lower than the core—a gradient that becomes highly relevant when anesthesia is induced and vasodilatation occurs.[100,102]

Just as defining terms for what comprise normothermia and hypothermia is important, choosing an appropriate site for monitoring is equally important. Wide discrepancies exist between different body sites and for different operative situations.[103,104] The skin temperature monitoring site is considered a peripheral temperature and correlates poorly to core temperature.[105] *Core temperature*, a term widely used by anesthesiologists, is somewhat nebulously defined but is generally accepted

[a] "Thermoregulation and Perioperative Hypothermia" was written by Dr. Hilary P. Grocott and Dr. Christopher Sulzer.

TABLE 89–4.

Major Consequences of Mild Perioperative Hypothermia in Humans[a]

Consequence	Reference	N	ΔT_{core} (°F/°C)	Value in Normothermic Patients	Value in Hypothermic Patients	P value
Surgical-wound infection	Kurz et al.[185]	200	35.2/1.9	6%	19%	<0.01
Duration of hospitalization	Kurz et al.[185]	200	35.2/1.9	12.1 ± 44 days	14.7 ± 6.5 days	<0.01
Intraoperative blood loss	Schmied et al.[178]	60	34.9/1.6	1.7 ± 0.3 L	2.2 ± 0.5 L	<0.001
Allogenic transfusion requirement	Schmied et al.[178]	60	34.9/1.6	1 unit	8 units	<0.05
Morbid cardiac events	Frank et al.[241]	300	34.3/1.3	1%	6%	<0.05
Postoperative ventricular tachycardia	Frank et al.[241]	300	34.3/1.3	2%	8%	<0.05
Urinary excretion of nitrogen	Carli et al.[192]	12	34.7/1.5	982 mmol/d	1,798 mmol/d	<0.05
Duration of action of vecuronium	Heier et al.[193]	20	35.6/2.0	28 ± 4 min	62 ± 8	<0.001
Duration of action of atracurium	Leslie et al.[242]	6	37.4/3.0	44 ± 4 min	68 ± 7 min	<0.05
Postoperative shivering	Just et al.[121]	14	36.1/2.3	141 ± 9 mL × min^{-1} × m^2	258 ± 60 mL × min^{-1} × m^2	<0.001
Duration of postanesthesia recovery	Lenhardt et al.[197]	150	35.2/1.9	53 ± 36	94 ± 65	<0.001
Plasma (norepinephrine)	Frank et al.[243]	74	34.7/1.5	330 ± 30 pg/mL	480 ± 70 pg/mL	<0.05
Thermal discomfort (VAS)	Kurz et al.[244]	74	36.7/2.6	50 ± 10 mm	18 ± 9 mm	<0.001

N, total number of subjects; ΔT_{core}, difference in core temperature between the treatment groups; VAS, a 100-mm-long visual analog scale (0 mm = intense cold, 100 mm = intense heat).

[a]Only prospective, randomized human trials are included; subjective responses were evaluated by observers blinded to treatment group and core temperature. Different outcomes of the first three studies are shown on separate lines.

to reflect mean temperature of the well-perfused organs (i.e., brain, heart, kidney, and lungs). Good measurement sites of core temperature include tympanic, nasopharyngeal, esophageal, and bladder sites.

Like many other physiologic systems, the thermoregulatory system has at least three major components: (a) sensory receptors (an afferent limb); (b) a central integrator or controller; and (c) an effector organ systems (an efferent limb). The sensory receptors provide information from thermosensitive sites in the skin and other body structures (spinal cord and viscera) to a central controller that then integrates this information and compares it with a standard reference or setpoint (Fig. 89–10).[99,106] The skin, deep tissues (viscera), spinal cord, hypothalamus, and other brain structures each contribute approximately 20% of the input to the autonomic thermoregulatory control center. On the basis of the difference between the afferent input and the target setpoint, the controller provides information to effector systems that then initiate changes to regulate heat production or loss. There is general agreement that the anterior hypothalamus is the central controller for body temperature, comparing the afferent input with the central setpoint, and instituting an appropriate autonomic neural response. Investigations by neuroanatomists and neurophysiologists have greatly increased understanding of how the three components of the thermoregulatory system function to maintain a thermal balance; details concerning these experimental studies are the subject of numerous books and review articles.[99,102,107–112]

An important concept to consider in the control of temperature is the interthreshold range. This is defined as the range between which thermoregulatory responses to cold versus those for warmth are activated. That is, if body temperature is in this range, no autonomic thermoregulatory defenses are triggered. In the normal adult, this range is typically 0.4°F (0.2°C) but may be wider in the elderly.[106,113] In premature infants, central thermoregulatory control appears to be intact, but it is evidenced in the elderly. Anesthesia significantly widens the interthreshold range to as much as 7.2°F (4°C).[114–117] With a range this wide, it is easy to understand how, during anesthesia body temperature is influenced by the environment and trends toward equilibrating with ambient temperature, thus defining the anesthetized patient as poikilothermic.

Normal Thermoregulatory Efferent Responses

In normal unanesthetized humans, behavioral regulation (dressing appropriately and/or modifying environmental temperature) is one of the most important mechanisms contributing to heat regulation. After this behavioral adjustment is made, humans further regulate heat exchange with their environment by balancing several thermoregulatory effects: (a) cutaneous vasomotor tone adjustments (vasodilatation, vasoconstriction); (b) sweating; (c) shivering; and (d) nonshivering thermogenesis.

In hypothermic situations where the hypothalamus activates heat conservation and production mechanisms, ther-

moregulatory vasoconstriction occurs via the activation of arteriovenous shunts in the periphery.[118] This is usually the first and most consistent thermoregulatory response to hypothermia. In doing so, cutaneous vasoconstriction raises thermal insulation provided by the skin and can decrease entire body heat loss by 25–50%.[119,120] If heat loss continues and core temperature continues to fall, shivering, with its metabolically driven increases in heat production, is initiated.

The shivering response is the primary mechanism for increased heat production when hypothermic conditions persist despite the usual vasomotor constriction and is dependent on central neuronal coordination and normal neuromuscular function. Shivering is initiated only after the failure of maximal vasoconstriction, nonshivering thermogenesis (in neonates), and behavioral adjustments have proven to be inadequate to maintain target body temperature (see Fig. 89–10). Shivering is an energy-inefficient means of heat production and can cause a 2–3-fold increase in whole-body oxygen consumption.[121]

Intermediate between the vasoconstrictive shivering efferent responses to cold is nonshivering thermogenesis. This response, occurring in both normal and premature infants, increases metabolic heat production without inducing any mechanical work.[122] Brown adipose tissue is an important site of nonshivering heat production in the neonate. The brown fat is rich in mitochondria (which gives it its brownish macroscopic hue) and is distributed over the neck, back, viscera, and great vessels. The metabolism of brown fat is initiated by β_3-adrenergic effects on terminal nerves within it.[123] Although the exact mechanism of heat production is not clearly understood, it is thought that it is either related to an uncoupling of oxidative phosphorylation within the mitochondria in the presence of fatty acids or results from lipolysis–lipogenesis coupled with ATP use.[99] It is generally agreed that nonshivering thermogenesis does not occur in adult humans.[124]

Under static conditions, heat produced by the body's metabolism must eventually be dissipated to the environment. Close to 95% of this heat traverses the skin with the remainder occurring via the respiratory track. As a result, factors the module heat loss must involve the skin itself (either directly via sweating or indirectly via modifying cutaneous blood flow). Sweating is the most effective method of heat loss. Evaporation of sweat is an energy absorbing process. In a dry environment, it alone can more than dissipate the heat generated at basal levels and more. Benzinger reported that an increase in temperature of 0.9°F (0.5°C) produces a 7-fold increase in sweat rate and body conductivity.[107,125,126] Sweating is mediated by cholinergic sympathetic fibers and can be nearly abolished by even small doses of atropine; something to consider in the perioperative state. Vasodilatation is important for the transfer of heat from the core to the periphery. Sweating and vasodilatory responses work synchronously to counter any increases in core temperature, with vasodilatation increasing cutaneous blood flow and heat delivery for the sweating mechanism.[127]

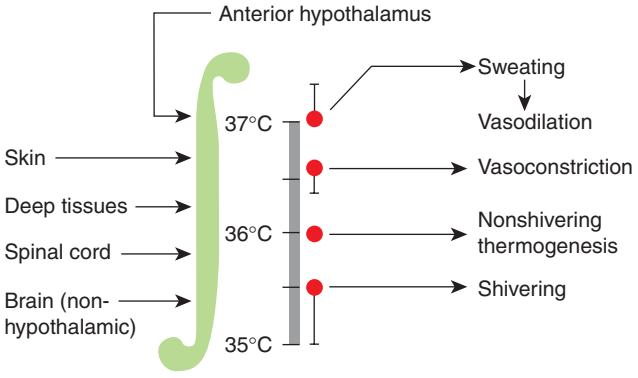

FIGURE 89–10. Hypothalamic thermoregulatory control. The hypothalamus, the primary thermoregulatory control center, is displayed as a *large square*. The skin, deep visceral thoracic tissue, spinal cord, and nonhypothalamic brain areas each contribute approximately 20% of the input that is integrated by the hypothalamus in the control of autonomic thermoregulatory defenses (this input is shown entering the hypothalamus from the left of the figure). The temperature of the hypothalamus itself also contributes 20% of the efferent information used in thermoregulatory control. The hypothalamus integrates body temperature comparing it with threshold temperatures that then trigger specific thermoregulatory responses. Values higher than the threshold for responses to warmth (i.e., sweating) or lower than the threshold for responses to cold (i.e., vasoconstriction and shivering) initiate the appropriate defense. Values between the thresholds for sweating and vasoconstriction lie in the interthreshold range (defined as the range of temperatures that do not trigger any thermoregulatory defenses, which is normally 0.4°F [0.2°C]). The thresholds for sweating, vasoconstriction, and shivering are from Lopez et al.[106] and are shown as means ± standard deviation (SD). The threshold for nonshivering thermogenesis is an estimated value.

General Anesthesia and Thermoregulation

It has long been known that anesthetized patients become hypothermic, with numerous studies documenting its incidence and severity.[128–131] Hypothermia that develops during general anesthesia typically follows a predictable pattern. Following an initial rapid decrease in core temperature (0.9–2.7°F [0.5–1.5°C]) during the first hour after anesthesia induction, a more gradual linear decline in core temperature occurs, usually lasting 2–3 hours. A plateau occurs when heat loss and production equilibrate, usually after 3–4 hours.[130,132] Figure 89–11 describes this pattern.

The rapid temperature decline is believed to be the result of internal redistribution of heat.[133] The linear second phase of the hypothermia curve is characterized by cutaneous heat loss exceeding metabolic heat production (typically 0.9–2.7°F [0.5–1.5°C]/h; Fig. 89–12).[134] Radiation results in 60% of the heat loss, with the remaining loss occurring by convection and evaporation, with negligible losses from conduction (Fig. 89–13). Most of the heat is lost via the skin, with radiation and convection resulting in the majority of the loss, far greater than evaporation on conductive losses.[99]

In unanesthetized patients, tonic thermoregulatory vasoconstriction maintains a significant core to peripheral temperature gradient. Induction of general anesthesia causes vasodilatation, which results in redistribution of heat from the core to the periphery. The result is a markedly decreased core temperature, but mean body temperature

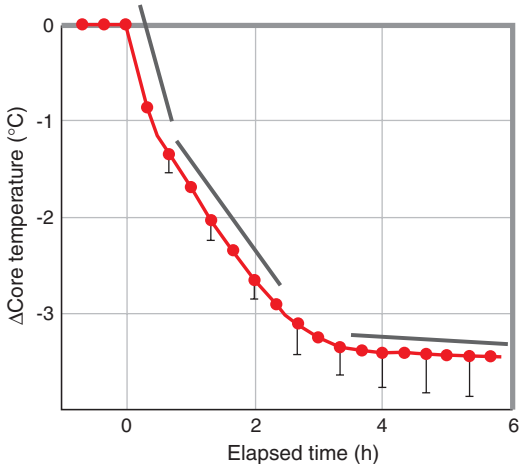

FIGURE 89–11. Typical pattern of hypothermia during general anesthesia. Hypothermia during anesthesia follows a predictable pattern. During the first hour, core temperature usually decreases rapidly by about 1.8–2.7°F (1–1.5°C). This is followed by a slower, nearly linear decrease in core temperature. Eventually, core temperature reaches a plateau. Each phase of hypothermia development has a different cause.

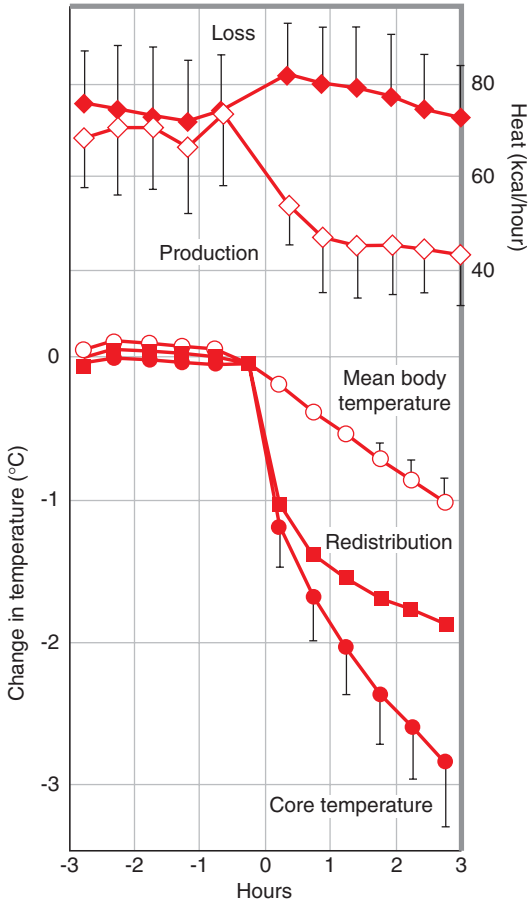

FIGURE 89–12. Changes in heat content and heat distribution in the body before and after the induction of general anesthesia. Hour zero denotes the induction of anesthesia in normal volunteers exposed to a typical operating room environment. The change in mean body temperature has been subtracted from the change in core temperature (tympanic membrane); the remainder represents the amount of core hypothermia specifically resulting from the redistribution of heat from the core to the periphery. Therefore, redistribution hypothermia is not a directly measured but instead is represented by the portion of the decrease in core temperature not attributable to the relatively small decrease in systemic heat content. After 1 hour of anesthesia, the core temperature had decreased by 2.9 ± 0.5°F (1.6 ± 0.3°C), with redistribution accounting for 81% of the decrease. Even after 3 hours of anesthesia, redistribution accounted for 65% of the entire decrease (5 ± 0.9°F [2.8 ± 0.5°C]) in core temperature.

and heat content remain unchanged (Fig. 89–14).[133] Although internal redistribution of heat is the major reason core body temperature decreases shortly after the induction of general anesthesia, several other factors also affect the patient's thermoregulatory balance. These factors include (a) decreased metabolic heat production under general anesthesia; (b) heat loss from the patient to the environment; and (c) the effects of anesthetic agents on thermoregulatory thresholds. Induction of anesthesia deceases metabolic heat production by approximately 20% by limiting muscular activity, reducing the metabolic rate, and diminishing the work of breathing.[135,136] Evaporation of surgical skin preparation solutions,[137] anesthetic-induced vasodilatation and impairment of central thermoregulatory control,[133,138] and cold operating room temperatures all increase cutaneous heat loss, although not enough to be the major cause of hypothermia during surgery.

Behavioral regulation is not relevant during general anesthesia, and shivering is frequently prevented because of muscle relaxants. Therefore, vasoconstriction is the major thermoregulatory response available to anesthetized, paralyzed, hypothermic adult patients. However, this response is profoundly affected by anesthetics. Clinically relevant doses of general anesthetics decrease the activation threshold (the temperature triggering a response) for hypothermia by 3.6–7.2°F (2–4°C).[130,138,139] Interestingly, activation thresholds for responses to hyperthermia are also affected, but to a lesser degree than those for hypothermia.[100] The result is an increase in the interthreshold range with core temperature changes passively determined by redistribution of heat within the body combined with environmental heat loss.

The exact central temperature that triggers thermoregulatory vasoconstriction is both anesthetic agent and dose dependent and may vary depending on the age of the patient and the intensity of surgical stimulation. Patients who become sufficiently hypothermic during surgery eventually reach the vasoconstriction threshold and trigger the response. Once triggered, the gain and maximum intensity of the thermoregulatory response remains near normal.[140–142] Markedly altered thermoregulatory thresholds with preserved gain and maximal intensities characterize the effect of gen-

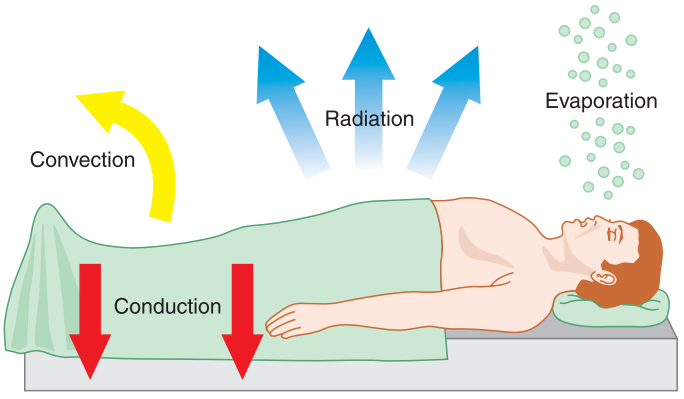

FIGURE 89–13. Mechanisms of heat loss. The linear second phase of the perioperative hypothermia curve results from heat loss exceeding metabolic heat production (approximately 1 kcal·kg^{-1}·h^{-1}). During anesthesia heat loss is usually greater, with losses caused principally by radiation accounting for roughly 60% of the total. The remaining loss is largely convective, with respiratory evaporative loss contributing only approximately 10% of the total. Cutaneous evaporative loss is relatively small except during sweating, although evaporative loss from the surgical incisions can be substantial. Conductive loss is negligible during anesthesia.

eral anesthetics on the thermoregulatory system.[143]

Regional Anesthesia and Thermoregulation

Regional anesthesia (in the form of spinal and epidural anesthesia) impairs thermoregulation via inhibition of both thermal afferents and efferents. As the usual thermoregulatory efferent responses are neuronally mediated, it is no surprise that central neuroaxial blockade would interfere with these responses (sweating, vasoconstriction, and shivering). Compounding these efferent abnormalities, blockade of thermoregulatory afferents results in the hypothalamic control centers incorrectly interpreting peripheral temperature to be normal (or high).[144,145] This explains development of the warming sensation that patients report with the injection of neuroaxial local anesthetics.[146] Regional anesthesia affects the interthreshold range increasing it by 3–4 times its normal value. With the impairment in thermoregulatory efferents, the warm sensation reported by patients, and the general lack of temperature monitoring in the awake patient, hypothermia is common and frequently not detected in the patient who is undergoing regional anesthesia.

Traditionally, hypothermia during regional anesthesia was believed to primarily result from increased heat loss to the environment secondary to sympathetic blockade-induced vasodilatation. However, Hynson et a1.[147] investigated the importance of different etiologic factors in causing hypothermia during epidural blockade. In healthy, nonpregnant, normal volunteers, core and skin temperature, heat loss, and O_2 consumption were measured before and after epidural blockade to an approximate T_4 level was induced. They found that during epidural anesthesia, skin temperature increased, core temperature decreased, and heat loss to the environment increased only slightly. Most subjects shivered during the epidural block, so heat production actually increased somewhat during the study. These data suggest that heat loss to the environment cannot account for the fall in core temperature seen during regional anesthesia. Indeed, the authors concluded that redistribution of heat within the body is the primary factor responsible for the development of central hypothermia during epidural blockade. A subsequent study by Glosten et al. confirmed this hypothesis.[148]

In summary, during regional anesthesia hypothermia occurs because (a) regional anesthetics depress regional thermal afferent input and efferent responses, such as vasoconstriction and shivering; (b) patients lose some heat to the operating room environment; but most importantly, (c) redistribution of heat within the body occurs.[149,150] Interestingly, rewarming from hypothermia can be accelerated in the patient with residual spinal anesthesia (if using active heating modalities) because of the relatively vasodilated state of the patient (Fig. 89–15).[151]

Hypothermia during regional anesthesia is often accompanied by tremor. The incidence of this shivering during regional anesthesia has been reported in up to 70% of patients.[152] There is some variability in clinical studies that demonstrate a consistent relationship between core temperature and shivering during major regional anesthesia, raising the question of whether this response is thermoregulatory or of some other etiology. As a result, shivering that occurs with regional anesthesia should be prevented if normothermia is maintained, although this is not always the case.[153] Cutaneous warming of patients for 2 hours prior to inducing epidural anesthesia can help in preventing hypo-

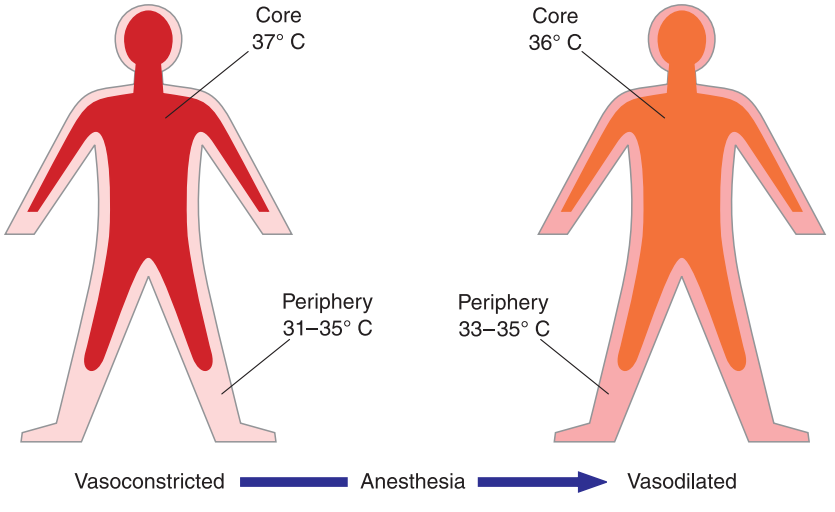

FIGURE 89–14. Cartoon showing redistribution hypothermia after induction of general anesthesia. Tonic thermoregulatory vasoconstriction usually maintains a core-to-peripheral temperature gradient. With the induction of general anesthesia, this vasoconstriction is inhibited, allowing a core-to-peripheral redistribution of body heat.

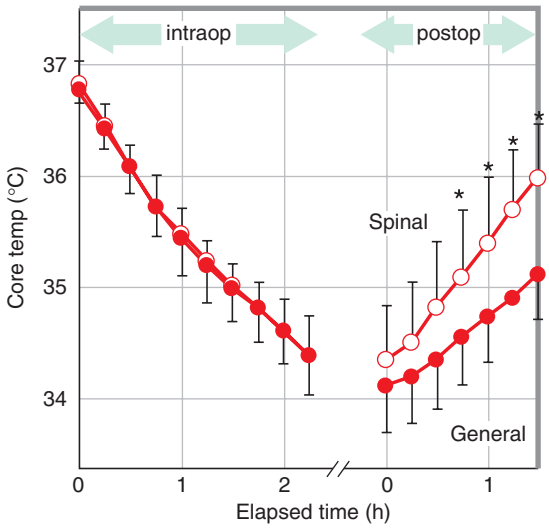

FIGURE 89–15. Residual spinal anesthesia can increase postoperative core rewarming as demonstrated in this study of intraoperative and postoperative core temperatures in patients assigned to general anesthesia (n = 20) and spinal anesthesia (n = 20). All patients were actively warmed during the postoperative period. Core temperature did not differ significantly during surgery but increased significantly faster postoperatively in patients given spinal anesthesia: 2.2 ± 0.2°F (1.2 ± 0.1°C)/h versus 1.3 ± 0.4°F (0.7 ± 0.2°C)/h . Data are presented as mean ± standard deviation (SD).

thermia and prevents shivering.[148] Pharmacologic treatment used to treat shivering in patients recovering from general anesthesia can also be used in regional anesthesia patients.

The tremor seen in pregnant patients who are undergoing regional anesthesia may have a different etiology. A number of studies show an increased incidence of shivering in pregnant patients when cold solution is injected epidurally.[154,155] This response is not seen in nonpregnant volunteers or patients, suggesting that thermosensitive tissue within the spinal canal contributes to the shivering observed with epidural anesthesia in parturients.[152]

Postanesthesia Shivering

In the anesthetized patient, it is unusual to reach temperatures where shivering is induced. However, in the postanesthesia period, shivering is common and has been reported to occur in up to 40% of patients.[156,157] This common perioperative problem is both uncomfortable for the patient and problematic for the caregiver, but more importantly, may also increase perioperative morbidity. In addition to cold sensations that accompany shivering, postanesthesia tremor itself can lead to an increase in perioperative pain by stretching within surgical incisions. It can also lead to increases in intracranial and intraocular pressure, in addition to its increases in metabolic demand.[121,158–160]

The etiology of this troublesome perioperative occurrence has been debated considerably.[112] General agreement suggests that the most likely explanation for this postanesthesia tremor relates to an abrupt change in anesthetic-induced thermoregulatory inhibition, thus increasing the threshold for shivering toward normal. That is, the residual low body temperature resulting from the dysregulation of thermoregulation by the anesthetic state itself, and upon discontinuation of anesthetics, is usually well below the near-normal threshold to activate thermoregulatory shivering.[161,162]

Despite this normal thermoregulatory response to intraoperative heat loss, there are alternative explanations for postanesthesia shivering that may partly explain some unusual observations. For example, postanesthesia shivering does not universally occur in the markedly hypothermic patient,[163] and shivering frequently occurs in normothermic postanesthesia patients.[161] As a result, there may be some other mitigating factors that influence whether or not one shivers after anesthesia. It has been suggested that surgery itself, as a consequence of the stress response or associated pain, can contribute to postoperative tremor.[164] For example, the surgical stress itself may abnormally increase the thermoregulatory setpoint.[165] There is also evidence that residual volatile anesthetics (e.g., isoflurane) may also cause a nonthermoregulatory shivering pattern.[147,166] The exact mechanism by which anesthesia may interact directly in causing the shivering pattern is unknown. However, the tremor pattern that is observed at low concentrations of isoflurane (0.2–0.4%) is very similar to the electromyographic pattern that is seen after spinal cord transaction, suggesting that the isoflurane may cause some inhibition of spinal cord reflexes resulting in this troublesome tremor.[167]

Postanesthetic shivering can be prevented in most patients by maintaining normothermia. Skin-surface warming may be effective therapy.[168] Pharmacologic treatments include meperidine (25 mg IV),[168–170] clonidine (75 μg IV),[171,171] and ketanserin (10 mg IV).[172–174] Most recently, dexmedetomidine has also been used.[169,175,176] The exact mechanism(s) by which these drugs abolish shivering is not completely understood, but the meperidine effect may be mediated via kappa opioid receptors.[176]

Complications of Hypothermia

Perioperative hypothermia is associated with a number of adverse consequences (Table 89–5). Although the mechanism linking hypothermia to these events is known for some, it is unclear for others. For example, although myocardial ischemia is a serious postoperative problem, and postoperative shivering can adversely affect oxygen consumption (increasing it by 200–400%),[101,105] there is little actual data linking shivering to the occurrence of ischemic events.[113,118,119] Despite this, there is a strong link in high-risk patients between mild postopera-

TABLE 89–5.

Strategies to Prevent and Treat Perioperative Hypothermia

Prewarming patient
Increase ambient operating room temperature
Skin insulation (cover patient)
Heating and humidification of inspired gases
Warm preparation solutions
Fluid warmers
Connective forced-air warmers
Circulating water-heating devices

tive hypothermia (1.8–5.4°F [1–3°C]) and overall adverse myocardial outcomes.[119] The mechanism by which this hypothermia leads to these adverse events is not clear, however. Potential mechanisms for the adverse myocardial events (other than shivering) include cold-induced hypertension.[121] The increase in circulating catecholamines accompanying this hypertension can augment cardiac irritability and lead to ventricular arrhythmias.[120]

Although long considered to be a factor in increasing perioperative blood loss, the effects of mild hypothermia in studies designed to examine blood loss and transfusion have produced variable results. Schmied et al. showed that just 2.9°F (1.6°C) of hypothermia increased blood loss by 30%, which in this study of hip surgery, amounted to 500 mL.[178] Overall, the data suggests that there is an increase in both blood loss and transfusion requirements,[178] although there are certainly other studies discounting this association.[179] In a study by Nathan et al., much greater degrees of postoperative hypothermia (6.3°F [3.5°C]) have not consistently been shown to have a significant impact on bleeding.[180] Despite these conflicting results, there are clearly some effects on platelet function and clotting factor function, as well as fibrinolytic activity induced by mild degrees of hypothermia. For example, Valeri et al. demonstrated that platelet function can be impaired by mild degrees of perioperative hypothermia.[181] This has subsequently been demonstrated by others to be potentially related to a defect in the release of thromboxane A_2.[182–184] The effects of hypothermia on in vivo clotting factor function is not clear (because most laboratory tests are performed at 98.6°F [37°C]), although most in vitro clotting tests, if performed at hypothermic temperatures, will show some impairment. There is little data outlining the effects of hypothermia on the fibrinolytic response. Paradoxically, one can theorize that fibrinolysis may actually be inhibited by mild hypothermia (thus decreasing bleeding) because of the temperature-related impairment of the enzyme responsible for the conversion of plasminogen to plasmin, which is fundamental to the fibrinolytic process.

Infection is one of the most serious consequences of hypothermia. Trials investigating warming interventions to treat postoperative hypothermia have been successful in reducing postoperative wound infection. A pivotal trial by Kurz et al. investigated 200 patients who were undergoing gastrointestinal surgery assigning them to either conventional treatment (hypothermia group) or additional warming (normothermia group).[185] The normothermia group had significantly fewer wound infections (6%) compared to the hypothermia group (19%), and also had evidence for improved wound healing and shorter hospitalization.[185] The mechanisms behind these adverse affects of hypothermia on perioperative wound infection and healing are likely related to the vasoconstriction induced by the thermoregulatory responses[130,186] that lead to decrease subcutaneous oxygen tension (tissue hypoxia),[187] as well as direct hypothermia mediated impairments in immune function.[188–191] In addition to the direct immune function impairment, the reduced oxygen tension in subcutaneous tissues also impairs wound healing. Duration of hospitalization, although clearly made worse by postoperative wound infection, also has been shown to be prolonged in hypothermic patients irrespective of the occurrence of any infection.[185] The mechanism behind this noninfection-related prolongation in hospitalization is not clear, but is certainly consistent with evidence of impaired wound healing or potential metabolic disturbances such as protein wasting.[192]

Although not necessarily a complication of hypothermia, there are several pharmacokinetic and pharmacodynamic effects of hypothermia that are relevant to anesthesia. For example, hypothermia has a significant impact on the duration of action of muscle relaxants. This is thought principally to be related to a pharmacokinetic effect (as opposed to a pharmacodynamic effect), although there is some evidence for a direct hypothermia effect on skeletal muscle responsiveness.[193–195] Another direct pharmacodynamic effect of hypothermia is its impact on minimal alveolar concentration. There is approximately a 5% reduction in minimal alveolar concentration per degree in core body temperature.[196] This can most dramatically be seen in the cardiac surgical patient undergoing hypothermic circulatory arrest where, as the temperature drops to more moderate to severe ranges (68°F [20°C]), significant changes (slowing) can be seen in the electroencephalogram, with the bispectral index significantly decreasing, which is consistent with a significant reduction in the requirement of inhaled or intravenous anesthetics. The principal hypothermic effects on intravenous anesthetics relate to changes in their pharmacokinetic profile with alterations in clearance from central and peripheral compartments. Some of these pharmacokinetic and pharmacodynamic effects may partly explain the prolonged recovery profiles in hypothermic patients in the postanesthesia period.[197]

Relatively minor (in terms of serious consequences) complications include thermal discomfort[198] and mild hypothermia-induced hypokalemia.[199,200] Lastly, monitoring the hypothermic patient can be a problem at times because shivering may lead to artifacts in electrocardiogram monitoring, as well as to vasoconstriction-induced reductions in cutaneous blood flow that impair pulse oximetry measurements. [201]

Prevention and Treatment of Perioperative Hypothermia

A number of strategies have been used to prevent and treat hypothermia (see Table 89–5). Most therapies target the linear phase of the hypothermic curve where heat is lost cutaneously. As a result, these modalities attempt to either minimize this cutaneous heat loss or deliver heat via skin-mediated mechanisms. However, as redistribution from the core to the periphery results in the initial and sharpest drop in temperature, minimizing the redistributive decrease in temperature should also be addressed.

Prewarming the patient prior to induction of either general or regional anesthesia has been successful,[148,202] but because of logistical and other time constraints, not as frequently practiced as it could be. It works through reducing the core–peripheral temperature gradient and also, in part, by increasing the overall body heat content. As a result of this reduced core–peripheral temperature gradient, there is less redistribution-mediated decrease in temperature with the onset of a much-reduced anesthetic vasodilatation.

Increasing ambient operating room temperature is an effective method of preventing heat loss in surgical patients; it is most effective if the operating room temperature is increased to at least 75.2°F (24°C). This modality also

relies on reducing the gradient between the body and the ambient environment, decreasing the heat that is lost across this gradient. However, this temperature is generally considered to be too warm for the comfort of others in the operating room.[108] Relying solely on this modality will not be effective in maintaining normothermia.

Insulation of the skin reduces heat loss by approximately 30%, principally by reducing radiation losses.[98] Blankets, however, work principally via the insulating layer of air trapped between the skin and the external environment such that regardless of whether covers are heated or not, they are equally effective. Heat loss is directly proportional to surface area. As a result, no skin surface is either more or less likely to lose heat. The head, for example, frequently thought to lose more heat than other parts of the body, does not do so any more than its 10% surface area would predict.[98] Radiant heaters have also been used, but have little use except in situations where skin contact is limited, such as in the neonate.

Heating and humidification of inspired gases address the <10% of metabolic heat that can be lost from the respiratory tract.[203] Although heating and humidifying inspired gases can prevent all of this heat loss, it has a negligible effect on core temperature.[134] Inspired gases can be passively warmed and humidified by artificial devices to a similar degree as that induced by the nasopharynx. Although these types of devices are good at maintaining humidity and minimizing heat loss, such devices cannot deliver significant heat.[203,204] However, they do have other advantages, including reducing the drying of pulmonary secretions.

Heated mattresses that usually circulate warmed water (104–105.8°F [40–41°C]) have not been shown to be effective in the prevention or treatment of hypothermia. When placed under the patient, they make poor contact with the body surface. In addition, very little heat is lost via the posterior body surface because of the relatively good insulation provided by foam operating table surfaces. It is the anterior surface of the body that loses 90% of the body heat.[134] In addition, these devices have significant limitations related to safety. As a result of body pressure points (with subsequent poor circulation) being unable to dissipate heat, they can increase the risks of burns to the skin.[134] Other non–water-heated mattresses would be expected to have similar limitations and poor efficiency.

Forced-air warming systems are one of the most effective active warming systems.[205,206] Lennon et al. compared the efficiency of a forced-air heating system to only covering patients with cotton blankets warmed to 98.6°F (37°C).[207] After activation of the forced-air heating system, patients were warmer at all time intervals. Numerous other studies have evaluated forced-air systems and found them to maintain normothermia, even during prolonged and extensive procedures.[134,198,199] Forced-air warming systems work via two principal mechanisms. First, they reduce radiant heat loss (by increasing the temperature of the surfaces surrounding the patient), and second, they increase heat gain via convection. As this modality of warming has grown in acceptance and wide-scale use, multiple devices have been brought to market. Although the various systems differ in their full capabilities, in the hypothermic patient, all convective forced-air warming systems provide excellent warming.[208]

Despite the failure of conventional heated water mattresses to efficiently warm patients, a new generation of circulating-water heating systems are now available (such as the Kimberly Clark Patient Warming System, Kimberly Clark, Roswell, GA; and Allon MTRE 3365, MTRE Advanced Technologies, Akiva, Israel). These devices differ from their predecessors by employing significantly better skin contact that optimizes conduction of heat to the skin. They have been trialed in cardiac surgery using both on- and off-pump procedures, and have demonstrated considerable efficiency.[198,200,209,210] They have significant advantages by heating the posterior body that is otherwise inaccessible in the supine patient. In addition, these devices excel in operations where there is large skin exposure (such as cardiac surgery) and forced-air warmers have limited skin surface contact.

When rapid infusion of large volumes of either cold IV fluids or blood products is required, significant hypothermia can result. For example, 1 unit of refrigerated blood, or 1 L of room-temperature crystalloid, can decrease core temperature in adults by approximately 0.45°F (0.25°C).[211] Fluid warmers are effective methods to warm both blood products and other IV fluids prior to administration. Although fluid warming can reduce the degree of hypothermia, it cannot add any significant heat to patients. Warming skin preparation solutions and irrigation fluids can also help prevent evaporative heat loss.

Intravascular warming with invasive intravascular catheters has also been used to warm patients, but also, in an opposite thermodynamic fashion, to intentionally cool patients. These systems are not widely available or extensively used, and are limited by the technical need for large-bore (up to 14 French or more) vascular cannulation with all its associated risks.[212–214] Their role in perioperative hypothermia treatment has not been directly examined.

Potential Advantages of Hypothermia: Neuroprotection

Although much of the previous discussion has outlined the spectrum of disadvantages of perioperative hypothermia, providing extensive reasons why it should be avoided at all costs, there are situations where catastrophic consequences would result without its use. This is nowhere more apparent than in the setting of the ischemic brain. A classic example of this is when deep hypothermia is used to protect the brain during circulatory arrest for surgery on the aorta[215,216] or cerebral aneurysms.[217] In these situations, the circulation to the brain and the rest of the body organs can be stopped for up to an hour without any significant long-term effect. This period of "suspended animation" makes possible lifesaving procedures that would have been impossible otherwise. This is not dissimilar to some of the anecdotal reports of accidental near drowning whereby cold-water immersion and the ensuing hypothermia that has followed has allowed for dramatic survival despite long periods without oxygen.

Although these extremes of temperature are clearly protective in that type of surgery, lesser degrees of hypothermia in other settings, such as cardiac surgery, are less obviously protective[201,218–220] and are also tightly linked to optimizing how rewarming is performed.[221] Interestingly, cardiac surgery is rather unique in its consideration of temperature. In addition to its use of hypothermic benefits, it is

also a setting that has had little evaluation and description of hypothermic complications. Indeed, most of the studies outlining the adverse effects of hypothermia in the perioperative patient have not been performed in the setting of cardiac surgery. Therefore, extrapolating all the potential adverse effects to cardiac surgical patients would be erroneous. However, common sense dictates that some of the effects of temperature (possibly the effects of wound healing, infection, and coagulopathy) would also apply to the cardiac surgery patient.

The salutary effects of hypothermia on the brain are a result of the numerous enzymatic and metabolic pathways modulated by temperature. In addition to depressing cerebral metabolism (approximately a 6–7% decline per °C),[222] its other putative neuroprotective effects of hypothermia are likely mediated by nonmetabolic pathways. In the ischemic brain, moderate hypothermia blocks the release of glutamate,[223] reduces calcium influx,[224] hastens recovery of protein synthesis,[225] diminishes membrane-bound protein kinase C activity,[226] can slow the time of onset of depolarization,[227] suppresses nitric oxide synthase activity,[228] and reduces the formation of reactive oxygen species.[229] Protection from hypothermia likely results from a summation of all these mechanisms. Although experimental demonstrations of the neuroprotective benefits of hypothermia have been well characterized for decades,[230–233] it is only recently that clinical examples of its benefits have been described.[234–237]

Outside the surgical setting, hypothermia has been evaluated as a direct neuroprotective strategy. In patients who were undergoing cardiac arrest, two large, well-controlled trials demonstrated that comatose survivors of out-of-hospital cardiac arrest significantly benefitted from prolonged (>24 hours) periods of postarrest-induced hypothermia. Bernard et al. studied 77 patients following witnessed cardiac arrest who, within 2 hours of return of spontaneous circulation, were reduced to a core body temperature of 91.4°F (33°C) for 12 hours.[234] Both the number of patients surviving as well as those having either minimal or moderate disability were significantly greater in the hypothermic group. In a similar, larger, multicenter trial of 275 patients, induced hypothermia (89.6–93.2°F [32–34°C]) for a period of 24 hours was associated with an increased number of patients with favorable neurologic outcomes, as well as a significant reduction in 6-month mortality.[235]

Subsequent to these two studies, guidelines were instituted recommending the use of therapeutic hypothermia after cardiac arrest as part of an overall resuscitation strategy.[238] Although there were few adverse affects reported in these studies, some interesting trends emerged that support some of the perioperative hypothermia studies that highlight the complications of hypothermia. For example, in the large, multicenter trial,[238] there were trends toward an increase in bleeding as well as pneumonia and sepsis, although the study was insufficiently powered to look at these complications. In general, however, for the nonsurgical patient who is suffering cardiac arrest, the weight of the evidence suggests that there is a significant advantage to the induction of a period of post-cardiac arrest hypothermia.

Mild to moderate hypothermia has also been investigated as a neuroprotective strategy in setting of neonatal hypoxic–ischemic encephalopathy.[239] Although hypothermia had been demonstrated to be protective against brain injury in animal models of asphyxia, only recently was it evaluated in humans. In a well-conducted, randomized, multicenter trial of 238 infants who presented with perinatal asphyxia, hypothermia (92.3°F [33.5°C]) was instituted within 6 hours of birth and maintained for 72 hours, followed by slow rewarming. Neurodevelopmental outcomes were assessed at 18–22 months of age. Whole-body hypothermia was shown to reduce the combined end point of death or moderate/severe disability compared to conventional therapy (maintaining these patients at a normothermic temperature). Importantly, the hypothermia did not increase severe disability in the survivors, a clinical situation that would be clearly disadvantageous. The wide-scale application of hypothermic therapy in these subsets (cardiac arrest and neonatal hypoxia) is only just beginning.

Considerable caution and balance should always be used when employing these clinical applications of hypothermia. Extrapolating these two beneficial situations to other surgical settings of potential brain injury has at yet, no foundation. Although there is a wealth of beneficial experimental studies outlining both the mechanism and the degree to which hypothermia can protect the brain, other clinical applications apart from those discussed above have been lacking. Most recently, hypothermia has been explored in patients who were undergoing cerebral aneurysm clipping, clearly a setting where the brain is at risk of ischemia. However, in a trial of 100 patients by Todd et al.,[237] there was no benefit to the use of mild degrees (91.4°F [33°C]) of hypothermia induced intraoperatively using convective forced-air devices for cooling. Again, some cautious findings were also identified, including a higher incidence of bacteremia in the hypothermic group.

Overall, one's enthusiasm for doing everything to reduce hypothermia must be tempered with the realization that there are likely situations where hypothermia can have a benefit. As in many areas of medicine, there is clearly no right or wrong answer, only a balance of risk *versus* benefit.

RESOURCES

Hyperthermia

The North American MH Registry (NAMHR) was established to collect and disseminate information regarding MH and the families involved. A chart review is eliminated if the patient or family member in question has been evaluated and entered into the registry by one of the MH diagnostic centers. If the patient is not registered, a chart review of the initial episode is necessary to rule out alternative explanations for the episode (see Box 89–4). If the diagnosis is still in question, contact MHAUS for the nearest MH diagnostic center available for consultation. Even if the diagnosis is inconsistent with MH, provide documentation and counseling to the family regarding the findings; this helps to eliminate confusion for the family and their future healthcare providers.

Public education and communication are provided by a layman's organization, the Malignant Hyperthermia Association of the United States (MHAUS, 11 E. State Street, P.O. Box 1069, Sherburne, NY 13460–1069; telephone: 1–607–674–7901; fax: 1–607–674–7910; website: *www.mhaus.org*) and by a medical professional's 24-hour, 7-day telephone service for emergency consultation, the MH Hotline (1–800–MH–

HYPER [1–800–644–9737]). The professional subsidiary of MHAUS, the North American MH Registry (NAMHR), collates findings from biopsy centers in Canada and the United States and provides access to specific patient data through the Hotline or its Director, Dr. Barbara Brandom (North American MH Registry of MHAUS, Room 7449, Department of Anesthesiology, Children's Hospital, University of Pittsburgh, 3705 Fifth Avenue at Desoto St., Pittsburgh, PA 15213–2583; telephone: 1–888–274–7899; fax: 1–412–692–8658; bwb@pitt.edu).

PART 8

CARE OF THE CHRONIC PAIN PATIENT

CHAPTER 90

Mechanisms of Chronic Pain

Gary J. Brenner, MD, PhD, and Clifford J. Woolf, MD, PhD

The cardinal function of the pain system is to protect the body from impending or actual damage. When functioning normally, the major components of the system—primary afferent fibers (primary sensory neurons), spinal cord, and brain—integrate key information about noxious stimuli, allowing for perception of its quality, intensity, and location and permitting an appropriate behavioral response that includes withdrawal from the stimulus, activation of the autonomic nervous system, an emotional response, and a deeply unpleasant sensation that we call pain. Sir Charles Sherrington a century ago defined *nociception* as the sensory detection of a noxious event or a potentially harmful environmental stimulus.[1] We now recognize that most clinical pain is not actually nociception—the detection of noxious stimuli—but rather production of pain either in the absence of any peripheral stimulus (spontaneous pain) or in response to a stimulus that normally would be experienced as innocuous (allodynia) and therefore is not noxious.

This chapter reviews the neuroanatomy and neurophysiology of the nociceptive system, providing a basis for understanding normal (physiologic) functioning of the nervous system, that is, nociception, and the mechanisms (both peripheral and central) underlying persistent pathologic pain.

Much of the information in this chapter is derived from preclinical models of physiologic and pathologic pain. We now have considerable insight into the mechanisms underlying the transduction, conduction, processing, transmission, and perception of acute noxious stimuli, as well as the mechanisms responsible for the persistent pain associated with inflammation, lesions to the nervous system, and dysfunction of sensory processing in the nervous system. Persistent pain is generated by a wide array of insults to, and changes within, the nervous system. The manifestation of chronic pain is highly complex and often cannot be correlated with a specific underlying lesion or disease. Through an understanding of the neurobiology of chronic pain, we can begin to move from a trial and error approach to pain management to a rational approach based on identifying the mechanisms responsible for pain in an individual patient and targeting therapy to these mechanisms.

NEUROPHYSIOLOGY OF NOCICEPTION

The pain system has four basic anatomical components. *Nociceptors* are specialized high-threshold sensory afferent or primary sensory neurons that are located in the peripheral nervous system (PNS) whose peripheral terminals are capable of detecting or reacting normally only to intense noxious stimuli and transmit this information along their axons, which run in peripheral nerves to the spinal cord. *Ascending nociceptive tracts,* including the spinothalamic, spinobulbar, and spinohypothalamic tracts, convey nociceptive information from the dorsal horn of the spinal cord to *higher centers in the central nervous system* that are responsible for cognitive, affective, and complex motor responses to noxious stimuli as well as production of conscious awareness or perception of the stimulus and interaction with learned behaviors. Finally, *descending systems* in the CNS are involved in the processing or control of transfer of nociceptive information at multiple levels of the nervous system (Fig. 90–1).

In the past, pain was thought to arise from the simple detection of adequate noxious stimuli in the periphery and the transfer of this information as action potentials to the CNS, where via specific circuits or pathways it produced both a withdrawal reflex response and an unpleasant sensation. This simple scheme implied that all pain was essentially similar; it was merely a question of what stimulus activated the pain pathway, where,

KEY POINTS

1. Understanding the mechanisms underlying chronic pain requires knowledge of the neuroanatomy, neurochemistry, and neurophysiology of nociception.
2. Generation of pain hypersensitivity results from changes in the function, chemistry, and structure of both the peripheral and central nervous systems.
3. Nociception has a protective function. In contrast, neuropathic and dysfunctional pain are not protective and as such represent or are a manifestation of pathology within the nervous system. In these circumstances, pain can be considered a disease.
4. Chronic pain may result from persistent tissue damage and inflammation leading to an ongoing drive to the nociceptive pathways. It may result from a trigger (usually to the nervous system) that heals, but the pain persists independent of any peripheral drive, or it may be a manifestation of abnormal function of the nervous system independent of any peripheral pathology or lesion to the nervous system.
5. Chronic pain can be categorized into the following broad etiologic groups: nociceptive (associated with an ongoing noxious stimulus), inflammatory (due to ongoing tissue inflammation), neuropathic (resulting from a lesion to the nervous system), or dysfunctional (pain in the absence of a peripheral noxious stimulus, peripheral pathology, or identifiable lesion to the nervous system and due to an abnormal functioning of the nervous system).
6. Neuropathic pain can be generated by lesions in both the peripheral and central nervous systems. It typically involves multiple mechanisms that act alone or in concert and may change over time.
7. Understanding the mechanisms underlying chronic pain is essential for rational application of pain therapeutics. This process requires diagnostic tools for identifying pain mechanisms in patients and introduction of novel forms of therapy targeted at specific mechanisms.

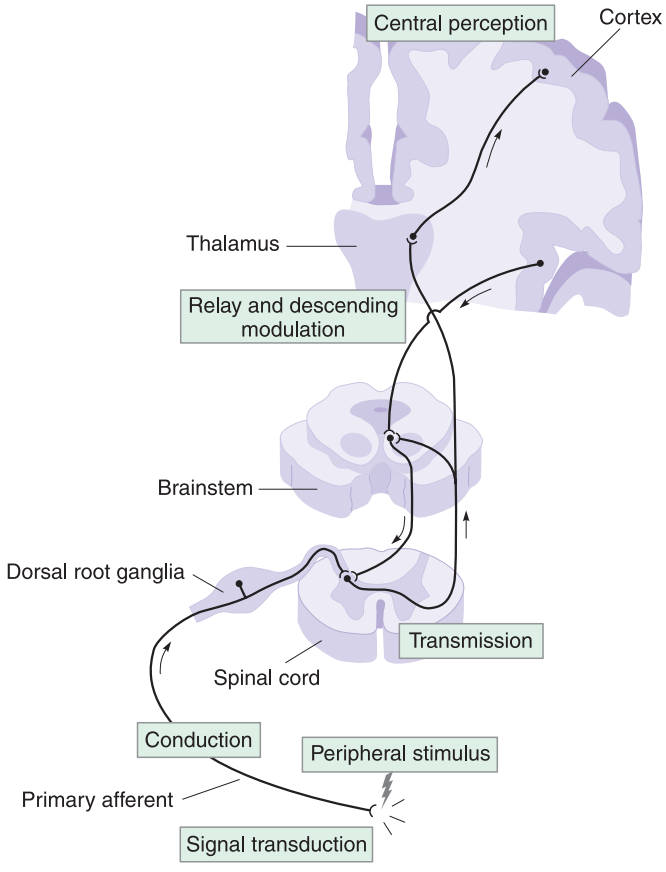

FIGURE 90–1. Overview of a basic nociceptive circuit. Activation of the peripheral afferent terminal by a noxious stimulus leads to generation of action potentials that are conducted to the dorsal horn of the spinal cord. Neurotransmission in the dorsal horn relays signals to second-order CNS neurons that convey the information to the brain. This circuit also is subject to descending modulatory control. (Modified from Golan DE, Tashjian AH, Armstrong EJ, et al., eds. Principles of Pharmacology: The Pathophysiologic Basis of Drug Therapy. Baltimore: Lippincott Williams & Wilkins, 2005, with permission.)

and for how long. It led to the assumption by patient and physician that pain reflected a peripheral pathology. We now appreciate that this notion of a static, fixed nociceptive system activated only in the periphery is quite wrong. Instead, substantial signal processing occurs in all components of the nociceptive pathway. These components are highly modifiable or "plastic," and it is this plasticity that drives clinical pain. In many cases, the pain arises not from the periphery where the sensation is interpreted (or "felt") as arising, but from changes within or intrinsic to the nervous system. Plasticity occurs at even the earliest stage of nociception—the transduction of noxious stimuli at the peripheral terminals of primary sensory afferents—as well as to a substantial extent in the spinal cord and brain. The plasticity/modifiability occurs in response to external stimuli (e.g., inflammatory mediators) and to the internal activity of the nociceptive system itself, and it can lead to either facilitation or depression of response.[2,3]

This chapter focuses on the mechanisms of acute and chronic somatic pain. Other important chronic pain problems, such as those involving visceral pain and headache, have overlapping but not necessarily identical mechanisms. These syndromes are reviewed elsewhere.[4,5]

Nociceptive Pathways: Neuroanatomy and Neurochemistry

Primary Afferents: Transduction and Conduction to the Spinal Cord

The high-threshold primary afferent neurons responsible for detection of high-intensity noxious stimuli are termed *nociceptors.* Nociceptors include both thinly myelinated A-delta (A-δ) and unmyelinated C-fibers. They represent one of several functional groups of sensory fibers in peripheral nerves (Table 90–1), including proprioceptors, low-threshold mechanoreceptors, and detectors of innocuous thermal stimuli. Nociceptors are classified based on the presence or absence of myelination and the type(s) of stimuli to which the sensory neuron responds. A-δ fibers conduct at 2–30 m/s. C fibers conduct at 0.2–2 m/s. The majority (80–90%) of nociceptors are C fibers. Nociceptors transduce mechanical, chemical, thermal (noxious heat or cold) single or, more commonly, combinations of stimuli (polymodal). Table 90–2 summarizes the characterization of nociceptors based on their response characteristics.

The membrane of peripheral terminals of nociceptors contains a set of highly specialized receptors/ion chan-

TABLE 90–1.

Classification of Fibers Found in Peripheral Nerves

Fiber Type	Innervation	Mean Diameter (μm)	Mean Conduction Velocity (m/s)
Sensory			
A-β	Cutaneous touch and pressure afferent fibers	8	50
A-δ	Mechanoreceptors, nociceptors, thermoreceptors	2–3	15
C	Mechanoreceptors, nociceptors, thermoreceptors, sympathetic preganglionic	1	1
Motor			
A-α	Primary muscle spindle, motor to skeletal muscle	15	100
A-γ	Motor to muscle spindle	6	20
Sympathetic			
B	Sympathetic postganglionic	3	7

TABLE 90–2.

Functional Classification of Primary Afferent Nociceptors

Type of Fiber	Nociceptor Type	Noxious Stimuli Detected
A-δ (2–30 m/s)	AM	Mechanical
	AMC	Mechanical and cold
	AH	Heat
	AMH type I	Mechanical, heat >53°C
	AMH type II	Mechanical, heat <51°C
	A-Chem	Chemical
C fiber (0.5–2 m/s)	CM	Mechanical
	CH	Heat
	CMH[a]	Mechanical, heat
	CMC	Mechanical, cold
	C-Chem	Chemical (algesic & pruritic)
	CMi[b]	None in resting state, mechanical (after activation)

[a]Many CHM nociceptors are also stimulated by algesic chemicals and are denoted "polymodal" nociceptors.
[b]CMi nociceptors are known as either C "mechanoinsensitive" or "silent" nociceptors and are sensitive to mechanical stimuli only in the presence of inflammation or other activating stimuli.

nels that transduce mechanical, chemical, and thermal noxious stimuli into inward currents that excite the terminal. The transduction proteins determine the threshold, specificity, and temporal properties of the nociceptors that express them (Fig. 90–2 and Table 90–3). Upon stimulation, transduction receptor/ion channels undergo conformational changes that alter their conductance, allowing an influx of cations. This cation influx leads to depolarization of the terminal membrane—known as the *generator potential*—that, if of adequate amplitude, reaches the threshold to generate an action potential. The generator potential is graded in amplitude and duration and reflects stimulus intensity and timing. In contrast, action potentials are all-or-none events. Primary afferent nociceptors transfer information from the periphery to the CNS by the pattern, frequency, and duration of firing of action potentials arising in the peripheral terminal that accurately encode the onset, intensity, location, and duration of nociceptive stimuli. One particular class of C-fiber afferents, termed *silent nociceptors,* is inactive in the resting state, becoming responsive to noxious stimuli only after inflammation or injury.

Thermal sensitivity is conferred upon nociceptors by the presence of thermosensitive nonselective cation channels called *transient receptor potential (TRP) channels.* The thermoresponsive TRPs are a family of channels, each sensitive to a different thermal stimulus range. TRPV1 (the capsaicin receptor) is activated by a variety of stimuli, including noxious heat (>108°F [>42°C]), vanilloid ligands including capsaicin (the pungent component of chili peppers), low extracellular pH, lipids such as anandamide (an endogenous cannabinoid agonist), and polyamines.[6–8] Other TRP receptors are sensitive to heat in other ranges: TRPV2 >126°F (>52°C), TRPM8 ~46–79°F (~8–26°C), and TRPA1 <63°F (<17°C). These receptors also respond to chemicals: TRPV1 to capsaicin, TRPA1 to mustard oil/wasabi, and TRPM8 to menthol and icilin.

Nociceptors respond to a variety of chemical stimuli, some of which directly activate the terminal, producing generator potentials (chemical activators) and thereby an action potential output and pain. Other agents alter the threshold of the nociceptor (sensitizing agents) without directly exciting them. We discuss these sensitizers later. Nociceptor activators typically are associated with injury, such as low pH (i.e., protons), adenosine triphosphate (ATP), and kinins or irritants such as capsaicin and mustard oil. TRPV1 is sensitive to protons, as are a family of channels known as acid-sensitive ion channels (ASICs). ATP is sensed by both ligand-gated (P2X) ion channels and G-protein–coupled receptors (P2Y). Injury and ischemia are associated with low extracellular pH and generation of ATP. Nociceptors have specific receptors for bradykinin, the G-protein–coupled B1 and B2 receptors. Bradykinin is produced by cleavage of the precursor kininogen by kallikrein.

The identity of the receptor–ion channel complex responsible for transduction of noxious mechanical stimulation ("pinch") is not clear. Evi-

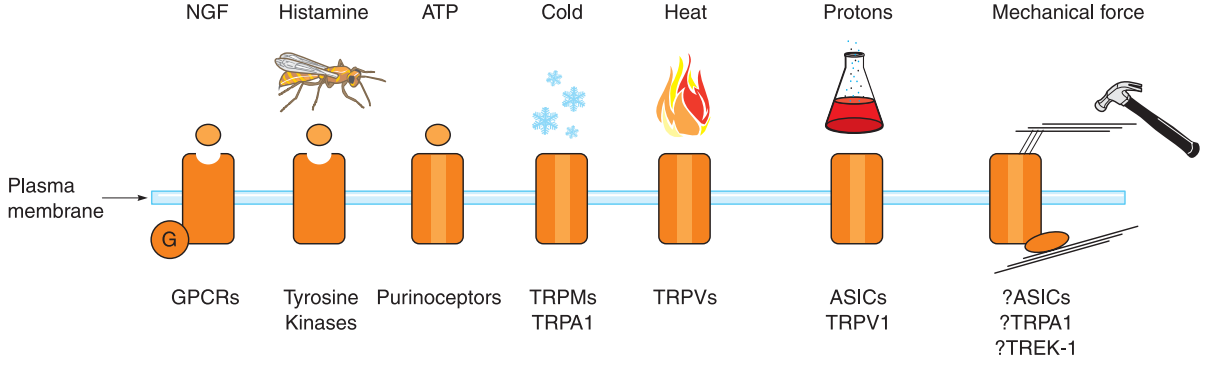

FIGURE 90–2. Transduction of nociceptive stimuli. The first step in the sensation of physiologic or "nociceptive" pain is the transduction of high-intensity stimuli by primary sensory afferents. These afferents, A-delta (A-δ) and C fibers, transduce mechanical-, chemical-, and temperature-related stimuli. The gain of the primary nociceptive afferents can be increased by translational and posttranslational modification, leading to pain hypersensitivity in a process termed *peripheral sensitization.* GPCRs, G-protein coupled receptors; TRP, transient receptor protein; ASICs, acid-sensing ion channels; TREK, a member of the 2-pore-domain K^+ channels. (We thank M. Costigan who provided a graphic from which Figure 90–2 was generated.)

TABLE 90–3.

Ion Channel and Metabotropic Receptors (Found on Primary Afferent Peripheral Terminals) Involved in Noxious Stimulus Transduction

Ion Channel Receptors	Permeable to	Activated by
Transient Receptor Potential (TRP) channels		
TRPV1	Cations, especially Ca^{2+}	Heat (>109°F [>43°C]), low pH, capsaicin
TRPV2	Cations, especially Ca^{2+}	Heat (>126°F [>52°C])
TRPV3	Cations, especially Ca^{2+}	Warm (88–102°F [31–39°C])
TRPV4	Cations, especially Ca^{2+}	Warm (>81°F [27°C])
TRPM8	Cations, especially Ca^{2+}	Cold (~ 46–79°F [~8–26°C]), menthol
TRPA1	Cations, especially Ca^{2+}	Cold (<63°F [17°C]), mustard oil
Acid-Sensing Ion Channels		
ASIC1, ASIC2, ASIC3	Na^+	Low pH, ? mechanical
Purine receptor, P2X3	Ca^{2+}	ATP
Metabotropic Receptors	**Second Messenger**	**Activated by**
Purine receptor, P2XY	G-protein–coupled receptor	ATP
Bradykinin receptor, B1& B2	G_q protein-coupled receptor	Bradykinin

ATP, Adenosine triphosphate.

dence in invertebrates suggests that such stimuli are transduced by the degenerin/epithelial family of cation channels.[9] It has been suggested that the AISC3 subtype is involved in noxious mechanical stimulation in mammals, although this may occur via an indirect mechanism.[10–12] Other data suggest that TRPA1 receptors have a mechanotransduction role as well as involvement in cold pain. Inhibitors of specific transduction proteins may reduce particular aspects of pain. For example, TRPV1 antagonists might reduce heat pain, which might not be a good idea if you drink very hot coffee and like a curry!

Voltage-gated sodium ion channels are critical for initiation of action potentials in the peripheral terminals of nociceptors and for their conduction along axons in peripheral nerves to the spinal cord (Table 90–4). Primary afferents express six types of voltage-gated sodium (Na^+) channels. Interestingly, four of these channels ($Na_V1.7$, $Na_V1.8$, $Na_V1.9$, Na_X) are expressed only by primary afferents, and two of these four ($Na_V1.8$ and $Na_V1.9$) are expressed predominantly by nociceptors. The relative restricted expression of $Na_V1.8$ and $Na_V1.9$ in nociceptive afferents in conjunction with their pharmacologic distinction from other Na^+ channels ($Na_V1.8$ and $Na_V1.9$ are tetrodotoxin [TTX] resistant) means that these channels have generated substantial interest as potential targets for pain therapeutics. Local anesthetics such as lidocaine are not sodium channel selective; they block all axons, nociceptors, nonnociceptor sensory fibers, and motor and autonomic as well sodium channels in the CNS and PNS (peripheral nervous system). Blockers specific for $Na_V1.8$ and $Na_V1.9$ could potentially produce blockade only of "pain" fibers, which would totally change regional anesthesia.

Nociceptors have a cell body located in the dorsal root ganglion (DRG), a peripheral process innervating the target tissue, and a central process that runs in dorsal roots and makes a synapse on second-order neurons in the dorsal horn of the spinal cord. The same is true of primary afferent sensory fibers of cranial nerves (V, VII, IX, and X), except that the cell bodies are located in their respective brainstem sensory ganglia. The visceral primary afferent nociceptors (both A-δ and C fibers) travel with sympathetic and parasympathetic nerves and have cell bodies in the DRG. The central axons of nociceptors enter the gray matter of the spinal cord via the dorsal root and synapse on neurons in the dorsal horn. The fibers can traverse 1–2 spinal segments rostrally or caudally through the Lissauer tract prior to making synaptic connections with nociceptive projection neurons and interneurons. The nociceptor terminals form a highly organized somatotopic map of the body surface in the dorsal horn encoding the location of the afferents' peripheral receptive field. The gray matter of the spinal cord is organized into 10 laminae (lamina of Rexed) based on histologic organization of the cell bodies and dendrites. Rexed laminae I–V compose the dorsal horn of the spinal cord. The majority of nociceptors terminate in lamina I (marginal zone), lamina II (substantia gelatinosa), and lamina V. Lamina I contains both interneurons and projection neurons. Lamina II contains few projection neurons and comprises predominantly interneurons, both excitatory and inhibitory. Like lamina I, lamina V contains both projection neurons and interneurons. The inputs to dorsal horn neurons are complex, and there is a con-

TABLE 90–4.

Ion Channels (Found on Primary Afferent Nociceptors) Involved in Membrane Excitation/Conduction and Synaptic Transmission

Channel	Permeable to	Activated by
Tetrodotoxin-sensitive sodium channels $Na_V1.1$, $Na_V1.3$[a], $Na_V1.6$, $Na_V1.7$	Na^+	Depolarization
Tetrodotoxin-resistant sodium channels $Na_V1.8$, $Na_V1.9$	Na^+	Depolarization
Inward-rectifying potassium channels (multiple subtypes)	K^+	Depolarization, Ca^{2+}
Voltage-gated calcium channels, esp. the N-type Ca^{2+} channel ($Ca_V2.2$)	Ca^{2+}	Depolarization

[a]$Na_V1.3$ is expressed on sensory neurons only following injury.

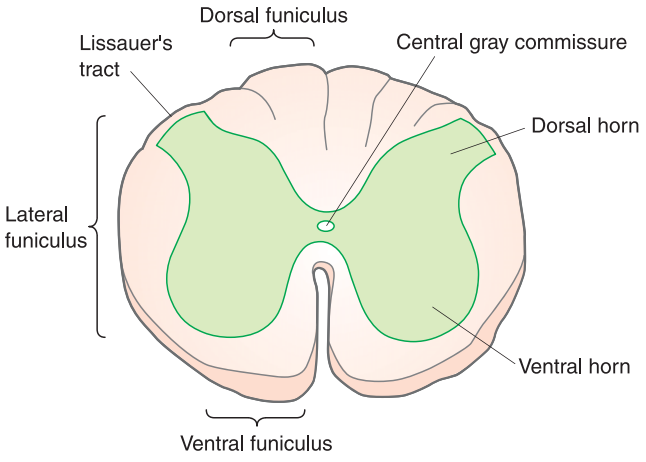

FIGURE 90–3. Cross-section of the spinal cord. Schematic of the spinal cord displays basic anatomic features. Cell bodies of second-order sensory neurons are located predominantly in the dorsal horn. Cell bodies of motor neurons are localized to the ventral horn. Nociceptive primary afferents may ascend or descend, covering as many as six spinal levels in the Lissauer tract prior to synapsing on second-order projection neurons and interneurons. Ascending and descending tracts in the white matter are not shown.

vergence of inputs from wide areas of skin or from different tissues. This is responsible for the phenomenon of referred pain. For example, the pain of myocardial ischemia is referred to the left upper extremity because of a convergence at the level of the dorsal horn of sensory afferents from the heart and left upper extremity.

Transmission in the Dorsal Horn of the Spinal Cord

The dorsal horn is a critical region for the processing, modulation, and projection of nociceptive information to the brain (Figs. 90–3 and 90–4). Individual second-order dorsal horn neurons are activated by stimulation of defined areas of the periphery known as a *receptive field.* Some are activated only by noxious stimuli (nociceptive specific), some are activated only by innocuous stimuli (low threshold), and some have a wide dynamic range and are activated by low-intensity and high-intensity peripheral stimuli (multireceptive). The most basic nocifensive response of the nervous system is the polysynaptic flexor withdrawal reflex generated in the spinal cord by nociceptor activation in the dorsal horn of a chain of excitatory interneurons leading to excitation of flexor motor neurons in the ventral horn. This results in rapid withdrawal from the stimulus of the part of the body in contact with the noxious stimulus. The neuronal components of the dorsal horn can be divided into four categories[13]:

1. Central terminals of primary afferents
2. Intrinsic neurons with cell bodies and terminations within the spinal cord
3. Projection neurons with axons that travel in ascending columns to terminate in the brain
4. Axonal projections of descending systems whose cell bodies reside in the brain

The intrinsic neurons can be divided into local interneurons and propriospinal neurons, which transfer information from one spinal segmental level to another. The great majority of dorsal horn neurons are local interneurons, both inhibitory and excitatory. Transfer of information from primary afferents to second-order neurons in the dorsal horn occurs at the synapse. Numerous transmitters and synaptic neuromodulators are involved in transmission and modulation of nociceptive

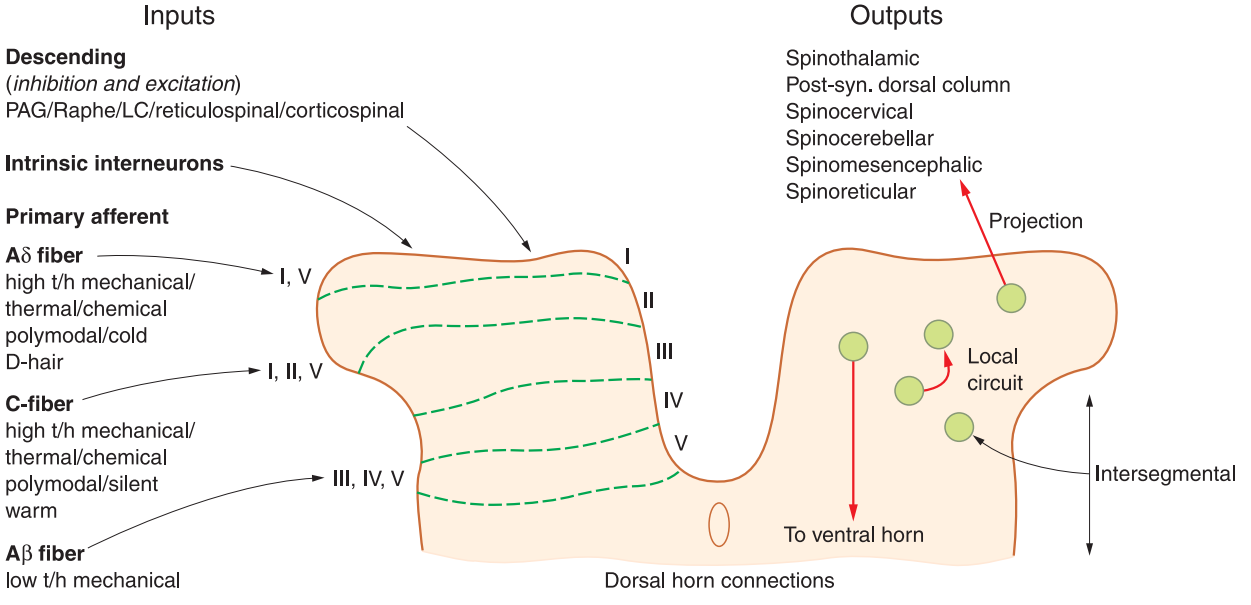

FIGURE 90–4. Connections of the dorsal horn of the spinal cord display major inputs and outputs. Left. Primary afferent input to the dorsal horn. Nociceptive afferents (A-δ and C fibers) synapse in Rexed laminae I, II, and VI. Low-threshold afferents (A-β fibers) synapse primarily in Rexed laminae III, IV, and V. Right. Some of the important circuits originating from dorsal horn neurons. The majority of dorsal horn neurons are interneurons that generate intrinsic circuits. Other dorsal horn neurons project to the brain, the dorsal horn at different spinal levels, and the ventral horn of the spinal cord.

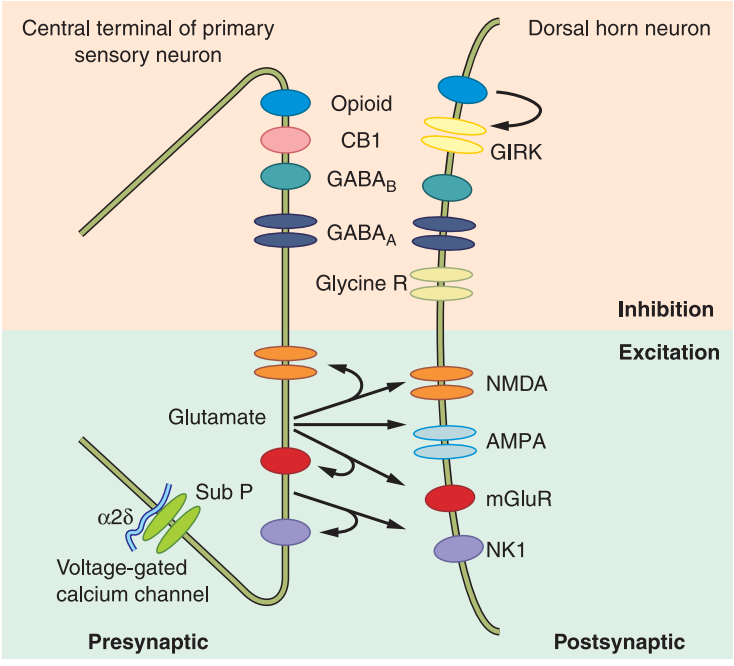

FIGURE 90–5. Inhibitory and excitatory influences of primary afferents in the spinal cord dorsal horn. Second-order neurons in the dorsal horn of the spinal cord are subject to both inhibitory and excitatory presynaptic influences by primary sensory afferents. This is one of several mechanisms through which excitability of dorsal horn neurons is controlled. Dorsal horn neurons also are subject to inhibitory and excitatory influences from local interneurons and descending brainstem pathways.

information in the dorsal horn (Fig. 90–5). Tables 90–5 and 90–6 list the major excitatory and inhibitory neurotransmitters and their receptors in the spinal cord. Invasion of the central terminal of nociceptors in the spinal cord by action potentials arriving from the periphery results in activation of voltage-dependent calcium channels and calcium entry, which activate release mechanisms of the synapse sufficiently to release transmitter. Sufficient transmitter may be released to produce depolarization of the postsynaptic cell large enough to initiate an action potential in the second-order neuron. Alternatively, the invading action potential may not result in any release of transmitter. Between these extremes lies a range of graded synaptic efficacies from strong to almost ineffective. Most input is subthreshold. Control of synaptic efficacy is one of the major driving forces of neuronal plasticity in general and of pain hypersensitivity in particular. A variety of factors control synaptic strength or efficacy. They include the following:

1. Density and activity of voltage-dependent calcium channels on presynaptic terminals
2. Type of transmitter, amount in each synaptic vesicle, and vesicle release mechanisms.
3. Receptors on the presynaptic axonal central terminals that can control transmitter release, such as γ-aminobutyric acid (GABA), opioid, and cannabinoid.
4. Transmitter degradation and uptake
5. Density, type, and state of postsynaptic receptors
6. Excitability of the postsynaptic membrane as determined by K^+ and Na^+ ion channels

All of these factors can be modified and in this way facilitate or depress nociceptive signal processing and transmission. Synaptic transmission between primary afferent nociceptors (predominantly C fibers) and second-order neurons has both fast and slow components. As in the case of the nervous system in general, the excitatory amino acid glutamate is the primary fast *excitatory* neurotransmitter used by nociceptors. Glutamate activates α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA)/kainate ionotropic glutamate receptors, leading to a short-lasting depolarization in second-order neurons (a few milliseconds), the fast excitatory postsynaptic potential. The *N*-methyl-D-aspartate (NMDA) ionotropic glutamate receptor is another ionotropic glutamate receptor that is also found on many neurons in nociceptive pathways. The channel of this receptor normally is blocked by Mg^{2+} at resting membrane potentials. Membrane depolarization is required for removal or relief of Mg^{2+} block, only then enabling, in the presence of glutamate, activation. The NMDA ion channel allows both calcium and sodium ion influx into the cell; calcium then can act as a second messenger and produce long-lasting changes in the cell.

C-fibers in addition to glutamate have a variety of other cotransmitters (e.g., substance P, calcitonin gene-related peptide [CGRP], neuropeptide Y [NPY], and brain-derived neurotropic factor [BDNF]). Whereas glutamate activates ionotropic AMPA/kainate receptors to produce a fast synaptic potential, the co-released neuropeptides activate G-protein–coupled receptors, resulting in a delayed and longer-lasting slow postsynaptic potential that persists for several seconds. This slow synaptic po-

TABLE 90–5.

Synaptic Mediators of Dorsal Horn Nociceptive Processing

Excitatory	Inhibitory
Amino acids: glutamate and aspartate	Endogenous opioids: enkephalin and β-endorphin
Neuropeptides: substance P (SP), calcitonin gene-related peptide (CGRP), vasoactive intestinal peptide (VIP)	Amino acids: glycine and γ-aminobutyric acid (GABA)
Growth factors: brain-derived neurotropic factor (BDNF)	Norepinephrine (NE)
Bradykinin	Serotonin (5-HT)
Somatostatin	Endogenous cannabinoids
Prostaglandin E_2 (PGE_2)	

TABLE 90–6.

Dorsal Horn Neuronal Receptors Involved in the Processing of Nociceptive Information

Receptor	Major Ligand(s)
Excitatory Ionotropic	
NMDA receptor	Glutamate (glycine is a co-ligand)
AMPA receptor	Glutamate
Kainate receptor	Glutamate
Excitatory Metabotropic	
Neurokinin receptors, NK1	Substance P
Metabotropic glutamate receptor, mGluR5	Glutamate
Prostaglandin receptors	Prostaglandin E_2, prostaglandin F2α
Tyrosine kinase B (TrkB) receptor	Brain-derived neurotrophic factor (BDNF) Neurotrophin 4/5 (NT4/5)
Inhibitory Metabotropic	
Opioid receptors	Endomorphins, enkephalins, dynorphin
α_2-Adrenergic receptor	Norepinephrine
Serotonin receptors, 5-$HT_{1B/D}$ & $5HT_3$[a]	Serotonin
$GABA_B$ receptor	γ-aminobutyric acid (GABA)
Cannabinoid receptor, CB1	Endocannabinoids
Inhibitory Ionotropic	
Glycine receptor	Glycine

[a]Serotonin may have facilitatory effects in the dorsal horn via activation of $5HT_3$ receptors.

tential contributes to one form of activity-dependent synaptic modification of dorsal horn neuron function called *windup.* Windup is a progressive increase in action potential generation in dorsal horn neurons in response to repetitive, low-frequency C-fiber stimulation. It is a form of activity-dependent plasticity that occurs over the course of the stimuli and terminates within a few seconds of the end of the afferent input. Only those synapses on second-order neurons that are directly stimulated by the repeated sensory afferent inputs show the increase, and windup is a form of what is called *homosynaptic* activity-dependent plasticity, limited to the activated synapse. The cumulative depolarization produced by summation of slow synaptic potentials recruits NMDA receptors by removing Mg^{2+} channel block, leading to progressive buildup in synaptic efficacy and hence windup.[14] It is possible to observe in human volunteers a progressively increasing pain response to repetitive peripheral noxious heat stimuli; in patients following nerve injury, a windup of pain can be observed for repeated mechanical stimulation. This clinical correlate of the windup phenomenon can be blocked by NMDA receptor antagonists such as ketamine.[15]

Glycine and GABA are the predominant mediators of *inhibitory* neurotransmission in the dorsal horn. Glycine and GABA activate glycine and $GABA_A$ ionotropic receptors to produce inward Cl^- currents that hyperpolarize and, therefore, inhibit neuronal activity. Several inhibitory metabotropic (i.e., G-protein–coupled) receptors are present on afferent central terminals and dorsal horn neurons, including $GABA_B$, opioid, cannabinoid, and adenosine receptors. Drugs that act as agonists on these receptors, such as morphine, reduce transmission in nociceptive pathways and thereby produce analgesia. Calcium channel blockers (N-type, $Ca_V2.2$), such as ziconotide, also reduce transmitter release and have analgesic activity. Gabapentin and pregabalin bind to the α_2-δ subunit of calcium channels and may reduce transmitter release in a use-dependent fashion.

Ascending Nociceptive Pathways

After processing in the dorsal horn, nociceptive information is transferred to the brain by projection neurons. There are several ascending projection systems; two of the more important are the spinothalamic and spinobulbar pathways. The spinothalamic tract carries information from dorsal horn lamina I (marginal zone), laminae IV-V (deep dorsal horn), and laminae VII–VIII (intermediate zone and medial ventral horn) to the lateral thalamus. Spinothalamic tract neurons project to six thalamic regions: ventral posterior nuclei, ventral medial nucleus, ventral lateral nucleus, central lateral nucleus, parafascicular nucleus, and medial dorsal nucleus. The thalamic neurons on which these fibers synapse then send projections to the somatosensory cortex: SI and SII. This pathway is thought to be involved in the sensory and discriminative aspects of pain as well as temperature and itch.[16]

There is substantial projection of nociceptive information from the dorsal horn to the brainstem. Cells of the spinobulbar pathway reside principally in laminae I, V, and VII.[17] This projection system terminates in four areas of the brainstem: regions of catecholamine cell groups (A1–A7), parabrachial nucleus, periaqueductal gray, and brainstem reticular formation.[18] The parabrachial nucleus is thought to be involved in homeostasis and autonomic functions. The periaqueductal gray, which has both ascending and descending projections, seems to be involved in homeostasis, limbic motor output, and integration of ascending nociceptive information with descending antinociceptive output.[19] Nociceptive information is carried from the dorsal horn to the hypothalamus by the spinohypothalamic tract.[20] Cells in this tract originate in laminae I, V, VII, and X[21] and are important for integration of pain with autonomic functions (e.g., sleep, appetite, temperature regulation) and emotional and neuroendocrine responses. These and other ascending spinal tracts provide input through multisynaptic pathways to a wide array of higher cortical areas. Positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) have been used to demonstrate brain activation associated with pain (see Representation of Pain in the Brain).

Descending Nociceptive Pathways

The ability to modulate nociceptive transmission is as important to an organism as the ability to detect such stimuli. Descending outputs from the brain modulate pain transmission at the level of the spinal cord. The descending controls are both inhibitory and facilitatory. The midbrain periaqueductal gray acting through the rostral ventromedial medulla (RVM) represents the key center for integration of the brain's descending output to the

dorsal horn.[19,22–24] Cells of the RVM have been classified into three types based on their response to peripheral noxious stimulation: "on," "off," and "neutral."[25] "On" cells are activated by prolonged noxious stimulation. These cells activate descending facilitatory pathways that enhance dorsal horn nociceptive conduction. "Off" cells are tonically active, provide inhibitory input to dorsal horn nociceptive circuits, and are inhibited by noxious stimuli. The descending output of the RVM, as related to nociception, uses several functionally interrelated systems: opioid, noradrenergic, and serotonergic systems.

The opioid system is active at multiple levels, including the brain, brainstem, spinal cord, and peripheral terminals of primary afferent neurons. The endogenous opioids—β-endorphin, the enkephalins, and the dynorphins—are peptides that inhibit synaptic transmission via activation of G-protein–coupled receptors. The opioid receptors are grouped into three functional distinct classes—μ, δ, and κ—which have both presynaptic and postsynaptic effects. Most clinically used opioids act on the μ receptor. In the spinal cord, opioid receptors exert their antinociceptive effects by inhibiting synaptic vesicle release from primary afferents and by hyperpolarizing second-order nociceptive neurons, decreasing their excitability. Inhibition of vesicle release is mediated by inhibition of voltage-gated Ca^{2+} channels, whereas hyperpolarization of the spinal cord neurons occurs principally via enhanced K^+ efflux by activating G-protein–coupled inwardly rectifying potassium K channels. Modulation of the opioid system has proven extremely useful in management of both acute and terminal pain, although the role of opioids in the management of chronic pain remains controversial because of their side effect profile, tolerance and dependency issues, and the problem of illicit use and diversion.

The noradrenergic system is a second major descending inhibitory nociceptive pathway. The primary receptor for norepinephrine in the spinal cord is the α_2-adrenergic receptor. Like the opioid receptors, it is a G-protein–coupled receptor that, through second messengers, both inhibits presynaptic neurotransmitter release from primary afferents and decreases excitation of postsynaptic neurons via hyperpolarization of those cells. α_2-Adrenergic receptor agonists such as clonidine have an analgesic action. Serotonergic descending input from the RVM provides both inhibitory and facilitatory control of dorsal horn nociceptive function.[26] There are multiple subtypes of the serotonin (5-hydroxytryptamine [5-HT]) receptor in the spinal cord, and 5-HT can produce antinociceptive and pronociceptive effects depending on the receptor subtype(s) activated. Descending 5-HT inhibition is a presynaptic effect mediated by metabotropic 5-HT receptors, activation of which decreases transmitter release. 5-HT–mediated facilitation is mediated by ionotropic receptors (5-HT_3 subtype) that enhance transmitter release from nociceptive primary afferents.

Selective serotonin reuptake inhibitors that increase 5-HT levels have minimal analgesic action. In contrast, dual-uptake inhibitor drugs that block uptake of both norepinephrine and serotonin, such as the tricyclic antidepressants and newer agents such as duloxetine, have demonstrated efficacy in the treatment of neuropathic pain and likely act by augmenting the actions of descending inhibitory systems in the spinal cord.[27]

Representation of Pain in the Brain

Cortical areas are critical for integration of information regarding peripheral noxious stimuli, the generation of a perception of "pain" and the response—motor, autonomic, psychological, cognitive—to the pain. The intensity of pain perceived depends on multiple factors, including the nature of the pain, level of arousal, emotional state, learned responses, anticipation, and reward. The representations of acute and persistent pain overlap but are not identical, and persistent but not acute pain may lead to (or be caused by) permanent changes in the brain. For example, chronic low back pain is associated with cortical atrophy.[28–30] Given the complexity of the processing, perception, and response to pain, it is not surprising that functional imaging (e.g., PET, fMRI, magnetoencephalography) reveals wide involvement of brain regions.[31] These areas include the thalamus, hypothalamus, limbic system, cerebral cortex, cingulate cortex, basal ganglia, and cerebellum.[32,33]

The integration and processing of pain in the brain has been postulated to consist of broad categories of function—discriminative, affective-motivational, and cognitive—that involve distinct but overlapping regions. *Discriminative* refers to perceptual identification of the location, nature, and intensity of a painful stimulus. It is somatotopically specific and involves the primary (SI) and secondary (SII) sensory cortex.[34,35] Localization of pain, in particular, appears to involve S1. The *affective-motivational* component of pain is thought to involve several limbic structures including the cingulate cortex and the amygdala.[36] Despite the ability to link specific regions with different aspects of pain, nociceptive processing in the brain represents a "matrix" in which multiple regions are recruited in the different aspects of the perception of, and response to, pain.[31]

There is a temporal sequence of cortical activation during the experience of pain. Because of the difference in conduction velocities of A (myelinated fast) and C (unmyelinated, slow) fibers, there exist "fast" and "slow" components of pain perception. It has been hypothesized that the fast component is important for immediate responses to pain (i.e., withdrawal), although the slow component is more important for behavioral responses that limit injury and promote healing.[37] Whereas the first component of pain is associated with SI activation (SI also is important for cutaneous localization of noxious stimuli), the second component maps to the anterior cingulate cortex. Expectation and past experience affect the response to noxious stimuli and hence the experience of pain. There exists a robust placebo effect related to analgesia, and this effect is a clear example of cognitive modulation of the pain experience. Using functional imaging in subjects who are experiencing placebo analgesia provides insight into the brain regions involved in modulation of pain perception.[38,39]

TAXONOMY OF PAIN

The International Association for the Study of Pain (IASP) defines *pain* as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage."

A basic tenant of pain taxonomy is that there are multiple types of pain, each with different underlying mecha-

nisms (Figs. 90–6 and 90–7). We divide pain states into the following categories:

Nociceptive

Inflammatory

Neuropathic

Dysfunctional (Fig. 90–8)

Nociceptive pain is pain that results from activation of nociceptors by noxious stimuli. This pain is "high threshold" and generally serves a protective function. The pain can potentially be "chronic" if stimulation of nociceptors is persistent, as may occur with mechanical destruction of a joint in osteoarthritis resulting in activation of nociceptor peripheral terminals upon movement of the joint. Clinically, pain is considered chronic if it lasts more that 3–6 months.[40] Acute trauma and procedural pain are examples of nociceptive pain.

Injured tissue and inflammatory cells release a variety of mediators that can activate or sensitize primary afferent nociceptors as well as alter gene expression in sensory neurons and facilitate central transmission, thereby generating *inflammatory pain* (Fig. 90–9). Although this pain can be regarded in some circumstances to serve an adaptive function, promoting healing and repair, there is a need to control the pain both in acute situations such as postoperative pain and in disease states such as chronic arthritis. Malignant cells may produce inflammatory mediators that sensitize nociceptors. In the past inflammatory pain

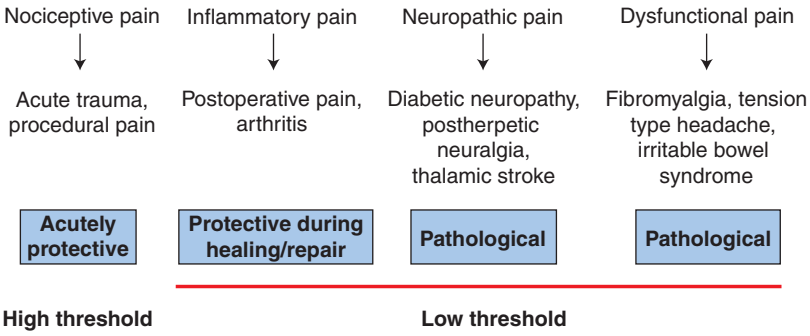

FIGURE 90–6. Four basic categories of pain. There are multiple types of pain, each with different causes and underlying mechanisms. Pain can be roughly categorized as nociceptive, inflammatory, neuropathic, and dysfunctional. Whereas nociceptive and inflammatory pain can have a protective function, both neuropathic and dysfunctional pain represent pathologic functioning of the nociceptive system. Nociceptive pain involves nociceptor activation by high-threshold stimuli only. With inflammatory, neuropathic, and dysfunctional pain, the nociceptive system can be stimulated by both high-threshold and low-threshold stimuli, and pain hypersensitivity (hyperalgesia and allodynia) occurs. Examples of each type of pain are listed beneath the arrows (note: the list is not exhaustive).

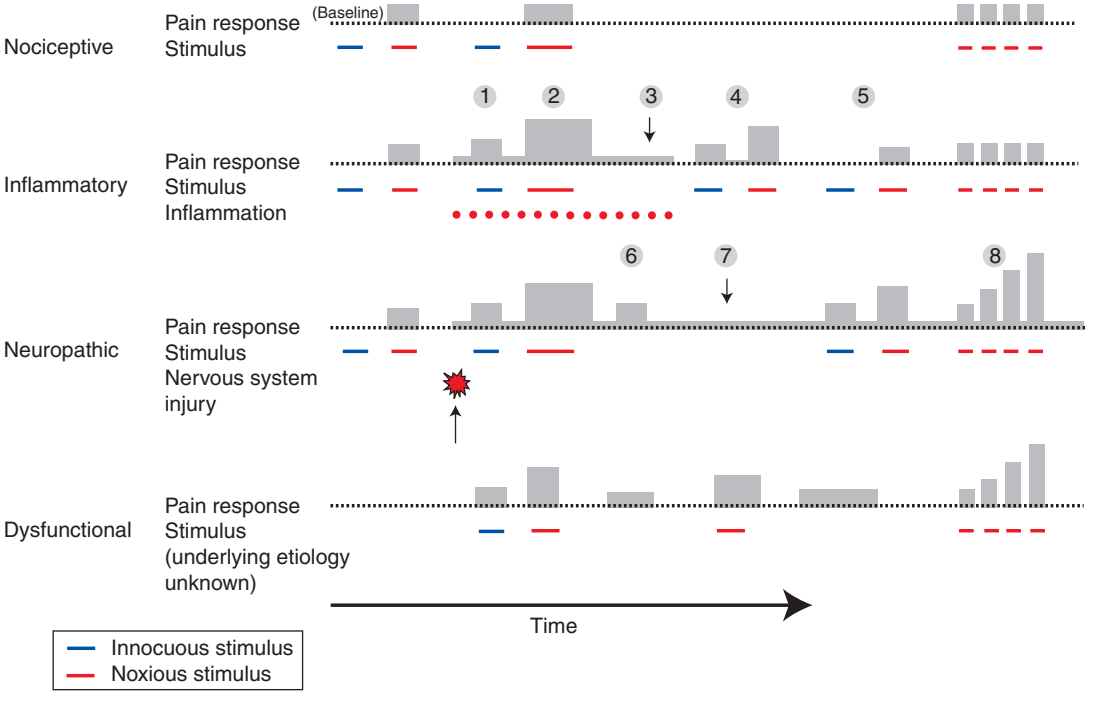

FIGURE 90–7. Clinical response characteristics of pain types. Different types of pain have different response characteristics following noxious and innocuous stimulation. Nociceptive pain is generated by noxious stimuli only, activates high-threshold sensory afferents only, and the pain resolves with resolution of the pain-evoking stimulus. Inflammatory pain is characterized by allodynia (**1**) and hyperalgesia (**2**). There also is continuous pain associated with ongoing nociceptive stimulation (**3**). With inflammatory-type pain, stimulus-independent pain and stimulus-dependent hypersensitivity may persist for some finite period following the resolution of inflammation (**4**) but typically resolve (**5**). Neuropathic pain and dysfunctional pain are characterized by allodynia, hyperalgesia, stimulus-independent pain, and windup. Stimulus-independent pain may include paroxysmal (**6**) and continuous (**7**) components. Windup (**8**) is the progressive pain response to repeated stimulation. It involves activation of *N*-methyl-D-aspartate (NMDA) receptors and results from changes at the level of the dorsal horn of the spinal cord. Nociceptive and inflammatory pain encourages an organism to avoid potentially or actually tissue-damaging stimuli; these pain types are physiologic and have a protective function. Neuropathic and dysfunctional pain lack protective function and are considered pathologic.

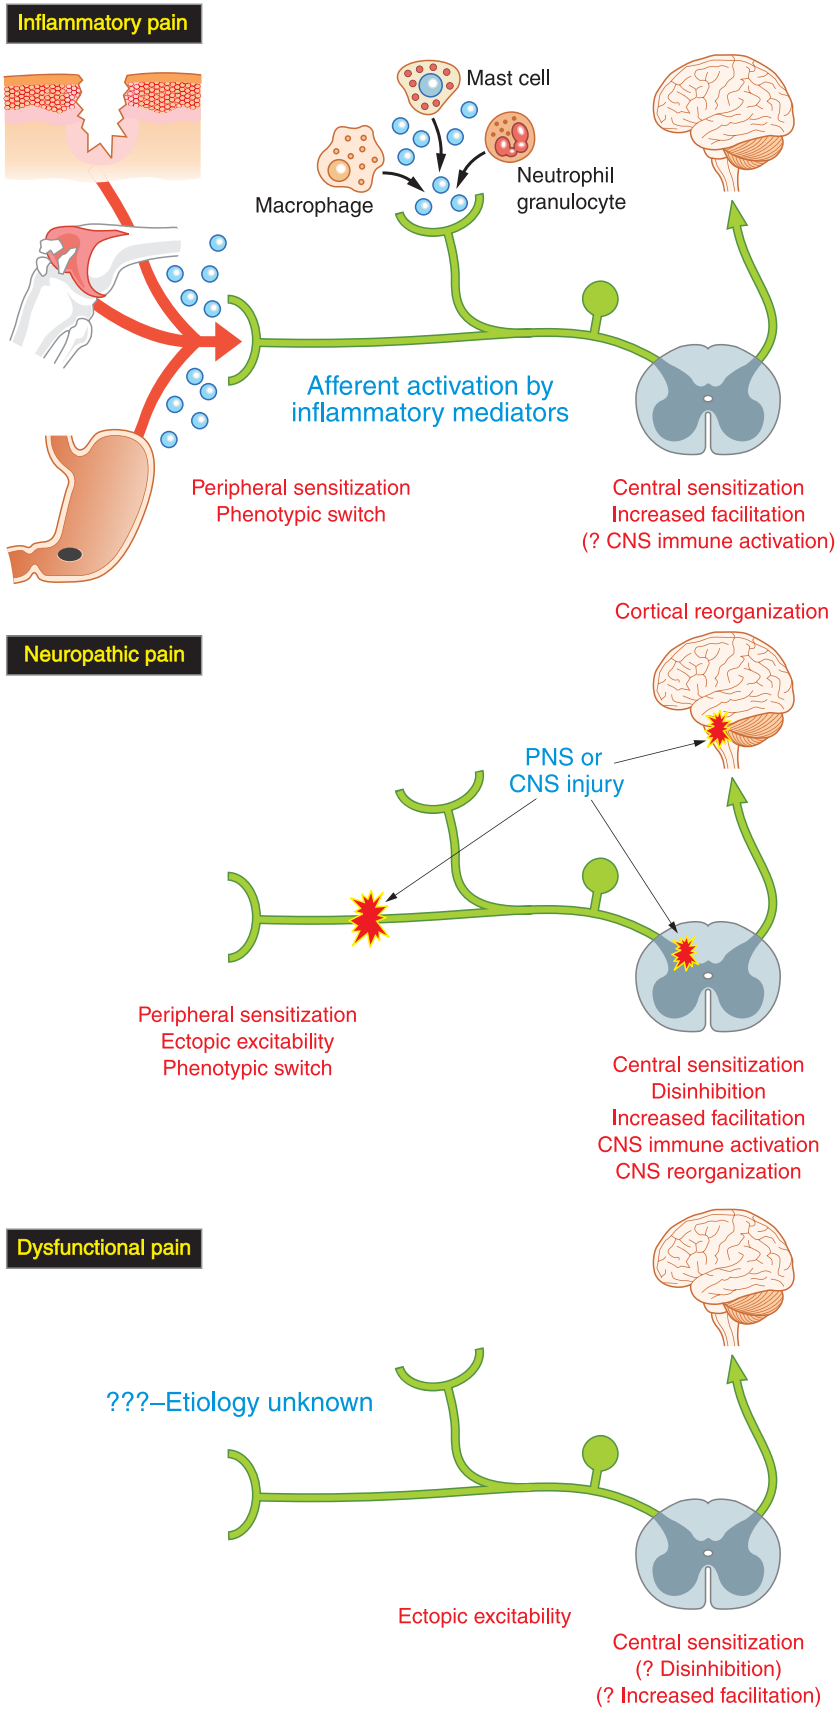

FIGURE 90–8. Underlying mechanisms of pain. Different types of pain (inflammatory, neuropathic, dysfunctional) have different etiologies and are associated with different, but overlapping, underlying mechanisms.

was grouped within the category of nociceptive pain,[41] but this is clinically and mechanistically incorrect. The two categories differ in that nociceptive pain only includes pain in response to suprathreshold nociceptor stimulation by noxious stimuli, whereas inflammatory pain includes changes in peripheral and central sensory pathways that generate facilitated pain processing so that pain now can be produced by low-intensity stimuli.

There exist chronic or persistent pain states for which the pain serves no adaptive function. These states, "neuropathic" and "dysfunctional" pain, are pathologic. The IASP defines *neuropathic pain* as pain initiated or caused by a primary lesion of or dysfunction in the nervous system. we believe this definition is too broad; we prefer to define neuropathic pain only as pain with an identifiable lesion to the nervous system that will cause a loss of function and thereby negative symptoms. Neuropathic pain is caused by a wide variety of disorders that are heterogeneous in etiology and presentation[42] and can by generated by lesions at many levels of the nervous system. Neuropathic pain is subdivided into *central* and *peripheral*, referring to whether the inciting lesion/dysfunction is in the CNS or PNS, respectively. Examples of peripheral neuropathic pain include painful diabetic neuropathy and carpal tunnel syndrome. Pain syndromes associated with thalamic strokes or spinal cord trauma are examples of central neuropathic pain. A cardinal component of the clinical diagnosis of neuropathic pain is the presence of both positive (e.g., allodynia, hyperalgesia, dysesthesia) and negative (e.g., loss of function such as sensory loss in a region of pain hypersensitivity, muscle weakness, absent reflexes) symptoms or signs. In addition, pain can be grouped into *stimulus evoked* and *stimulus independent*. The former is characterized by the presence of hyperalgesia and/or allodynia, whereas the latter spontaneous pain may be paroxysmal or persistent.

Inflammatory pain and neuropathic pain share some underlying mechanisms, but there is an important distinction between the two. Upon resolution of inflammation and removal of the chemical stimuli that mediate sensitization, the associated pain hypersensitivity usually resolves completely. In the case of neuropathic pain,

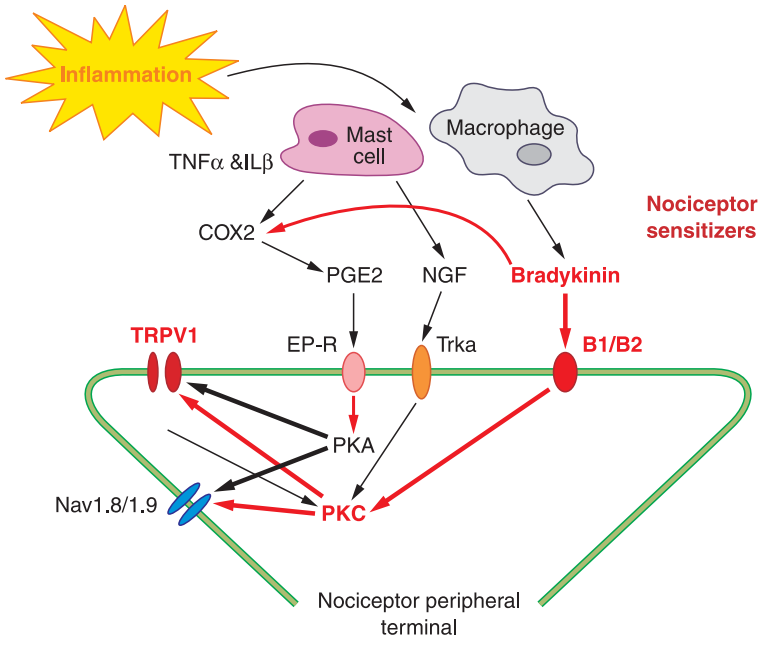

FIGURE 90–9. Primary afferent nociceptor sensitization. Following peripheral injury, a variety of inflammatory mediators are generated that are capable of sensitizing primary afferent nociceptors. These mediators bind to cell-surface receptors, activating a variety of second-messenger pathways that in turn can alter the transduction properties of both the receptors and ion channels involved in action potential generation and conduction.

however, the alterations in nociceptive processing, and hence the presence of pathologic pain, typically persist long after resolution of the initiating insult to the nervous system.

Dysfunctional pain represents a diagnosis of exclusion. It can be defined as persistent pain in the absence of a noxious stimulus, peripheral inflammation, or an identifiable lesion to the nervous system. There are no focal neurologic findings or negative symptoms. Instead, the pain appears to result from abnormal function of the nervous system, creating an abnormal sensitivity or gain. Examples of dysfunctional pain include fibromyalgia, irritable bowel syndrome, and tension-type headache.

This categorization provides a schema for approaching clinical problems but does not imply specific underlying mechanisms. Multiple mechanisms underlie the generation of chronic pain, and multiple mechanisms often are simultaneously active. We now discuss the different mechanisms that produce clinical pain.

PAIN HYPERSENSITIVITY

Nociceptive pain is characterized by a clear relationship between stimulus intensity (once threshold has been exceeded) and the response or pain perception until tissue damage occurs. An additional defining feature of this pain is that it abates upon cessation of the noxious stimulus, provided tissue is not damaged. Nociception depends upon high-threshold afferents being activated only by relatively intense stimuli. Nociception is highly adaptive in that it is associated with behaviors and responses that minimize tissue injury. The pain is an early or alarm warning system.

If actual tissue damage occurs (producing inflammation), hypersensitivity is generated by a variety of mechanisms that convert high-threshold nociception to low-threshold inflammatory pain. Like nociceptive pain, inflammatory pain in some circumstances can be adaptive. For example, the pain hypersensitivity that follows a burn discourages further contact with the damaged skin until the skin is fully healed. After healing has occurred, the alterations in nociceptive processing and the associated hypersensitivity in most cases tend to resolve completely. Pain that is persistent, is severe, or interferes with function and quality of life is a clinical problem that must be controlled. Neuropathic and dysfunctional pain syndromes, which are not related to any threat to the organism and which perform no protective or reparative function, also are characterized by hypersensitivity. These states constitute true pathologic or maladaptive pain. Clinical pain typically presents as pain in the absence of a stimulus, spontaneous pain, and pain hypersensitivity, the latter manifesting as allodynia, hyperalgesia, and hyperpathia.

Allodynia is a state in which normally innocuous stimuli are perceived as painful. Dynamic tactile allodynia to stroking stimuli, such as brushing the skin, is the prototypic example, but pain in response to nonnoxious temperatures (cool and warm) also occurs. *Hyperalgesia* is a state of exaggerated or prolonged response to noxious stimuli. *Hyperpathia* refers to an explosive, intensely unpleasant, usually long-lasting pain.

Primary hyperalgesia refers to hyperalgesia or allodynia occurring at the site of an injury. *Secondary hyperalgesia* is the pain hypersensitivity that occurs outside the area of injury, in normal tissues. Several of the pain-related definitions discussed are listed in Table 90–7.

MECHANISMS UNDERLYING CLINICAL PAIN

The mechanisms underlying clinical pain are divided into broad categories, which include the following:

- Peripheral sensitization
- Central sensitization
- Ectopic excitability
- Disinhibition
- Phenotypic switch
- Structural reorganization
- Immune activation

Genetic Factors

These different mechanisms are the neurobiologic building blocks that underlie clinical pain but do not individually define specific pain conditions. Nor do particular disease states imply involvement of specific mechanisms. Multiple mechanisms may coexist, and the mechanisms may change over time.

Inflammatory Pain

Inflammatory pain involves changes in the threshold and responsiveness of nociceptor terminals at the site of inflammation (peripheral sensitization),

TABLE 90–7.

Pain-Related Definitions

Noxious stimulus	Intense, potentially or actually tissue-damaging stimulus
Nociceptor	High-threshold primary sensory neuron normally activated by and only encoding noxious stimuli
Nociception	Detection, processing, and perception of noxious stimuli by the nervous system
Nociceptive pain	Pain due to activation of nociceptors by noxious stimuli
Neuropathic pain	Pain initiated or caused by a lesion of the peripheral nervous system or central nervous system
Inflammatory pain	Pain associated with ongoing tissue damage and inflammation
Dysfunctional pain	Pain in the absence of a noxious stimulus, tissue damage, or lesion to the nervous system resulting from abnormal processing by the nervous system
Sensitization	Heightened responsiveness of neurons
Peripheral sensitization	Reduction in threshold and increased responsiveness of nociceptor peripheral terminals
Central sensitization	Hyperresponsiveness of nociceptive neurons in the central nervous system
Allodynia	Pain in response to a nonnoxious stimulus that normally would produce an innocuous sensation
Hyperalgesia	Heightened pain in response to a noxious stimulus

alterations in the chemical expression or phenotype of sensory neurons innervating the inflamed tissue (phenotypic switch), augmentation of synaptic transmission in the spinal cord (central sensitization) and altered input from the brain to the spinal cord. All of these mechanisms tend to occur in response to peripheral inflammation, but their relative contribution to pain hypersensitivity depends on the site, nature, extent, and duration of peripheral pathology.

Peripheral Sensitization

Peripheral sensitization refers to a reduction in the threshold and increase in the responsiveness of the peripheral terminals of nociceptors such that the terminals now can be activated by nonnoxious stimuli, and noxious stimuli evoke a greater action input from the peripheral terminal. Typically the inciting event is exposure to inflammatory mediators or sensitizers that act on the nociceptor terminal, changing its functional properties (Fig. 90–9). Inflammatory mediators that sensitize peripheral nociceptors include the cytokines tumor necrosis factor α (TNF-α) and interleukin-1β (IL-1β), bradykinin, ATP, prostanoids, particularly prostaglandin E_2 (PGE_2), amines, and nerve growth factor (NGF; Table 90–8). These mediators either sensitize nociceptors directly or act indirectly by causing the release of other effector molecules from mast cells or macrophages. The phenomenon of peripheral sensitization is most closely associated with inflammatory pain, which is not surprising given that the process is driven by inflammatory mediators.

All forms of tissue injury and inflammation can generate peripheral sensitization. Surgical trauma and sunburn are examples of an external injury that induces acute peripheral sensitization, whereas chronic inflammatory disease, such as rheumatoid arthritis, causes peripheral sensitization of the sensory afferents innervating inflamed joints. Pain hypersensitivity at the site of inflammation is the clinical manifestation of peripheral sensitization. For example, at the site of a burn injury there is increased pain to noxious heat stimulation (hyperalgesia) and a reduced mechanical and thermal threshold to pain in response to light touch or innocuous warm stimuli (allodynia). Not all the pain hypersensitivity at an inflamed site is due to peripheral sensitization; it may be due to central changes too, but peripheral sensitization is limited to the inflamed site where nociceptor terminals are exposed to inflammatory mediators.

Many sensitizing inflammatory mediators are secreted by macrophages, mast cells, and infiltrating leukocytes and exert their effects via activation of cell-surface G protein-couple receptor or membrane receptor tyrosine kinases expressed on the peripheral terminals of nociceptor sensory neurons. Peripheral sensitization is due both to an increase in the sensitivity of transduction receptor/ion channels (reducing their threshold) and to excitability of the membrane of the nociceptor peripheral terminal (increasing the responsiveness of the terminal). Both changes are triggered by activation of signal transduction pathways in the peripheral terminal by the sensitizing mediators. An example of altered transduction is that of the TRPV1, the high-threshold heat responsive ion channel. Repeated heat exposure, by allowing sufficient calcium entry through the channel, activates intra-

TABLE 90–8.

Some Receptors Involved in Nociceptor Sensitization

Metabotropic Receptors	Intracellular Transduction Mechanism
Serotonin receptors, $5HT_1$ and $5HT_2$	$G_{i/o}$-mediated inhibition of adenylate cyclase
Prostanoid receptors, EP, DP, IP	G-protein–mediated effects
ATP receptor, P2Y	G-protein–mediated effects, including TRPV1 sensitization
Histamine receptors, H_1, H_2, H_3, H_4[a]	G-protein–mediated effects
Growth Factors Receptors	**Major Ligand**
Tyrosine kinase (Trk) receptor, TrkA	Nerve growth factor (NGF)
Cytokine Receptors	**Ligand**
Tumor necrosis factor-α (TNF-α) receptor	TNF-α
Interleukin-1 (IL-1) receptor	IL-1α, IL-1β

[a]Activation of histamine receptors on cutaneous C-fibers causes itch under physiologic conditions. When neuropathic pain is present, application of histamine generates pain rather than itch.

cellular signal transduction pathways in the terminal that feed back and alter the receptor. This is a rare example of peripheral sensitization in the absence of peripheral inflammation. Alternatively, extrinsic inflammatory mediators such as prostaglandins and kinins, via activation of G protein-couple receptor expressed on the nociceptor terminal membrane, can lead, via signal transduction cascades, to changes in TRPV1 channel properties without it necessarily being activated.[43–45] Sensitization of TRPV1 in both cases occurs via phosphorylation of the ion channel/receptor.[6] This process reduces its activation threshold to 100–104°F (38–40°C) from 108°F (42°C). The reduced threshold now is in the nonpainful, warm range. The channel, and therefore the nociceptor, now can be activated by innocuous thermal stimulation. Thus, normally innocuous warm stimuli are perceived as painful, as after sunburn. NGF, a growth factor produced and released during inflammation, not only sensitizes the TRPV1 channel but also increases the membrane density of TRPV1 channels by increasing transport of the channel from cytoplasmic stores, providing another mechanism through which inflammation can facilitate TRPV1-mediated nociceptor activation in the terminal.[46] Sensitization of other members of the TRP family also occurs and likely contributes to peripheral sensitization and the increased response to thermal and mechanical stimuli.[47] Reductions in heat pain threshold in skin and in mechanical sensitivity in inflamed joints are the two major changes mediated by peripheral sensitization. $PGE_{2,}$ bradykinin, and NGF appear to be the major sensitizers.

Transduction receptor/ion channels are not the only substrate for intracellular kinases, such as protein kinase A (PKA) and protein kinase C (PKC), that are activated by inflammatory mediators. These kinases also phosphorylate the voltage-gated sodium channels $Na_V1.8$ and $Na_V1.9$ in nociceptor membranes, decreasing the activation thresholds of these channels and increasing their conductance[48] and thereby the nociceptor terminal membrane excitability. Induction of the cyclooxygenase-2 (COX-2) isoform at the site of peripheral inflammation has a major role in the generation of peripheral sensitization.[49,50] COX-2 upregulation is mediated largely by peripheral generation of IL-1.[51] Cyclooxygenase induction in inflamed tissue contributes to the peripheral analgesic action of nonsteroidal antiinflammatory drugs (NSAIDs), both nonselective and COX-2–selective agents.

Peripheral sensitization can be reduced by drugs targeted at the production, levels or receptor activation of inflammatory mediators. Anti-inflammatory agents include COX inhibitors, anti-NGF or anti-IL1 sequestering antibodies, and prostaglandin EP receptor antagonists. Other possible targets are the kinase enzymes, such as the PKC-ε isoform in nociceptors; the transduction receptors such as TRPV1; and sodium channels.

Neurogenic Inflammation

Activated nociceptors themselves can contribute to the inflammatory response. Repeated activation of peptide-expressing nociceptors can lead to release of the neuropeptides CGRP and substance P from their peripheral terminals. These neuropeptides lead to increased vascular permeability and edema (wheal), vasodilatation (flare) in peripheral tissues, and hence neurogenic inflammation. CGRP and substance P also lead to the release of inflammatory mediators such as TNF-α and histamine from inflammatory cells.[52]

Altered Phenotype in DRG Neurons after Peripheral Inflammation

Peripheral inflammation results in release not only of mediators that act locally but also of some that are taken by the nociceptors and transported from the terminal to the cell body. The best example of this is NGF, which in addition to its direct local action on nociceptor terminals is retrogradely transported to the sensory neuron cell body, where it increases synthesis of substance P and CGRP. NGF can also induce synthesis of substance P and CGRP in neurons that do not normally express these transmitters, thus generating a "phenotypic switch."[53] NGF also increases the rate of synthesis of TRPV1 by increasing the translation rate of TRPV1 from its mRNA.[54] An increase in expression of the μ-opioid receptor may contribute to increased sensitivity to opioid agonists in inflammatory pain.

Central Sensitization and Inflammatory Pain

Synaptic transmission in the spinal cord is highly modifiable[55,56]; therefore, there is considerable *"plasticity"* in the processing of nociceptive input. This synaptic plasticity is a critical player in the generation and maintenance of inflammatory pain. Central sensitization in inflammatory pain has two forms: *activity depen-*

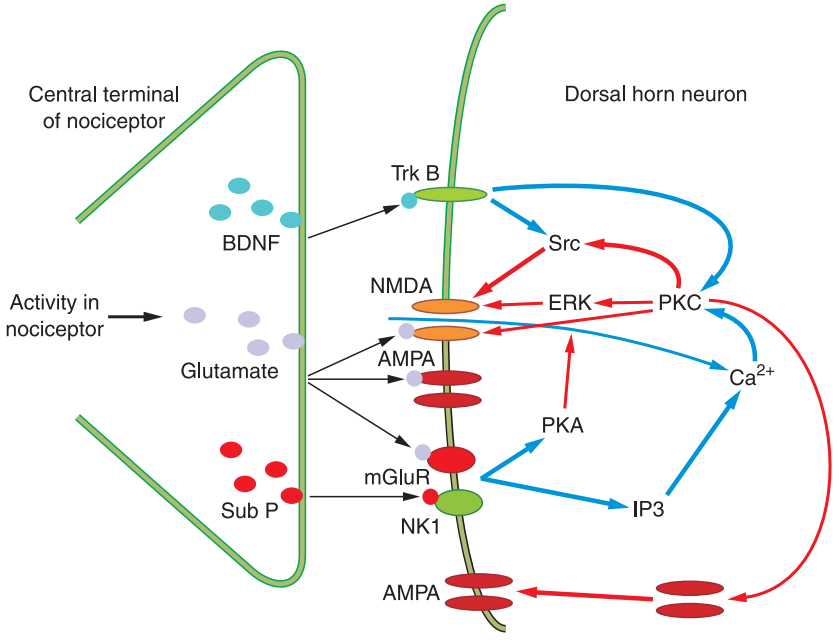

FIGURE 90–10. Activity-dependent central sensitization. Persistent or intense activation of central transmission can lead to postsynaptic calcium influx, primarily through *N*-methyl-D-aspartate (NMDA) and α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) receptors. In conjunction with a variety of neuromodulatory signals, calcium influx activates signal transduction cascades that can facilitate both short-term and long-term excitability of the dorsal horn synapse.

dent (Fig. 90–10), which is rapid in onset and short lasting, and *transcription dependent,* which has a longer latency and duration. Although inflammatory pain hypersensitivity once was considered to be largely, if not exclusively, due to changes in the periphery driven by the local inflammation, we now appreciate that central changes, collectively constituting central sensitization, drive much of the pain, particularly in the more chronic phases. This means that treatment targeted only at the periphery is generally insufficient.

Activity-Dependent Central Sensitization

This form of central sensitization is driven by input from nociceptor afferent fibers onto, and produces changes in, dorsal horn neurons. The sensitization is largely due to posttranslational modification and altered trafficking of receptors and ion channels. Any stimulus sufficient to generate a high sustained level of nociceptor activation will induce central sensitization. Once central sensitization is induced, much lower levels of peripheral input are required to sustain it. Activity-dependent central sensitization manifests as pain in response to activation of low-threshold primary afferents producing tactile allodynia and secondary hyperalgesia, a heightened pain sensitivity outside of an area of tissue injury.[57]

Heterosynaptic Central Sensitization

This is the major form of activity-dependent central sensitization in nociceptive neurons and can be induced by a short (as few as 10–20 seconds) barrage of nociceptor stimulation. It results from an increase in synaptic efficacy that outlasts the cessation of the initiating stimulus for tens of minutes. Furthermore, the increase not only affects synapses directly activated by the nociceptor input but also synapses not stimulated by the "conditioning" input.[58] This is an example of synaptic plasticity termed *heterosynaptic* facilitation, because the synapses activated by the noxious initiating and subsequent test stimuli can be different. The effect within the neurons is widespread. In contradistinction, in *homosynaptic* facilitation, only the stimulated synapses are altered; the effect is very local. Thus, whereas the conditioning input must be in nociceptors (A-δ and C fibers) in order to induce the central sensitization, the test stimuli may include either the same or other nociceptors or indeed low-threshold sensory afferents such as mechanosensitive A-β fibers. This phenomenon enables nociceptor input to dramatically alter the response of the spinal cord to low-threshold and high-threshold afferents. Heterosynaptic central sensitization has three manifestations at the cellular level: reduction in threshold due to recruitment of low-threshold input, increase in responsiveness of dorsal horn neurons to suprathreshold input, and expansion of the size of receptive fields of dorsal horn neurons.[57] These changes produce corresponding alterations in pain hypersensitivity: reduction in threshold, increased responsiveness, and spread of pain sensitivity.

The molecular mechanisms underlying this form of central sensitization are complex (Table 90–9). Induction of activity-dependent central sensitization in dorsal horn neurons is due to activation by transmitters and synaptic modulators released by nociceptors of intracellular signal transduction cascades in nociceptive dorsal horn neurons that then effect the changes in synaptic efficacy. The transmitters involved are glutamate acting on NMDA and metabotropic receptors, as well as substance P on NK1 receptors. We have started to appreciate that both PGE_2 and bradykinin are released in the spinal cord after nociceptor inputs and act on their respective EP and B2 G-protein–coupled receptors. All of these receptors activate mitogen-activated protein (MAP) kinases in the neurons, both ERK and p38, which in turn activate several other downstream kinases that phosphorylate various substrate proteins. The major changes underlying increased synaptic efficacy involve alterations in the NMDA receptor, which after it is phosphorylated loses the Mg^{2+} block of the channel normally present at resting membrane potentials, dramatically increasing sensitivity to glutamate at the resting membrane potential. Also, NMDA channel open time increases, prolonging the effect of receptor activation by glutamate. NMDA is involved in the initiation of activity-dependent central sensitization and in its maintenance; therefore, it plays a pivotal role. NMDA receptor antagonists such as ketamine can prevent establishment of central sensitization as well as reverse it once it has occurred. Unfortunately, because of the wide distribution of NMDA receptors in many parts of the brain and their involvement in many cortical functions, such antagonists produce unacceptable psychotropic side effects. These effects notwithstanding, NMDA antagonists at low doses or acutely as part of acute perioperative treatment have some, albeit limited, role in reducing central sensitization clinically. Antagonists targeted at specific NMDA receptor subunits, such as NR2B, may offer a greater therapeutic window. AMPA receptors show trafficking from the cytoplasm to the membrane during activity-dependent central sensitization, thus boosting glutamate sensitivity and increasing synaptic efficacy. Other contributory changes are a reduction in potassium channels, an increase in calcium channels, and no mediated retrograde signaling to the presynaptic terminal altering transmitter release.

Clinical correlates of heterosynaptic facilitation include dynamic tactile all-

odynia resulting from activation of nociceptive dorsal horn neurons by previously subthreshold inputs from low-threshold sensory afferents (i.e., A-β fibers). This depends upon the existence of synaptic input (monosynaptic and polysynaptic) from low-threshold afferents to normally high-threshold nociceptive dorsal horn neurons. One of the major implications of the discovery of central sensitization is that pain hypersensitivity has a central component and that the central component can last for prolonged periods once it is triggered. This led directly to recognition of the possible difference between treating established pain and trying to prevent its establishment, the concept of preemptive analgesia. Today, attempts are made, whenever possible, to reduce sensory inflow in nociceptors from reaching the spinal cord using regional anesthesia and to begin treatment with opioids well before the patient requires them, preoperatively or intraoperatively. The input that drives central sensitization will continue after completion of surgery from the injured tissue, and preemptive treatment must continue until the injury has healed; treatment is not simply preoperative.

A behavioral surrogate of heterosynaptic central sensitization can be demonstrated in volunteers using capsaicin-mediated C-fiber activation.[59] Capsaicin activates TRPV1 receptors, leading to a barrage of activity in C fibers that is experienced as intense pain. Following the intense pain, secondary mechanical allodynia to light touch and secondary mechanical hyperalgesia to pinprick develops in the area surrounding capsaicin injection.

Long-Term Potentiation and Activity-Dependent Central Sensitization

Brief high-frequency stimulation of nociceptors induces a potentiation of AMPA receptor-mediated excitatory synaptic transmission in NK1-expressing dorsal horn projection neurons in lamina I. This homosynaptic potentiation is NMDA receptor dependent and, unlike heterosynaptic potentiation, persists for many hours and may even be irreversible. This prolonged facilitation of monosynaptic excitatory synaptic transmission shares many of the mechanisms responsible for the long-term potentiation, including NMDA receptor dependence, observed in higher CNS centers such as the CA1 region of the hippocampus that contribute to memory.[60] Long-term potentiation in the spinal cord does not contribute to allodynia or secondary hyperalgesia.

Activity-dependent central sensitization can occur in the absence of peripheral inflammation; it manifests whenever nociceptors are intensely activated for an extended period. This was the first form of central sensitization discovered (Woolf, 1983).[55] More recently another form of central sensitization unique to inflammatory pain, transcription-dependent central sensitization, has become evident.

Transcription-Dependent Central Sensitization

After several hours, peripheral inflammation induces alterations in the levels of peptides and protein in sensory neurons innervating the inflamed tissue, such as an increase in substance P. After transport to the central terminals of nociceptors in the dorsal horn, these peptides and proteins will produce greater synaptic activation of dorsal horn neurons, increasing the degree of central sensitization evoked. In addition, changes in gene expression in dorsal horn neurons occur. One of the earliest recognized was that of NK1 paralleling the increase in its ligand, substance P. Another change is an induction of COX-2 in dorsal horn neurons, generating an increase in PGE_2 production.[51] This central COX-2 induction is the result of a humoral factor produced at the site of local inflammation (possibly IL-6), which acts on endothelial and meningeal cells to produce IL1-β, which in turn induces COX-2 in neurons. Because the effect is not driven by afferent input (i.e., is not activity dependent), it is widespread within the CNS. PGE_2 has many central actions. It increases primary afferent transmitter release and directly depolarizes dorsal horn neurons, both of which increase excitability. However, the major action of PGE_2 released after peripheral inflammation is to reduce inhibitory glycinergic neurotransmission in the spinal cord. PGE_2 acts on stimulatory G-protein–coupled EP2 prostaglandin receptors expressed on nociceptive dorsal horn neurons to increase intracellular cAMP, activating PKA that in turn phosphorylates and inhibits postsynaptic glycine receptors.[61,62] Glycine receptors in the spinal cord have a unique subunit composition (α3) that, when knocked out in a mouse, results in substantial reduction of the more chronic phases of inflammatory pain (>2 days).[63] Inhibition of centrally induced COX-2 produces analgesia. It is likely that more of the analgesic action of NSAIDs and COX-2 selective inhibitors derives from their central than their peripheral action. Complementing the decrease in local inhibition is an increase in descending facilitatory influences from the brainstem.[64–66]

The early phases of inflammatory pain likely are to be a combination of peripheral sensitization at the site of the inflammation and activity-dependent central sensitization in the spinal cord. The later phases shift to alterations in the phenotype of nociceptors, increasing their capacity for peripheral sensitization and inducing central sensitization. In addition, transcriptional changes in dorsal horn neurons can produce profound alterations, increasing excitation and decreasing inhibition that collectively produce local and distant pain hypersensitivity. Therefore, treatment must be targeted peripherally and centrally. However, once the inflammatory drive resolve, most of the changes revert and the pain system returns to its preinflammatory level. Some small residual changes may remain, increasing response to subsequent insults.

Neuropathic Pain

In a proportion of patients, injury to peripheral nerves results in persistent severe pain through recruitment of a variety of different mechanisms in the PNS and CNS. Characteristic of peripheral and central neuropathic pain are the presence of negative symptoms due to the injured nervous system and the chronicity of the pain. The impact on patients can be very severe, not only because of the intensity and intractability of the pain but also because of alterations in mood and function. In consequence, the economic and social toll to society is large.

In response to axonal lesions, injured primary sensory neurons, neighboring noninjured sensory neurons, Schwann cells, and immune system cells undergo substantial modifications in the peripheral nerve. These changes lead to activation of sensory fibers and enhanced excitability, with generation of spontaneous activity in primary afferents in the affected nerve. The two major underlying mechanisms are the

release of soluble pain-producing factors in the nerve that drive sensory afferents and phenotypic switches in the sensory neurons that increase membrane excitability.

Soluble "Pain" Mediators after Nerve Injury

Injury to peripheral nerves results in release of a variety of soluble factors capable of activating nociceptors. Cytokine TNF-α is released following nerve injury by denervated Schwann cells and in the DRG. It activates nociceptors[67,68] by increasing activity of TTX-resistant Na^+ channels.[69] IL-1β also may be involved.[70] In addition to cytokines, multiple chemokines produced by injured neurons and nonneuronal cells exert effects on sensory neurons and dorsal horn cells.[71,72]

Altered Membrane Excitability and Ectopic Activity

Membrane excitability is determined by the presence, state, and density of a variety of ion channels. The properties of many ion channels are markedly affected by nerve injury. Changes may be intrinsic, including altered kinetics (i.e., activation and/or inactivation properties) and conductance, as well as altered membrane density secondary to changes in their expression and trafficking.[73–75] Following nerve injury, sensory fibers begin to generate action potentials in the absence of any peripheral stimulation, the phenomenon of ectopic activity. First, within 24 hours of the injury, myelinated fibers (A-β and A-δ) begin to generate spontaneous electrical activity, followed by activity in C fibers.[76] Ectopic activity originates at multiple sites, including the neuroma and the cell body of primary afferents in the DRG.[77] Ectopic activity occurs in both injured and neighboring noninjured fibers and is a major contributor to stimulus-independent spontaneous pain that manifests clinically as persistent burning pain and paroxysms of shooting, electrical pain. In addition to spontaneous or intermittent shooting pain, ectopic activity generates paresthesias and dysesthesias, depending on the specific nerves and types of fibers affected. Patients with neuromas frequently complain that palpation of their neuroma generates paroxysms of pain that outlast the stimulus (i.e., Tinel sign). This may reflect accumulation of mechanosensitive channels in axons in the neuroma.

The TTX-resistant channel $Na_V1.8$ is downregulated and redistributed following peripheral nerve injury from the DRG to peripheral axons, where it has been suggested to play a role in altering membrane excitability.[78] However, knockout of $Na_V1.8$ and $Na_V1.9$ diminishes inflammatory pain but not neuropathic pain[79,80]; therefore, these channels are unlikely to have a major role in neuropathic pain. The TTX-sensitive channel $Na_V1.3$, which is barely detectable in the intact adult PNS, is markedly upregulated in DRG neurons following peripheral nerve injury. This channel produces currents that rapidly recover from inactivation, allowing it to sustain high-frequency firing[81]; therefore, it may be a driver of ectopic input after injury. Pacemaker channels also are implicated in the generation of ectopic activity.[82] They are found in the membrane of the cell body, are hyperpolarization activated and cyclic nucleotide modulated, and are permeable to sodium and potassium ions. Their blockade reduces pain behavior in animal models of neuropathic pain.[83] In addition to Na^+ channels, nerve injury affects the expression of other ion channels, such as Ca^{2+} and K^+ channels.[84–86] Voltage-gated potassium channels are downregulated,[85] and this change, which depolarizes the membrane, is regulated by BDNF and neurotropin-3.[85] One major action of systemically administered sodium channel blockers, such as lamotrigine and carbamazepine, is to reduce ectopic activity. Whether abnormal sodium channel expression/activity determines pain in individual patients can be tested with IV lidocaine infusions. Peripheral nerve blocks temporarily block ectopic inflow, whereas topical local anesthetics, as used in patients with postherpetic neuralgia, interrupt activation of peripheral terminals of nondamaged sensory neurons. More invasive treatment, such as radiofrequency or chemical lesions to nerves, may produce longer-lasting relief but may actually exacerbate the pain in the long run because they damage the nerve. Surgery to remove a neuroma frequently results in reformation of the neuroma and return of the pain. In general, treating neuropathic pain by damaging nerves is like putting out a fire with gasoline.

Phenotypic Switch

Injured neurons undergo profound changes in gene expression after nerve lesions, with alterations in the expression of many hundreds of genes that change neuronal phenotype. Some changes are unrelated to pain but assist with survival and regrowth of injured neurons; others do contribute to altered function. The normal differentiated phenotype of the neurons can undergo major switches. For example, BDNF normally is expressed predominantly by nociceptors. Following peripheral nerve injury, small neurons switch off normal synthesis of BDNF, whereas larger neurons assume a BDNF phenotype.[87–89] Similar alterations for neuropeptide Y (NPY) and substance P occur.[90] Thus, following injury, sensory neurons that do not convey nociceptive information can begin to express transmitters/synaptic modulators normally found only in nociceptive primary afferent pathways. These changes may contribute to pain when nonnociceptive afferents release mediators that activate second-order nociceptive neurons in the dorsal horn in a way that normally occurs only in response to nociceptor inputs.

Peripheral nerve injury results in downregulation of μ-opioid receptors in DRG neurons. This process may underlie the decreased efficacy of opioids in some patients with neuropathic pain.[91,92] In addition, expression in the A2-δ accessory protein of voltage-gated calcium channels is increased. Gabapentin binds to this subunit, and its induction after nerve injury may contribute to the efficacy of gabapentin and pregabalin in neuropathic pain. Increased expression of adrenergic receptors contributes to the development of sensitivity to humoral epinephrine and to norepinephrine release from sympathetic fibers. Sympathetic fibers sprout into the DRG after nerve injury; this, in addition to the adrenosensitivity of injured afferents, provides the basis for a sympathetic component of neuropathic pain that is present in some patients. In these patients, sympathetic blockade may reduce their pain.

Central Sensitization and Neuropathic Pain

Central sensitization plays a major role in the generation of neuropathic pain. The three major forms of central sensitization in this context are activity dependent, transcription dependent, and disinhibition. The activity-dependent variant closely resembles that occurring in inflammatory pain, except that

the trigger for its initiation is not nociceptor input from inflamed or damaged tissue but ectopic input as a result of a lesion to a nerve. If the ectopic input is in nociceptors, central sensitization will occur through the same general molecular and cellular mechanisms described and will drive similar clinical manifestations (e.g., tactile allodynia and secondary hyperalgesia). Ketamine, by virtue of blocking NMDA receptors, decreases this form of central sensitization and reduces pain hypersensitivity in patients with neuropathic pain, again with usually unacceptable psychotropic side effects.

Transcription-dependent central sensitization in neuropathic pain differs considerably from that in inflammatory pain. The alterations in transcription occurring in injured sensory neurons are different from those occurring after inflammation, as are the changes that occur in the dorsal horn. One difference from inflammatory pain is that, because large A fibers begin to express synaptic transmitters and modulators normally expressed only by nociceptors, activity in these fibers can begin to drive initiation of central sensitization. Unlike the situation after inflammation, no induction of COX-2 occurs within the dorsal horn. This means that NSAIDS and COX-2 inhibitors have no role in neuropathic pain because these drugs can have no analgesic activity without the presence of their targets.

Disinhibition

A major component of central sensitization after nerve injury is not simply an increase in excitation driven by increased amounts or responses to excitatory transmitters but a decrease in inhibition. Local inhibitory interneurons and descending inhibitory pathways provide both tonic and phasic inhibition of spinal nociceptive pathways. There now is compelling evidence that suppression of this inhibition—"disinhibition"—is an important generator of neuropathic pain. Inhibitory interneurons use GABA and glycine as their neurotransmitters and are activated by primary sensory afferents as well as descending and local inputs. Some axons of GABAergic interneurons make synaptic contact with the central terminals of primary afferents, inhibiting release of excitatory transmitters by the central terminals of primary afferents. This presynaptic inhibition has both fast and slow components. The fast component depends on activation of the Cl^--permeable ionotropic $GABA_A$ receptor. The slow component results from activation of the G-protein–coupled $GABA_B$ receptor. Other axons of inhibitory GABAergic and glycinergic interneurons make contact with dorsal horn neurons, producing hyperpolarizing inhibitory postsynaptic potentials.

Loss of inhibitory GABAergic currents is an important contributor to disinhibition after peripheral nerve injury and to establishment of neuropathic pain.[93,94] Disinhibition occurs via a variety of mechanisms. One involves increased activity of GABA transporters decreasing synaptic GABA. Another results from changes in Cl^- ion levels in neurons due to altered activity of ion exchange pumps resulting in decreased GABA hyperpolarization and even GABA-mediated excitation in some cases. Finally, disinhibition occurs as a result of apoptosis or degeneration of GABAergic inhibitory interneurons in the superficial dorsal horn.[88,95,96] Loss of these neurons appears to result from NMDA receptor-mediated excitotoxicity consequent to the abnormal barrage of ectopic input entering the dorsal horn. Caspase inhibitors that block apoptosis can reduce cell loss and the pain phenotype. In this situation, chronic pain can be considered a neurodegenerative disease, raising the intriguing possibility of using neuroprotective treatment as a preemptive disease-modifying treatment of neuropathic pain.

Structural Reorganization

Peripheral nerve injury results in structural changes at multiple levels within the nervous system. In the periphery, some largely C-fiber sensory neurons die after axonal injury, and sympathetic terminals sprout into the DRG. In the spinal cord, there is a loss of inhibitory interneurons in the dorsal horn and alterations in synaptic connectivity. In the brain, there is an association of atrophy in particular cortical areas with chronic pain. Loss of neurons results in an irreversible loss of function that may partly be compensated for by, but might contribute to, the persistence of neuropathic pain, whereas the formation of new synaptic connections may dramatically alter function. For example, A-β large myelinated fibers are activated by low-intensity mechanical stimulation and normally produce innocuous sensations. However, the tactile mechanical allodynia associated with peripheral nerve injury is mediated by these large myelinated sensory afferents.[97] How does this happen? One mechanism is the recruitment of previously subthreshold inputs after induction of central sensitization or loss of inhibition. Another is a possible alteration in the connectivity of the central terminals of these afferents due to sprouting and novel synapse formation driving cells that normally receive only nociceptor input.[98–100] Individuals with chronic low back pain have a 5–11% reduction in neocortical gray matter and thalamic volume compared to matched controls, suggesting that chronic pain is associated with significant cell loss in these regions.[30] Amputation of major sensory nerves frequently leads to phantom sensations, including persistent phantom pain. Although there are peripheral and spinal contributions to phantom pain, there also is a rapid reorganization of the cortical somatosensory representation of amputated body parts.[101,102]

Glial Activation

In the CNS, glial cells outnumber neurons by approximately 10:1 and appear to have a role in the pathogenesis of neuropathic pain. Peripheral nerve injury leads to activation of microglia in the dorsal horn.[103] Microglia assume an amoeboid morphology, become highly mobile, and begin secreting a wide array of cytokines, chemokines, and other neuromodulators, including IL-1β, TNF-α, IL-6, IL-10, and BDNF, which can act on neurons to alter their function.[104–107] Two important components of the microglial pain pathway are p38 MAP kinase and the P2X4 and P2X7 ionotropic ATP purinoreceptors.[108–111] For example, activation of P2X4 by ATP results in activation of p38, which in turn leads to release of BDNF, which then acts to reduce the inhibitory action of GABA on certain lamina I neurons. Inhibition of p38 and antagonism of P2X4 and P2X7 in microglia reduce pain in experimental models. Thus, microglia may become important models for future treatment options.

Genetic Factors and Predisposition to Pain

Rodent strain-related differences in the development of allodynia and/or hyperalgesia following injury indicate a heritable component to the development of

neuropathic pain.[89,112–115] Human studies support this idea. A common functional genetic polymorphism that affects the metabolism of catecholamines is associated with differences in responsiveness to sustained acute pain.[116] Individuals homozygous for the met158 allele of the catechol-*O*-methyltransferase (COMT) polymorphism (val158met) have a higher sensory and affective response to experimental pain than do heterozygotic individuals. Patients who are homozygous for the met158 allele also show diminished regional brain μ opioid system responses to the painful stimulus as measured by PET. Cancer patients homozygous for the allele require more morphine to control pain.[117]

Dysfunctional Pain

Dysfunctional pain is defined as pain in the absence of an identifiable noxious stimulus, tissue damage, inflammation, or lesion to the nervous system. The mechanisms involve abnormal function of the nervous system. This can occur in the PNS, as for erythromelalgia, and in the CNS, for fibromyalgia and noncardiac chest pain. The specific mechanisms responsible for many conditions that are part of this syndrome, such as tension-type headache and irritable bowel syndrome, are not known. Given the prevalence of these conditions and the limited treatment options, this area requires more attention.

Erythromelalgia is an autosomal dominant chronic pain disorder characterized by edema and burning pain of the extremities in response to warm stimuli or moderate exercise. The disease is due to a mutation of the $Na_V1.7$ sodium channel leading to reduced action potential thresholds and high-frequency firing in DRG neurons.[118,119] The syndrome resembles ectopic activity in neuropathic pain in that pain results from increased excitability of nociceptor membranes; however, no injury has occurred, and the pain tends to require mild activation of nociceptors to produce an attack.

Fibromyalgia is difficult to diagnose because of the complex combination of primary and secondary symptoms. However, it has one essential feature: a reduced pain threshold in deep tissue (trigger points) with no peripheral pathology. Functional imaging and sensory testing reveal abnormal processing of sensory input in the CNS leading to heightened and prolonged pain, changes indicative of central sensitization. Drugs that target the CNS, such as pregabalin, do reduce this pain, normalizing abnormal activity.

CONCLUSION

Pain is not a homogenous state. Multiple pains exist. Some are adaptive, protecting the body from injury or helping healing; others are pathologic or maladaptive, representing severe disturbances in nervous system function such that the pain and not the initial etiologic trigger factor is the disease. In order to treat pain in a rational rather than a trial and error approach, we must identify the pain syndromes and understand the neurobiologic mechanisms driving the pain. We need to understand the risk factors for developing chronic pain, avoid damaging the nervous system, and target treatment at the mechanisms rather than the symptoms.

CHAPTER 91

Common Pain Syndromes

Basem Hamid, MD

Many pain conditions are encountered in clinical practice. This chapter provides a concise, practical, updated review of the most common pain syndromes. Along with the other pain chapters in this book, a comprehensive view of pain is given.

MECHANISMS OF CHRONIC PAIN

Knowing the pathophysiology of chronic pain is essential for understanding the clinical features of different pain and the rationale of different treatment options used in the field. Chapter 92 covers this topic in detail. This chapter brief summarizes the mechanisms of pain.

Pain sense starts by detecting noxious stimuli at the level of nociceptors, which are specialized receptors in the peripheral nervous system. An electrical signal is generated (transduction) and transmitted by the afferent fibers, A-δ fibers (slow thin myelinated fibers), and C fibers (the unmyelinated slowest fibers) of the spinal and cranial nerves. The first-order neurons of these fibers are located in the dorsal root ganglia or cranial nerve ganglia. Visceral afferent nociceptive fibers (A-δ and C) travel with sympathetic and parasympathetic fibers; their cell bodies also are found in the dorsal root ganglia. Muscles are also innervated by both A-δ and C fibers. The pain signal then is transmitted to the sensory (second-order) neurons of the dorsal horn of the spinal cord. The ascending nociceptive tracts convey nociceptive stimuli from the dorsal horn of the spinal cord to higher centers in the central nervous system (CNS). These tracts include the spinothalamic, spinohypothalamic, spinoreticular, and spinopontoamygdala tracts. Multiple cortical and subcortical neural structures contribute to processing the pain signal, leading to pain perception. Pain is modified by the CNS via inhibitory descending tracts. Many inhibitory and excitatory neurotransmitters and other biochemical mediators mediate the physiologic process of pain perception.

Repeated peripheral tissue injury may result in a maladaptive phenomenon—*peripheral sensitization*—which refers to a decreased threshold and an increased response to stimulation, and is maintained by various endogenous biochemicals. Moreover, sensitization of the entire nociceptive pathway can arise secondary to chronic plastic changes in the CNS, resulting in a phenomenon called *central sensitization.* As a result, multiple clinical features may arise and produce neuropathic pain (see Chapter 90). Once sensitization is established, it may be impossible to separate central contributions from peripheral contributions to the process of sensitization. Because of sensitization, pain may persist or may partially respond to therapy even when the primary injury is no longer active.

Treatment of chronic pain targets the different components contributing to the sense of pain by blocking the signal before it travels to the CNS, potentiating the inhibitory descending tracts, modifying the process of sensitization, or a combination of one or more of these mechanisms.

MUSCULOSKELETAL PAIN SYNDROMES

Myofascial Pain Syndromes

Myofascial pain originates from active trigger points (TPs) within muscle structures and/or surrounding connective tissue. A typical TP is characterized by the presence of a taut band in the muscle, tenderness to palpation, and a reference pain zone distant from the TP center. MPS can be primary or secondary to other painful conditions.

Although no clear mechanism has been defined, TPs are believed to begin after an initial macro or micro injury, which in vulnerable individuals evolves into a chronic myofascial pain syndrome (MPS) through the cascade of peripheral and central sensitizations.

Patients with myofascial pain usually present with muscle ache, which is well localized to certain muscles with distinct radiating patterns or is of vague location and radiation. The pain usually is persistent but may fluctuate in intensity. It usually is associated with other symptoms such as joint ache, stiffness, paresthesias, decreased range of motion, fatigue, poor sleep, or headache. When the pain is chronic, autonomic features such as edema and hyperemia may appear.

Diagnosis of MPS is established by identifying TPs. TPs should be sought in a systematic manner. Fig. 91–1 illustrates some of the common TPs. TPs are best identified by palpation with the finger tips and application of steady incremental pressure over different areas until hypersensitive points are found and the patient's pain is reproduced. Tight bands are felt by rubbing the fingers across the muscle fibers. When the applied pressure is altered quickly, a brief local muscle twitch response can be observed.[1]

KEY POINTS

1. Central sensitization is a cardinal element of chronic pain syndromes.
2. Treatment of chronic pain should be multidisciplinary and aim for function restoration.
3. Myofascial pain syndromes are characterized by presence of trigger points.
4. Fibromyalgia is characterized by the presence of tender points.
5. Osteoarthritis is the most common joint disorder, is one of the most common chronic diseases in the elderly, and is a leading cause of disability.
6. Tricyclic antidepressants and antiepileptic drugs are good first-line options for treatment of most neuropathic pain syndromes.
7. Treatment of complex regional pain syndrome remains controversial but should start early and focus on mobility of the affected limb.
8. Neck and back pain can be generated by different anatomic structures, which are targeted in the treatment plan.
9. International Headache Society guidelines are useful tools for the diagnosis of different headache syndromes.

Treatment of MPS should focus on eliminating TPs to break the cycle enhancing chronic pain and to restore normal tone and function of the affected muscles. TP injections have been widely used to facilitate this process. Although clinicians use different solutions and medications for TP injections, no specific solution has been shown to be superior to others. Repeated steroid injection is associated with a risk for local muscle atrophy.

An alternative to injections is spraying of TPs with a vapocoolant such as chlorofluoromethane or ethyl chloride, with simultaneous stretching of the muscle. In combination with these treatments, muscle rehabilitation with exercises and thermal modalities is also useful. If analgesia is required, nonsteroidal antiinflammatory drugs (NSAIDs) usually are given. Despite the wide use and acceptance of these therapies, no clear evidence supports their efficacy. Chronic MPS can be complex and refractory to treatment.

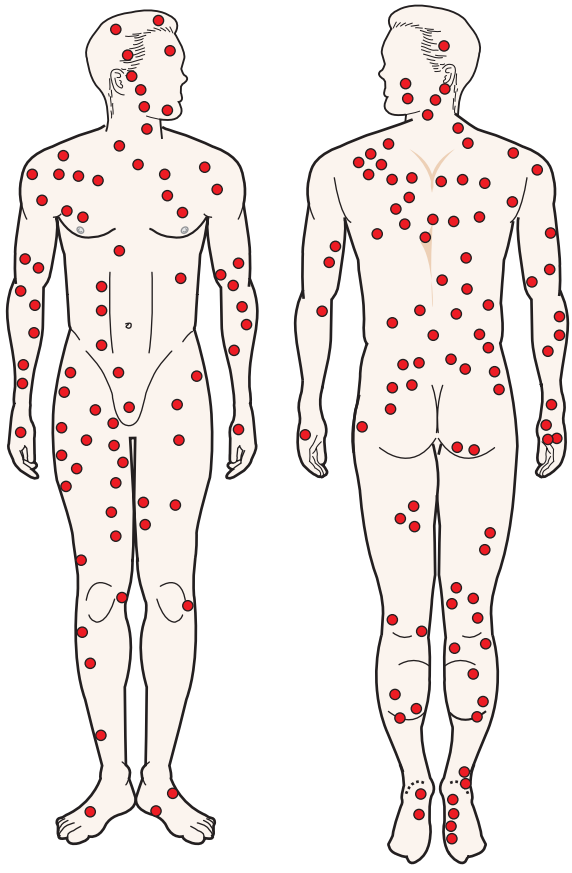

FIGURE 91–1. Common trigger points.

Fibromyalgia

Fibromyalgia (FM) is a multisymptomatic syndrome defined by the core feature of chronic widespread pain. FM is a common entity that affects women more than men and increases steadily with age.[2]

Although a definitive causal relation has not been established, FM usually is precipitated by trauma, stress, infections, or other factors. It commonly accompanies a wide range of medical conditions, including rheumatoid arthritis (RA), low back pain, systemic lupus erythematosus, Sjögren syndrome, osteoarthritis (OA), inflammatory bowel disease, irritable bowel syndrome, headache, mood disorders, restless leg syndrome, and sleep disturbance, particularly stage 4. Research shows that certain individuals might have vulnerability to FM because of past life events or a complex genetic component interacting with environmental insults.[2,3]

Patients typically present with chronic widespread stiffness and pain that is described as a constant dull ache worsened by muscle overactivity. FM usually is associated with a constellation of symptoms such as easy fatigability, nonrestorative sleep, cognitive dysfunction, depression, and somatic complaints other than musculoskeletal pain.[2]

The diagnosis of FM usually is based on the 1990 recommendations of the American College of Rheumatology (ACR) classification criteria, which comprise one historical feature—the widespread pain of at least 3 months' duration, and one physical finding—the presence of tender points over at least 11 of 18 specified tender point sites on palpation at a force of 4 kg (amount of pressure required to blanch a thumbnail).[2] The locations of the 18 tender points are shown in Fig. 91–2. Palpation of control sites that typically are not tender is recommended. Some of these sites are the forehead, the medial third of the clavicle, the dorsum of the middle phalanx of the third digit, and the medial malleolus. If tenderness is present in these sites, the diagnosis of FM is questionable and a psychiatric disorder should be considered. Tenderness points are different from TPs in that they lack the other associated features. FM is distinguished from MPS by the absence of true TPs.

Treatment of FM is multidisciplinary and should consist of psychological intervention, physical therapy, especially aquatic-based exercises, treatment of comorbid mental disorders and associated sleep disorders, and pharmacologic therapies. Pregabalin is approved by the Food and Drug Administration for FM. Tricyclic antidepressants (TCAs) have been the mainstay in the treatment of FM and improving sleep. NSAIDs are used in patients with FM with varying degrees of success. Tramadol, a dual reuptake inhibitor of norepinephrine and serotonin with weak μ-receptor affinity, is proving useful. Pramipexole, an antiparkinsonian dopamine agonist, at a dose of 4.5 mg also appears to be a promising option for treatment of FM.[4,5] Opioids have not been shown to be effective. Most FM patients tend to have a chronic course, with exacerbations, remissions, and fluctuating symptoms.

Bursitis and Tendinitis

Tendinitis, bursitis, and other periarticular structures painful conditions are common causes of regional pain. Understanding of the musculoskeletal

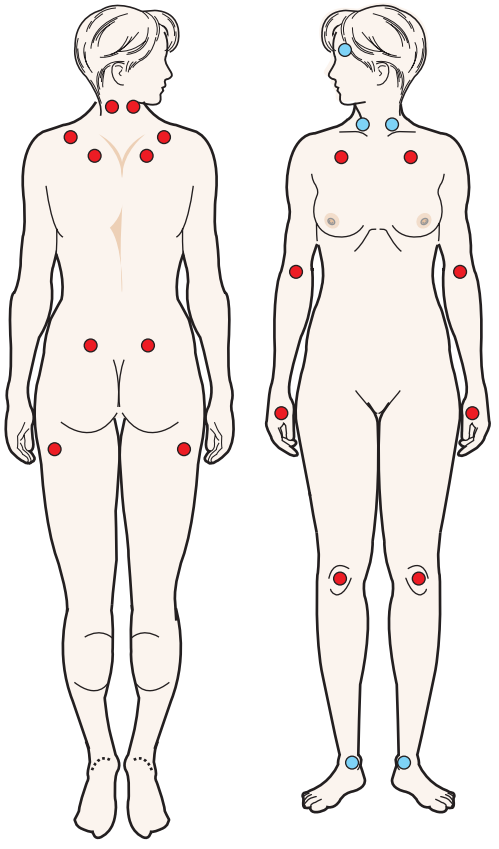

FIGURE 91–2. Recommended tender and control point locations in fibromyalgia.

anatomy and a careful clinical examination are essential in determining the true cause of pain. Whereas arthritis (or synovitis) causes effusions in the synovial space or diffuse swelling of the synovium, producing global joint swelling, bursitis causes an effusion or swelling limited to the bursa only, and tendinitis causes little, if any, swelling limited to the tenosynovial structure. In synovitis, direct palpation of the synovium elicits diffuse tenderness over the entire synovial surface area. In bursitis, tenderness is localized to the bursal structure and spares the synovium. The tenderness in tendinitis is elicited best by active range of motion and active isometric loading against resistance but can be detected by direct palpation. Tendinitis is painful with active or passive range of motion as the inflamed tendon experiences loading. Passive range of motion elicits tenderness only if the inflamed tendon is stretched and passively loaded, and active range of motion or isometric testing elicits tenderness by actively loading the tendon.

Table 91–1 lists each anatomic region and the more common periarticular conditions for each region.

In general, treatment of bursitis, tendinitis, and other periarticular conditions is similar and usually conservative. Physical therapy is helpful in most cases and may be more successful when therapy includes a combination of passive modalities, such as ice and heat, and active modalities, such as strengthening exercises to improve any biomechanical imbalances. Ultrasound is sometimes helpful and is of proven benefit for symptomatic calcific tendinitis of the shoulder. NSAIDs are helpful as analgesics but are of limited usefulness in alleviating chronic conditions. Judicious intralesional injections of steroids are helpful. However, caution should be exercised when considering intralesional steroids for bicipital and Achilles tendinitis because tendon rupture is a risk. Surgery may be required for refractory conditions.

Arthritides

Arthritides and related syndromes are common causes of pain, with a steady increase of prevalence. An estimated 15% (40 million) of Americans had some form of arthritis in 1995. By the year 2020, an estimated 18.2% (59.4 million) of Americans will be affected.[6] Thus, although the pain specialists may not be the primary treating physicians, they should be familiar with these syndromes and be able to recognize them and participate in the overall management plan to help in reducing the associated morbidity and disability. Detailed coverage of these syndromes is beyond the scope of this chapter, which provides a general overview.

Osteoarthritis

OA is by far the most common joint disorder, is one of the most common chronic diseases in the elderly, and is a leading cause of disability. Increased weight is the most significant independent predictor of both incidence and progression of OA in weight-bearing joints. The risk for development of OA is increased by high-impact repetitive activities. Smoking and osteoporosis increase the frequency of OA.

The joints most commonly involved in OA are the metatarsophalangeal (MTP) joint of the great toe (hallux valgus or "bunion"), proximal interphalangeal (PIP) and distal interphalangeal (DIP) joints of the fingers, and carpometacarpal (CMC) joint of the thumb, hips, knees, and both lumbar and cervical spines. Other joints, even major weight-bearing joints such as the ankle, are regularly spared unless they are involved in secondary forms of OA. Pain is the main symptom leading to the diagnosis of OA. The pain is most often described as a deep ache, accompanied frequently by joint stiffness that follows periods of inactivity (on arising in the morning or after sitting). Pain is aggravated by using the involved joints, may radiate, or may be referred to surrounding structures. In the early stages of the disease, pain is commonly relieved by rest. With more severe disease, pain may be persistent, interfering with normal function and preventing sleep, even with medical management.

On physical examination, the joints may demonstrate tenderness, crepitus, and a limited range of motion. Joint swelling may be due to an accompanying synovial effusion or to bony enlargement and the presence of osteophytes. Radiographic findings help confirm the diagnosis. Joint space narrowing, subchondral bone sclerosis, subchondral cysts, and osteophytosis are characteristic.[2]

Nonpharmacologic management of OA includes correction of body me-

TABLE 91–1.

Common Periarticular Painful Conditions

Shoulder	
Glenohumeral arthritis	• Usually preceded by trauma • Anterior tenderness below the coracoid process with passive range of motion, especially rotation • Swelling may not be easily appreciated because this joint lies deep beneath the deltoid muscle
Adhesive capsulitis (frozen shoulder)	• Loss of normal distensibility of the glenohumeral joint capsule and subsequent adhesions between the capsule and the humeral head • Usually preceded by joint limiting states, such as rotator cuff, strokes, fractures • Gradually worsening pain and progressive loss of passive and active range of motion in all directions, especially external rotation and abduction • May be complicated by complex regional pain syndrome
Subacromial bursitis	• Largest and most frequently inflamed shoulder bursa • Pain in the lateral aspect of the shoulder, worsening with movement • Differs from rotator cuff tendonitis by the presence of tenderness on direct palpation beneath the acromion process
Rotator cuff	• Inflammation of suprapinatus and infraspinatus tendons lying between the humeral head and the acromial process • Pain aggravated by overhead reaching • Pain on active abduction of the shoulder focused over the lateral aspect • Normal passive range of motion • Tenderness on active resisted abduction or external rotation rather than on passive abduction or external rotation • Passive forward flexion to 90° impinges on the inflamed rotator cuff and confirms the diagnosis
Biceps tendinits	• Inflammation of the long head of the biceps tendon as it traverses the humeral bicipital groove • Anterior shoulder pain aggravated by lifting or overhead reaching • Tenderness over the bicipital groove • Positive arc maneuver • Complete rupture may occur in chronic cases and presents as bulging in the antecubital fossa
Elbow	
Olecranon bursitis	• Inflammation of the bursal sac located on the dorsal surface of the olecranon process of the ulna • Tenderness and swelling over the olecranon bursa (just below the elbow) • Can be differentiated from elbow arthritis, as the latter causes swelling and tenderness in the paraolecranon grooves
Lateral epicondylitis (Tennis elbow)	• Injury of the common extensor tendon at the lateral epicondyle due to overuse • Pain and local tenderness at the lateral epicondyle • Pain aggravated by resisting wrist extension and radical deviation • Weak grip
Medical epicondylitis (golfer's elbow)	• Injury of the common extensor tendon at the medial epicondyle due to overuse • Pain and tenderness just distal to the medial epicondyle • Pain aggravated by resisting wrist extension and radial deviation • Weak grip
Wrist and Hand	
de Quervain tenosynovitis	• Inflammation of the tendons of abductor pollicis longus and extensor pollicis brevis within the first dorsal extensor compartment • Typically affects middle-aged women • Pain and swelling along the radial aspect of the wrist worsened by gripping • Finkelstein test confirms the diagnosis: thumb is held within the fist and the hand is deviated passively in an ulnar direction, eliciting exquisite tenderness
Trigger finger	• Inflammation of the flexor tendons of the finger at the metacarpophalangeal head • Caused by repetitive activity over the palm of the hand • Pain, swelling, and "locking" of the finger
Hip	
Trochanteric bursitis	• Inflammation of the bursa between the gluteus maximus muscle and the trochanteric process • Pain over the outer thigh, worsened by walking • Local tenderness over the trochanteric process

(continued)

TABLE 91–1.

Common Periarticular Painful Conditions (Continued)

Iliopsoas tendonitis/ bursitis	• Inflammation of the iliopsoas tendon and/or bursa anterior to the true hip joint • Tenderness in the anterior groin or anterior hip joint • Local enlargement in the groin with bursitis
Knee	
Prepatellar bursitis	• Inflammation of the bursa overlying the patella due to injury or infection • Pain, swelling, and tenderness in the prepatellar area overlying the patella • May become chronic
Pes anserine	• Inflammation of pes anserine bursa, which lies medial to the anterior tibial tuberosity and inferior to the medial joint line • Pain along the medial aspect of the knee below the medial tibial plateau • Swelling not often observed • Localized tenderness to the bursa unaffected by passive range of motion of the knee
Patellar tendonitis	• Inflammation of the patellar tendon due to overuse injury • Anterior knee pain exacerbated by active use of the quadriceps • Localized tenderness to palpation to the patellar tendon
Iliotibial band bursitis	• Caused by tight iliotibial band • Pain over the lateral aspect of the knee • Clicking as the band passes over the lateral femoral condyle • Tenderness confined to the lateral area of the knee with absence of knee effusion
Ankle	
Retrocalcaneal bursitis	• Inflammation of the retrocalcaneal bursa lying between the calcaneus and the Achilles tendon • Posterior ankle pain reproduced by active loading of the Achilles tendon (as occurs with walking) • Local tenderness and swelling in the space between the Achilles tendon and the ankle, aggravated by plantar flexion
Achilles tendinitis	• Inflammation of the musculotendinous junction due to repetitive irritation of overuse • Posterior ankle pain with tendon loading • Local tenderness aggravated by dorsiflexion • Paratendinous thickening above the calcaneus • May be complicated by tendon rupture or chronic tendinitis
Foot	
Plantar fasciitis	• Inflammation of the origin of the longitudinal ligament • Many biomechanical abnormalities of the foot predispose to this condition, such as pes cavus deformities, ples planus deformities, and Achilles tendon tightness • Pain along the plantar surface of the medial heel • Tenderness to calcaneal compression

chanics and posture, weight loss, and physical therapy. Analgesia can be achieved by using acetaminophen and NSAIDs as first line therapy. Intraarticular corticosteroid injections might have a positive role but should be judiciously implemented and not repeated more than three times per year because of possible secondary cartilage damage. The structure-modifying effects of drugs are being evaluated, and both glucosamine sulfate and diacerein have shown different results in treating pain.[7–9] Doxycycline has been proved to slow the rate of joint space narrowing in knees with established OA.[10]

Intraarticular injection of a viscosupplement such as Hylan has been shown to be effective in reducing pain in knee OA.[11] When conservative therapy fails, joint replacement surgery might be the only option to help with analgesia.

Rheumatoid Arthritis

RA is a chronic multisystem disease with inflammatory polyarthritis of symmetric distribution affecting the peripheral joints of the hands (sparing DIP joints), feet, wrists, elbows, shoulders, hips, knees, and ankles. The cervical spine is generally the only axial skeleton affected by RA.

RA manifests in constitutional symptoms of fatigue, low-grade fever, weight loss, and morning stiffness. Synovitis (inflammation of the synovium) is the hallmark of RA. It produces pain, swelling, and tenderness of the joints. RA is characterized by a waxing-and-waning course with relapses and remissions. Pain in RA is multifactorial. In the early stages, it is secondary to inflammation. At later stages, the damaging effects of erosion of cartilage and bone also cause pain. RA can be accompanied by FM. RA complications can also result in pain such as vertebral body fractures, compression of the median nerves by synovial tissue in the carpel tunnel, rheumatoid vasculitis, cervical spine instability at the C1–2 level, and septic arthritis.[12]

Diagnosis is based on the history and physical examination and is supported by the presence of rheumatoid factor, which is present in 80% of patients with RA. Radiographically, soft-tissue swelling, juxtaarticular osteopenia, symmetric space narrowing, and bony erosions are seen.

Pharmacologic treatment of RA relies on NSAIDs, corticosteroids, analge-

sics, and disease-modifying antirheumatic drugs (DMARDs). Early and aggressive use of DMARDs is essential once the diagnosis is confirmed. Anti–tumor necrosis factor α agents, such as infliximab, etanercept, and adalimumab, have very potent antiinflammatory properties and provide dramatic improvements of symptoms and signs. Interleukin-1 receptor antagonists such as anakinra also have been shown to be effective in slowing the damage of cartilage and progression of arthritis.

When pain is unresponsive to treatment, surgical options should be pursued, including synovectomy, arthroplasty, and joint replacement. Opioids might be the only option to provide adequate analgesia in advanced cases refractory to treatment or when contraindications to other analgesics exist.

Other Arthritides

Multiple other arthritic syndromes may have pain as a cardinal feature. They include spondyloarthropathies, gout, and pseudogout. Arthritis can also accompany other systemic diseases, such as systemic lupus erythematosus, scleroderma, polymyalgia rheumatica, giant cell arteritis, Reiter syndrome, and inflammatory bowel disease.

Treatment should always focus on treating the underlying condition. NSAIDs usually provide acceptable analgesia. Often, opioids are required for more severe cases.

NEUROPATHIC PAIN SYNDROMES

Neuropathic pain is a pathologic pain that results from sustained transmission of pain signals in the absence of ongoing tissue injury or activation of pain-sensitive afferent peripheral nerves. Neural injury or dysfunction at any point along the somatosensory system from the peripheral nerve endings to the brain can cause neuropathic pain. Multiple mechanisms (peripheral and central) are responsible for sustaining neuropathic pain. Although its role is less identified than in nociceptive pain conditions, primary sensitization of nociceptive nerve endings might be a contributing factor to sustaining neuropathic pain. Damaged nerve fibers, especially neuromas, may generate ectopic action potentials, which contribute to neuropathic pain. When input from peripheral nociceptors into the dorsal horn of the spinal cord decreases, as encountered in deafferentation conditions such as shingles and after amputation, the dorsal horn neurons become hyperexcitable and may even develop spontaneous activity. In addition, the reduction of peripheral sensory input leads to ephaptic sprouting of the neurons neighboring the affected central neurons, resulting in magnification of the perceived pain field. Central sensitization, as outlined, also plays a major role in neuropathic pain. Because the inhibitory interneurons normally are excited by peripheral input, attenuation of this input will decrease inhibition and amplify the pain signal. In general, the inhibitory circuits of pain signal are downregulated at the level of both the spinal cord and the brain. At the level of the brain, different sites are involved in the processing of pain signal, and the somatosensory-pain homunculus is not quite preserved. The initial neural injury and subsequent evolving mechanisms explain the complexity of clinical features encountered in neuropathic pain syndromes.

Some clinical features are common among neuropathic syndromes, whereas others are unique to specific syndromes. Patients usually have different types of pain. A stimulus-independent pain is a spontaneous pain experienced by patients without sensory stimulation. It consists of a background constant pain, intermittent exacerbations, and brief episodes of other symptoms. The pain usually is burning, aching, crushing, gnawing, lancinating, shooting, electrical or lightening in quality, and associated with painful numbness and paresthesia (dysesthesias). The stimulus-evoked pain includes a variety of signs, such as hyperalgesia, mechanical and thermal allodynia, and hyperpathia. Table 91–2 summarizes some features of neuropathic pain.

Associated clinical features include abnormalities of reflexes and muscle function. Increased reflexes and tone are indicative of an upper motor neuron disease and suggest a central lesion such as stroke, whereas reduced reflexes or tone suggest peripheral origin as in compressive radiculopathies or neuropathies. Secondary motor changes could be a result of disuse and abnormal position. Autonomic abnormalities can be seen and include changes in color and temperature in the affected tissues, swelling due to abnormal leakage of intravascular fluid, and growth of skin, hair, nails, and other cutaneous structures. Other systemic features of autonomic dysfunction that could be seen include orthostatic hypotension, impotence, delayed gastric emptying, abnormal sweating and/or thermoregulation, difficulties with elimination, and occasionally cardiac arrhythmias.

Table 91–3 lists the most common neuropathic pain syndromes.[13]

Following is a brief discussion of common neuropathic pain conditions.

TABLE 91–2.

Clinical Features of Neuropathic Pain

- Hypesthesia: Decreased sensation or increased threshold for sensation
- Hyperesthesia: Increased sensitivity to stimulus
- Parethesia: Abnormal (but not painful) sensation (like pins-and-needles sensation), spontaneous or evoked
- Dysesthesia: Unpleasant (painful) sensation, spontaneous or evoked
- Hyperalgesia: Increased response to painful stimulus
- Allodynia: Pain due to a stimulus that does not normally provoke pain
  - Mechanical: Mechanical stimulus is the cause
  - Thermal: Thermal stimulus is the cause
- Hyperpathia: Abnormally painful and exaggerated reaction to stimulus, especially repetitive, where the stimulus is perceived initially less intense
- Causalgia: Constant burning pain accompanied by allodynia and hyperpathia following nerve injury[99]

Painful Peripheral Neuropathies

A wide variety of etiologies lead to peripheral neuropathies. It is important to realize that not all neuropathies are painful, as is the case with most of the inherited neuropathies. Some patients with neuropathy have chronic pain due to other conditions, and their pain should not be immediately blamed on the concomitant nonpainful neuropathy. The distribution of

TABLE 91–3.

Common Neuropathic Pain Syndrome

- Peripheral Neuropathic Pain
  - Acute and chronic inflammatory demyelinating polyradiculoneuropathy (Guillain-Barré syndrome)
  - Alcoholic polyneuropathy
  - Chemotherapy-induced polyneuropathy
  - Complex regional pain syndrome (CRPS)
  - Congenital painful neuropathies
  - Entrapment neuropathies (e.g., carpel tunnel syndrome)
  - Hereditary painful neuropathies
  - HIV neuropathy
  - Iatrogenic neuralgias (e.g., postmastectomy or postthoracotomy pain)
  - Idiopathic sensory neuropathy
  - Compression neuropathy (i.e., by tumor)
  - Nutritional deficiency-related neuropathies
  - Painful diabetic neuropathy
  - Paraneoplastic neuropathy
  - Phantom limb pain‘
  - Postherpetic neuralgia
  - Postradiation myelopathy/plexopathy
  - Radiculopathy syndromes (cervical, thoracic, lumbosacral)
  - Toxic exposure-related neuropathies
  - Cranial neuralgias (e.g. trigeminal, glossopharyngeal)
  - Posttraumatic neuralgias
- Central Neuropathic Pain
  - Compressive myelopathy (e.g., spinal stenosis, tumor)
  - HIV myelopathy
  - Multiple sclerosis-related pain
  - Parkinson disease-related pain
  - Postischemic myelopathy
  - Postradiation myelopathy
  - Poststroke pain
  - Posttraumatic spinal cord injury pain
  - Syringomyelia

Modified from Dworkin RH, et al.,[13] with permission.

neuropathy can be generalized and symmetric (polyneuropathy), such as diabetic and alcoholic polyneuropathy; multifocal (mononeuropathy multiplex), such as collagen vascular disease–related neuropathies; or focal (mononeuropathy), as seen in trauma and entrapment neuropathies. Polyneuropathy usually is symmetric and starts in a distal-to-proximal gradient in a "glove and stocking" distribution. Mononeuropathy multiplex affects multiple peripheral nerves arbitrarily and sometimes can be difficult to differentiate from polyneuropathy. Mononeuropathy follows the distribution of the affected nerve. Neuropathies may result from injury to the axons (axonal neuropathies), to myelin (demyelinating neuropathies), or mixed. Most of the neuropathies encountered in pain medicine practice are axonal neuropathy types. Acute (AIDP) and chronic inflammatory demyelinating polyradiculoneuropathy (CIDP) are examples of demyelinating neuropathies usually seen in pain practice. Table 91–4 highlights most of the painful neuropathies that a pain physician might encounter.

Although the evaluation of neuropathy usually is conducted by neurologists, it is important for the pain medicine practitioner to be familiar with the diagnostic workup. Fig. 91–3 shows a simple diagnostic approach that leads to the diagnosis of most neuropathies.[14]

Small-Fiber Neuropathy

Small-fiber neuropathy (SFN) is the most common type of painful neuropathy. The smaller axons A-δ (small myelinated) and C (unmyelinated) are affected. The larger fibers usually are preserved but could be involved at a later stage. SFN is a disease of late middle age, but symptoms could start as early as the third decade or as late as the ninth decade.[15] SFN is vastly underrecognized, and most cases are "idiopathic." SFN may predate diabetes mellitus[16] and neoplastic conditions by many years. Although SFN is more common in men, patients presenting with pain of SFN are more likely to be women.[17]

Pain and decreased temperature sensation are the predominant features. Proprioception, vibratory sensation, and muscle-stretch reflexes usually are intact because they are mediated by the larger nerve fibers A-β and A-α, which are not involved in the pathologic process.

Injury of affected fibers cannot be detected by standard nerve conduction studies (NCS) and electromyography (EMG), so these tests usually are unrevealing. Therefore, the diagnosis usually is clinical and relies on ruling out other possibilities. A definite diagnosis of SFN could be reached by autonomic testing or a skin biopsy if warranted. When fasting blood glucose or glycosylated hemoglobin (HgA_{1C}) levels are diagnostic of diabetes mellitus, obtaining a oral glucose tolerance test may unveil impaired glucose tolerance or early diabetes mellitus.[18–20]

The distinction between SFN and "large-fiber" neuropathies is important because the underlying cause is more likely to be identifiable when both large and small fibers are affected.

Diabetic Peripheral Neuropathic Pain

Current estimates suggest that more than 18 million Americans have diabetes.[21] Peripheral neuropathy is one of the most common complications of diabetes,[22] and conversely diabetes is the most common cause of peripheral neuropathy in developed countries.[23] Studies suggest that 30–60% of all diabetics have signs and/or symptoms of peripheral neuropathy.[21,24–26] The risk is >50% in individuals who have had diabetes for more than 20 years. The prevalence of any neuropathy is 66% for patients with type 1 diabetes mellitus and 59% for those with type 2.[22] Neuropathy can be seen at any stage of diabetes progression, and approximately 10% of newly diagnosed type 2 diabetics may have neuropathy.[22] Neuropathic symptoms may be the presenting complaint leading to the diagnosis of diabetes. Neuropathy also has been reported in patients with impaired glucose tolerance, or "prediabetes."[22] Multiple risk factors contribute to the risk of diabetic neuropathy, including duration of diabetes, age, male gender, increased height, hypertension, and smoking.[24] Poor glycemic control is a major modifiable risk factor for neuropathy, as demonstrated by the reduction in risk of neuropathy with intensive glucose lowering. This is demonstrated by a decrease of approximately 60% in type 1 diabetic patients treated with intensive insulin therapy compared to those who received conventional therapy.[27]

The clinical manifestations of diabetic peripheral neuropathy depend on the specific nerves affected. Because all branches of the peripheral nervous system are susceptible to damage from diabetes, patients can

TABLE 91–4.

Common Painful Neuropathies

Type of Neuropathy	Predisposing Factors	Features on Examination	Laboratory Findings
Idiopathic small-fiber painful sensory neuropathy	Age >50 y	Normal muscle-stretch reflexes Normal muscle strength Normal sensation of position and vibration Reduced pinprick sensation in lower extremities	Normal EMG and NCS Reduced sudomotor function Abnormal skin biopsy Normal blood tests
Diabetic peripheral neuropathy	Family history Obesity	Reduced muscle-stretch reflexes Reduced distal sensation May have orthostatic hypotension (rarely, may have findings similar to those in idiopathic small-fiber painful sensory neuropathy)	Abnormal EMG and NCS (rarely, normal EMG and NCS) 2-hour glucose-tolerance test ≥200 mg/dL Fasting blood glucose concentration ≥126 mg/dL
Inherited neuropathies	Family history	Per cavus or hammer toe Usually reduced muscle-stretch reflexes Reduced distal sensation	Abnormal EMG and NCS Normal blood tests
Peripheral neuropathy with connective tissue disease	History of rheumatoid arthritis, systemic lupus erythematosus, mixed connective tissue disease, Sjögren syndrome, or symptoms of sicca syndrome	Reduced muscle-stretch reflexes Reduced distal sensation	Abnormal EMG and NCS Positive for antinuclear antibodies, extractable nuclear antigens, or rheumatoid factor
Peripheral nerve vasculitis	Known systemic vasculitis (nonsystemic vasculitis may occur without systemic features)	Multifocal examination findings (may mimic polyneuropathy)	Abnormal EMG and NCS Blood test abnormalities may include antineutrophilic cytoplasmic antibodies, antinuclear antibodies, rheumatoid factor, hepatitis C, cryoglobulins
MGUS neuropathy	Age >50 y	Variable findings Reduced or normal reflexes Reduced distal sensation	Abnormal EMG and NCS (may be normal in rare cases) Monoclonal gammopathy
Paraneoplastic sensory neuropathy	Tobacco smoking, family history, asbestos exposure, occupational exposure to dyes, paints, printing rubber, textiles or leather	Reduced muscle-stretch reflexes Reduced distal sensation	Abnormal EMG and NCS Anti-Hu antibodies
Familial amyloid polyneuropathy	Family history	Reduced muscle-stretch reflexes Sensory loss preferentially small-fiber Postural hypotension	Abnormal EMG and NCS NCS may show carpal tunnel syndrome
Acquired amyloid polyneuropathy	Known plasma cell dyscrasia or monoclonal gammopathy	Reduced muscle-stretch reflexes Sensory loss preferentially small-fiber Postural hypotension	Abnormal EMG and NCS NCS may show carpal tunnel syndrome Monoclonal gammopathy
Neuropathy with renal failure	Known renal disease	Reduced muscle-stretch reflexes Variable sensory examination	Abnormal EMG and NCS Abnormal renal function
Hereditary sensory autonomic neuropathy	Family history, foot ulcers, painless injuries	Reduced muscle-stretch reflexes Variable sensory examination Pes cavus and hammer toe Foot ulcers	Abnormal EMG and NCS

TABLE 91–4.

Common Painful Neuropathies (Continued)

Type of Neuropathy	Predisposing Factors	Features on Examination	Laboratory Findings
Sarcoid polyneuropathy	Pulmonary sarcoidosis	Multiple monoeuropathy or features of polyneuropathy	Abnormal EMG and NCS Elevated angiotensin-converting enzyme Abnormal chest radiography
Arsenic neuropathy	Industrial exposure to pesticides, wood preservatives, copper smelting	Reduced muscle-stretch reflexes Loss of all types of sensation Usually some distal weakness Mees lines	Abnormal EMG and NCS Elevated arsenic levels (in plasma, urine, nails, hair)
Fabry disease	Onset before age 20 y Renal failure, stroke	Normal muscle-stretch reflexes Normal muscle strength Normal sensation of position and vibration Normal or reduced pinprick sensation in feet	Normal EMG and NCS Reduced levels of α-galactosidase A in serum, leukocytes, or tears
Celiac disease	Gastrointestinal symptoms	Variable features may be normal except for loss of distal pinprick sensation or loss of all types of sensation Reduced muscle-stretch reflexes	EMG and NCS usually normal Positive serologic test for celiac disease (IgA antigliadin and IgA endomysial antibodies)
HIV-related neuropathy	Homosexual activity, drug abuse, blood transfusions, treatment with antinucleosides	Variable features may be normal except for loss of distal pinprick sensation or loss of all types of sensation Reduced muscle-stretch reflexes	EMG and NCS usually abnormal HIV antibody sensation

EMG, Electromyography; HIV, human immunodeficiency virus, MGUS, monoclonal gammopathy of undetermined significance, NCS, nerve conduction studies.
From Mendell and Sahenk[14] with permission.

exhibit abnormalities of sensory, motor, or autonomic function. Deficits frequently overlap or coexist.

Diabetic peripheral neuropathy is a heterogeneous condition that can manifest clinically as several types,[22] which can exist individually or overlap. Table 91–5 lists the different types of diabetic peripheral neuropathy.

NCS and quantitative sensory testing (e.g., quantitative vibration threshold testing) can be used to confirm neuropathy suggested by the physical examination or to confirm the diagnosis in patients with symptoms but no abnormalities on physical examination. Normal NCS do not necessarily rule out neuropathy as a cause of pain because neuropathic symptoms may be due to SFN.

Multiple pharmacologic agents have been used for treatment of diabetic peripheral neuropathic pain. Duloxetine[28,29] and pregabalin[30–33] are the only FDA-approved drugs for diabetic peripheral neuropathic pain. Multiple other medications have been shown to be effective, such as TCAs,[34,35] gabapentin,[23,36] venlafaxine,[37–39] tramadol, capsaicin,[25,40–44] opioids,[45–47] and a combination of more than one of these medications.[46,48] Zonisamide[49] also appears to be promising. Antiepilepsy drugs (AEDs)[50] and many other drugs have been used extensively, with varying degrees of success.[13,14,51] In a small case series, spinal cord stimulation was successful in the treatment of diabetic peripheral neuropathic pain refractory to conventional therapies, including opioids.[52,53]

HIV/AIDS-Related Neuropathy

Neuropathic pain occurs in approximately one third of patients with human immunodeficiency virus (HIV) and acquired immunodeficiency syndrome (AIDS).[54] A variety of disorders can result in neuropathic pain in HIV and AIDS patients. The different types of HIV/AIDS-related neuropathies are summarized in Table 91–6.[55,56]

Treatment of HIV/AIDS-related neuropathic pain relies on treatment of the underlying infection(s) and removal of toxic agent if possible. Neuropathic agents have been used, with variable results. Lamotrigine[57,58] and probably ziconotide[59] have documented efficacy.

Carpal Tunnel Syndrome

Carpal tunnel syndrome (CTS) is the most common painful mononeuropathy of the upper limb. It results from compression (entrapment) of the median nerve as it passes under the ligamentous canal in the wrist. Multiple factors predispose to or precipitate CTS, such as fractures, ganglions, synovial disorders, wrist arthritides, ergonomic stressors, repetitive use, pregnancy, obesity, chronic renal insufficiency, and other systemic disorders such as diabetes and acromegaly.

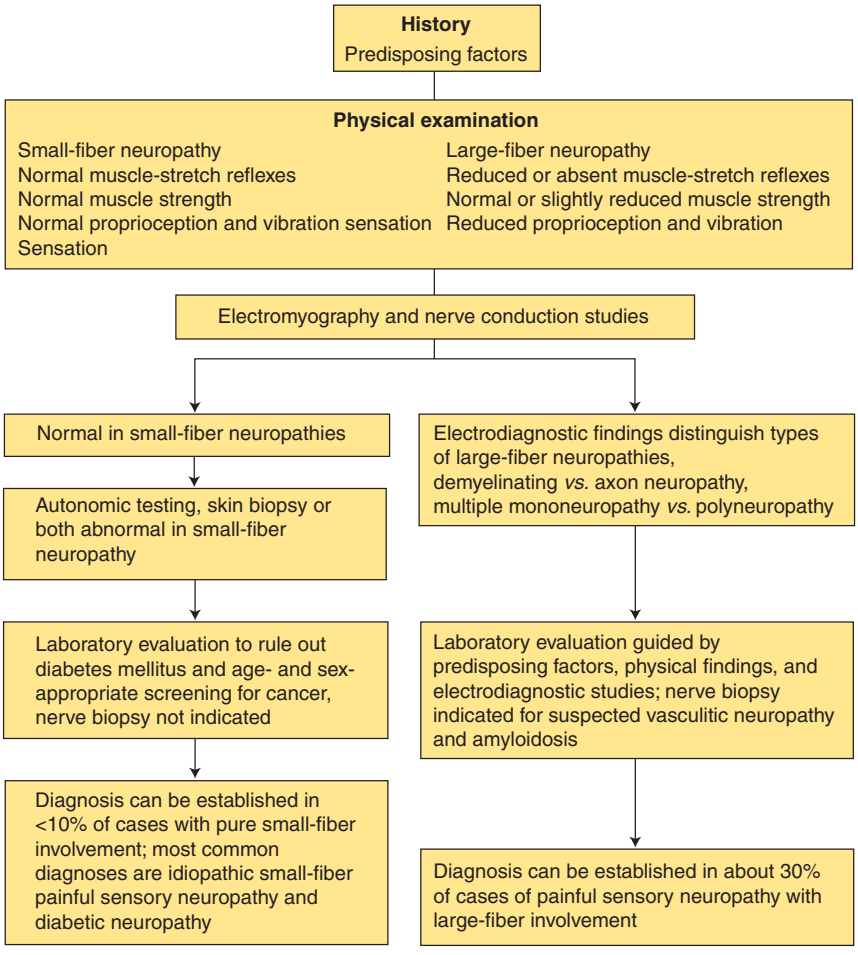

FIGURE 91–3. Algorithm for evaluation of painful peripheral neuropathy. (From Mendell and Sahenk[14] with permission.)

TABLE 91–5.

Common Diabetic Peripheral Neuropathies

1. Diffuse Neuropathies
   - A. Distal symmetric sensorimotor polyneuropathy (peripheral polyneuropathy). This is the most common form of diabetic peripheral neuropathy. The small fibers, the large fibers, or a combination of both could be affected. It typically starts in the feet but may progress to a "stocking glove" distribution in all of the extremities. Sensory symptoms predominate.
   - B. Autonomic neuropathy.
   - C. Symmetric proximal lower limb motor neuropathy (amyotrophy).
2. Focal Neuropathies
   - A. Mononeuropathies involving any of the peripheral or cranial nerves.
   - B. Entrapment neuropathies such as carpal tunnel syndrome.

CTS is characterized by paresthesias and dysesthesias over the median nerve sensory area of the hand, which includes the thumb, index, and median half of the middle fingers. Weakness of the thenar muscles can occur. Symptoms are most pronounced upon awakening.

Physical examination shows decreased sensation over the palmer aspect of the thumb through the middle finger. At later stages, the thenar muscles are weak and could be atrophied. Tinel sign and Phalen test are not sensitive but help support the diagnosis when they are present.[60,61] Tinel sign is the elicitation of distal paresthesias by percussion on the wrist or at the base of the palm. Phalen test attempts to elicit paresthesia by applying pressure (inflating a tourniquet to 60 mm HG) on the arm or holding the wrist in a flexed position.

The diagnosis of CTS can be confirmed by NCS and EMG.

Most patients respond well to conservative treatment, which includes wrist splinting, NSAIDs, or steroid injections. If treatment fails, surgical decompression at the wrist may be necessary, especially when weakness progresses.

Acute Herpes Zoster

Acute herpes zoster (shingles) is the most common cause of sensory neuropathy. It results from infection reactivation of the dormant varicella-zoster virus in the ganglionic neurons or satellite cells, followed by transmission of the virus particles to the nerve endings proximally and distally. The incidence of herpes zoster varies with age and immune status, ranging from 0.4–1.6 cases per 1000 among healthy people younger than 20 years to 4.5–11 cases per 1000 among those 80 years or older.[62] The risk of a second attack is as high as the risk of a first attack.[63] The risk of acute herpes zoster is higher among patients with HIV infection or cancer and particularly among children with leukemia and transplant recipients.[62,64–67]

Dermatomal distribution and vesicular rash are the hallmarks of acute herpes zoster.

The most affected nerves follow this order: thoracic spinal roots, ophthalmic division of the trigeminal nerve (V1), maxillary division of the trigeminal nerve (V2), cervical spinal roots, and sacral spinal roots.[68] The involvement is unilateral in most cases but can rarely be bilateral.

The earliest clinical features of acute herpes zoster noticed by patients are dermatomal dysesthesias associated with pruritus. This could be accompanied or followed shortly by the appearance of the typical rash, which matures through different stages until it crusts and heals. The pain worsens with progression and consists of dysesthesias, burning, and shooting pain. It tends to resolve spontaneously as the crust falls off, a process that takes 4–5 weeks.

Treatment of acute herpes zoster is discussed in the section on Postherpetic Neuralgia because of the close therapeutic strategies.

Postherpetic Neuralgia

Many definitions have arbitrarily been used for postherpetic neuralgia (PHN). Results of recent research distinguishes among three phases of pain: acute pain (which occurs within 30 days after rash onset; described earlier), PHN (pain that persists ≥ 120 days after rash onset), and subacute herpetic neuralgia (pain that persists beyond the acute

TABLE 91–6.

HIV/AIDS Related Neuropathies

1. Acute (AIDP) and chronic inflammatory demyelnating polyradiculoneuropathy (CIPD). AIDP (Guillain-Barré syndrome) occurs in the early stages of HIV infection. Symptoms usually peak in 4 weeks after onset and improve gradually to variable degrees. In CIDP, symptoms evolve over several weeks or months and have periods of remissions and relapses.
2. Distal sensory polyneuropathy (DSPN). DSPN is the most common HIV-associated neuropathy. It has similar presentation to the other distal symmetrical sensory neuropathies.
3. Drug-induced neuropathies. Several drugs used for treatment of HIV infection or AIDs complications can cause neuropathy that is identical to DSPN. Antiretroviral medications include didanosine (ddI; Videx), stavudine (d4T; Zerit), and particularly zalcitabine (ddC).
   Chemotherapeutic agents such as vincristine and paclitaxel used for Kaposi sarcoma and lymphoma also cause neuropathy. DSPN is a common side effect of thalidomide used for treatment of aphthous ulcers and isoniazid, an antituberculosis agent. Typically drug-induced neuropathies improve after the neurotoxic agent is withdrawn.
4. Mononeuropathy multiplex (MM). MM can occur early or late in the disease. Individual nerves are affected, resulting in isolated symptoms as seen in cranial neuropathies, hand or foot drop.
5. Cytomegalovirus (CMV) polyradiculopathy. This entity occurs in severely immunosuppressed HIV patients. It initially presents with pain and paresthesias in the saddle distribution due to involvement of the sacral roots, in association with or followed by severe symptoms that progress distally down both lower extremities. If this condition is left untreated, flaccid paraparesis, areflexia, and sphincter function impairment follow. CMV infection must be aggressively treated.

phase but resolves before the diagnosis of PHN is made).[69,70] PHN may develop after a pain-free interval. Nearly all patients have pain in association with acute herpes zoster, and 10–70% of these patients go on to have PHN.[62,63,71] Not only does the risk of PHN increase with age, but so does the intractability of the pain.[62] The presence of prodrome, female gender, greater rash severity, and greater acute herpes zoster pain severity have been associated with increased risk for PHN.[70] The risk of PHN is not increased in immunocompromised patients.[65,71] Symptoms consist of a background dermatomal burning pain and dysesthesias with superimposed intermittent lancinating pain. Hypoesthesia, hyperalgesia, allodynia, and hyperpathia may be present.

Treatment

The goal of treatment of acute herpes zoster is to alleviate the symptoms, shorten its course, and prevent the evolution of PHN. Antiviral drugs (famciclovir, valacyclovir, acyclovir) started within 72 hours after the rash appears reduce acute pain in immunocompetent patients, thus providing relief in the greatest number of patients and possibly reducing the likelihood of evolution of PHN.[62,72,73] Although corticosteroids do not alter the course of PHN, they improve the quality of life after zoster, thus justifying their administration in combination with an antiviral drug in high-risk patients 50 years or older with moderate-to-severe pain in whom corticosteroids are not contraindicated.[62]

Some reports suggest the efficacy of infiltration of the skin, peripheral nerves, sympathetic nerve blockade, or paravertebral or epidural spaces with local anesthetic drugs with or without steroids in patients with acute herpes zoster.[62,74–76]

A large retrospective study suggested that any benefits of somatic nerve blocks are limited to the first 2 months of pain.[62]

Treatment of pain associated with established PHN can be challenging. In general, drugs used for neuropathic pain are used for treatment of PHN. TCAs have well-documented efficacy.[35] Anticonvulsants are widely used.[77] Gabapentin[78–80] and pregabalin[81–83] have documented efficacy and are FDA approved. Opioids may be required for more severe cases. Topical lidocaine patches have been shown to be effective for PHN, especially in alleviating allodynia.[39,84,85] Data suggest the possible efficacy of epidural or intrathecal steroids injections in chronic PHN.[86–88]

Numerous other treatment modalities have been attempted, such as the transcutaneous electrical nerve stimulation unit,[89] topical agents, acupuncture, and hypnosis, with various results. In refractory PHN, more invasive surgical options have been implemented, including dorsal root entry zone lesions, cordotomy, rhizotomy, spinal cord stimulation, and sympathectomy.

Meralgia Paresthetica

Meralgia paresthetica is an entrapment mononeuropathy of the lateral femoral cutaneous nerve as it passes under the inguinal ligament. It is associated with a number of conditions and factors, such as increased pressure on the nerves, as occurs with tight belts, pregnancy, CTS, regional operations, obesity, or after rapid weight changes.[90,91]

Meralgia paresthetica is characterized by a patch of dysesthesias and decreased sensation over the anterolateral thigh. Diagnosis can be easily confirmed by blocking the nerve. Management is conservative. Corticosteroids injections also can be used. The prognosis is a very good, with most patients experiencing spontaneous remission in 6–12 months. Surgery might be helpful in refractory cases.[92]

Trigeminal Neuralgia

Trigeminal neuralgia, previously called *tic douloureux,* is a disorder of the trigeminal nerve. It is characterized by brief electric shock-like pain that is abrupt in onset and termination and is limited in distribution to one or more divisions of the trigeminal nerve. Pain is commonly evoked by trivial trigger factors such as washing, shaving, talking, and/or brushing the teeth. Small areas in the nasolabial fold and/or chin may be particularly susceptible to the precipitation of pain (trigger areas). The pain usually remits for variable periods.

Trigeminal neuralgia classically starts in the second or third division and affects the cheek or chin. The first division is involved in <5% of patients. Trigeminal neuralgia is a unilateral disorder but in rare cases is bilateral, in which case a central lesion such as

TABLE 91–7.

International Headache Society Diagnostic Criteria for Trigeminal Neuralgia

A. Paroxysmal attacks of pain lasting from a fraction of a second to 2 minutes, affecting one or more divisions of the trigeminal nerve and fulfilling criteria B and C
B. Pain has at least one of the following characteristics:
   1. Intense, sharp, superficial or stabbing
   2. Precipitated from trigger areas by trigger factors
C. Attacks are stereotyped in the individual patient
D. No clinically evident neurologic deficit
E. Not attributed to another disorder

multiple sclerosis should be excluded. Between paroxysms, patients usually are asymptomatic but may have a persistent dull background pain. In some cases, the trigeminal root in the posterior fossa is compressed by tortuous or aberrant vessels. Classic trigeminal neuralgia usually is responsive, at least initially, to pharmacotherapy.

Table 91–7 lists the International Headache Society (IHS) diagnostic criteria for trigeminal neuralgia.[93]

Carbamazepine is still the first-line treatment. Other AEDs, such as gabapentin, also have been shown to be effective.[94] TCAs are effective.[95] In refractory cases, invasive procedures (e.g., ablative lesioning or decompression of the trigeminal ganglion) may be required.[96]

Glossopharyngeal Neuralgia

Glossopharyngeal (cranial nerve IX) neuralgia is a severe transient stabbing pain experienced in the distribution of this nerve and the distribution of the auricular and pharyngeal branches of the vagus nerves. The pain is felt in the ear, base of the tongue, tonsillar fossa, or beneath the angle of the jaw. The pain is commonly provoked by swallowing, talking, or coughing and may remit and relapse as in trigeminal neuralgia. Table 91–8 lists the IHS diagnostic criteria for glossopharyngeal neuralgia.[93]

In Eagle syndrome, the nerve is compressed by a calcified or ossified stylohyoid ligament, which is visible on x-ray or CT scan.[97]

TABLE 91–8.

International Headache Society Diagnostic Criteria for Glossopharyngeal Neuralgia

A. Paraoxysmal attacks of facial pain lasting from a fraction of a second to 2 minutes and fulfilling criteria B and C
B. Pain has all of the following characteristics:
   1. Unilateral location
   2. Distribution within the posterior part of the tongue, tonsillar fossa, pharynx, or beneath the angle of the lower jaw and/or in the ear
   3. Sharp, stabbing, and severe
   4. Precipitated by swallowing, chewing, talking, coughing, and/or yawning
C. Attacks are stereotyped in the individual patient
D. No clinically evident neurologic deficit
E. Not attributed to another disorder

Pharmacologic treatment of glossopharyngeal neuralgia is similar to that of trigeminal neuralgia. In Eagle syndrome, resection of the stylohyoid ligament is effective.

Occipital Neuralgia

Occipital neuralgia is a paroxysmal stabbing jabbing pain in the distribution of the greater or lesser occipital nerves or the third occipital nerve, sometimes accompanied by diminished sensation or dysesthesias in the affected area. It is associated with tenderness over the affected nerve. Table 91–9 lists the IHS diagnostic criteria for occipital neuralgia.[93]

Treatment can be conservative using different analgesics, including TCAs and AEDs, or application of nerve blocks. For refractory cases, neuroablative measures can be used.[98]

CENTRAL PAIN SYNDROMES

Central pain is a "deafferentation" pain that can result from any lesion found in the CNS.[99] Virtually any type of lesion can produce this type of pain, including demyelinating, vascular, infectious, inflammatory, and traumatic. Pain onset may be delayed by several months after the initial insult, reflecting the slow degeneration process within the CNS. Pain usually correlates

TABLE 91–9.

International Headache Society Diagnostic Criteria for Occipital Neuralgia

A. Paroxysmal stabbing pain, with or without persistent aching between paroxysms, in the distribution(s) of the greater, lesser, and/or third occipital nerves
B. Tenderness over the affected nerve
C. Pain is eased temporarily by local anesthetic block of the nerve

to the anatomic site of the causative lesion. The pain features are those of neuropathic pain.

Brain central pain results from a variety of etiologies. Thalamic pain (Dejerine-Roussy syndrome) is the prototype of central pain, but lesions in the brainstem and other sites also can produce central pain. Strokes are the most common cause, with pain reported to occur in up to 8% of poststroke patients.[100] Other etiologies include multiple sclerosis, brain abscess, encephalitis, and tumors.

Spinal cord central pain is a common complication of spinal cord injuries. Trauma is the most common etiology.[101] Iatrogenic, inflammatory, demyelinating, vascular, neoplastic, and congenital lesions are other possible causes. The most common level of injury associated with pain is cauda equina followed by the central cord injuries. Syringomyelia and syringobulbia can occur as delayed consequences of trauma or congenital malformations and produce neuropathic pain of segmental pattern.

Central pain is one of the most difficult pain states to effectively treat. Lamotrigine shows encouraging results.[102,103] Some evidence exists for the benefit of TCAs.[35] Other agents used for neuropathic pain, such as AEDs and opioids, have been used, but no sound evidence supports their efficacy.

Sympathetically Maintained Pain and Complex Regional Pain Syndromes

Sympathetically maintained pain (SMP) is defined as "pain that is maintained by sympathetic efferent innervation or by circulating catecholamines."[104] Thus, SMP is not a clinical diagnosis but rather a pathophysiologic mechanism in chronic pain marked by improvement

of pain when sympathetic blockade is performed. When the pain does not respond to sympathetic blockade, it is called *sympathetically independent pain* (SIP). SMP is thought to be a major culprit in many chronic pain states, such as peripheral and central neuropathic pain syndromes.[105–107]

Complex regional pain syndrome (CRPS) is considered to be a neuropathic SMP syndrome. The two types of CRPS are type I (previously called reflex sympathetic dystrophy) and type II (previously called causalgia). CRPS is more common in women than in men, and the incidence reaches its peak in the fifth decade.[108,109] It involves one limb in most cases,[110] and there is a history of noxious traumatic injury with or without nerve involvement.[109] There is no correlation between the severity of injury and the severity of the ensuing pain syndrome. Direct injuries to CNS structures have been reported as causative, including spinal cord[111] and brain[112] injuries. In CRPS type II particularly, there may be a stretch injury to the nerve, without interruption of the nerve. Multiple risk factors have been postulated to predispose to CRPS, including immobilization,[113] smoking,[114] genetic predisposition,[115] and psychological factors.[116]

The exact mechanism of CRPS is not known, but it appears to be a disease of both the CNS and the peripheral nervous system.[117,118] Peripherally, α-adrenergic sensitization of the nociceptive afferent fibers occurs. As a result, nociceptors are activated by release of norepinephrine by sympathetic postganglionic fibers. Release of certain mediators, such as prostaglandins, by sympathetic fibers can further sensitize the nociceptive afferents. If the injury results in myelin loss of the fibers, artificial synapses develop between the affected sensory afferents and sympathetic efferents, a process called *ephaptic transmission.* The dorsal root ganglion is thought to be another site for ephaptic transmission resulting from sprouting of sympathetic postganglionic fibers around sensory neurons. At the level of the dorsal horn of the spinal cord, the wide dynamic range neurons, which are second-order neurons, are activated and sensitized by the active injured C-fibers. Sensitized wide dynamic range cells are thought to be activated by other stimuli, such as light touch, explaining the phenomenon of allodynia. At the level of the brain, there is altered sensorimotor processing and increased hyperexcitability.[119,120] Thus, CRPS results from interaction between the CNS and the periphery. Central changes are reflected as alterations in somatic sensation (including pain), the motor system, and the peripheral autonomically regulated effector systems (vasculature, sweat glands, inflammatory cells).[117]

In most cases the presenting symptom of CRPS is pain, which most often is burning and does not follow a dermatomal pattern.[108,121] Other common symptoms and signs include decreased range of motion, weakness, hyperpathia, allodynia, hyperalgesia, color change, altered skin temperature, edema, hyperesthesia, hypoesthesia, sweating change, nail or hair changes, and dystonia.[108,121] Although symptoms typically start in a distal limb, CRPS has been reported to start in other regions of the body, such as the head, proximal limbs, and genitalia.[122] Spread of CRPS features proximally or to other regions of the body has been well described.

The diagnosis of CRPS can be made only in the absence of any other diagnosis explaining the findings. Table 91–10 summarizes the International Association for the Study of Pain (IASP) diagnostic criteria for CRPS.[123–126] These criteria are very sensitive and less specific. Criteria with improved specificity are proposed and summarized in Table 91–11.[124,126]

No specific diagnostic test is available for CRPS.[127] Several tests can help confirm the diagnosis or rule out other conditions. Blood tests, including erythrocyte sedimentation rate, blood cell count, and rheumatologic testing, may be necessary to help rule out infection or a rheumatologic condition.[127] When vasomotor features are present, vascular studies can exclude a vascular etiology. NCS and EMG may clarify the presence of nerve injury necessary for the diagnosis of CRPS type II. An important distinction between CRPS type II and peripheral mononeuropathy is that the somatosensory symptoms in CRPS extend beyond the distribution of the affected nerve.[127] Radiographic studies including magnetic resonance imaging often are necessary to exclude bone or soft-tissue pathology as the source of pain. Plain radiographic studies may show findings of bony demineralization, which is not specific to CRPS and could be the result of disuse.[128] A three-phase bone scan of the affected extremity has variable sensitivity and is relatively nonspecific in the diagnosis of CRPS. Classic findings include increased periarticular uptake throughout the three phases (blood pool, blood phase, scan phase).[127] Thermography can assist in confirming thermal dysregulation. Simple measures also can provide this information, using infrared thermometer or skin temperature probes that document the temperature of the normal and the affected limbs. A temperature difference of 0.6°C between limbs is considered significant.[129] Quantitative sudomotor axonal reflex testing evaluates autonomic function by measuring sweat output in response to a cholinergic agent. Although a positive response to a sympathetic block can help in establishing the diagnosis, it is not required to diagnose CRPS.[127] A pharmacologic sympathetic block can be performed with intravenous infusion of phentolamine. However, the more common approach is performance of a local anesthetic sympathetic trunk block. A lumbar paravertebral sympathetic block is performed for lower limbs, and a cervicothoracic block (stellate ganglion block) or upper thoracic sympathetic block is performed for upper limbs. Evidence of a satisfactory sympathetic block (e.g., thermography) in

TABLE 91–10.

International Association for the Study of Pain Diagnostic Criteria for Complex Regional Pain Syndrome

1. Presence of an initiating noxious event or cause of immobilization
2. Continuing pain, allodynia, or hyperalgesia, with pain disproportionate to any inciting event.
3. Evidence at some time of edema, changes in skin blood flow, or abnormal sudomotor activity in the region of pain
4. Diagnosis is excluded by the existence of conditions that would otherwise account for the degree of pain and dysfunction.

Type I: Without evidence of major nerve damage

Type II: With evidence of major nerve damage

TABLE 91–11.

Proposed Modified Clinical Diagnostic Criteria for Complex Regional Pain Syndrome

1. Continuing pain that is disproportionate to any inciting event.
2. Must report at least one symptom in three of the four following categories:
   - Sensory: Reports of hyperesthesia and/or allodynia
   - Vasomotor: Reports of temperature asymmetry and/or skin color changes and/or skin color asymmetry.
   - Sudomotor/Edema: Reports of edema and/or sweating changes and/or sweating asymmetry.
   - Motor/Trophic: Reports of decreased range of motion and/or motor dysfunction (weakness, tremor, dystonia) and or trophic changes (hair, nails, skin).
3. Must display at least one sign at the time of evaluation in two or more of the following categories:
   - Sensory: Evidence of hyperalgesia (to pinprick) and/or allodynia (to light touch and/or deep somatic pressure and/or joint movement).
   - Vasomotor: Evidence of temperature asymmetry and/or skin color changes and/or asymmetry.
   - Sudomotor/Edema: Evidence of edema and/or sweating changes and/or sweating asymmetry.
   - Motor/Trophic: Evidence of decreased range of motion and/or motor dysfunction (weakness, tremor, dystonia) and/or trophic changes (hair, nails, skin).
4. No other diagnosis better explains the signs and symptoms.

the absence of a somatic nerve block should be demonstrated.[127] If favorable results are achieved by sympathetic blocks, then their continued administration may be useful.

Treatment of CRPS remains controversial because of the lack of adequate evidence on most therapies implemented in clinical practice. A consensus statement released in 2002 by an interdisciplinary expert panel produced a reasonable treatment approach.[130,131] Rapid initiation of multidisciplinary treatment is recommended, with advancement to higher levels of intervention if initial therapy shows no benefit in 2 weeks. Simultaneous physical rehabilitation, psychological therapy, and provision of adequate analgesia are key elements in the treatment plan. The primary goal of treatment is functional restoration of the affected region. In some studies, physical therapy has shown to be effective and thus should be started as soon as possible while effective analgesia is provided. Multiple physical and occupational therapy measures can be used in the process of rehabilitation, starting with desensitization and stress loading, then gentle active range of motion and stretching to increase flexibility, and eventually normalization of use and general conditioning.[132]

Psychological therapy should focus on educating patients that pain sensations in CRPS type I do not indicate tissue damage, and that reactivation of the affected limb is important. With persistent symptoms, clinical psychological assessment is recommended, eventually followed by cognitive behavioral therapy. Comorbid conditions such as depression sleep disturbance, anxiety, and generalized physical deconditioning should be treated.

Analgesia is achieved using oral or topical neuropathic pain agents, including TCAs, AEDs, NSAIDs, opioids, and other agents.[133] Corticosteroids may be effective, especially if the inflammatory component is profound.[134] Calcitonin, topical dimethylsulfoxide (DMSO), and α_1-adrenoceptor antagonists (e.g., terazosin, phenoxybenzamine) may be helpful. Many other drugs have been anecdotally used, with varied results (including prazosin, clonidine, mexiletine, ketamine, baclofen, bisphosphonates, muscle relaxants, and calcium channel blockers).[135]

When symptoms are persistent, patients who had favorable results with diagnostic sympathetic blockade are often offered intravenous regional sympathetic blocks (IRSBs). IRSBs using phentolamine, guanethidine, reserpine, droperidol, and atropine have been shown to be ineffective.[135] Patients who have not had good results with sympathetic blockade may require a combined somatic/sympathetic block using indwelling catheters to allow adequate physical therapy and rehabilitation. Epidural catheters also have been used in this fashion.[130] If sympathetic blocks are effective in producing analgesia but duration is limited, neurolysis with either neurolytic injections or radiofrequency-lesioning techniques can be considered.[136] Spinal cord stimulation appears to be an effective treatment, especially for CRPS type I.[137,138] Spinal analgesia may be an effective treatment of CRPS when other modalities fail.[130,139,140]

Postamputation Pain

Stump Pain

Stump pain is a chronic sensation of pain at the site of amputation. It also is referred to as residual limb pain.[141] It may occur with phantom limb pain or alone. Several factors may account for stump pain and should be evaluated, including surgical trauma, ischemia, local infection, ill-fitting prostheses, or a painful neuroma formation.

Treatment should focus on treating the underlying etiology. Treatment of painful neuromas ranges from simple injections to surgical interventions, with varying degrees of success.[142]

Phantom Pain

Phantom sensation is the perception of the amputated part and occurs in almost all amputees. Phantom pain is the perception of pain distal to the amputation site. It has unclear etiology, but deafferentation of central neurons seems to play a major role in the development of phantom pain. Its incidence peaks approximately 1 month after amputation and gradually improves as the pain "telescopes" toward the stump. The pain results in paroxysms of burning and twisting sensation in the amputated part. Phantom pain should be differentiated from stump pain.

Treatment of phantom pain is challenging. Pharmacologic agents for neuropathic pain should be attempted. TCAs, tramadol, and gabapentin have been shown to be effective.[143,144] Nerve blocks can be tried for more difficult cases. In refractory cases, surgical options (e.g., dorsal root entry zone lesions) and more invasive procedures might be the only effective methods for treating the pain. Preemptive analgesia may prevent phantom pain, although this remains controversial.[145]

Back and Neck Pain

Low back pain is one of the most common symptoms that prompt patients to seek medical care and is the leading cause of disability among workers younger than 45 years. Current data suggest that more than three

fourths of people will have back pain at one point in their life, with an annual prevalence up to 45%.[146,147]

Neck pain is a less common complaint but still has a point prevalence of approximately 10–35% and a lifetime prevalence of approximately 15–50%. It is more common in women.[148]

Pain can originate due to pathology in a variety of neuraxial structures, including vertebral bodies, intervertebral disks, ligaments, muscle structures, joints (facet, sacroiliac), nerve roots, meninges, and epidural space. A combination of etiologies is common and may be difficult to delineate. Table 91–12 summarizes the most common etiologies of back and neck pain.

Obtaining an adequate history and physical examination is crucial for reaching the correct diagnosis and implementing a successful treatment plan. Special attention should be given to excluding emergency situations, such as epidural infection, epidural hemorrhage, cauda equine syndrome, spinal cord compression, spine metastasis, and aortic aneurysm. This chapter discusses only the more common pain syndromes.

Discogenic Pain

Discogenic pain is believed to occur as a result of damage to the annular lamellae by the disrupted inner internal disk and the resultant decreased pain threshold to mechanical loading. Usually a deep axial ache radiates to shoulders and scapular areas from cervical disks and to buttocks and posterior thighs from lumbar disks. The pain is worsened by mechanical loading maneuvers such as sitting, standing, and particularly bending forward.

Although computed tomographic (CT) scanning and magnetic resonance imaging (MRI) of the spine may show signs of disk degeneration, establishing clinical correlation with imaging findings is difficult.[149] A provocative discography test that consists of dye injection into the disk material followed by CT imaging has been advocated to confirm discogenic pain.[150]

Treatment is conservative, consisting of physical therapy, weight reduction, and NSAIDs. Patients with one or two diseased disks who are refractory to conservative therapy may benefit from intradiscal electrothermal therapy (see Chapter 93).[151–153]

Radicular Pain

Radicular pain originates as a result of irritation of a nerve root due to a herniated nucleus pulposus or degenerative neuroforaminal narrowing. The most commonly affected levels in the lower back are L5–S1 and L4–5. In the neck, the affected levels are C5–6 and C6–7. Typically, the pain radiates from the neck or back in a dermatomal pattern. Usually the patient has associated sensory disturbance and reflex decrease in the distribution of the affected root. A positive straight-leg raising (SLR) test while the patient in a supine or sitting position indicates nerve root irritation. SLR test is considered positive when pain is reproduced in a dermatomal distribution. However, nerve root irritation is not always present in patients with low back pain or posterior thigh discomfort. MRI is helpful in identifying anatomy and changes near the nerve roots. NCS/EMG can help confirm the diagnosis and assess the severity of injury.

Conservative treatment, including NSAIDs and PT, is sufficient for most cases. Epidural steroid injections can provide symptomatic management.[154,155] Transforaminal steroid injections might be superior and prevent from surgery but may result in more complications, especially at the cervical spine level.[156–159] Surgical intervention may be required for refractory pain, especially if neurologic deficits are present. Microdiscectomy is the gold standard treatment for uncomplicated herniated nucleus pulposus.

Facet Arthropathy

The facet joints (zygapophysial or Z joints) are true synovial joints whose main function is to limit rotation and resist compression during lordosis. Facet joint pain results from conditions that increase the load on them,

TABLE 91–12.

Common Causes of Back and Neck Pain

- Vertebral bodies
  - Fractures
  - Neoplastic lesions
    - Primary
    - Metastatic
  - Metabolic derangements
    - Osteoporosis
    - Paget disease
    - Osteitis fibrosa
    - Hyperthyroidism
    - Hyperparathyroidism
    - Cushing syndrome
  - Infections
    - Osteomyelitis
- Intravertebral disks
  - Structural lesions
    - Degeneration and herniation
    - Chondromalacia
  - Infections
    - Diskitis
- Ligaments
  - Acute strain
  - Involvement with other conditions
- Muscle structures
  - Primary myofascial pain
  - Secondary myofascial pain
- Joints
  - Facets joints (zygapophysial or "Z" joints)
    - Osteoarthritis
    - Mechanical arthropathy
    - Synovial impingement
    - Meniscoid entrapment
- Sacroiliac joints
  - Mechanical arthropathy
    - Pregnancy
  - Degenerative and inflammatory
    - Osteoarthritis
    - Ankylosing spondylitis
    - Psoriatic arthritis
    - Reiter syndrome
    - Chronic inflammatory bowel disease
- Nerve roots (and dorsal root ganglia)
  - Compressive lesions
  - Neuroradiculopathies
- Meninges
  - Arachnoiditis
  - Scar tissue
- Epidural space
  - Hematoma
  - Infection (abscess)
- Multifactorial
  - Structural
    - Spine instability
    - Kyphosis
    - Scoliosis
    - Spondylolithiasis
  - Degenerative
    - Spinal stenosis
    - Spondylosis
  - Trauma
  - Infection
  - Psychosocial
  - Referred pain

such as arthritis, decreased disk space, and increased lordosis (as in obesity).

Pain usually is a gradual-onset deep axial ache that radiates to the scapular regions in the neck or to the buttocks and posterior thighs. It is associated with morning stiffness. The pain is reproduced by facet loading maneuvers by hyperextension and lateral rotation, which provokes pain ipsilaterally. Paraspinal tenderness often is present.[160,161]

MRI or CT can reveal arthritic changes in the facets joints, such as hypertrophy and joint space narrowing. The diagnosis can be confirmed by diagnostic block of the joints or of the medial branches innervating them.

Treatment is conservative, consisting of oral analgesics, weight loss, and PT. Intrajoint steroid injection can be attempted. Radiofrequency ablation of the medial branches appears to be promising.[162,163]

Sacroiliac Arthropathy

The sacroiliac joint connects the sacrum to the iliac bones. It is subject to degenerative and inflammatory arthritides as well as mechanical dysfunction. The pain usually is precipitated by an injury, such as falling, lifting, or turning.

The pain is a unilateral ache that radiates to the buttock, groin, and thigh area. It rarely goes below the knee. The pain is worsened by loading the joint, as occurs during prolonged sitting, standing, or bending. There is tenderness over the joint area, and the pain typically is reproduced by the Patrick test, in which the hip is forced into external rotation by placing the ankle on the opposite knee or thigh and pushing down on the knee. Intraarticular local anesthetic block can help confirm the diagnosis.

Treatment with NSAIDs and PT can be helpful. Fluoroscopy-guided intraarticular steroid injection has been the mainstay of treatment in clinical practice. Lateral branch block and radiofrequency ablation have been reported useful in advanced cases.[164]

Spinal Stenosis

Spinal stenosis results from narrowing of the central canal, lateral recesses, or neuroforamina due to age-related degenerative changes, including osteophyte formation, facet hypertrophy, ligamentum flavum hypertrophy, and diffuse broad-based disk bulge. Its occurrence in the cervical spine is referred to as cervical "spondylosis." When spinal stenosis occurs in people younger than 60 years, other comorbidities, such as diabetes or congenital stenosis due to short pedicles, scoliosis, and spondylolisthesis, should be ruled out.

Pain manifests as radicular when the narrowing occurs in the lateral recesses or neuroforamina. In the case of lumbosacral spinal canal stenosis, axial low back pain and neurogenic claudication are the predominant features.[165] Neurogenic claudication worsens with walking (especially downhill) and with extension of the spine. Rest and flexion of the spine usually provide temporary relief.

Cervical spondylosis can progress and cause cervical spondylotic myelopathy (CMS) and cord compression of varying severity. Motor weakness, spasticity, hyperreflexia, Babinski sign, Hoffman sign, paresthesias, imbalance, bowel and bladder function, and other features of spinal cord compression should be carefully assessed. Acute cervical spondylotic myelopathy can occur as a result of abrupt hyperextension of the neck. Radiographic changes reflecting degeneration associated with stenosis are common with aging; thus, clinical correlation is critical in the assessment and management of related symptom complexes.[165]

Treatment of spinal stenosis should start with conservative measures, including oral analgesics, translaminar or transforaminal epidural steroid injections, and PT. Surgical options should be preserved for cases with rapid neurologic progression, CMS, or cauda equina syndrome, or for patients who remain symptomatic despite a course of nonsurgical therapy and who have advanced imaging studies that correspond to existing symptoms. Surgical management of lumbar and cervical stenosis includes discectomy, neural decompression, and spinal arthrodesis. Several studies report that surgical treatment produces better outcomes than nonsurgical treatment in the short term; however, improved results tend to regress over time.[166–170]

Failed Back Surgery Syndrome

Failed back surgery syndrome refers to the persistence or recurrence of low back pain after surgical intervention on the lumbosacral spine. Potential causes of surgical intervention failure include the following[56]: (1) poor patient selection, (2) unindicated surgery, (3) inadequate surgical decompression, (4) recurrence of lesions, (5) established neural injury, (6) complications of diagnostic and/or surgical intervention, and (7) secondary instability or degeneration. One study found the predominant specific diagnoses in patients with failed back surgery syndrome were (in order) foraminal stenosis, painful disk(s), pseudarthrosis, neuropathic pain, instability, and psychological problems. Recurrent disk herniation is seen less often than in the past.[171]

Physical examination and imaging studies are essential to confirm the diagnosis and rule out other emerging etiologies. Treatment should be focused on the specific underlying etiology and may include repeated surgical intervention. Epidurolysis of adhesions via epiduroscopy or by catheter technique has limited evidence of efficacy.[172,173] Spinal cord stimulation was found to be both more effective and less costly than conservative medical management over the lifetime of a patient.[174–176]

Whiplash Injury

Whiplash injury refers to neck injury caused by abrupt hyperextension due to indirect force, as occurs with acceleration–deceleration mechanisms.

Whiplash injury is estimated to occur in 1% of the general population and to become chronic in up to 25% of these patients. Up to 60% of car accident victims evaluated in emergency departments have neck pain and up to 26% of them have persistent symptoms after 1 year.[177] Cervical facet joint pain is the most common source of pain after whiplash injury. The most common cervical segments involved are C2–3 and C5–6.[177,178]

Physical examination is nonspecific and may reveal tenderness and limited range of motion. Patients who have normal plain radiographic findings and no evidence of a neurologic deficit do not require additional MRI.[179]

Diagnostic medial branch block is helpful in delineating etiologies and differentiating between facet arthropathy and other causes of neck pain.

Treatment of acute whiplash injury is conservative and includes oral NSAIDs, PT, and transcutaneous electrical nerve stimulation unit.[180] In chronic conditions where facet arthrop-

athy is confirmed with diagnostic blocks, radiofrequency ablation appears to be promising.[178,181]

Head Pain

Headache is one of the most common symptoms encountered in clinical practice. A pain medicine physician should be familiar with the common types of syndromes and be able to provide appropriate management. The IHS provides valuable sources for the classification and diagnosis of different syndromes.[93]

The prevalence of headache in the United States is estimated to be 78% in women and 68% in men. In general, headache is classified as primary or secondary. Primary headaches are diseases by themselves, as seen with migraine, tension-type, and cluster headaches. Secondary headaches are caused by an underlying condition. The majority of headaches seen in clinical practice are primary headaches (approximately 90% or more).[182] The most common headache is tension headache, with a prevalence of 78%. Migraine also is very common, with an estimated prevalence of 16%. Among secondary headaches, the most common cause is attributable to fasting. Nasal- and sinus-related headaches and head trauma are less common. Many fear that headaches are caused by intracranial disease such as tumors; however, this actually occurs in a very small percentage of the population (0.5%).[183]

Evaluation of headache requires thorough history and physical examination. Special attention should be given to any "red flags" that may point to a secondary disorder. In the absence of warning signs, most likely the headache is of a primary disorder, with the majority of headaches being either tension-type or migraine. Even in the absence of warning signs, possible secondary headache disorder may exist in patients presenting with "atypical features," such as migraine with prolonged aura lasting more than 60 minutes, migraine that lacks characteristic features (e.g., no nausea, photophobia, or phonophobia), and migraine that does not quite meet all the diagnostic criteria, especially if they do not respond to normal therapy. These are the signals that are frequently elicited in a headache evaluation.

The most important feature is the temporal profile of the headache, specifically the mode of onset. Headache with a rapid time to peak intensity should always suggest an underlying cause of secondary headache. Not only the mode of onset but also the age at onset is important, as headache onset after age 50 years should raise concern of secondary headache. Other "red flags" include association with systemic signs or symptoms; the presence of a new or different headache, particularly in those with systemic malignancy, which may signify intracranial disease (e.g., metastases); a change in headache pattern, such as progressive headache with loss of headache-free period; and a change in frequency or severity of a previously existing headache disorder (because underlying secondary causes in patients with a history of migraine can mimic normal headache patterns). Any, even subtle, abnormal neurologic findings also should raise suspicion.[184]

Electroencephalography is not useful in the routine evaluation of patients with headache. However, electroencephalography may be useful in patients with headache who have an alteration of consciousness, encephalopathy, or focal neurologic deficits and atypical symptoms.[185] Lumbar puncture (LP) is indicated in the evaluation of thunderclap or sudden headache to exclude the possibility of subarachnoid hemorrhage. CT can be negative in up to 25% of patients within 24 hours of occurrence of subarachnoid hemorrhage and can be negative in up to 50% of patients 1 week after initial presentation of headache resembling thunderclap. LP is indicated in any patient with subacute and progressive headache in order to exclude infections, an inflammatory condition, or carcinomatous meningitis. Any patient who presents with headache and fever, confusion, or seizure should be suspected of having acute intracranial infection. LP should be performed in patients with high or low intracranial pressure syndrome (idiopathic intracranial hypertension), even in the absence of papilledema. LP should be performed to confirm low-pressure states, as occurs with cerebrospinal fluid (CSF) leaks. In the absence of "red flags," CT or MRI typically are not performed unless a change in headache pattern occurs or the patient experiences changes in neurologic status as evidenced by seizures or focal neurologic signs or symptoms.[186]

Following is a discussion of IHS criteria for common headaches and a brief review of major treatment options.

Migraine

Multiple types of migraine exist. The more common types are discussed here.

Migraine without Aura

Migraine without aura previously was called *common migraine.* Table 91–13 lists the IHS diagnostic criteria[93] for migraine without aura.

Migraine with Aura

This type of headache previously was called classic migraine. It fulfills the criteria of migraine as described earlier and is associated with aura. The aura is a complex of neurologic symptoms that occurs just before or at the onset of migraine headache. A typical aura consists of visual and/or sensory and/or speech symptoms. It has gradual development, duration no longer than 1 hour, and complete reversibility.[93] Some patients have typical aura without having a typical migrainous headache.

Treatment of migraine headaches is abortive and preventive. Abortive treatment is directed toward the acute attacks as they occur. Many drugs have been shown to be effective abortive medications. Nonspecific treatments, such as acetaminophen, aspirin and caffeine combination (Excedrin), and

TABLE 91–13.

International Headache Society Diagnostic Criteria for Migraine without Aura

A. At least five attacks fulfilling criteria B–D
B. Headache attacks lasting 4–72 hours (untreated or unsuccessfully treated)
C. Headache has at least two of the following characteristics:
   1. Unilateral location
   2. Pulsating quality'
   3. Moderate or severe pain intensity
   4. Aggravation by or causing avoidance of routine physical activity
D. During headache at least one of the following
   1. Nausea and/or vomiting
   2. Photophobia and phonophobia
E. Not attributed to another disorder

TABLE 91–14.

International Headache Society Diagnostic Criteria for Cluster Headache

A. At least five attacks fulfilling criteria B–D
B. Severe or very severe unilateral orbital, supraorbital, and/or temporal pain lasting 15–180 minutes if untreated
C. Headache is accompanied by at least one of the following:
   1. Ipsilateral conjunctival injection and/or lacrimation
   2. Ipsilateral nasal congestion and/or rhinorrhea
   3. Ipsilateral eyelid edema
   4. Ipsilateral forehead and facial sweating
   5. Ipsilateral miosis and/or ptosis
   6. Sense of restlessness and agitation
D. Attacks have a frequency ranging from one every other day to 8 per day
E. Not attributed to another disorder

TABLE 91–15.

International Headache Society Diagnostic Criteria for Postdural Puncture Headache

A. Headache that worsens within 15 minutes after sitting or standing and improves within 15 minutes after lying down, with at least one of the following and fulfilling criteria C and D:
   1. Neck stiffness
   2. Tinnitus
   3. Hypacusia
   4. Photophobia
   5. Nausea
B. Dural puncture has been performed
C. Headache develops within 5 days after dural puncture
D. Headache resolves (in 95% of cases) either:
   1. Spontaneously within 1 week
   2. Within 48 hours after effective treatment of the spinal fluid leak (usually by epidural blood patch)

NSAIDs are effective for simple and less severe migraines. Other nonspecific migraine agents include corticosteroids, antiemetics, and opioid analgesics. The migraine-specific agents are considered the mainstay abortive treatment of migraine. They include ergotamine, dihydroergotamine, and the more selective serotonin antagonists (triptans). Multiple triptans are available in different forms, half-lives, and potencies. Preventive treatment of migraine should focus on modifying and/or eliminating the triggering factors, such as sleep disturbance, caffeine intake, analgesics overuse, and stressors. Pharmacologic preventive treatment is indicated when migraine intensity, duration, or frequency is severe enough to warrant chronic use of a daily medication. Preventive treatment also is indicated for more serious forms of migraine, such as basilar-type migraine (migraine with neurologic signs of posterior circulation dysfunction), migraine with complications (focal neurologic features), and hemiplegic migraine. TCAs (e.g., amitriptyline), nonselective β-blockers (e.g., propranolol), and AEDs (e.g., topiramate and divalproex sodium) are effective preventive agents.

Tension-Type Headache

Tension-type headaches are the most common primary headache. Many features contrast them from migraines. Each attack of tension-type headache can be much shorter or much longer than migraine. The pain generally is bilateral, is of mild-to-moderate intensity, is constant, and is not aggravated by movement or activity. Photophobia or phonophobia may be present but usually not both, and the patient experiences no nausea or vomiting. Tension-type headaches have a wide spectrum of frequency that varies from sporadic episodes to chronic forms.[93]

Infrequent episodes of tension-type headaches can be treated with simple analgesics. For more frequent and chronic forms, preventive treatment is essential.

Cluster Headache

Cluster headaches are much less common than tension-type and migraine headaches but are excruciatingly painful and devastating. Table 91–14 lists the IHS diagnostic criteria for cluster headaches.[93]

As for treatment of migraine headaches, treatment of cluster headaches is abortive and preventive. Abortive treatment consists of inhaled oxygen, triptans, especially the injectable form (sumatriptan), or dihydroergotamine. Multiple preventive agents can be tried. They include corticosteroids, hypertension medications (β-blockers and calcium channel blockers), and lithium. In refractory cases, invasive treatments might be required. They include sphenopalatine ganglion blockade, trigeminal nerve and/or ganglion blockade, or deep brain stimulation.

Postdural Puncture Headache

Low-CSF pressure headache results from a dural tear and subsequent CSF leak. Postdural puncture headache is the more common type of low-CSF headache. The IHS diagnostic criteria for postdural puncture headache are listed in Table (91–15).[93]

Epidural blood patch at the expected site of leak remains the mainstay treatment. Conservative therapy includes bedrest, aggressive hydration, caffeine, and analgesics.

CHAPTER 92

Medical Management of Chronic Pain

Marc A. Huntoon, MD

The approach to the patient with chronic pain shares some similarities with the treatment of acute pain, with several notable differences. Whereas acute pain involves a specific tissue injury and an often easily identifiable initiating event, chronic pain may not have a definable source, tissue injury may not always be apparent, and treatment may be ineffective (Fig. 92–1). In general, if pharmacologic therapy is the mainstay of treatment, then the long-term implications of popular drugs used for treatment of acute pain, such as opioids and nonsteroidal antiinflammatory agents (NSAIDs), must be considered. Acute pain is caused by a short-term event (trauma, surgery, burn, etc.) and is appropriately managed with opioids, regional/neuraxial local anesthetics, numerous adjuvant drugs, and corticosteroids or NSAIDS. Long-term issues of drug-induced toxicities, such as opioid-induced hyperalgesia and cardiovascular side effects of certain cyclooxygenase-2 (COX-2)–blocking NSAIDs, must be considered relevant to patients with chronic medical problems. When acute pain becomes chronic, the physician must understand the mechanism of the pain in order to choose treatments based on validated outcome studies. This mechanism-based approach to pain therapy[1] likely will continue to dominate chronic pain treatment strategies for many years. With the realization that all pain is not initiated and maintained by similar mechanisms, treatments must be tailored to the specific individual. The pain problem also must be considered within the fabric of the patient's health profile and the context of the patient's current psychosocial situation. This evaluation and management model of treating the patient with pain as a whole person often is characterized as the *biopsychosocial model* of care.[2,3] The chronic pain, after beginning with some acute process, gradually is supplanted by increasing layers of complexity as the patient's psychosocial environment and internal suffering interacts with the pain, essentially amplifying its perception and magnitude (Fig. 92–2). Because most anesthesiologists currently do not possess significant training in physical medicine and rehabilitation, neurology, neurosurgery, and psychiatry (among many related pain medicine fields), the optimal care of patients nearly always requires a multidisciplinary approach. In today's health systems approach, with its multiple regulatory and managed care cost containment issues, getting several specialists together at one time has become increasingly difficult and inefficient. Thus, new models of care must be found, likely those in which the pain specialist interacts in parallel with multiple disciplines to find the cause and appropriate treatment of the pain, with ongoing primary care physician involvement and renewed basic management until pain relapse or exacerbation. These patients often are therapeutically challenging, and cognitive–behavioral therapies, physical therapies, and group therapies may be best administered in a controlled structured environment, such as a pain rehabilitation and management program. These programs are characterized by concomitant management by multiple physician and allied health therapists to effect changes in the patient's cognition regarding the pain and an emphasis on functional status and behavioral change.

EVALUATION OF THE CHRONIC PAIN PATIENT

History

The initial evaluation of any patient presenting with chronic pain begins with a good medical history. The *chief complaint* should be noted. The pain history should include a screen for descriptive features of the pain: *what*—the descriptors that best characterize the pain, such as burning, stabbing, pricking, aching, shooting, lancinating, dull, boring, etc.; *where*—the current location of the pain and any radiation or referral, or the specific pattern that the pain takes going from one area to another (sometimes they follow known dermatomal patterns or are specific for a certain myofascial trigger point syndrome); *when*—the time that the pain occurs and what activities it may be associated with (e.g., an arthritic patient with most pronounced pain on awakening and attempting to get up in the morning); *how much* (i.e., the score

KEY POINTS

1. Patients with chronic pain usually require multimodal (pharmacologic, behavioral, physical modalities, and procedural) therapies for pain that are chosen based on the underlying mechanism.
2. Fear of reinjury, catastrophizing, and poor coping skills may undermine the success of any mode of therapy.
3. The success of opioid therapies in acute pain must be tempered by the realization that for chronic pain treatment, opioid-induced hyperalgesia, pharmacologic tolerance, drug diversion, patient outcomes, and legal issues must be balanced appropriately for optimal care. Continuous monitoring and attention to the physician–patient relationship is vital.
4. Multiple new agents targeting ion channels and neurotransmitters are being developed, with improving efficacy. Optimal use of these agents requires a thorough understanding of their pharmacology as well as the ability to compare their effects through standardized study (allowing meta-analysis) and measures such as "number needed to treat" analysis.
5. New studies examining combination therapy (e.g., an opioid plus anticonvulsant agent) are likely to represent future practice because of the complexity of pain treatment and the realization that one agent rarely is sufficient.
6. Several studies suggesting that physical modalities plus cognitive–behavioral interventions are equivalent to large surgical procedures are interesting. These studies point to a future "blending" of traditionally separate pain clinic and pain rehabilitative programs to include even more comprehensive approaches.

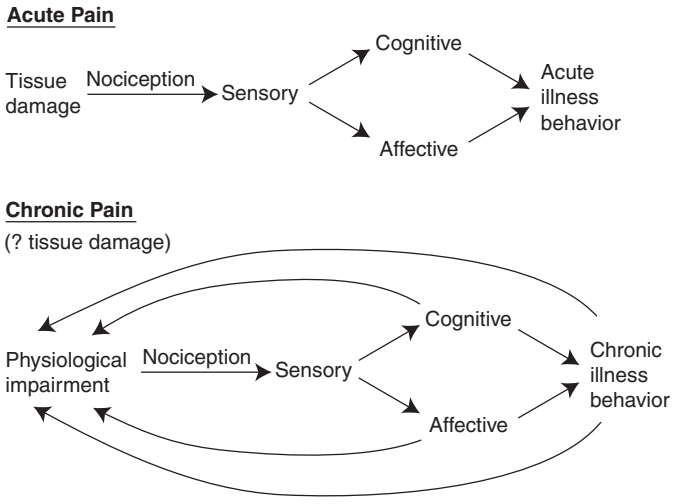

FIGURE 92–1. **Top.** In acute pain, tissue damage leads to a predominately sensory phenomenon of pain, with some superimposed cognitive, affective response. **Bottom.** In chronic pain, tissue damage may not be apparent, and symptom magnification, affective distress, and illness behavior may be the primary identifiable manifestation of pain. (Reprinted from Waddell G, Newton M, Henderson I, et al. A fear-avoidance beliefs questionnaire (FABQ) and the role of fear-avoidance beliefs in chronic low back pain and disability. Pain 1993;52:157–168, with permission from International Association for the Study of Pain.)

the patient assigns the pain on an 11-point numerical scale from 0–10, or the impact on a measurable function such as walking distance).

The *history of present illness* should describe the origins *(the why)* of the pain, to the extent that they are discernible, and what has transpired up to the patient's presentation. *Past treatment history* should completely describe all previous attempts to diagnose and treat the current condition. All pain patients should have a *numerical pain scale* assessed for each visit and at appropriate followup times after new interventions or medications are started. This allows a chronology of any improvement or worsening. Often, a pain diary can be kept by the patient and may be useful in identifying trends. All *therapeutic trials* should entail past pharmacologic treatments (maximum dosage reached and reason for cessation) as well as previous procedural, physical, and behavioral therapies (to understand exactly what was done and why). The *current medications* should list drug, dosage, and what the agent is treating. This list should include traditional pharmaceuticals as well as herbal and over-the-counter agents. *A substance use history* is critical, including not only prescribed opioids and benzodiazepines but also illicit substances used and a history of their use. Many pain patients will have extremely long and detailed lists of "allergies" secondary to numerous previous failed drug trials, with cessation secondary to side effects. Thus, *allergies* should document the specific nature of the reaction (true anaphylaxis versus side effect).

The remainder of the history should look specifically at the *functional impact* of the pain on the person's activities of daily living, work/physical activities, regularity of exercise, leisure/hobbies, yard work/housework, and social activities or evidence of withdrawal and isolation from activities. *Goals of care* should be discussed so that both patient and provider have an understanding of what is potentially and realistically achievable. A complete *review of systems, past medical and surgical histories, and social and family histories* should be documented. Finally, the presence of *fear-avoidance beliefs* should be evaluated, and, if present, a behavioral intervention should be instituted. Psychosocial pain-reinforcing mechanisms, such as patient beliefs, perceptions, and expectations about the impact of work, exercise, and disability, are important to treating persistent pain.[2,3]

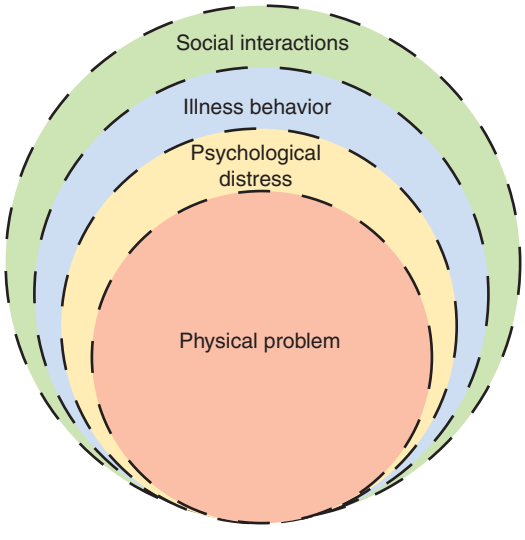

FIGURE 92–2. Pain, initially caused by an underlying physical problem, is increasingly magnified by psychosocial stressors. (From Waddell G, Main CJ, Morris EW, et al. Chronic low-back pain, psychologic distress, and illness behavior. Spine 1984;9:209–213, with permission.)

Physical Examination

The chronic pain patient should undergo a complete physical examination, not only looking at the relevant areas to his or her chief complaint but also evaluating major systems (e.g., cardiovascular, renal, hepatic, pulmonary) that may interact with or potentially limit therapeutic pharmaceutical trials or participation in an exercise-based program. A complete examination may include specific tests of joint movement/range of motion, for example, as well as correlation of examination findings with imaging modalities.

A thorough *mental status* examination should focus on the following areas: presence of confounding *personality disorders*; *affective* state, presence of alterations in mood, flattened/depressed affect, or hypomania/mania; *cognitive* state, orientation to person, place, and time, intelligence, judgment, insight; *speech*, fluidity, goal driven, presence of word-finding difficulties, comprehensibility; *attention,* concentra-

TABLE 92–1.

Muscle Grading System

Muscle Grading	Activity
5: Normal	Full ROM against gravity with full resistance
4: Good	Full ROM against gravity with some resistance
3: Fair	Active ROM gravity eliminated
2: Poor	Active ROM gravity eliminated
1: Trace	Slight contraction only
0: Zero	No contraction

ROM, Range of motion.

tion, abstract thinking, perception; and *emotionality*, anxiety, hopefulness, anger, frustration, fear. For example, the presence of a personality disorder may be a specific contraindication to ongoing opioid therapies because patients may experience worsening of behavioral manifestations while taking opioids.[4] Because the most prevalent types of pain commonly seen in pain clinics may include back/spine, extremity pain, and head pain, thorough examination of the musculoskeletal and neurologic systems should be emphasized. The neurologic examination should grade motor strength in major muscle groups (Table 92–1) and other exam findings (Table 92–2, and Fig. 92–3). In addition, *Waddell signs* (Table 92–3) should be sought for patients whose neurologic and musculoskeletal examinations diverge from expectations. For example, a patient may present with positive straight-leg raising sign in the supine position that changes with distraction. An understanding of the presence of these nonorganic physical signs may prevent the misapplication of pointless therapies.

The presence of *spasticity* (upper motor neuron, corticospinal tract; increased resistance when the examiner moves a joint briskly or forcefully) versus *rigidity* (basal ganglia, e.g., parkinsonism; enhanced resistance to movement throughout the range of a specific muscle–joint system) should be noted. Presence of *myopathy*, such as corticosteroid-induced or statin-induced muscle weakness (symmetric weakness without atrophy and normal sensation), should be documented. Evidence of true *atrophy* may signify a radiculopathy caused by spinal nerve irritation involving a specific muscle (Tables 92–4A and 92–4B); a more diffuse lumbosacral radiculoplexopathy, as occurs in diabetic patients; or peripheral neuropathy with distal weakness, atrophy, sensory loss, and possibly even fasciculations. Sensory examination, generally performed with a safety pin, light touch, temperature source, and two-point discrimination and tuning fork, can help discriminate abnormalities. Knowledge of tender points (Fig. 92–4) in fibromyalgia can aid musculoskeletal examination of pain at these sites, and tenderness at

TABLE 92–2.

Summary of Reflexes

Reflexes	Afferent Nerve	Center	Efferent Nerve
Superficial Reflexes			
Corneal	Cranial V	Pons	Cranial VII
Nasal (sneeze)	Cranial V	Brain stem and upper cord	Cranials V, VII, IX, and X, and spinal nerves of expiration
Pharyngeal and uvular	Cranial IX	Medulla	Cranial X
Upper abdominal	T7, T8, T9, T10	T7, T8, T9, T10	T7, T8, T9, T10
Lower abdominal	T10, T11, T12	T10, T11, T12	T10, T11, T12
Cremasteric	Femoral	L1	Genitofemoral
Plantar	Tibial	S1, S2	Tibial
Anal	Pudendal	S4, S5	Pudendal
Tendon Reflexes			
Jaw	Cranial V	Pons	Cranial V
Biceps	Musculocutaneous	C5, C6	Musculocutaneous
Triceps	Radial	C7, C8	Radial
Brachioradialis	Radial	C5, C6	Radial
Patellar	Femoral	L3, L4	Femoral
Achilles	Tibial	S1, S2	Tibial
Visceral Reflexes			
Light	Cranial II	Midbrain	Cranial III
Accomodation	Cranial II	Occipital cortex	Cranial III
Ciliospinal	A sensory nerve	T1, T2	Cervical sympathetics
Oculocardiac	Cranial V	Medulla	Cranial X
Carotid sinus	Cranial IX	Medulla	Cranial X
Bulbocavernosus	Pudendal	S2, S3, S4	Pelvic autonomic
Bladder and rectal	Pudendal	S2, S3, S4	Pudendal and autonomics
Abnormal Reflexes			
Extensor plantar (Babinski)	Plantar	L3–5, S1	Extensor hallucis longus

11 of the 18 sites meets diagnostic criteria. Referral zones for various regional myofascial syndromes also may help discriminate discomfort in various areas. For example, temporomandibular joint pain may radiate to the temple, face, and head.

Nonorganic Physical Signs

As previously discussed, patients who are being evaluated for chronic pain disorders may demonstrate confusing physical examination findings that confound the clinician's ability to categorize and treat their condition. Waddell and Main[5] described seven inappropriate symptoms that seemed to be best characterized as magnifiers of physical illness. The seven symptoms were (1) pain at the tip of the coccyx, (2) entire leg pain, (3) entire leg sensory loss, (4) giveaway weakness of the entire lower extremity, (5) absence of pain-free periods, (6) intolerance to procedural or pharmacologic treatments, and (7) frequent emergency department visits and admissions for intractable pain. These symptoms had little presence in patients who were asymptomatic but had satisfactory test–retest reproducibility in patients with chronic back pain.

The *pain drawing* is another tool commonly used by pain practitioners to evaluate new patients with chronic pain complaints (Fig. 92–5).[6] Patients are evaluated by having them draw the areas of their pain and concomitantly having the Minnesota Multiphasic Personality Inventory (MMPI) test scored along with the drawing. The authors

TABLE 92–3.

Waddell Signs

Non-anatomic	Widespread tenderness
Simulation tests	Axial loading
	Stimulated rotation

found a strong correlation between patients evaluated having a normal MMPI (no evidence of hysteria [Hy] or hypochondriasis [Hs]) and those having fewer than two penalty deductions on their pain drawing. The authors reported that the pain drawing might help physicians screen out up to 93% of patients who would have poor psychometrics related to (1) unreal drawings; (2) expansion or magnification of pain (e.g., pain outside the bodily limits); (3) areas of excessive annotation of particularly severe pain (stars, circling, lightning bolts, etc.); and (4) low back pain radiating pain indicators. Waddell et al.[7] described a series of physical examination signs that can be used as an aid in the examination of patients with low back pain.

Increasingly, the pain medicine clinician needs a thorough understanding of contemporary imaging modalities, such as plain radiographs, magnetic resonance imaging, and computed tomography. Imaging complements and reinforces the appraisals and clinical impressions of pain patients.[8] Likewise, correlating imaging study abnormalities with physical examination findings using a thorough understanding of anatomy enables the physician to differentiate significant from confounding findings. For example, it is well known that abnormalities found on imaging studies may not correlate with the patient's pain or examination. Significant changes may be found on spine magnetic resonance studies in 35% of asymptomatic patients.[8,9]

PHARMACOLOGIC THERAPY

It is quite apparent to physicians who engage in chronic pain therapy that currently available pharmacologic agents often are insufficient as single therapies. Finding treatments through a mechanism-based approach offers the best chance for rational selection of therapies.[10] It may be difficult to determine what level of clinical improvement actually is significant when performing randomized controlled trials of the various pharmaceutical agents currently available. Farrar et al.[11] examined 10 recently completed drug trials using one agent (pregabalin) for treatment of a variety of different pain conditions (diabetic peripheral neuropathies, postherpetic neuralgia, fibromyalgia, chronic low back

pain, and osteoarthritis). Essentially, the best correlation of patient global impression of change with the 11-point pain intensity numerical rating scale was determined to be an approximately 30% improvement or a two-point scale decrease. This approximate relationship persisted regardless of the condition being treated and other patient demographic variables. Thus, the authors recommended that application of these standards for all pain studies not only was reasonable, but that such standardization of future pain studies would render the studies more readily comparable, valid, and clinically useful. A 30% improvement is seemingly small, but when combination therapies are used, each contributing a small percentage toward clinical improvement, the reason for increased interest by pain clinicians in multimodal therapies is understandable.

Specific Pharmacologic Adjuvants

Antidepressants

Many of the antidepressant agents are useful as either primary or adjuvant therapy for neuropathic pain syndromes as well as other types of pain, such as myofascial pain syndromes. It is generally accepted that the mechanism of action of these drugs in pain is complex and may be related to reuptake inhibition of various neurotransmitters important in descending bulbospinal inhibitory pathways.[12] Additional mechanisms may be important, including effects on *N*-methyl-D-aspartate (NMDA) excitatory amino acid receptors,[13,14] sodium channel blockade,[15] and even other mechanisms. Earlier studies addressed initial speculation that these agents were working as *antidepressants only* in pain patients with concomitant depression. Max et al.[16] demonstrated that amitriptyline was effective in patients with diabetic peripheral neuropathy pain both in the presence and the absence of depressed mood. Early comparisons of different types of antidepressants with selective serotonergic or nonselective reuptake inhibition of both noradrenaline and serotonin suggested that drugs with nonselective mechanisms were more effective in treating neuropathic pain states (Fig. 92–6).[17] The selective serotonin reuptake inhibitors in particular were generally believed to be devoid of efficacy in pain conditions, but newer studies suggest that these agents have an occasional but less pronounced role.[18–20]

Tricyclic antidepressants (TCAs) have a characteristic three-ring nuclear structure and are chemically similar to phenothiazines and antihistamines, sharing side effects such as sedative and antimuscarinic actions. These side effects are perhaps the main detractors to the use of these agents in pain treatment, given their limited ability to reach effective doses. Certainly, the sedative properties of tricyclics can be used to advantage in the treatment of concomitant sleep deprivation, which frequently is present in chronic pain syndrome patients. However, many patients feel groggy or cognitively impaired even with introductory doses of these agents. Elderly patients in particular may have cardiac or urinary conditions that are exacerbated by the antimuscarinic actions of tricyclics, and the drugs may be contraindicated in some patients.

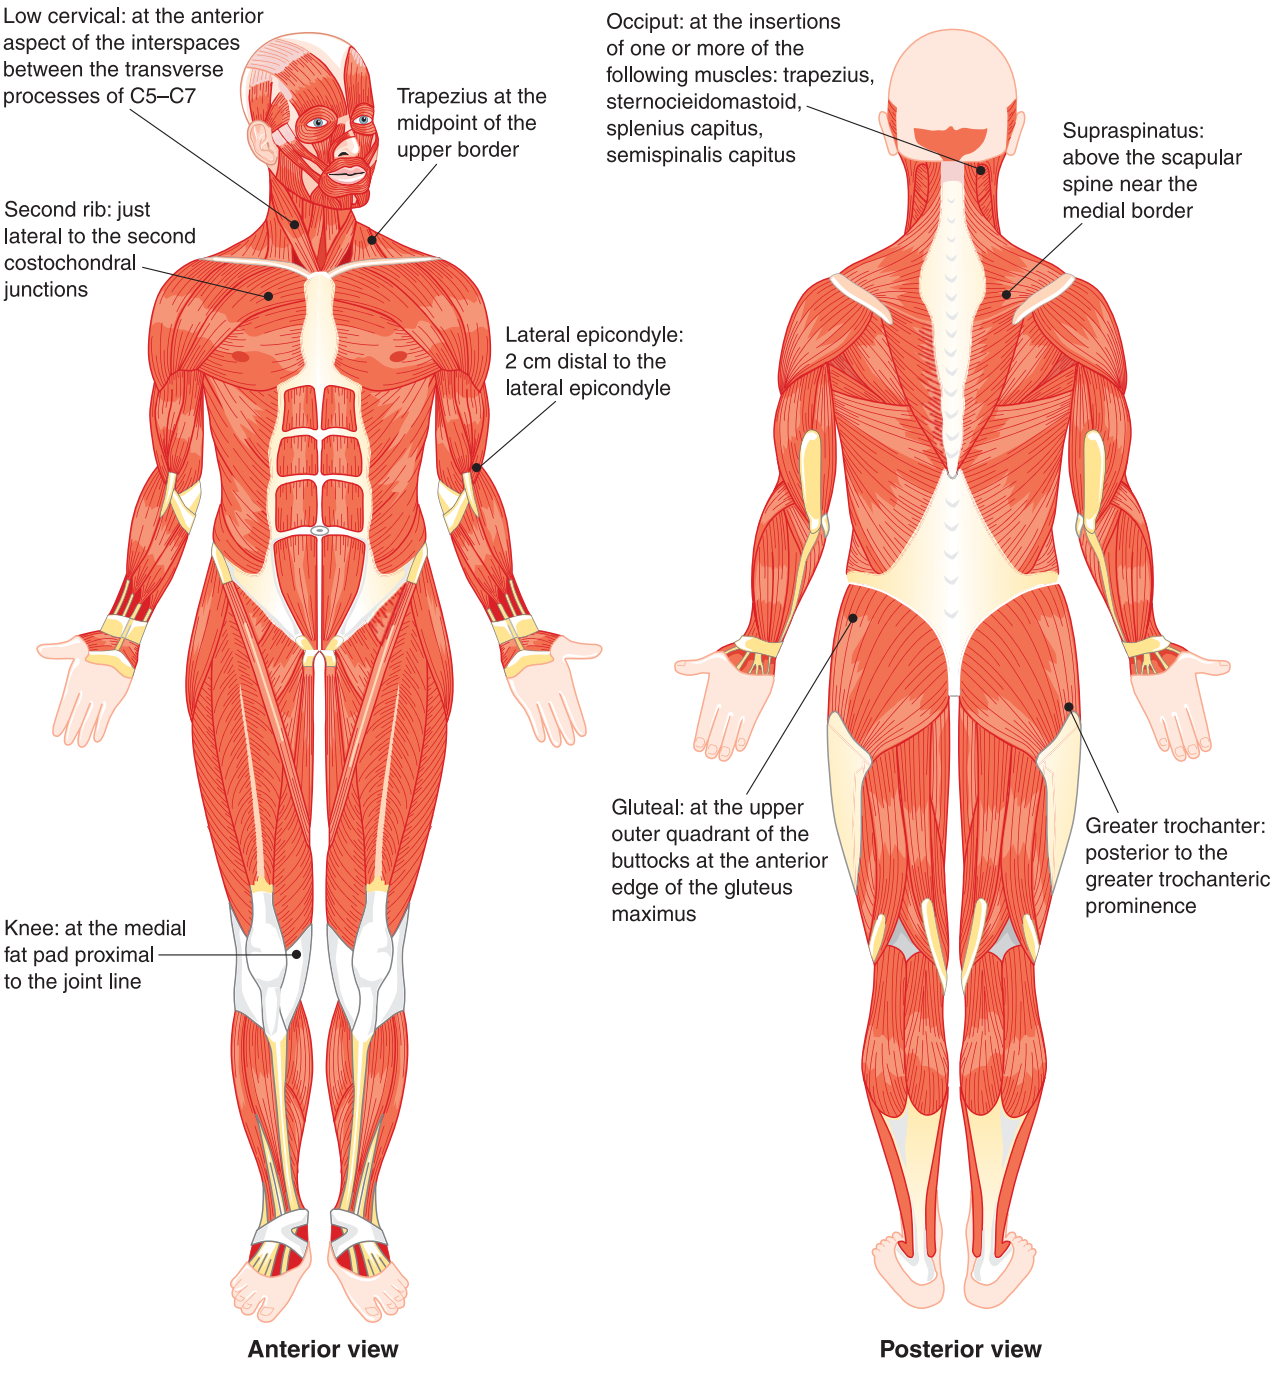

FIGURE 92–4. The 18 primary fibromyalgia tender points. (From The patient with diffuse pain. In Imboden JB, Hellmann DB, Stone JH, eds. Current Rheumatology: Diagnosis and Treatment. 2nd ed. New York: McGraw-Hill, 2004.)

Nortriptyline Roose et al.[21] studied the serotonin specific reuptake inhibitor paroxetine in comparison to nortriptyline in ischemic heart disease patients with depression. Approximately 60% of patients in both groups experienced improvement in depressive symptoms, but the nortriptyline group had significantly more adverse cardiac events, involving 18% of the study group. The patients in the nortriptyline group were titrated to target plasma levels over the first 3–7 days rather than the more typical slow ramping dose used by many physicians treating pain. Nevertheless, the development of adverse events illustrates the precautions that must be considered with the use of tricyclic agents. The prototype TCAs amitriptyline and imipramine are metabolized via mono-demethylation to the active metabolites nortriptyline and desipramine, respectively. Imipramine, similar to amitriptyline, has been successfully used for treatment of painful diabetic neuropathy.[22] However, the second-generation tricyclic agents (nortriptyline and desipramine) tend to be better tolerated because of less intense antimuscarinic and sedative properties and thus are more popular with pain physicians (Table 92–5).[23–25]

Amitriptyline Amitriptyline was one of the first agents shown to be effective in the treatment of postherpetic neuralgia[26] and has been a prototypical pain adjuvant drug for more than 2 decades. Although the drug is effective compared to placebo, its individual effects are generally not sufficient to re-

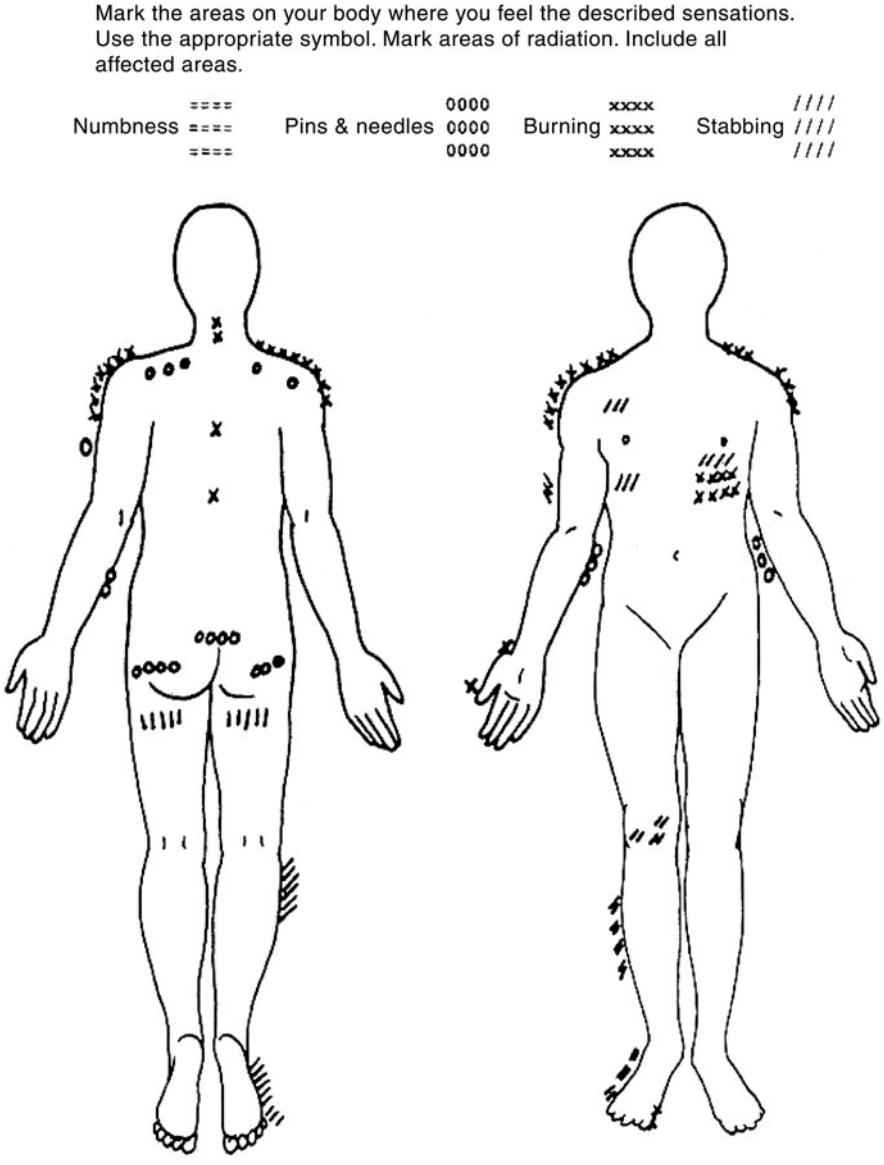

FIGURE 92–5. Example of a pain drawing from a patient with multiple noncontiguous areas of pain with amplification and somatic preoccupation. (From Ransford et al.[9] with permission.)

sult in complete analgesia. Preemptive use of amitriptyline in elderly patients has been associated with a decreased incidence of pain prevalence 6 months after the diagnosis of herpes zoster. The author recommended early institution of amitriptyline in this group.[27] Dosing of tricyclics for pain treatment generally begins at low evening doses and is increased gradually until limited by side effects or pain improves. Meta-analysis suggests that an average dose of approximately 75–100 mg/d of these agents may be required to achieve optimal results.[28] Studies have demonstrated that amitriptyline and other tricyclic agents have important NMDA-blocking activity[13,14,29,30] as well as significant and long-acting inhibitory action at the neuronal sodium channel. Renewed research interest has focused on the use of these agents for neural blockade.[15,31]

A randomized trial comparing amitriptyline with nortriptyline showed that despite the study's small sample size, there appeared to be no major differences between the two drugs with respect to pain scores, patient satisfaction, disability, preference, or mood. Intolerable side effects were more prevalent in the amitriptyline group.[23] Although most studies have been positive, a randomized controlled trial did study the use of amitriptyline for treatment of spinal cord injury pain compared to the pharmacologically active "placebo" benztropine. The study was conducted over only 6 weeks and did not detect any difference between the groups receiving amitriptyline or benztropine.[32] Recently, the role of coadministration of agents acting on different pharmacologic targets has been advocated. Raja et al.[24] compared the tricyclic agents nortriptyline and desipramine to the opioid drugs morphine and methadone in a randomized group of 76 patients with postherpetic neuralgia.

Both opioids and tricyclics had statistically significant analgesic effects relative to placebo; however, more patients (54%) preferred the opioids to the tricyclics (30%) despite similar pain reductions. Interestingly, although opioid agents are commonly thought to induce deleterious cognitive effects, the tricyclics were responsible for significant differences in hand-grooved pegboard tests as well as symbol substitution compared to the opioids.

Other Antidepressants

Multiple studies have evaluated the potential role of non-TCAs. Previous studies had demonstrated no difference between placebo and fluoxetine.[17] Based on the study by Max et al.,[17] it is believed that drugs with properties of nonspecific reuptake inhibition may be superior as analgesics to those with specific serotonin effects. Venlafaxine, a nonspecific reuptake inhibitor of noradrenaline, serotonin, and some actions on dopamine, has been studied in comparison to imipramine. Interestingly, venlafaxine is similar to amitriptyline in terms of reuptake inhibition pattern. In the comparison with imipramine, the authors found that both agents were effective in a painful diabetic neuropathy model.[33] Another double-blind, randomized trial of bupropion for treatment of neuropathic pain also was positive (Table 92–5).[34]

Duloxetine In contrast to fluoxetine, the newer agent duloxetine, a nonselective serotonin and norepinephrine reuptake inhibitor, has shown early promise in the treatment of neuropathic pain and was approved by the U.S. Food and Drug Administration (FDA) for treatment of diabetic neuropathy. The mechanism of action of duloxetine appears to be descending inhibition, with potent inhibition of reuptake of both norepinephrine and serotonin and weak inhibition of dopamine reuptake (Fig. 92–6).

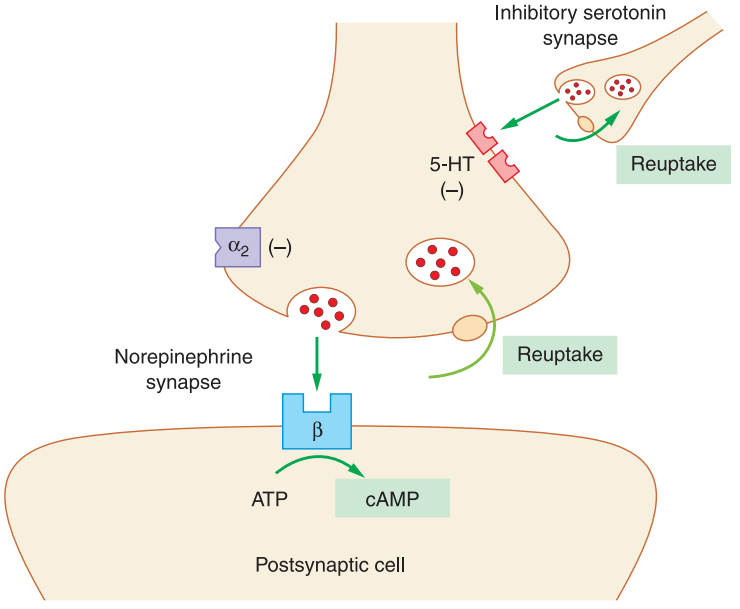

FIGURE 92–6. Mechanism of action of nonspecific reuptake inhibition of neurotransmitters, serotonin (5-HT), and norepinephrine in the descending inhibitory pathway. (From Potter WZ, Hollister LE. Antidepressant agents. In Katzung BG, ed. Basic and Clinical Pharmacology. New York: McGraw-Hill, 2004.)

Duloxetine has no major active metabolites and a long elimination half-life of approximately 12 hours. In studies of duloxetine 60 and 120 mg/d versus placebo for treatment of diabetic neuropathy, both doses were effective in reducing pain and interfering with nighttime pain. Duloxetine appears to be particularly effective for treatment of nighttime pain severity. Significant depression was not present in the study patients with diabetic neuropathy.[35] Duloxetine therapy had been considered safe, with only the minor risk of elevated serum transaminase levels.

Some cases of cholestatic jaundice and hepatitis have been reported postmarketing. Patients particularly at risk seem to be those with preexisting liver disease, with possible increased risk for further liver damage. Deleterious liver effects may be compounded in patients who consumed substantial amounts of alcohol. Gastrointestinal upset, constipation, and other side effects are common findings with use of the drug.[35]

In studies of patients with both painful physical symptoms and depression, duloxetine 60 mg/d was found to be an effective treatment for both.[36]

Evaluating the primary efficacy measure of Brief Pain Inventory (BPI) average pain scores, improvements in the duloxetine patient groups averaged 25–50%. Side effects included nausea, dry mouth, fatigue, and decreased appetite.

Opioids

Opioid use for treatment of chronic pain has increased considerably over

the last 2 decades. In 1980, only 2% of patient visits for chronic musculoskeletal pain conditions resulted in opioid prescriptions. In 2000, this number more than quadrupled to 9%,[37] representing a net increase of 4.6 million prescribed opioid visits compared to 20 years earlier. The increase in total musculoskeletal patient visits over the same time period was negligible, indicating that physician prescribing practices had changed significantly. The authors[37] theorized that the reasons for increased prescribing were related to advocacy by major pain organizations,[38] increased pharmaceutical company direct marketing campaigns to healthcare consumers, national guidelines published by the Agency for Health Care Policy and Research,[39] and Joint Commission on Hospital Accreditation emphasis on pain assessment and treatment.[37] Chronic pain patients were increasingly referred by noninstitutionally employed ambulatory care providers to pain specialists, 34% in 1980 versus 49% in 2000.[37] Fewer patients were seen for chronic headache complaints, but more were seen for extremity pain. Unfortunately, these increases in opioid prescribing were not without problems.

Prescription opioid mentions in the Drug Abuse Warning Network (DAWN) from 1994 to 2001 were analyzed.[40] During that period, hydrocodone combinations increased form 9320 to 21,567, an increase of 131%. Similarly, oxycodone combinations increased from 4069 to 18,409, an increase of 352% that has not yet plateaued.[41] The authors of a position statement noted that illicit use of opioid prescriptions had risen faster than legal use of these drugs.[41] They also noted that almost no research had determined the abuse liability of different agents. Nonmedical use had increased from 1% to 3% during that period. In 2000, two million people used opioids for nonmedical reasons. Another study noted that opioid analgesics accounted for 9.85% of all drug abuse, an increase of 5.75% from 1997.[40] Increases in illicit use may be due in part to unscrupulous physician behavior, the nature of prescribing to chronic pain patients as a group, and illegal substance diversion by some patients. Theft has risen as a new problem for the Drug Enforcement Agency (DEA) monitoring illicit drug use. A total of nearly 13,000 theft loss events occurred in 22 eastern U.S. states from 2000 to 2003, including 4.4 million dose units of oxycodone alone.[42]

Use of opioids for various pain syndromes has been studied, but adverse effects are troublesome. In a study of neuropathic pain patients resistant to treatment, patients received either high-strength or low-strength levorphanol capsules up to a maximum 21 capsules per day.[43] Pain intensity, quality of life, psychological and cognitive function, and blood levels were outcome measures. Patients in the high-strength group took 11.9 capsules (89 mg/d), and those in the low-strength group took 18.3 capsules (2.1 mg/d). Pain was reduced by 36% in the high-strength group versus 21% in the low-strength group. Central poststroke neuropathic pain was least likely to improve. Despite obvious analgesic effects, higher doses produced more side effects without significant additional benefits in terms of other outcome measures. More than one fourth of patients withdrew from the study, and episodic anger and irritability were reported more by the HS group.[43] Although the patients had improvement in symptoms, one wonders if the large number of withdrawals and the anger/irritability issues justify this treatment. In contrast to evidence of efficacy in some patients with neuropathic pain taking daily scheduled opioids, other pain states may not be as efficacious. In a population of patients with intractable head pain, 160 sequential patients were monitored, and 70 of these patients qualified for inclusion in the analysis. Of those reviewed, only 26% had >50% pain relief. Multiple problems with compliance including requests for early refills of opioids, lost prescriptions, multiple providers of opioids, and other problems occurred in *50%* of patients. The authors concluded that daily scheduled opioids were associated with low overall efficacy and an unexpectedly high incidence of maladaptive behaviors.[44]

In response to the study by Caudill-Slosberg et al.,[37] an editorial discussed the current state of opioid prescribing practices and the lack of a clear evidence-driven approach to opioid therapies for chronic noncancer pain syndromes.[45]

In an effort to better manage chronic pain patients taking opioids and to avoid legal and regulatory hassles, many pain treatment facilities use an opioid agreement or "contract." To determine the key attributes included in the opioid consumption contracts of major academic centers, Fishman et al.[46] evaluated the opioid contracts of 39 major academic centers and the major care statements/prohibitions for their core meaning. The most common categories included (1) terms of treatment, (2) prohibited behavior, and (3) points of termination. Rank ordering of statements included (1) improper use of medications, (2) disciplining by termination (for missed appointments, medication abuse, etc.), (3) limitations on replacement of lost medications or prescription changes, (4) informing physician of relevant information, including side effects and changes in medical condition, and (5) submission to random drug screens. Unfortunately, little evidence indicates that drug contracts improve patient compliance. Monitoring is an intensely time-consuming task that is not possible to accomplish in most clinical settings. Many potentially indispensable statements on opioid treatment, including prohibited usage during pregnancy, driving automobiles, prohibition of alcohol use, and many others, are present in less than half of opioid contracts. Long-term opioid studies of chronic pain syndromes generally consist of small numbers and short duration. Short-term data limit the ability to generalize the reproducibility of opioid treatment outcomes to large groups of chronically treated patients.[47]

Opioid Side Effects Rajagopal et al.[48] noted significant decreases in sex hormone production in male cancer survivors taking opioids for at least 1 year. Evidence of central hypogonadism, including decreased testosterone and reduced sexual desire, was noted in this group. This finding is similar to those in patients taking chronic intrathecal opioids.[49] Immunologic studies have indicated significant impairment immunologic function caused by opioid therapies, particularly natural killer cell cytotoxicity with chronic opioid use.[50,51] In a mouse model,[52] the covalent agent buprenorphine did not significantly suppress immunity in contrast to fentanyl. This finding suggests that differential effects may be associated with different opioids.

Opioid-Induced Hyperalgesia It is well understood that several agents (e.g., TCAs) may provide part of their

analgesic activity by augmentation of descending inhibitory pathways from the brainstem to the spinal cord.[12] It also appears that just as there are descending inhibitory pathways, there also are descending *facilitatory pathways.* Animal models suggest that the rostroventromedial medulla (RVM) contains populations of neurons that are characterized as either *on cells* or *off cells,*[53] which may be an important reason for opioid hyperalgesia and apparent opioid-induced pain. The on cells seem to promote nociception, whereas the off cells seem to inhibit nociceptive neural firing. Morphine and other μ-agonists decrease firing of the on cells and increase activity of the off cells. Cholecystokinin (CCK) appears to be a pro-nociceptive peptide neurotransmitter that is important in decreasing morphine antinociception.[54] Researchers have demonstrated that within the RVM, CCK may augment descending pain facilitation in response to ongoing opioid exposure. In an animal model, continuous morphine significantly increased thermal and tactile hypersensitivity after 3 days, and microdialysis of the RVM demonstrated a 5-fold increase in CCK in the RVM.[55] Previous research had demonstrated that either a lesion of the bilateral dorsolateral funiculus (neuronal tracts used for descending modulation) or lidocaine injection into the RVM could abort evidence of opioid-induced hyperalgesia.[56] Evidence indicates that descending facilitation enhances local spinal cord release of dynorphin (a potent algogesic substance), leading to enhancement of spinal afferent nociceptive receptivity. Continuous morphine infusion leads to increasing spinal dynorphin. Dynorphin then evokes release of excitatory peptides such as calcitonin gene-related peptide and substance P at dorsal root ganglia primary afferents.[57] Injection of dynorphin antiserum abolishes the pro-nociceptive opioid pain facilitation.[57] These studies point to a major change in the way we look at concepts such as opioid tolerance. Increased opioid requirements may be a true tolerance, that is, a rightward shift of dose–response curves, or evidence that opioid-induced descending facilitation is occurring (opioid hyperalgesia). Future research to develop compounds that either block CCK activity in the RVM or block the dynorphin-induced excitatory peptides to allow ongoing analgesia from opioid agents may be indicated.[58]

Tolerance Tolerance can be characterized as the state of physiologic adaptation to a certain level of opioid dosing, recognized as declining effects of the opioid over time. This may be related to downregulation of opioid receptors or accumulation of antianalgesic substances. For example, opioid therapy may cause NMDA receptor activation and induce intracellular cascades that result in activated protein kinase C feedback inhibition on available opioid receptors.[59] Tolerance is predominately a concept relative to analgesia, as a right shift in the dose–response curve occurs over time. Some side effects, such as sedation and cognitive slowing, seem to be less of an issue over time, sometimes resolving within the first 1–2 weeks of therapy and being less prominent than with other agents.[24] Tolerance is not seen with other side effects such as urinary retention or opioid-induced constipation, which can be an overwhelming problem with higher doses of these agents. This lack of tolerance to opioid-induced constipation is being addressed by efforts to develop the drug methylnaltrexone. Inherently a charged compound, methylnaltrexone may be able to block the peripheral actions of opioids (e.g., colonic opioid receptors) and may not be able to reverse central analgesic effects because of its inability to cross the blood–brain barrier.[60]

Physical Dependence Physical dependence implies a state of requirement for receptor occupancy to prevent a physiologic withdrawal syndrome after abrupt cessation of opioid agonist. This state of dependence occurs within days to weeks of starting the sustained delivery of a receptor-specific agonist. In contrast to withdrawal of alcohol, benzodiazepines, barbiturates, and other agents, withdrawal of opioids is rarely a life-threatening situation but nonetheless is symptomatic. Symptoms of opioid withdrawal include piloerection, nausea and vomiting, diarrhea, diaphoresis, agitation, dysphoria, nasal congestion, and seizure. Psychological dependence is more complex and implies that the patient has an expectation of withdrawal or a fear of lack of analgesia and therefore may resist efforts to taper opioid agents.

Addiction Addiction can be defined as a primary chronic neurobiologic disease, with genetic, psychosocial, and environmental factors influencing its development and manifestations. It is characterized by one or more of the following behaviors: impaired control over drug use, compulsive use, continued use despite harm, and craving.[61]

Pseudoaddiction Weissman and Haddox[62] described a state in which patients who had been given drug doses that were inadequate to control their pain or who had abruptly stopped or were tapered too rapidly from a drug manifested what appeared to be drug-seeking behavior (consistent with addiction). However, in reality the patients simply were experiencing a normal reaction in response to pain that previously was well controlled but now had an acute exacerbation caused iatrogenically. These patients may seem to have significant knowledge of opioid agents and dosages that previously worked for them; thus, they appear to be drug seekers.

Equianalgesic dosing tables are commonly used to guide therapy with weak or potent opioids based on equivalent doses (Table 92–6). In clinical reality, most patients respond well to opioids dosed in this manner. Sometimes a disparity is observed upon switching to another opioid based on equivalency tables, but the results are generally both safe and "close" to the right dose. The equianalgesic dosing tables are universally used by pain specialists when switching from one drug to another. The referenced doses for these tables are based on single-dose administrations, so use of these tables for chronic dosing of opioid agents is unclear. Pereira et al.[63] reviewed the literature from 1966 to 1999 and determined that the literature lacked studies examining long-term dose ratios and that the published studies were not homogenous; wide ranges existed; methadone in particular was more potent than originally thought and correlated highly with the dose of previous opioid given; the ratios might change depending on the direction of change; and discrepancies existed with respect to fentanyl and oxycodone.

Many researchers have postulated that use of opioid agents in the future may be determined and administered based on pharmacogenomics. An individual's specific genome likely is better suited for specific agents based on

TABLE 92–6.

Opioid Analgesics for Adults Age 15 Years or Older

Drug	IM Dose	IM Duration (Hours)	Starting Oral Dose	Comments
Agonists Related to Morphine				
Morphine	10 mg	3–6	15–30 mg	Available as 8 to 12 h sustained-release tablets (*MS-Contin*, *Oramorph-SR*), 12 to 24-sustained-release capsules (*Kadian*-Nonformulary), and suppository Oral: Prompt release: 15–30 mg every 4 hours as needed; controlled release: 15–30 mg every 8–12 hours I/V PCA: Usual 1–3 mg, range 0.1–5 mg; lockout interval: usual 5–20 minutes; 4-hour lockout: usual range 10–30 mg, maximum 30 mg I/V, SC continuous influsion: 0.8–10 mg/h; may increase depending on pain relief/adverse effects
Hydromorphone (*Dilaudid*, others)	1 mg	3–5	4–8 mg	Available as high-potency injectable (*Dilaudid*-HP) and as suppository
Oxymorphone (*Numorphan*)	1 mg	3–5	—	Available as suppository
Agonists Related to Codeine				
Codeine	15 mg	3–5	30–60 mg	60 mg PO equivalent to 650 mg of aspirin or acetaminophen; usually used orally in combinations with these drugs; some patients resistant to analgesic effect
Hydrocodone (*Vicodin*, others)	—	—	5 mg	10 mg PO equivalent to codeine 80 mg PO; available in combinations
Oxycodone (*Roxicodone*, others)	—	—	5 mg	10 mg PO equivalent to codeine 90 mg PO; available in combinations and as 12-h sustained-release tablets (*OxyContin*)
Synthetic Opioid Agonists				
Meperidine (*Demerol*, others)	50–100 mg	2–4	50 mg	Irritating to tissues IM; toxic metabolite with long half-life causes CNS excitation and convulsions
Fentanyl (*Sublimaze*)	0.1 mg	1–2	—	Transdermal patch (*Duragesic*) for chronic pain releases fentanyl over 72 hours, possibly with less constipation than morphine; *Actiq* "Transmucosal system" FDA-approved for breakthrough pain
Methadone (*Dolophine*, others)	10 mg	4–6	10–20 mg	Long half-life; risk of CNS depression with repeated use
Propoxyphene HCI (*Darvon*, others)	—	—	65 mg	65 mg of HCI or 100 mg of napsylate PO equivalent to codeine 32 mg PO; available in combinations with acetaminophen or aspirin; toxic metabolite with long half-life causes convulsions and cardiotoxicity; not better than plain acetaminophen; use discouraged inn the elderly
Levorphanol (*Levo-Dromoran*, others)	2 mg	4–6	2–4 mg	Long half-life; risk of CNS depression with repeated use
Tramadol (*Ultram*)	—	—	50–100 mg q6h	50 mg equivalent to codeine 60 mg; 100 mg comparable to aspirin 650 mg plus codeine 60 mg
Partial Agonists and Mixed Agonist/Antagonists				
Buprenophine (*Buprenex*, others)	0.3 mg	4–6	—	Partial agonist; virtually no psychotomimetic effects; sublingual preparation effective
Pentazocine (*Talwin-NX*, *Talacen*) Nonformulary, use discouraged	60 mg	2–4	50 mg	Mixed agonist/antagonist; 60 mg PO equivalent to codeine 60 mg PO, very irritating to tissues; psychotomimetic effects; available in combinations with acetaminophen, aspirin or naloxone (to discourage IV drug abuse)
Butorphanol (*Stadol*) Nonformulary	1–2 mg	3–6	—	Mixed agonist/antagonist; nasal spray (*Stadol NS* 1 mg/spray) comparable to IM injection
Nalbuphine (*Nubain*, others)	10 mg	3–6	—	Mixed agonist/antagonist; less psychotomimetic effect than pentazocine
Dezocine (*Dalgan*) Nonformulary	10 mg	3–6	—	Mixed agonist/antagonist

the expression of specific receptor characteristics, variations in metabolic processing, and other features. Cloning of opioid μ-type receptors gives credence to this line of reasoning.[64]

Opioids in Neuropathic Pain Opioid use for many pain states is supported by randomized controlled drug studies showing efficacy. Although often characterized as an opioid-resistant type of pain, neuropathic pain syndromes may have the most hearty evidence for efficacy with opioid therapies.[24,65–69] Generally, the major neuropathic pain studies have examined patients with postherpetic neuralgia, painful diabetic peripheral neuropathy, or central pain syndromes, including postspinal cord injury and postcerebrovascular accident pain. For example, Watson and Babul[65] performed a randomized controlled trial involving 50 patients with postherpetic neuralgia and symptom duration of at least 3 months. In this study, 38 patients completed the study, which compared oxycodone tablets at a dose up to 30-mg controlled-release agent twice daily compared to placebo. Pain scores of patients showed improvement in pain relief of 2.9 points versus 1.8 points for the placebo group and a decrease in allodynia and steady and paroxysmal pain.[65] Raja et al.[24] compared the TCA agent amitriptyline to morphine or methadone in a total of 76 patients with postherpetic neuralgia symptoms of long duration. Three treatment periods were studied over 24 weeks, with administration of opioid, TCA, and placebo. Interestingly, although both the TCA and opioid groups had improvements in study end points, 54% of patients favored opioids compared to 30% who favored the TCA. Methadone is commonly thought to be superior to other opioids for treatment of neuropathic pain because of its dual action on μ-opioid receptors as well as NMDA receptors, but this was not demonstrated in the study. In patients with intolerance to morphine, patients switched to methadone achieved doses of only 15 mg versus 91 mg for morphine. Reduction in pain intensity was less for methadone (1.2 points on a visual analogue scale compared to a pain scale reduction of 2.2 points with morphine). Another interesting finding of this study was that although most pain practitioners commonly attribute side effects such as psychomotor and cognitive slowing to opioids, patients taking the TCA actually performed worse on pegboard placement skills and other tests of psychomotor skills.[24]

NMDA Antagonists With our enhanced understanding of the development of both peripheral and central sensitization (windup) and the role of excitatory amino acids acting at NMDA receptors, blockade of this central hyperalgesic response has assumed greater therapeutic importance. Likewise, use of NMDA blockers for opioid tolerance and opioid-induced hyperalgesia is a reasonable therapy. Currently available NMDA blockers include ketamine, methadone, dextromethorphan, amantadine, magnesium, and memantine.

Methadone Methadone, an opioid first synthesized in the mid-20th century, has become the agent most commonly used for management of long-term opioid addiction. Methadone is highly lipophilic and has high oral bioavailability. Unlike many modernly formulated long-acting continuous relief opioids, it is inherently long-acting. The drug is a racemic mixture[70]; the D-isomer reverses morphine tolerance and blocks development of hyperalgesia thought to be mediated by NMDA receptor activation.[71] Methadone has tremendous utility for both treatment of neuropathic pain and management of cancer pain, predominately as a second-line agent when other opioids become ineffective. The equianalgesic dosing ratio seems to increase with increasing opioid doses and may exceed 10:1 compared to morphine.[72] Dosing paradigms to change from other opioids[73] have been designed to more effectively load the drug and prevent respiratory depression secondary to methadone's prolonged pharmacologic actions. Possible side effects at high doses include QT-interval prolongation and a propensity to sudden cardiac death.[74] Patients receiving higher doses may be reasonably monitored for QT-interval prolongation.

Ketamine Ketamine, a noncompetitive antagonist at the NMDA receptor, has been found efficacious in the treatment of primary neuropathic pain and hyperalgesic states in both intravenous (IV) and oral applications. When used orally, the drug appears to work primarily through its metabolite norketamine.[75] Psychomimetic effects appear to be most limiting, although the deleterious side effects were minimized at lower doses (40–60 mg/d) and when coupled with oral benzodiazepine therapy. Ketamine has been attempted as intermittent IV infusion for chronic neuropathic pain states such as postherpetic neuralgia[76] and for posttraumatic pain,[77] with some apparent efficacy. In a small study comparing ketamine to magnesium (another NMDA antagonist), ketamine administered IV at 0.3 mg/kg/h resulted in significant improvement in a group of patients with neuropathic pain, but magnesium did not reach significance.[78] Other NMDA agents have been used with inconclusive results. A double-blind, placebo-controlled trial of the agent memantine in postherpetic neuralgia patients did not show separation from the placebo group in terms of allodynia, spontaneous pain, or hyperalgesia; both groups improved. The authors concluded that the agent was ineffective in reducing postherpetic pain.[79] Dextromethorphan also has been studied, with inconclusive results. In a randomized, double-blind, controlled trial of two doses of dextromethorphan over a 10-day treatment period, no clinically significant difference between any of the tested outcome measures was observed.[80] Amantadine, better known as an agent for parkinsonism or influenza prophylaxis, is a noncompetitive NMDA antagonist and has been well tolerated from a side-effect profile. Intravenous infusion of amantadine was evaluated for treatment of surgical neuropathic pain (postmastectomy, postthoracotomy, postherniorrhaphy). Amantadine reduced both mean pain intensity and hyperalgesic "windup" pain on a statistically significant basis.[81]

Overall, the NMDA antagonists appear to have some therapeutic potential, but further well-designed randomized trials with larger numbers of patients are necessary to make conclusions. At this time, methadone and ketamine appear to have better evidence supporting their use.

Clinical Rationale for Antiepileptic Drugs

In neuropathic pain, changes in sodium channel expression lead to alterations and accumulation in sensory nerves and nociceptive neural path-

ways. Voltage-gated sodium channels have critical functions in the neuronal transmission of action potentials. They also play an important role in the genesis of neuropathic pain via an increase in neuronal excitability. For the development of neuropathic pain, complete expression of $Na_V1.8$ seems to be necessary.[82] It appears that injured axons are functionally degraded and do not play a role in neuropathic pain. However, the role of neighboring C-fibers that are not injured appears to expand, with C-fibers playing an important role in the development of aberrant pain transmission (Fig. 92–7).

Thus, redistribution of the tetrodotoxin-resistant (TTX-R) sodium channels $Na_V1.8$ and $Na_V1.9$ to peripheral sites of injury is critical in the development of neuropathic pain. These sodium channel subunits congregate near the site of injury and result in spontaneous neural ectopic firing. Likewise, in addition to the $Na_V1.8$ and $Na_V1.9$ sodium channels, β3 is found in increased concentration at the site of nerve injury. β3 messenger RNA is found in increased concentration within these neurons. Neuropathic pain and epilepsy have functional similarities. In animal models of limbic epilepsy, sodium channel expression and upregulation of $Na_V1.3$ were increased, and changes in β subunits occurred. Thus, the ability to pharmacologically block these redistributed, uninjured, unmyelinated C-fiber sodium channels may be the most useful approach to therapy for neuropathic pain caused by partial nerve injuries.

Calcium channels may be altered in neuropathic pain states. A commonly used neural constriction injury animal model shows that, after peripheral ligation injury, the $\alpha_1\delta_1$ segment of the calcium channel is upregulated in dorsal ganglion neuropathy. This change is associated with the production of tactile allodynia (Table 92–7).[83]

Evidence indicates that neuronal-type voltage-gated calcium channels play a role in neuropathic pain induced by peripheral nerve injury. Agents have been developed for intrathecal use acting via the ω-conopeptide, which is known to inhibit N-type gated calcium channels.[84] Gabapentin suppresses allodynia. Dorsal root ganglion $\alpha_2\delta$ upregulation likely plays a significant role in the neuroplasticity of pain expression after peripheral nerve injuries and contributes to allo-

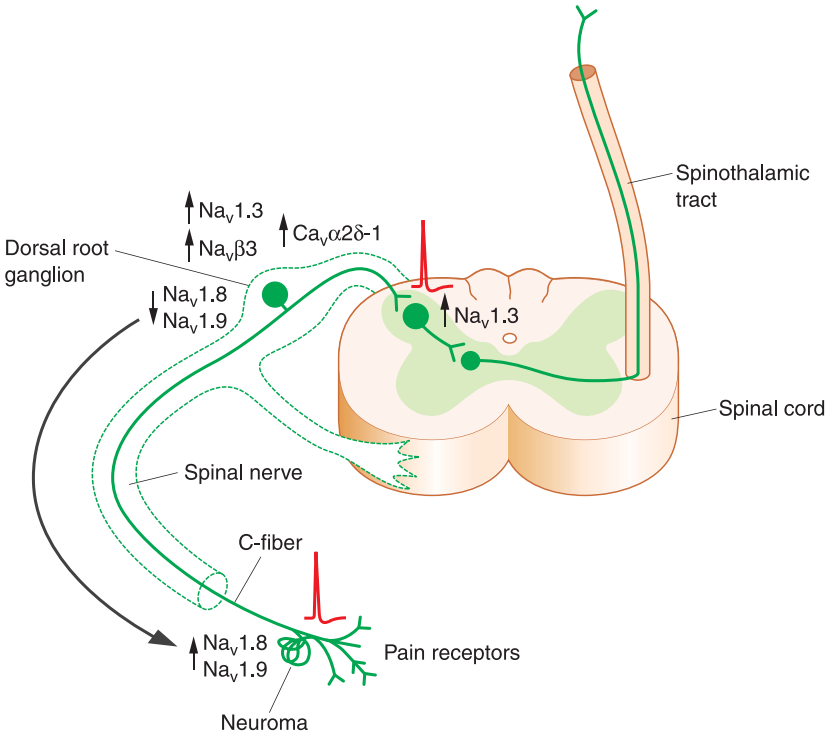

FIGURE 92–7. Injury to peripheral axons results in redistribution of tetrodotoxin-resistant sodium channel subunits ($Na_V1.8$, Na_V19) from normal areas, leading to spontaneous ectopic firing at sites of injury. Other sodium channel ($Na_V\beta3$) and calcium channel ($Ca_V\alpha21$) alterations also may cause increased neuronal activity. (Reprinted from Rogawski GA, Loscher W. The neurobiology of antiepileptic drugs for the treatment of nonepileptic conditions. Nat Med 2004;10:685–692, with permission.)

Neuropathic Pain States

Vascular	Postischemic myelopathy, central poststroke pain
Infectious	HIV myelopathy, CMV sensory neuropathy; Lyme disease neuropathy, postherpetic neuralgia
Metabolic/ nutritional	Thiamine (beriberi) deficiency neuropathy, Niacin (pellagra) deficiency neuropathy, diabetic neuropathy, alcoholic neuropathy
Traumatic/ iatrogenic	Postsurgical: postmastectomy syndrome, postnephrectomy syndrome, postthoracotomy syndrome; complex regional pain syndrome, phantom limb pain, brachial plexus avulsion injury; traumatic spinal injury; syringomyelia; postradiation myelopathy
Hereditary	Fabry disease, Guillain-Barré neuropathy
Toxic	Arsenic, thallium, mercury, others
Compressive	Spinal stenosis, foraminal stenosis, entrapment syndromes: carpal tunnel, cubital tunnel, tarsal tunnel, pronator teres, syndrome, others
Inflammatory	Radiculopathy, diabetic lumbosacral radiculoplexopathy, inflammatory demyelinating polyradiculopathy
Drug-induced	Cis-platinum, vincristine, paclitaxel (Taxol), isoniazid, stavudine, zalcitabine
Neoplastic	Nerve infiltration, brachial plexus compression (e.g., Pancoast tumor)
Idiopathic	Idiopathic sensory neuropathy, Multiple sclerosis, Parkinson disease

Neuropathic pain may be due to a variety of different causes, which may have treatment implications.
CMV, Cytomegalovirus; HIV, human immunodeficiency virus.

dynia development. Peripheral but not central axonal injury significantly upregulates the expression of dorsal root ganglion $\alpha_2\delta$ calcium channel subunits. These precede the onset of allodynia. Evidence also indicates that messenger RNA upregulation occurs after spinal nerve ligation. In a rat model, the L5–6 dorsal root ganglions ipsilateral to nerve injury showed a 6- to 7-fold increase of $\alpha_2\delta$ expression at 7 days. Likewise, as recovery from tactile allodynia occurs, the upregulation in dorsal root ganglion $\alpha_2\delta$ subunits diminishes.[83]

Specific Anticonvulsant Agents

Carbamazepine Carbamazepine is a tricyclic compound chemically similar to imipramine. It is effective for treatment of trigeminal neuralgia and has long been the drug of choice.[85] It also has been found useful for treatment of manic-depressive illness and seizures.[86] No studies have compared imipramine to other recently released anticonvulsants for treatment of trigeminal neuralgia. The drug acts chiefly by blocking sodium channels and is thought to be most useful for treatment of shooting or lancinating types of pain. In experimental neuromas, peripherally located ectopic discharges are suppressed within the typical ranges of serum concentrations.[87] In patients, dosing generally begins at 100–200 mg/d and can be titrated very slowly (4–8 weeks) up to 1200 mg/d. Significant side effects can occur, including agranulocytosis, aplastic anemia, hepatic function abnormalities, and Stevens-Johnson syndrome. The chief drawback to use of carbamazepine is poor tolerability in elderly patients, often related to diplopia, sedation, and ataxia. In particular, combining carbamazepine with structurally similar agents (such as TCAs) may enhance sedating side effects.[86] Drug interactions may occur due to carbamazepine induction of hepatic microsomal enzymes. Monitoring of carbamazepine should include baseline serum hepatic function tests, complete blood counts, and serum sodium, with particular screening for complications in the first 4–6 months of therapy. Carbamazepine is commonly used for treatment of diabetic peripheral neuropathy and other neuropathic pain conditions.[88,89] Table 92–8 compares various anticonvulsant therapies for neuropathic pain, migraine headache, and trigeminal neuralgia.

Oxcarbazepine Oxcarbazepine is an antiepileptic drug chemically similar to carbamazepine. The drug acts at voltage-gated sodium and calcium channels to block epileptiform or ectopic discharges. The major clinical advantage to carbamazepine may be the requirement for less frequent serum monitoring. Although carbamazepine may induce agranulocytosis, hyponatremia, and hepatic function abnormalities, it appears that hyponatremia is the only reason for ongoing generalized serum monitoring of this agent. An open-label, 9-week trial of 30 patients with diabetic painful neuropathy demonstrated improvement of patients' visual analogue pain scores of 29 points (48.3%), with side effects of dizziness and drowsiness. Other studies have demonstrated improvements in pain with use of oxcarbazepine.[90–92] Additional randomized controlled studies with oxcarbazepine are needed to reliably predict the effects of this agent in various pain syndromes.

Topiramate Topiramate is an interesting substituted monosaccharide agent that is significantly different from other anticonvulsant drugs. Topiramate has three main mechanisms of action. Like other anticonvulsants, the drug is a sodium channel blocker, with some action at voltage-gated calcium channels. It can potentiate γ-aminobutyric acid (GABA)-mediated inhibition at separate sites from the benzodiazepines. Interest also has focused on its action at the kainate and α-amino-3 hydroxy-5-methylisoxazole-4-propionic acid (AMPA) receptors, where it can decrease excitatory amino acid (glutamate) neurotransmission. Topiramate has found its greatest usage in headache therapy as a preventative agent for migraine headache. Large trials have demonstrated significant decreases in migraine headache prevalence when the drug has been used as a preventative agent.[93,94]

Three randomized controlled trials of topiramate for painful diabetic neuropathy did not support a statistically significant difference between topiramate and placebo in visual analogue scores or any of the secondary efficacy end points.[95] However, pain reductions were numerically greater in the topiramate study groups in two of the studies. Patients were allowed rescue analgesia throughout this study, and it was believed that this may have confounded the results. In another randomized controlled trial, patients with painful diabetic neuropathy were found to have evidence of analgesia with topiramate. In this study, rescue analgesia was permitted only for a 6-week period. The major findings of the study were that pain visual analogue scores decreased from 68 to 46.2 in the topiramate groups versus a decrease from 69 to 54 in the placebo group (*P*

< .003). Fifty percent of the topiramate patients versus 34% of the placebo patients had a >30% response.[96] The other notable finding was that topiramate reduced body weight significantly versus placebo. The weight loss had no adverse effect on serum glycemic control of diabetic patients. Topiramate has been used in diet clinics to aid weight loss and has been used for essential tremor, binge eating disorders, and bipolar disorder.[86] In a study of patients taking topiramate for epilepsy, weight reduction was maintained in 86% of patients despite a return of caloric intake to normal baseline levels. Obese patients appeared to develop reductions in weight of greater magnitude than patients who were not obese.[97] Thus, it appears that topiramate is potentially an ideal agent for patients with obesity, diabetes, and painful neuropathy or migraine.

Topiramate is generally started at 25 mg at night and ramped higher every 1–2 weeks on a twice-daily schedule to a target dose of 200–400 mg/d. Patient side effects are frequent and include cognitive slowing, somnolence, nervousness, fatigue, dizziness, and diarrhea.[86] As with all anticonvulsants, female patients with the potential for pregnancy should be using birth control because of the risks of teratogenicity and altered effectiveness of birth control pills.[86]

Gabapentin Gabapentin is a GABA analogue that binds to the $\alpha_2\Delta_1$ ligand of voltage-sensitive neuronal calcium channels.[98] There is no evidence that it functions through GABA-mediated actions despite its structural similarity with GABA. Gabapentin is approved by the FDA for adjunctive therapy of tonic–clonic and partial seizures and for postherpetic neuralgia at doses of 1800 mg or more. Early case series showed the drug had some efficacy in other neuropathic pain syndromes, including complex regional pain syndrome.[99] Subsequently, several excellent-quality randomized studies demonstrated the efficacy of gabapentin for a variety of neuropathic pain syndromes (Tables 92–8 and 92–9).[100–105]

Backonja et al.[100] found that gabapentin was effective for the symptomatic treatment of neuropathic pain in patients with diabetes mellitus. The study compared 70 patients who received gabapentin and 65 who completed the study in the placebo group. Using an intent-to-treat analysis, gabapentin-treated patients had significantly lower mean daily pain scores (P < .001) compared to placebo patients. Pain scores decreased in the active gabapentin group from 6.4 at baseline to 3.9 compared to baseline scores of 6.5 versus 5.1 at end in the placebo group. Additionally, secondary outcome measures were significantly better in the gabapentin group, including the Short-Form 36 (SF-36) quality-of-life questionnaire and profile of mood states. Similar to other anticonvulsants, gabapentin should be titrated slowly to maximum doses of 3600 mg/d, usually dosed on a 3–4 times per day schedule secondary to the short half-life of 5–8 hours.[86] Gabapentin is not metabolized, and, unlike carbamazepine, it does not induce hepatic enzymatic function. It is eliminated by the kidneys, and dosage should be reduced according to creatinine clearance in renally impaired patients. Adverse events include somnolence, peripheral edema, memory loss (usually high doses), dry mouth, dizziness, and nausea.

TABLE 92–9.

Pharmacologic Therapy for Neuropathic Pain in Peripheral Neuropathy

Medication	Starting Doses	Maintenance Doses and Comments
First Line		
Gabapentin	100–300 mg TID	↑ by 300 to 400 mg increments every 5 to 7 days to 3600 mg daily divided in 3–4 doses
Tricyclic antidepressants	10–25 mg qhs	↑ by 10 to 25 mg increments every 7 days to 100–150 mg qhs; titration can continue following blood levels (stay below 500 ng/mL) and ECG
Tramadol	50 mg QD or BID	↑ by 50-g increments every 5–7 days to a maximum of 100 mg QID
Second Line		
Lamotrigine	25 mg GD or BID	After 2 weeks, ↑ by 25-mg increments weekly to 100–200 mg/BID
Carbamazepine	100–200 mg QD or BID	↑ by 100–200 mg every 7 days to 600 mg QD in divided doses; titration can continue following blood levels; extended release forms can be given on BID schedule
Bupropion SR	150 mg QD	After 1 week, ↑ to 150 mg BID
Venlafaxine XR	75 mg QD	↑ by 75-mg increments every 7 days to 150—225 mg QD
Opiate analgesics	Varying doses; initiate with short-acting agent QID PM	After 1–2 weeks, replace with longer-acting agent on QD or BID schedule; careful titration is necessary
Topical Agents		
Capsaicin 0.075%	Apply TID or QID	Continue with starting dose; may be considered

Pregabalin Pregabalin is an agent that causes inhibition at the neuronal calcium ion channel. This mechanism of action and its molecular structure are similar to gabapentin, which has perhaps become the first-line, broad-spectrum agent used for many painful neuropathic syndromes. Pregabalin has been found to selectively bind at the $\alpha_2\delta_1$ subunit, an auxiliary protein commonly associated with voltage-gated calcium channels.[98]

Pregabalin binding causes reduction of calcium influx and neurotransmitter release, including substance P, glutamate, and noradrenaline.[106]

In a randomized, double-blind, controlled trial, patients received either placebo, 150 mg or 300 mg daily of pregabalin, and primary end points included decreased mean pain scores, health-related quality of life, and SF-36 health survey scores. Overall, patients with postherpetic neuralgia had significantly lower pain scores and less sleep interference.[107] In another group of patients with painful diabetic peripheral neuropathy, a placebo-controlled trial demonstrated significant improvements in pain scores and sleep interference.[108] Pregabalin may be better tolerated than gabapentin, and less dose titration is necessary. Pregabalin has been reported to cause symptoms of somnolence, dizziness, and peripheral edema, which are similar to side effects reported with gabapentin.[108] Drug dosage can be started at 50 mg twice or three times daily and increased to 100 mg three times daily by 1 week. The drug has been scheduled for both diabetic peripheral neuropathy and postherpetic neuralgia by the FDA. Dosages should be reduced for renal impairment based on creatinine clearance similar to gabapentin.

Levetiracetam Levetiracetam is a novel oral antiepileptic drug with structural features unrelated to those of other antiepileptic drugs. Most antiepileptic drugs are screened for inhibition of epileptiform activity by maximal electroshock or pentylenetetrazol seizure induction. Levetiracetam antiepileptic action seems to occur via inhibition of neuronal hypersynchronization.[109] Levetiracetam appears to have minimal interactions with other agents. It causes occasional increased drowsiness and cognitive dysfunction and may place patients at risk for driving or other activities exacerbated by cognitive dysfunction or altered wakefulness. It has a low protein binding (<10%) and is not hepatically metabolized.[86] Small case series have described three patients who achieved partial or complete relief of pain related to sensory motor peripheral neuropathy.[110] At this time, levetiracetam-controlled studies are limited, and no comparison studies exist for other more commonly used antiepileptic drugs.

Lamotrigine Lamotrigine is thought to act similarly to phenytoin in decreasing rapid firing of neurons. It causes use-dependent inhibition of voltage-gated sodium channels.[86] Several studies have demonstrated the efficacy of lamotrigine in a variety of pain syndromes, but because of side effects it is generally relegated to second-line therapy.

In a randomized controlled study of 59 patients with painful diabetic neuropathy, lamotrigine was titrated from 25 mg/d up to 400 mg/d over a 6-week period compared to similar titration of placebo. The lamotrigine group improved compared to the placebo group, and the authors concluded lamotrigine was both safe and effective.[111] Lamotrigine also has been studied in HIV-associated neuropathy, with a small improvement seen compared to the placebo group. In this study, the titration schedule was very slow and similar to that used in other studies, beginning at 25 mg/d up to 300 mg/d over 7 weeks. Despite the gradual titration, the dropout rate was high, with 5 of the 13 dropouts from a sample of 42 patients citing rash.[112] Among a group of 14 patients with refractory trigeminal neuralgia, those given lamotrigine improved significantly better than those on placebo. Although the patients already were taking either phenytoin or carbamazepine, these drugs were continued during the study. The one patient who withdrew from the study did so during the placebo arm of this crossover design.[113]

In a randomized, double-blind, placebo-controlled crossover study, lamotrigine was given to 30 patients with spinal cord injury pain syndromes. The drug was titrated from an initial 25 mg/d dosage up to 400 mg/d over a 9-week period, compared to a 9-week placebo titration. There was a 2-week washout period between each arm of the study. Twenty-two patients completed the trial. Daily numerical pain scale in the group treated with lamotrigine was reduced from 6.4 $\pm$ 0.1 to 4.2 $\pm$ 0.1, and numerical pain scales decreased from 6.5 $\pm$ 0.1 to 5.3 $\pm$ 0.1 in the control group. The difference between groups was statistically significant ($P < .001$ at lamotrigine doses of 200–300 and 400 mg). The primary finding of this study was that, in patients with incomplete spinal cord injuries, lamotrigine significantly reduced the pain at the same level of injury or below the level of injury. Patients who had evidence of central sensitization (windup pain) and brush-evoked allodynia were more likely to have a positive response to lamotrigine. The drug appeared to have no effect in patients with complete spinal cord injuries. The drug was generally well tolerated.[114]

Lamotrigine most notably has been associated with the development of Stevens-Johnson syndrome (a severe exfoliating dermatitis that can be a dermatologic emergency). Pediatric patients may be most prone to these dermatologic complications, which may be seen in up to 1–2% of patients in that age group.[86] Significant evidence now indicates that lamotrigine has a role in the treatment of various neuropathic pain syndromes, but side effects (particularly rash) must be closely monitored and a slow titration schedule adhered to.

Tiagabine Tiagabine has not been studied in a randomized fashion for treatment of pain syndromes. Tiagabine is an inhibitor of the GABA transporter protein GAT-1. It also acts as a GABA reuptake inhibitor, thus increasing available GABA within neuronal synapses and surrounding glia.[86] An open-label study of tiagabine compared to gabapentin in 91 patients with chronic pain suggested that both drugs were efficacious.[115] Notably, the effects of tiagabine on sleep quality in this study suggest that it may have utility for patients who have both pain and sleep disturbances. Further randomized studies will clarify its role in pain management.

Phenytoin Phenytoin has been used for several decades for treatment of epilepsy, cardiac arrhythmias, and various pain syndromes. Phenytoin alters Na^+, Ca^{2+}, and K^+ conductance and inhibits repetitive high-frequency

discharges.[86] Phenytoin was used in a study of 40 patients with painful diabetic neuropathy who received either the active drug 100 mg three times per day or placebo for 2 weeks, followed by a 1-week washout period prior to crossing over to the other group. In group 1, 70% of the phenytoin patients versus 25% of the placebo patients had improved pain. In group 2, similarly 78% of the phenytoin patients had improved pain compared to 28% of the placebo patients. Nearly one fourth of the phenytoin patients had complete relief.[116] Although phenytoin is cost effective, it does have significant side effects, including gingival hyperplasia, hirsutism, and rash. Long-term use can result in peripheral neuropathy.[86] One advantage of phenytoin is its availability in IV form. A study of IV infusion of 15 mg/kg phenytoin in patients with neuropathic pain resulted in significant improvement of several features of altered nerve conduction (shooting pain, burning pain, sensitivity, and numbness). The author concluded that IV phenytoin could be useful for acute flares of pain (Table 92–10).[117]

Topical Agents

During a 1-week open-phase segment of a pilot trial studying the analgesic efficacy of a topical formulation of 1% amitriptyline and 0.5% ketamine, 11 patients had a significant analgesic effect for a variety of different neuropathic pain syndromes, including postherpetic neuralgia and painful diabetic peripheral neuropathy. In a followup of this initial pilot trial, 92 patients with mixed neuropathic pain syndromes, including postherpetic neuralgia, postsurgical, posttraumatic neuropathic pain, and diabetic neuropathy with evidence of allodynia, hyperalgesia, and pinprick hypesthesia, were randomly assigned to receive placebo, 2% amitriptyline, or 1% ketamine, combined with a primary outcome measure of change in average daily pain intensity.[118] Unfortunately, a reduction in pain score of 1.1–1.5 units was observed in all groups, and there were no differences between the groups. Blood concentrations showed no significant systemic absorption. Other studies have shown that higher doses may be required to produce significant analgesia.[119] This abstract detailed a comparison of high-dose amitriptyline–ketamine (4% amitriptyline/2% ketamine) cream for 1 week. Of the 129 subjects who responded, 118 patients were randomized

TABLE 92–10.

Number Needed to Treat to Obtain One Patient with More than 50% Pain Relief

	Painful Neuropathy	Postherpetic Neuralgia	Peripheral Nerve Injury	Central Pain	Trigeminal Neuralgia
Antidepressants

to receive either high-dose (4% amitriptyline/2% ketamine) or low-dose (2% amitriptyline/1% ketamine) cream, or a placebo cream for 2 additional weeks. After 3 weeks of treatment, results showed the high-dose group had average daily pain intensity that decreased from 6.5 to 3.28 versus the placebo pain intensity score of 4.34. There was no difference between the placebo and the low-dose group. The percentage of subjects with 30% reduction was superior to placebo for patient sleep quality and global satisfaction. Plasma levels were detectable in <10% of subjects and were well below therapeutic levels. Topical cream was well tolerated. This finding may imply that, compared to the study by Lynch et al.,[118] higher concentrations of amitriptyline–ketamine cream are required to produce analgesia for mixed neuropathic pain syndromes.

Older topical agents for treatment of neuropathic pain include capsaicin. A multicenter, double-blind, vehicle control study was conducted by the capsaicin study group.[120] The trial was conducted over 8 weeks, and either capsaicin or vehicle cream was applied to painful areas four times per day. Pain intensity and relief were recorded every 2 weeks using the physician's global evaluation as well as visual analogue pain scales. Two hundred fifty-two patients were studied. Capsaicin showed 69.5% versus 53.4% improvement according to the physician's global evaluation scale, and 38.1% versus 27.4% decrease in pain intensity (Tables 92–9 and 92–10). Other studies have also demonstrated efficacy for chronic postherpetic neuralgia.[121] As in previous studies, initial burning at the application site was noted. The mechanism of action of capsaicin is depletion of substance P at peripheral thermal receptors, a process that can take several weeks. Over the past decade, capsaicin has been used less frequently by pain physicians secondary to poor tolerance of the drug when used by patients with postherpetic neuralgia and other peripheral neuropathic conditions.

Intravenous Analgesics

Intravenous Lidocaine Therapy

IV lidocaine has been used for the last 2 decades for the control of predominantly neuropathic pain syndromes. Intravenous lidocaine is generally given via a 1 mg/kg bolus and infusion of 4 mg/kg over 30–60 minutes. Intravenous lidocaine for phantom and stump pain was compared to morphine infusion, but lidocaine IV infusion was effective only for stump pain.[69] In an animal model, systemic lidocaine suppressed aberrant impulses at the dorsal root ganglia and at sites of experimentally induced nerve injuries. Minimal affect was seen on normal sensory conduction. ED_{50} was lower at dorsal root ganglia sites.[122] Local anesthetics administered systemically also depress evoked unmyelinated C-fiber activity in the dorsal cord.[123] In another study comparing the effects of systemic lidocaine to morphine, both agents relieved the pain of postherpetic neuralgia.[68]

In a study by Finnerup et al.,[124] IV lidocaine was found to significantly reduce spontaneous pain in all patients either with or without evoked pain. There was no difference in the number of responders. Both spinal cord injury pain at and below the level of injury as well as brush-evoked dysesthesia were relieved. The authors concluded that agents with systemic sodium channel blocking properties may be treatment options for spinal cord injury pain. IV lidocaine also has been studied for painful chronic diabetic neuropathy pain, with positive results.[125,126] Mexiletine, an oral class IB antiarrhythmic drug, also has been used for pain relief and is thought to have oral lidocaine-like activity. Galer et al.[127] studied a small group of patients receiving one of two IV lidocaine doses. Although the higher dose of IV lidocaine was more analgesic, both doses were highly correlated with mexiletine responsiveness. The authors concluded that IV lidocaine could be used as a predictor of ultimate response to mexiletine. Previous studies have demonstrated that oral mexiletine is helpful for painful diabetic neuropathy, particularly in reducing symptoms such as burning and stabbing.[128] Mexiletine can be limited by intolerance to the drug, particularly abdominal symptoms and nervousness/tremor in some patients. Dosing should begin with 150 mg twice daily or less, with a goal of at least 10 mg/kg (Table 92–10).

Combination Therapy

Few trials have examined the combination of different antinociceptive agents either from the same class (i.e., antiepileptic drugs) or from multiple classes (pairing opioids, antiepileptic drugs, and antidepressant agents). Although most of these medications have numbers needed to treat of 3 or greater,[28] therefore necessitating a multimodal analgesic approach, the rationale for combination therapies has not been adequately studied. A study by Gilron et al.[67] evaluated patients with diabetic neuropathy or postherpetic neuralgia, comparing gabapentin, morphine, or the combination of both drugs versus placebo. The study demonstrated a reduction in mean daily pain from 5.72 at baseline to 3.06 with the gabapentin–morphine combination. Both agents were analgesic. At the maximal tolerated doses, the combination was well tolerated but did produce higher frequencies of dry mouth and constipation for gabapentin and morphine, respectively. The authors concluded that there was merit to additional trials of this type comparing combinations of antinociceptive agents as a multimodal approach to pain control. Number needed to treat evaluations can be important in determining the relative effects of different pharmacologic treatments. In a review, Sindrup and Jensen[28] reported numbers needed to treat of various agents in different classes. The comparison is useful in choosing an agent(s) that has high efficacy and is safe, based on numbers needed to harm analysis (Table 92–10).

Skeletal Muscle Relaxants

Skeletal muscle relaxants include a disparate group of medications with multiple modes of action. *Benzodiazepines* include drugs such as diazepam and clonazepam. These agents act to depress the central nervous system via the chloride channel component of the inhibitory neurotransmitter GABA receptor. Benzodiazepines have broad effects on patients, including functioning as anxiolytics, sedatives, and relaxants. Diazepam, as a prototypical benzodiazepine, has rapid onset of action with a prolonged half-life, high lipophilicity, and high protein binding.[129] Although generally not considered potent analgesics in their oral/parenteral forms, research has focused on their use as intrathecal drugs where they are quite analgesic.[130] Clonazepam has perhaps the most robust evidence for conventional oral or topical forms for conditions such as burning mouth pain and

other facial neuropathic pain syndromes/trigeminal neuralgia.[131] Clonazepam is perhaps the agent of choice as an inhibitor of myoclonic jerking that can be frequently seen in high-dose opioid patients.[132]

Tizanidine, an α_2-adrenergic agonist chemically, has been used for painful spasm and headache prophylaxis.[133] The drug initially was marketed for control of spasticity in association with brain injury[134] and has been found useful in controlling spastic hypotonia as measured by Ashworth scale improvement.

Baclofen, a $GABA_B$ agonist used for spasticity, has found limited utility for control of neuropathic pain. Three subtypes of the GABA receptor have been described: $GABA_A$, $GABA_B$, and $GABA_C$. $GABA_B$ receptors are primarily located in the lamina I–III area of the dorsal spinal cord.[135] A small trial of oral baclofen given to 15 patients compared the effects of the racemic mixture of baclofen versus the levorotatory form alone and noted greater improvement in patients who received the levorotatory form than in patients treated with the mixed form.[136] A comprehensive review of intrathecal baclofen use indicates several reports of analgesic effects of baclofen in animals and humans.[135]

More conventionally used oral muscle relaxants include agents such as cyclobenzaprine, methocarbamol, orphenadrine, metaxalone, and carisoprodol. Of these agents, cyclobenzaprine has perhaps the best evidence for efficacy in pain control. Chiefly, cyclobenzaprine has been compared to ibuprofen as therapy for acute neck and back pain in a randomized trial.[137] In this study, the combination of ibuprofen with cyclobenzaprine provided no advantage over cyclobenzaprine alone. A review of the use of three commonly prescribed muscle relaxant agents—carisoprodol, cyclobenzaprine, and metaxalone—demonstrated that these agents represent 45% of all prescriptions for musculoskeletal pain. The review concluded that all were effective, some based on good randomized trial evidence, particularly for cyclobenzaprine. Unfortunately, although carisoprodol represented 13.3% of all prescriptions, its utility is significantly limited by its abuse potential.[138] Carisoprodol blocks descending reticular formation interneuronal activity and is metabolized to meprobamate. Meprobamate is a potent anxiolytic and sedative agent with a high propensity for physical and psychological dependency, which ultimately led to the parent drug's removal from the market. Meprobamate is similar in function to barbiturates.[139] The danger of the effects of carisoprodol on driving have been detailed, with more of the impaired drivers manifesting higher blood carisoprodol levels. Impairment appeared to mimic that seen with benzodiazepine use but with several other manifestations, including horizontal nystagmus, hand tremor, and involuntary movements.[140]

Nonsteroidal Antiinflammatory Drugs

NSAIDs are used on a daily basis by millions of people and on an occasional basis by many more. The proportion of patients using NSAIDs is nearly 4-fold higher in an older age group compared to a younger group.[141] In a study of 3154 elderly patients in Italy, 24.7% were taking NSAIDs, one third chronically.[142] As the percentage of baby-boomer Americans older than 65 years advances in the next two decades, the number of patients taking these agents likely will continue to expand. NSAIDs are commonly and appropriately used for many acute pain syndromes, including traumatically induced pain, surgical pain, pain from sprains and strains, temporomandibular joint pain, some headaches, menstrual cramping/dysmenorrhea, and some chronic conditions such as rheumatoid arthritis, seronegative arthritides, osteoarthritis, and other painful states. The ultimate goal of therapy with NSAIDs is to decrease inflammation, harness any ongoing tissue destruction, prevent peripheral sensitization of nociceptors by locally released inflammatory factors (bradykinin, histamine, substance P; Fig. 92–8), provide analgesia during restorative healing, and to do so without causing concomitant gastrointestinal injury, renal effects, or cardiovascular thrombotic events. The major mechanism of NSAID action occurs by arresting the action of COX enzyme breakdown of arachidonic acid precursors. The COX enzyme is involved in the synthesis of cyclic endoperoxides from these arachidonic acid precursors to prostaglandins (Fig. 92–9). Prostaglandins have varied effects, often as proinflammatory substances, as well as generation of a gastric mucus membrane protective barrier and modulation of renal plasma flow and electrolyte balance Two isoforms of the COX enzyme exist: COX-1 and COX-2. The COX-1 enzyme normally is present or constitutive and functions in homeostasis, as in the gastric mucosa. One of the main side effects of prolonged NSAID use is gastric ulceration related to inhibition of COX-1 activity. The COX-2 form of the enzyme is constitutive in the central nervous system and renal tissues but is inducible at sites of pain and inflammation. Efforts to block the inducible form of the enzyme at sites of peripheral inflammation (i.e., COX-2) led to the introduction of COX-2–selective NSAIDs in the last decade.[143]

The COX-2–specific agents had demonstrated lower risks of gastric ulceration compared to nonspecific COX agents, but all COX inhibitors have a propensity to cause gastrointestinal bleeding depending on dose and duration of therapy. Platelet aggregation is permanently affected with aspirin, which irreversibly acetylates platelet COX. The older nonacetylated salicylates, such as salsalate and magnesium choline salicylate, as well as the selective COX-2 blockers appear to have less effect on platelet function.[143] Thus, some NSAIDs and aspirin, in particular, may react adversely with other anticoagulant agents (e.g., warfarin).

Unfortunately, the apparent effects of increased cardiovascular risk have led to the withdrawal from the U.S. market of two COX-2 selective drugs (rofecoxib and valdecoxib) and have derailed the ultimate availability of an IV COX-2 form of valdecoxib (parecoxib). Celecoxib, which is much less selective for the COX-2 isoform than are rofecoxib and valdecoxib, remains available. It is thought that, to some extent, all NSAIDs as a class may have deleterious effects on the cardiovascular system. Therefore, use of these agents for prolonged periods, particularly by chronic pain patients, should be done with utmost caution and with appropriate balancing of risks versus benefits. An initial study investigated the risks of rofecoxib compared to naproxen was performed (Vioxx Gastrointestinal Outcomes Research [VIGOR]).[144] In the VIGOR study, 8000 patients with rheumatoid arthritis were treated with rofecoxib 50 mg/d or naproxen 1000 mg/d. A statistically significant increase in non-

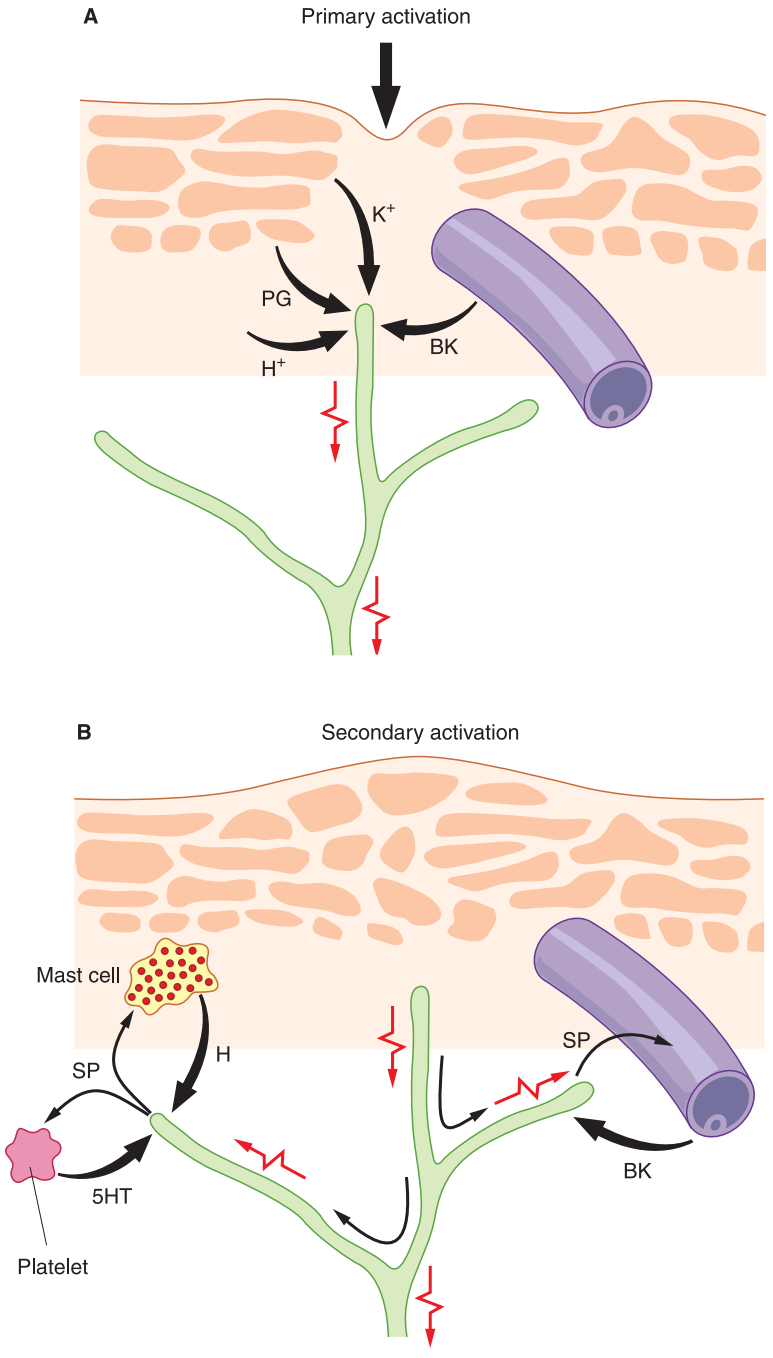

FIGURE 92–8. **A.** Release of local factors at the site of tissue injury causes primary activation of nociceptors. Release of prostaglandins (PG), bradykinins (BK), hydrogen ion (H^+), and potassium (K^+) contributes to ongoing pain and inflammation. **B.** Release of platelet 5-HT (serotonin) and mast cell histamine, other peptides (substance P), and bradykinin (BK) leads to peripheral sensitization of the nociceptor. (From Pain: pathophysiology and management. In Kasper DL, Braunwald E, Fauci AD, et al., eds. Harrison's Principles of Internal Medicine. 16th ed. Harrison's Online. Available at: accessmedicine.com. New York: McGraw-Hill, 2004–2005:Figure 11–2, with permission.)

fatal myocardial infarctions was noted in the rofecoxib patients compared to the naproxen patients. In the Celecoxib Long-term Arthritis Safety Study (CLASS),[145] 20–22% of patients were commonly receiving low-dose aspirin in addition to celecoxib. Early recommendations that concomitant low-dose aspirin therapy along with the COX-2 agent might be protective against thrombotic events were discussed with practitioners.

In the Adenomatous Polyp Prevention on Vioxx (APPROVe) trial, 2586 patients with a history of colorectal adenoma were studied, as it appeared that NSAIDs might have beneficial effects in primary prevention. Comparing a 25-mg dose of rofecoxib to placebo, 46 patients in the rofecoxib group and only 26 patients in the placebo group had confirmed thrombotic events, which included myocardial coronary syndromes, cerebrovascular events, and cardiac/pulmonary failures. The risks became apparent at 18 months of therapy.[146] Nussmeier et al.[147] studied the use of perioperative valdecoxib in coronary bypass patients and found a similar result. As for rofecoxib, valdecoxib appeared to increase the incidence of acute thrombotic events compared to placebo therapy, even though these patients already had diseased vasculature.

NSAIDs as a rule are weak acids and are highly protein bound. Particular care is mandatory when prescribing these agents to older debilitated or cachectic patients who are critically ill, are intravascularly volume depleted, or have protein-deficient nutritional states. NSAIDs are metabolized by either the CYP 2C or CYP 3A cytochrome P450 enzymes and are excreted in the urine. It is generally believed that NSAIDs are prescribed according to their specific chemical class. Many of the more popular analgesic agents are propionic acids (e.g., ibuprofen, ketoprofen, oxaprozin, naproxen), but multiple classes exist. No evidence indicates that one particular agent or class is superior in specific patients if comparable doses are given. Some clinicians believe that a failed drug trial from one class necessitates a trial with another group, but this has not been demonstrated.[148] Patients with a history of other GI problems, who are nicotine or alcohol users, who are taking concomitant oral steroids, or who are taking warfarin or other anticoagulant substances are least likely to do well. The wisdom of long-term NSAID use as a chronic pain treatment appears to be suspect considering the high degree of adverse drug side effects.

An association has been reported between long-term administration of NSAIDs (>180 days) and increased radiographic evidence of osteoarthritis progression. A large group of 1695 patients with either hip or knee osteoarthritis was studied. Radiographs from baseline to a mean of 6.6 years were reviewed. The authors concluded that chronic use of diclofenac, a generally well-tolerated and popular

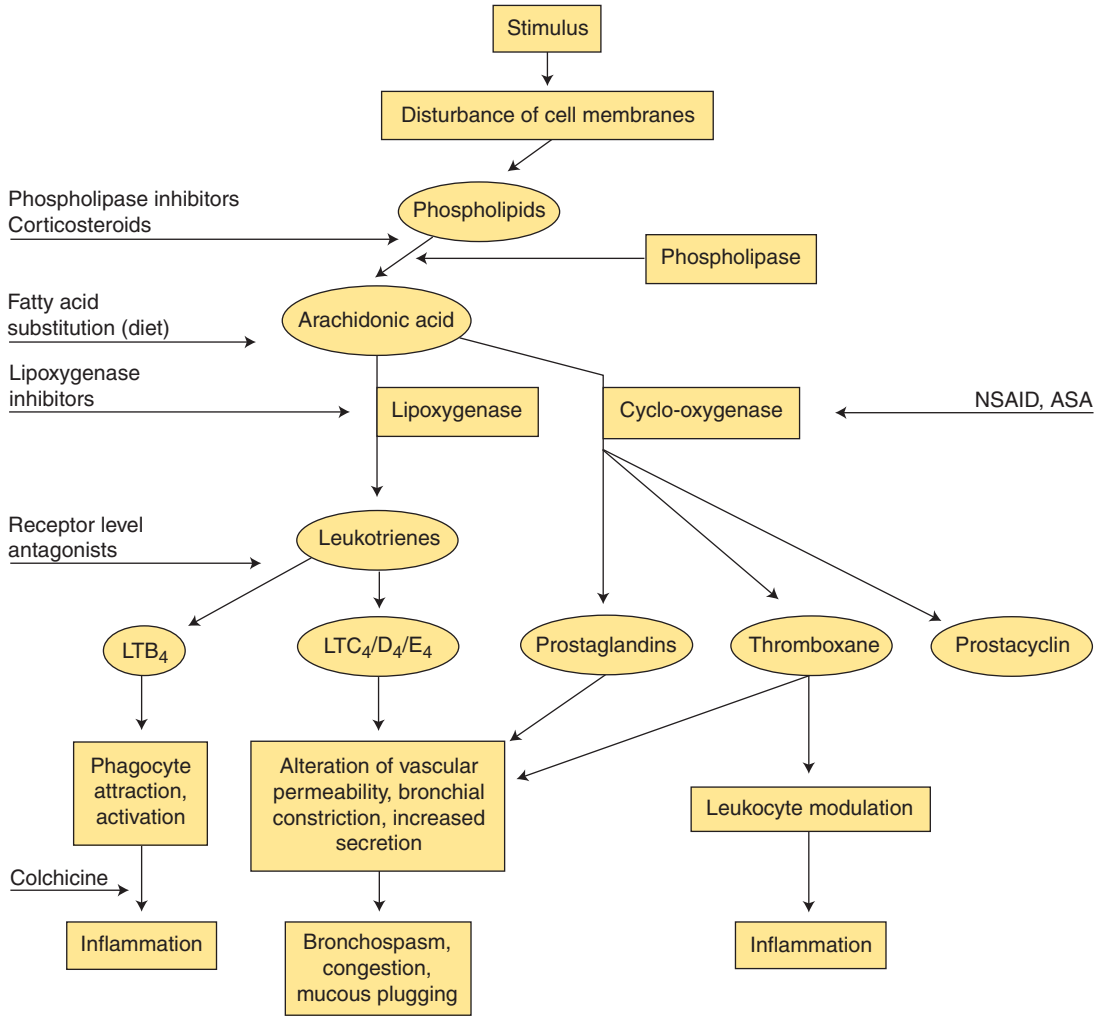

FIGURE 92–9. Cellular disturbance at the membrane level induces production of prostaglandins and leukotrienes active in the inflammatory process. (From Wagner W, Khanna P, Furst DE. Nonsteroidal anti-inflammatory drugs, disease-modifying antirheumatic drugs, nonopioid analgesics, and drugs used in gout. In Katzung BG, ed. Basic and Clinical Pharmacology. 9th ed. New York: McGraw-Hill, 2004:576–577, with permission.)

NSAID, was associated with a 2.4-fold (hip) or 3.2-fold (knee) increased risk of osteoarthritis progression compared with short-term use.[149]

Topical NSAIDs may have a therapeutic effect in certain well-localized situations. A systemic review and meta-analysis of topical NSAIDs for musculoskeletal pain concluded that although the number needed to treat was approximately 4.7 to achieve one patient with ≥50% pain relief, the topical agents were well tolerated with few side effects. Interestingly, three trials in the meta-analysis demonstrated no difference between oral and topical NSAIDs.[150]

In some cases, acetaminophen may be a safer alternative than NSAIDs. Even though millions of patients take acetaminophen daily, the drug's mechanism of analgesia is not clear. Previously, acetaminophen was considered a weak nonspecific COX inhibitor with little antiinflammatory action and predominately central versus peripheral effects, but this may not be correct. An emerging concept of its mechanism of action is that acetaminophen has a COX-3 inhibition profile. COX-3 is expressed in the cerebral cortex and heart in humans and is effectively and selectively blocked by acetaminophen as well as some NSAIDs.[151] A more recent proposal is that the acetaminophen functions via supraspinal serotonergic mechanisms (Table 92–11).[152]

Early studies comparing acetaminophen to NSAIDs have been somewhat surprising, particularly given the fact that acetaminophen's actions are primarily central. Bradley et al.[153] compared acetaminophen 4 g/d to ibuprofen up to 2.4 g/d in a randomized, double-blind experiment of 182 patients with knee osteoarthritis. The patients had improved rest pain and less disability independent of which agent they given, and the authors concluded that presumptive evidence of synovial inflammation does not necessarily predict which agent will provide a greater response. In another study of 382 patients comparing rofecoxib, celecoxib, and acetaminophen, patient functional end points including measures such as walking pain, rest pain, and morning stiffness improved in all groups, but only significantly for rofecoxib. In terms of average 6-week functional disability score, only the 25-mg rofecoxib group was statistically different than acetaminophen. No cardiac events were noted, and adverse events were generally limited.[154] Given that rofecoxib is no longer clinically available, these results indicate that practitioners should be wary in potentially higher-risk groups and strongly consider acetaminophen.

Acetaminophen-induced hepatic failure has been thought to be a risk for

TABLE 92–11.

Available Antiinflamatory Drugs and Dosing Strategies

Medication	Daily Dosage Range	Dosage	Frequency
Acetaminophen	2–4 g	325–650 mg	4 h
		650–1000 mg	QID
Salicylic acid derivatives			
Acetylsalicylic acid (aspirin)	2.4–6 g	600–1500 mg	QID
Choline magnesium trisalicylate	1.5–3 g	500–1000 mg	TID
		750–1500 mg	BID
Salsalate	1.5–3 g	750–1500 mg	BID
Propionic acid derivatives (ibuprofen)	1.2–3.2 g for pain	200–400 mg	QID
		400, 600, or 800 mg	TID to QID, to a maximum dose of 3200 mg/d
Naproxen	500 mg–1 g	250, 350, or 500 mg	BID
Naproxen sodium	550–1100 mg	275–550	BID
Flurbiprofen	100–200 mg	50–100 mg	BID
Ketoprofen	75–225 mg	25–75 mg	TID
Acetic acids (diclofenac,	150–200 mg	50 mg	TID
		75 mg	BID
etodolac)	400–1200 mg	200–300 mg	BID, TID, or QID
Indomethacin	<200 mg	25–50 mg	TID or QID
Sulindac	300–400 mg	150 or 200 mg	QD to BID
Tolmetin	800–1800 mg	400, 600, or 800 mg	TID
Enolic acids (meloxicam [Mobic])	7.5–15 mg	7.5 mg for osteoarthritis 15 mg rheumatoid arthritis	QD
Piroxicam	10–20 mg	10 or 20 mg	QD
Naphthyalkanones (nabumetone)	1–1.5 g	500 mg	BID up to 1.5 g
Cyclooxygenese-2/selective (celecoxib)	200–400 mg	100 or 200 mg	QD to Q12 h
Fenamates (meclofenamate)	50–400 mg	50–100 mg	TID to QID
Mefenamic acid (Ponstel)	1–2 g	250 mg	QID

patients with existing hepatic disease as well as those ingesting toxic levels of the drug. Patients ingesting >2 oz of alcohol per day should have dose reductions to a maximum of 2.5 g/d acetaminophen.[148] Risk of analgesic nephropathy is possible with acetaminophen but is a rare occurrence. Evidence suggests that even in patients with hepatic disease, although the serum half-life of acetaminophen may be prolonged, glutathione stores are not sufficiently depleted to critical levels at recommended doses.[155] Overall, according to American Pain Society guidelines, the favorable risk-to-benefit ratio of acetaminophen warrants ongoing use if efficacy is present during the first few weeks at doses of at least 2–3 g/d.[148]

PAIN REHABILITATION STRATEGIES

Anesthesiologists are extremely well prepared in the application of pharmacologic and interventional principles because of excellent command of the perioperative care of complex patients. However, chronic pain patients often defy treatment in a strictly biomedical model of care. The biomedical model presupposes a definable injury, disease, or process that can be treated.[156] Unfortunately, despite extensive and often expensive evaluations to explain patient pain syndromes, a precise diagnosis cannot always be made. Furthermore, patients presenting to a chronic pain treatment facility have often tried multiple therapies without significant improvement. Thus, a biopsychosocial model of care, wherein the patient is treated wholistically, understanding their reaction, beliefs, and coping mechanisms regarding the physical pain within the broad context of their work and family and social environments, often is more successful.

For example, more than half of patients admitted to a pain rehabilitation program had already tried opioids, NSAIDs, physical therapy, antidepressants, injections, anticonvulsants, and other therapies; many also had tried alternative medical treatment and surgery. Many of these trials had temporary effects, but ultimately they all failed for a variety of reasons inherent to many chronic pain patients.

Gallagher[156] recommended multiple approaches to maximizing the results of pharmacologic trials: (1) carefully plan medication trials; (2) consider alternative (nonpharmacologic) treatments for pain fluctuation; (3) select medications based on pain mechanism and consider associated medical and psychological morbidities; (4) utility of a goal-oriented management plan for each problem with "time-limited" target outcome measures; (5) close scrutiny during initial 2-week medication trials with frequent patient contact; and (6) upon failure of a drug trial, gradual reduction of the dose, keeping other agents at stable levels.

The most common reasons for failed drug trials are improperly low (inadequate dose) or too high (side effects limit trial) doses or inadequate durations of trials.

Modern pain rehabilitation programs aim to treat the whole patient in order to modify maladaptive behaviors, overcome psychosocial detractors, allow functional restoration, and improve coping skills. These programs generally include physical reconditioning/exercise, aided by physical and occupational therapists, and cognitive behavioral therapies, including biofeedback, relaxation, stress management, substance use educational interventions, introduction of concepts of pacing and pain-inducing activity moderation, and use of positive reinforcements of appropriate instead of maladaptive behaviors (Fig. 92–10).

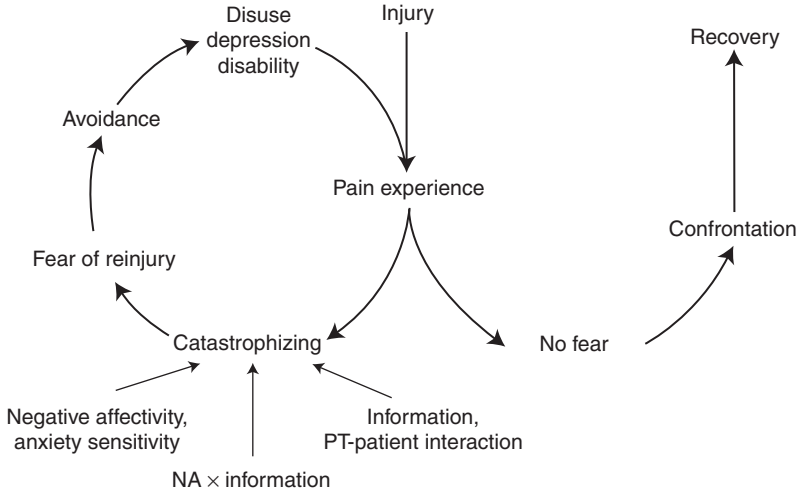

FIGURE 92–10. Injury occurs, and the patient experiences pain. Some patients have a "catastrophizing" coping response to the experience of pain, reinforced by physicians and physical therapists, who may encourage abstinence from the painful activity. Further activity induces fear of (re)injury and gradual social, sexual, and functional disability. This continued cycle of pain is difficult to overcome. (Reprinted from Vlaeyen JWS, Crombez G. Fear of movement/(re)injury, avoidance and pain disability in chronic low back pain patients. Man Ther 1999:4:187–195.)

Multiple studies have demonstrated that functional improvements are sustained over time, as well as the ability to decrease or eliminate medications (opioids, NSAIDS, muscle relaxants).[157,158] Rome et al.[159] studied 356 patients admitted to the pain rehabilitation program for an entire year. Of this group, 274 patients completed both the program and all questionnaires; 99 patients were taking opioids before the program and 175 were not. Only three of the opioid patients were still taking opioids at the conclusion of the 3 week program, and significant improvement was noted in all outcome variables in both groups.[159] This is important, because it demonstrates that despite a presumed acute increase in pain due to opioid withdrawal, the opioid group was also able to achieve program goals.

Robbins et al.[160] evaluated the effect of deleting the behavioral medicine portion of a pain rehabilitation approach and "carving out" only the physical therapy portion of the care plan. In this study, patients did not fare as well on either short-term or long-term followup. Thus, insurers' and managed care organizations' approaches to chronic pain care often can be "penny wise and pound foolish."

A number of studies have started to question the role of spinal operations as therapy for chronic lumbar pain due to discogenic disease. Soon many other therapies will be scrutinized for chronic pain care, and evidence, if lacking, will spurn new approaches to care of patients. Spinal fusion for discogenic pain is an example of a quickly growing procedure that seems to be outpacing the growth of other joint replacements for arthritic conditions such as hip or knee replacement.[161] Brox et al.[162] studied patients with degenerative disk disease at L4–5 or L5–S1 and chronic pain for more than 1 year. Patients were randomized to either spinal instrumented fusion plus postsurgical physical therapy or exercise and cognitive interventions. After 1 year, there was no clear advantage to instrumented fusion over cognitive interventions/exercise. Surgical patients had improved leg pain, and cognitive interventions/exercise patients had better fingertip to floor distance ability. Oswestry disability scores improved in both groups.[162] Based on a study by Fairbank et al.,[163] in which only marginal, not clearly advantageous, improvement was noted in the surgical group versus intensive rehabilitation, a cost study was performed in which the authors determined that surgical stabilization was not a cost-effective use of scarce health care resources in Great Britain.[164] These studies are the first of several that are beginning to clearly demonstrate to patients and payers that the combination of behavioral medicine techniques with physical therapeutics is effective for patients with chronic lower back pain.

Pain Catastrophizing

Catastrophizing can be summarized as a negative cognitive belief state associated with actual or potential pain experiences. Three major attributes of catastrophizing are (1) magnification, (2) rumination, and (3) helplessness.

Catastrophizing is associated with a heightened pain experience and is one of the most important psychological factors contributing to perceived pain intensity. Catastrophizing is associated with increased disability, pain-induced healthcare-seeking behavior, and analgesic use.[165] It is apparent that patients who catastrophize in response to painful experiences have intense emotional distress and increased pain overall. Patients appear more likely to be female than male. Thus, the role of gender in pain has been studied. For example, in a large study examining gender differences, women reported greater levels of pain from chronic spinal conditions than did men. Interestingly, the patients taking opioids had poorer function and disability whether they were men or women, but men had more affective distress while taking opioids and women had less.[166]

Physical Modalities and Exercise

Physical modalities can be applied within an overall pain treatment plan to aid in functional rehabilitation. Many pain rehabilitation programs provide vigorous inpatient or (day treatment) outpatient programs in which subjects receive both cognitive behavioral strategies combined with

physical therapy/functional restoration techniques. Likewise, many of these programs will modify or eliminate unnecessary or problematic pharmaceutical agents causing side effects to the patient, particularly opioids or other narcotics. Prior to beginning any physical training sessions, a functional capacity evaluation can be useful in identifying and quantifying specific limitations of the patient. The practitioner must realize that most chronic pain disorders have evolved over time, so any specific regimens must be applied in a graded and preferably supervised fashion to prevent (re)injury, which would reinforce in the patients' mind once again that they are disabled by the pain. Patients who catastrophize may understand that they need to exercise, but education alone often is insufficient to overcome their fear. Introduction of graded exposure to the feared activity in a sense "teaches" the patient that he or she actually can do the activity (Fig. 92–10).[167]

Pain causes may be multifactorial, including muscle atrophy, joint/ligamentous laxity, joint derangement, edema/inflammation, muscle spasm/fatigue, vasomotor derangements, ischemia, and peripheral/spinal hyperalgesia. Caution may be in order with aggressive reintroduction of activities. Chronic visceral/pelvic pain with intestinal dysmotility, nausea, diarrhea, cramping, and bloating may complicate functional tasks. Patients may have multiple forms of disability, including alterations in activities of daily living, work, social and cultural withdrawal, sexual dysfunction/decreased libido, anhedonia, depression, low self-esteem, and ongoing forms of compensation litigation. Many patients suffer from a sense of loss and have anger and hostility issues directed at other drivers (motor vehicle-related injuries), employers (work-related injuries), physicians (alleged malpractice), caregivers, family, and others.

Vocational Rehabilitation

When chronic pain interferes with a patients' ability to return to work, the physician can utilize programs such as work conditioning and work hardening. Although similar, these two programs differ in their content and structure. The work-conditioning program provides structured progressive reconditioning that relies less on passive modalities and more on activities for physical fitness. The program often runs 1–2 hours, 3–5 times per week for period of 2–6 weeks. In contrast, the work-hardening program provides a more comprehensive approach to the patient who has been off work for prolonged periods. These programs incorporate job-specific work simulation and address psychological and vocational issues along with physical reconditioning. The programs often are located in environments that appear "work-like" to minimize the patient's perception of illness and to facilitate the return to work mindset. Education is an important part of both types of programs and includes proper body mechanics, safe lifting techniques, stress management, and promotion of a healthy lifestyle.

Vocational rehabilitation assists the chronic pain patient when return to his or her former occupation is unlikely. Vocational counseling may be provided by individual rehabilitation facilities or accessed through local or state agencies when available. Physical modalities are used in conjunction with therapy to provide temporary pain relief, improve stiffness, and allow the patient to more fully participate in performance of specific tasks that will manifest long-term gains in functionality. Heat, cold, iontophoresis, transcutaneous electrical nerve stimulation (TENS), and electrical stimulation of the muscles, along with traction, myofascial release techniques, massage, and desensitization activities often are used.

Exercise

A review of randomized, controlled trials and observational studies of therapeutic exercise in adults with chronic low back pain supports the theory that therapeutic exercise is effective for reducing chronic pain.[168] Individually tailored programs that emphasize stretching or strengthening may be superior. A typical physical therapy regimen may include low-impact forms of movement education, such as aquatic therapies, walking, and passive and active stretching, with gentle progression to the patient's tolerance. Occupational therapy is used to teach patients energy conservation techniques or to assess for adaptive equipment needs such as gait and grasp aids, braces, and orthotics, which may be useful for promoting independence and protecting against injury. One important goal supported by both the physician and physical therapist is patient autonomy. A home-based therapy routine should be encouraged from the onset of physical/occupational therapy and monitored or modified on a regular basis as needed. The patient should be encouraged to adopt a more active lifestyle, incorporating the skills acquired in physical/occupational therapy into daily life.

Transcutaneous Electrical Nerve Stimulation

The gate control theory—activation of specific large fiber afferents carried in A-fibers might compete at the dorsal horn with slower unmyelinated sensory afferent (C-fibers) and functionally "close" the gate to this slower noxious information—may explain the rationale for TENS analgesia. TENS may be one of the most useful therapies based on these concepts. TENS units are multichannel devices in which surface electrical stimulation is applied through gel pads with an external generator over sites of pain. In order to maximize analgesia, different amplitudes, frequencies, and pulse waveforms are used to decrease pain perception. TENS has been studied for treatment of several types of pain, with some studies demonstrating benefit and others showing equivocal results. Most reports of benefit have derived from studies in which stimulation was below motor threshold strength. High-frequency stimulation may give long-lasting pain relief.[169]

Ice and Heat

Cryotherapy and heat are the most commonly used physical modalities available to the patient because of their efficacy, ease of use, and safety profiles. Both heat and cold produce analgesia; heat also produces hyperemia, whereas cold decreases nerve conduction.[170] The decrease in blood flow found with cryotherapy may decrease delivery of inflammatory chemicals to the site of injury. Some patients with chronic low back pain have found ice massage to be as effective as TENS.[171]

Heat applications via superficial heat combined with exercise are commonly used for various arthritic and musculoskeletal injuries.[172,173] Heat can be provided in the form of moist heat (hot packs), heat lamps (incandescent or infrared), hydrotherapy, ultrasound, paraffin baths, and short-wave diathermy. Cryotherapy is provided in more limited forms, such as hydro-

therapy, ice packs, ice massage, and iced compression wraps; it also can be applied through vapocoolant sprays, such as ethyl chloride.

Acupuncture

The ancient art of acupuncture has been used for several millennia for treatment of a variety of medical conditions including pain. The Chinese typically are credited for developing acupuncture. The premise of acupuncture is that energy flow, called *qi,* is important to good health, which is maintained by a smooth flow of the qi. Thus, disease or pain results from disruptions or stagnation of the flow of qi.[174] Qi is thought to reside in specific channels or meridians located along specific anatomic regions of the body. Along these meridians are multiple points considered important for accessing qi, called *acupuncture points.* Over the past several decades, acupuncture has grown in popularity as an option for treatment of multiple pain conditions.

On a neurobiologic basis, the needling that occurs at specific acupuncture points has been shown to cause release of peptides such as endorphins and enkephalins.[175] Functional MRI studies have shown patterns of activation in distinct regions of the brain, such as the auditory/visual cortex when traditional acupuncture points for hearing and vision are used[176] as well as common activation areas between healthy volunteers when identical acupuncture points are selected.[177]

Data regarding the efficacy of acupuncture in chronic pain states are conflicting.[178,179] However, a 1998 National Institutes of Health consensus panel extensively reviewed the available literature and concluded that use of acupuncture was acceptable as "an adjunct treatment or acceptable alternative or may be included in a comprehensive management program" for the treatment of headache, tennis elbow, fibromyalgia, myofascial pain, low back pain, and osteoarthritis.[180]

CONCLUSION

Chronic pain management is an evolving discipline that requires broad knowledge and management skills. Peak physician performance demands well-trained compassionate providers who are familiar with not only pharmacological and interventional therapies but also with the patient's overall cognitive state. Pain mechanisms now are better understood, and therapies can be better targeted, often from a multimodal approach. Comparative studies of different pharmacologic, cognitive behavioral, and interventional therapeutics are needed to determine which are based on solid evidence.

CHAPTER 93

Interventional Management of Chronic Pain

Carlos A. Pino, MD, and
James P. Rathmell, MD

The subspecialty of "interventional pain medicine" involves minimally invasive treatments and minor surgery as part of pain care, including neural blockade and implantable analgesic devices. Despite the paucity of scientific evidence to guide pain practitioners, particularly evidence supporting the use of many interventional modalities, a number of techniques appear to have efficacy based on limited observational data and have been adopted into widespread use. As practitioners we are left to choose from among available treatment modalities, often with only anecdotal and personal experience to guide us in treating a group of desperate patients with intractable pain who are willing to accept almost any treatment, even those that remain unproven. There is no single practice pattern that any pain specialist can point toward as the correct way to treat patients with chronic pain. Training programs vary widely in the scope of what they train practitioners to do. The best pain medicine practitioners strike a reasonable balance between interventional and noninterventional management. This practice pattern is sustainable, and those adopting a balanced style of practice will be able to adapt to evolving scientific evidence that appears in support of pain treatment, regardless of the type of treatment. A balance between treatment modalities also allows practitioners to switch from one mode to another or to incorporate multiple treatment approaches simultaneously. Although this chapter focuses on interventional treatments used to treat chronic pain, use of these interventional modalities is just a small part of the armamentarium of the skilled pain practitioner.

KEY POINTS

1. The best pain medicine practitioners strike a reasonable balance between interventional and noninterventional management. This practice pattern is sustainable, and those adopting a balanced style of practice will be able to adapt to evolving scientific evidence that appears to support pain treatment, regardless of the type of treatment.
2. Although the evidence supporting the need for routine radiographic guidance is still evolving, the intuitive appeal of this more precise approach has caught firm hold to the point where the majority of practitioners now perform at least a portion of their injections using fluoroscopic guidance.
3. The key to success in any interventional pain technique is a clear understanding of normal anatomy. The procedures described in this chapter require an understanding of the normal anatomy of the spine, including the epidural and subarachnoid spaces, zygapophyseal joints, intervertebral disks, and, most importantly, the spinal cord with its somatic and sympathetic components.
4. Epidural steroid injections are indicated in acute lumbosacral radicular pain or in radiculopathies secondary to herniated or bulging disks. Epidural steroid injections also have been used to treat back pain secondary to degenerative disk disease, spinal stenosis, trauma, spondylolysis or spondylolisthesis, and in pain following laminectomy. The epidural space can be approached through the interlaminar space (median or paramedian), intervertebral foramen (transforaminal), or sacral hiatus (caudal). The approach selected will depend on patient selection, indication for injection, practitioner's experience, and availability of imaging. Currently no evidence shows better clinical outcome with the transforaminal versus the interlaminar approach.
5. Many practitioners continue to use sympathetic blockade as a part of a multidisciplinary approach to treating complex regional pain syndrome. Sympathetic blocks are one tool that can reduce pain and facilitate functional recovery.
6. Intraarticular facet injection has been largely supplanted by radiofrequency treatment techniques for facet-related pain. Clinical experience and a limited number of published observational studies suggest that intraarticular injection of local anesthetic and steroid leads to relief of facet-related pain that is of limited duration. In contrast, radiofrequency treatment is safe and modestly effective in producing longer-term pain relief in the same group of patients.
7. Discography is a diagnostic test in which radiographic contrast is injected into the nucleus pulposus of the intervertebral disk. Although originally developed for the study of disk herniation, discography now is used most commonly to identify symptomatic disk degeneration
8. Intrathecal morphine and other opioids are now widely used as adjuncts in the treatment of acute and chronic pain, and a number of agents show promise as analgesic agents with spinal selectivity. Patient selection for intraspinal pain therapy is empiric and remains the subject of debate. In general, intrathecal drug delivery is reserved for patients with severe pain that does not respond to conservative treatment.
9. Direct electrical stimulation of the dorsal columns, known as spinal cord stimulation or dorsal column stimulation, has proven effective, particularly for treatment of chronic radicular pain. Patient selection for spinal cord stimulation is empiric and remains a subject of some debate. In general, spinal cord stimulation is reserved for patients with severe pain that does not respond to conservative treatment. The pain responds best when relatively well localized because success of spinal cord stimulation depends on the ability to cover the entire painful region with electrical stimulation.

USE OF IMAGE-GUIDED TECHNIQUES IN PAIN MEDICINE

A little more than a decade ago, radiographic guidance was used infrequently by pain practitioners; it was reserved for use in major procedures such as neurolytic celiac plexus block. During the last several years, two forces have been at work. First, pain practitioners now are being called upon to serve as diagnosticians. Patients and referring practitioners expect pain physicians to have familiarity with imaging modalities and their usefulness in diagnosing pain conditions. At the same time, pain practitioners have come to realize the usefulness of radiographic guidance in achieving precise anatomic placement of needles and catheters. Although the evidence supporting the need for routine radiographic guidance is still evolving, the intuitive appeal of this more precise approach has caught firm hold to the point where the majority of practitioners now perform at least a portion of their injections using fluoroscopic guidance.[1] In some cases (e.g., patients with intractable pain associated with metastatic cancer), radiographic guidance has proven invaluable in the planning and implementation of therapy directed toward pain relief.

We have examined the distribution of injectate in a series of patients who received epidural steroid injections for radicular pain associated with a new herniated disk.[2] We found that the injectate often spread to the side opposite the disk herniation. This finding is not at all surprising. A disk herniation present on one side might well obstruct the flow of fluid through the relatively confined epidural space. The fluid would follow the path of least resistance, spreading preferentially to the contralateral, unaffected side and exiting the contralateral intervertebral foramina. This study and others[3,4] have challenged the conventional wisdom that suspending the steroid in a modest volume is sufficient to consistently produce spread of the injectate to the affected levels, regardless of where the solution was placed within the epidural space. Perhaps the blind loss-of-resistance technique is not the best way to deliver steroid to the site of inflammation.[3,4]

Using radiographic guidance, bony structures can be visualized directly and in real time. The needle can be seen within the radiographic field, and simple geometry can be used to guide the needle directly from the skin's surface to its destination. However, the field of pain medicine suffers from a lack of well-controlled studies to guide our choice of the most effective therapies. Indeed, many of the techniques described in this chapter lack clear evidence supporting their efficacy. Even so, the techniques described are in widespread clinical use. In the following sections, a clear summary of the current evidence available supporting the use of each technique is given, but all too often the data are scant. With more consistent methodology, we can begin the much-needed work of assembling randomized controlled trials to determine which among these techniques are most useful in aiding those with intractable pain.

SPECIFIC TECHNIQUES USED IN IMAGE-GUIDED INTERVENTION FOR CHRONIC PAIN

This chapter provides an overview of the most common techniques used in interventional pain medicine. The section begins with a discussion of the anatomy relevant to image-guided interventions for treating chronic pain. Thereafter, the clinical utility of each technique and the technical aspects of conducting each intervention are described. Illustrations for the most common techniques are provided, as detailed illustration of each technique is beyond the scope of this chapter. Many books with detailed technical descriptions of these techniques have been published, and we refer the interested reader to one of these texts.[5]

Anatomy Relevant to Image-Guided Intervention for Chronic Pain

The key to success in any interventional pain technique is a clear understanding of the normal anatomy. The procedures described in this chapter require understanding of the normal anatomy of the spine, including the epidural and subarachnoid spaces, the zygapophyseal joints, intervertebral disks, and, most importantly, the spinal cord with its somatic and sympathetic components. The basic anatomy relevant to common interventions used in the treatment of chronic pain is reviewed here.

Anatomy of the Spine

The spinal cord is protected within the vertebral canal and extends from the foramen magnum to the first or second lumbar vertebra in human adults. Its is covered by three meninges. The most internal pia mater lies in close apposition to the cord. It is separated from the thin arachnoid mater by the free-flowing cerebrospinal fluid (CSF). The dense dura mater lies most external, surrounding the arachnoid and accompanying the segmental nerve roots well into the vertebral foramen. The epidural space lies within the bony vertebral canal surrounding the dura matter and spreads from the base of the skull to the sacrococcygeal membrane.

Normally, the vertebral canal is nearly triangular, surrounded by the bony components of the vertebrae. There are 33 vertebrae: 7 cervical, 12 thoracic, 5 lumbar, 5 fused elements that make up the sacrum, and 4–5 fused ossicles that form the coccyx (Fig. 93–1).[6] A typical vertebra consists of a vertebral body and two pedicles that extend posteriorly surrounding the spinal canal and epidural space to join a pair of arched laminae (Fig. 93–2). The laminae fuse in the midline to form a dorsal projection called the spinous process. Near the junction of the pedicles and the laminae are found the lateral projecting transverse processes, the superior and the inferior articular processes (zygapophyses or facets). The pedicles and their articulating processes form the superior and inferior vertebral notches. In the articulated spine, these notches form the intervertebral foramina.[6]

The zygapophyseal or "facet" joints are paired structures that lie posterolaterally on the bony vertebrae at the junction of the lamina and pedicle medially and the base of the transverse process laterally. The facet joints are true joints, with opposing cartilaginous surfaces and a true synovial lining. They are subject to the same inflammatory and degenerative processes that affect other synovial joints throughout the body.[6] Two opposing articular surfaces compose each facet joint. The facet joint articular processes are named for the vertebra to which they belong. Thus, each vertebra has a superior articular process and an inferior articular process.

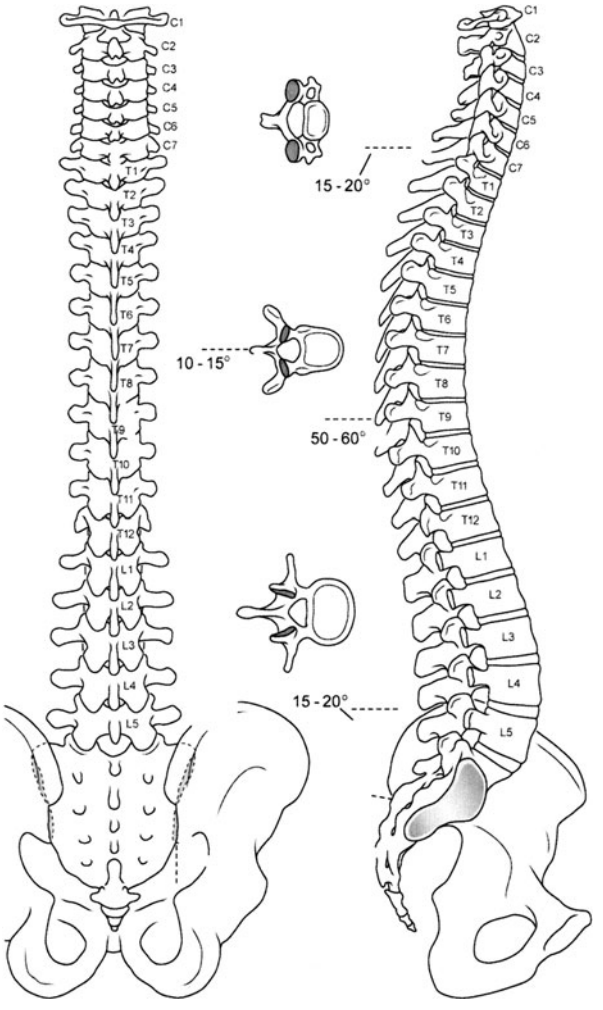

FIGURE 93–1. Anatomy of vertebral column. In most humans, the most prominent spinous process at the base of the neck is C7 (the vertebrae prominens). Note the angle of the spinous processes changes dramatically from cervical to lumbar levels, with the steepest angle in the midthoracic region. The approximate plane of needle entry for interlaminar epidural injection is shown for cervical, thoracic, and lumbar levels. (Adapted from Rathmell JP. Atlas of Image-Guided Intervention in Regional Anesthesia and Pain Medicine. Philadelphia: Lippincott Williams & Wilkins, 2006:33, with permission.)

This nomenclature can be confusing, as the superior articular process of a given vertebra actually forms the inferior portion of each facet joint.

The intervertebral disk is composed of glucosaminoglycans with a relatively fluid inner nucleus pulposus surrounded by a stiff lamellar outer annulus fibrosus.[6] With aging, hydration of the intervertebral disks declines, leading to loss of disk height and fissure formation in the annulus fibrosus. These fissures begin centrally near the border between the nucleus pulposus and the annulus fibrosus and can extend to the periphery of the disk space. This process of degradation is called internal disk derangement and is believed responsible for producing discogenic pain. The annulus contains neural elements from the sinuvertebral nerve, which is believed to be responsible for pain transmission.[7] These same radial fissures within the annulus represent paths through which nuclear material can pass and extrude as a herniated nucleus pulposus. When this extruded material is adjacent to an exiting spinal nerve root, it can lead to intense inflammation, nerve root compression, and radicular pain with or without radiculopathy (nerve root dysfunction in the form of numbness, weakness, and/or loss of deep tendon reflexes). The paired facet joints, along with the vertebral bodies and intervertebral disks, form the three weight-bearing support columns that distribute the axial load on the vertebral column while allowing for movement in various planes. The structure of the vertebrae varies from

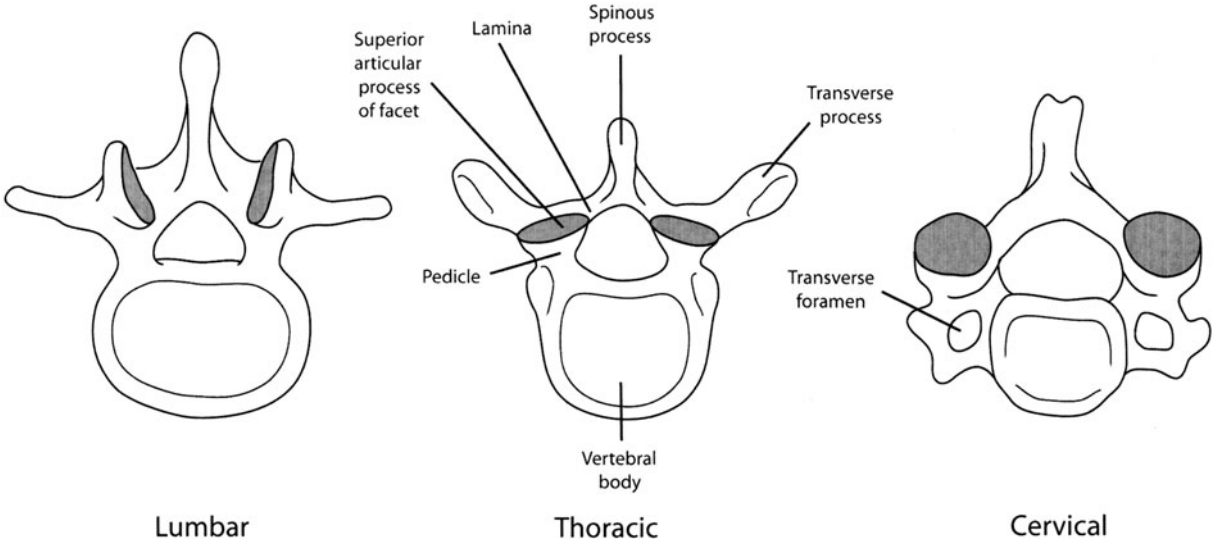

FIGURE 93–2. Anatomy of the cervical, thoracic, and lumbar vertebrae. (Adapted from Rathmell JP. Atlas of Image-Guided Intervention in Regional Anesthesia and Pain Medicine. Philadelphia: Lippincott Williams & Wilkins, 2006:32, with permission.)

cephalad to caudad and should be thoroughly reviewed by the practitioner, especially when using imaging (Figs. 93–1 and 93–2). Of importance when performing injections, the spinous processes of the cervical and lumbar regions approach the lamina in a nearly perpendicular fashion, which facilitates a midline approach when performing epidural or subarachnoid injections. The cervical facet joints are oriented nearly parallel to the axial plane where the atlas (C1) articulates with the occiput and become gradually more steeply angulated in a cephalad to caudad direction at lower cervical levels. The orientation of the cervical facet joints in a plane close to the axial plane allows for a great degree of rotation of the neck as well as flexion and extension.

The midthoracic (T5–9) spinous processes are acutely angled caudad, making the midline approach to the epidural space more difficult than the paramedian approach. The thoracic facet joints are so steeply angulated that they approach the frontal plane, which makes intraarticular injection difficult or impossible. At midthoracic levels, the inferior articular process of the vertebra forming the superior portion of each thoracic facet joint lies directly posterior to the superior articular process forming the inferior portion of each joint. This allows for some degree of flexion and extension but limited rotation of the spinal column in the thorax.

The spinous processes of the lumbar vertebrae approach the lamina in a nearly perpendicular fashion. The lumbar facet joints are angled with a somewhat oblique orientation, allowing for flexion, extension, and rotation that is greater than that in the thorax but less than in the cervical region. The sacral hiatus is the area where the fifth sacral vertebra lacks both the laminae and the spinous process posteriorly (Fig. 93–3). The two sacral cornua lie on either side of the sacral hiatus and cephalad to the coccyx and are useful landmarks when performing an epidural from a caudal approach.

The midline distance from the ligamentum flavum to the dural sac varies considerably, depending on the level of entry, increasing from 2 mm at C3–6 to 5–6 mm in the midlumbar region.[8] The epidural space narrows posterior and laterally toward the intervertebral foramina. The anterior boundary of the epidural space is provided by the posterior longitudinal ligament covering the vertebral bodies and the intervertebral disks. Posteriorly, the epidural space is limited by the periosteum of the anterior surfaces of the laminae, the articulating facet processes (zygapophyses), and the ligamentum flavum. Laterally, the pedicles and the intervertebral foramina limit the epidural space.

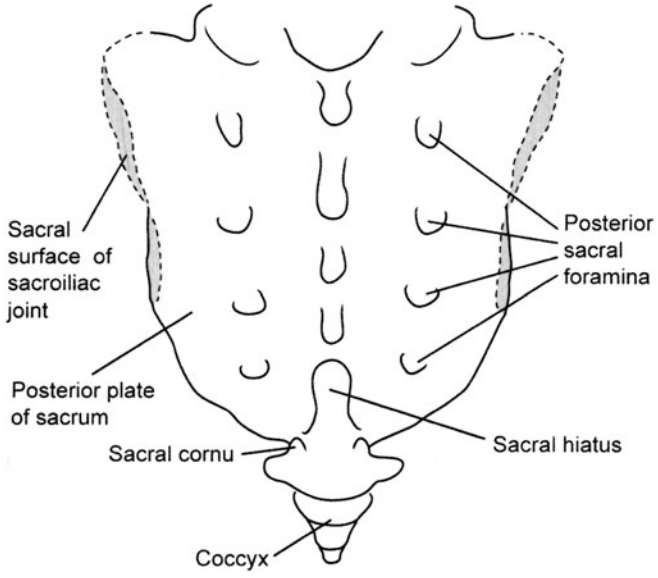

FIGURE 93–3. Anatomy of the posterior sacrum and coccyx. (Adapted from Rathmell JP. Atlas of Image-Guided Intervention in Regional Anesthesia and Pain Medicine. Philadelphia: Lippincott Williams & Wilkins, 2006:33, with permission.)

Knowledge of surface anatomy enhances safety when performing procedures under imaging guidance and is an absolute necessity when imaging is not available. Important surface landmarks include the spinous process at C7 *(vertebra prominens),* which is the most prominent cervical spinous process palpable when the neck is flexed. The spinous process at T7 lies opposite the inferior angle of the scapula when the arm is at the side. A line joining the superior aspects of the iliac crests passes through the spinous process of the fourth lumbar vertebrae. The spinal cord generally terminates at the L2 level and the dural sac ends at S2, which corresponds to the level of the posterior superior iliac spines. The tip of an equilateral triangle drawn between the posterior superior iliac spines and directed caudally overlies the sacral cornua and sacral hiatus.

Additionally, the articulated spine is supported by the anterior and posterior longitudinal ligaments, the supraspinous and interspinous ligaments, and the ligamentum flavum.[8] Many of the pain management procedures discussed here make reference to the ligamentum flavum. The ligamentum flavum or "yellow ligament" is a structure of variable thickness and completeness, composed of elastic fibers, that defines the posterolateral soft-tissue boundaries of the epidural space. Because its leather-like consistency resists active expulsion of fluid from a syringe, loss of this resistance is valuable in signaling entry into the epidural space. The ligament's structure is steeply arched and tent-like, so much so that the lateral reflection may be up to 1 cm deeper than at the midline. In the cervical and thoracic epidural spaces, the ligamentum flavum often does not fuse in the midline, which can become problematic during loss-of-resistance techniques. When the dense ligamentum flavum is absent in the midline, it is possible to enter the epidural space without ever sensing significant resistance to injection. The ligamentum flavum is thickest at the lumbar and thoracic levels and thinnest at the cervical level. Its thickness also diminishes at the cephalad aspect of each interlaminar space and as the ligamentum flavum tapers off laterally. In patients who have undergone spinal surgery, scarring of the posterior epidural space is common, such that the loss of resistance and the flow of injected solutions are less predictable.

The spinal cord is a cylindrical structure composed of an external white matter and internal gray matter, pro-

tected by the bony vertebral column. White matter represents the myelinated ascending and descending tracts of the spinal cord, which conduct information to and from the brain. The gray matter contains axons, dendrites, and synaptic terminals arranged grossly in the shape of butterfly wings. The spinal cord receives its vascular supply from arteries of the brain and from segmental spinal arteries of the subclavian artery, aorta and iliac arteries.[6] The posterior spinal cord receives its blood supply from a paired system of arteries arising from the posterior inferior cerebellar arteries. The anterior spinal artery is a single, discontinuous vessel formed by the union of a terminal branch from each vertebral artery that descends along the anterior midline of the spinal cord. In all regions of the cord, the anterior spinal artery provides nutrition to approximately 75% of the cord tissue, including all of the gray matter,[8] which makes this territory most vulnerable to ischemia.

The segmental spinal arteries reach the spinal cord by way of the intervertebral foramina and the epidural space, to reach the spinal nerve roots. Although the main purpose of these segmental arteries is to provide blood supply to the nerve roots, some send branches that penetrate the dura to join the anterior and posterior spinal arteries that provide blood supply to the spinal cord. The largest of the segmental arteries is the artery radicularis magna (artery of Adamkiewicz), which supplies the anterior spinal artery for the thoracolumbar region of the cord. In 78% of cases, it enters by way of a left intervertebral foramen between T8 and L3; in 15% of cases, the artery of Adamkiewicz takes off more cephalad, at about the level of T5.[8] It is important to keep in mind that many of our pain management procedures are performed in this region, and damage to the artery of Adamkiewicz can result in ischemia of the anterior two thirds of the lumbar spinal cord, with its resultant predominantly motor lesion.[9]

Venous drainage of the spinal cord occurs via large epidural veins, which are more prominent in the anterior and lateral portions of the epidural space. These veins are valveless and connect to the systemic circulation via the basivertebral venous plexus, intracranial veins, and azygos veins. Inferiorly, this plexus communicates with the sacral venous plexus, which drains into the uterine and iliac veins. At each level, the vertebral plexus sends branches through the intervertebral foramina that anastomose with the thoracic and abdominal veins. The extensive communication between the epidural venous plexus and the systemic circulation is responsible for the distension of the epidural veins that occurs with increases in intraabdominal pressure. Thus, significant obstruction of the inferior vena cava results in rerouting of the venous return through the epidural venous plexus to the azygos vein.

The spinal nerve at each level exits the intervertebral foramen and divides into anterior and posterior primary rami. The anterior ramus contains the majority of sensory and motor fibers at each vertebral level. Of importance, a small branch of the anterior ramus, the sinuvertebral nerve, provides neural branches to the posterior outer layers of the annulus of the disk.[7] The posterior primary ramus, in turn, divides into a lateral branch, which provides innervation to the paraspinous musculature, and a small variable sensory distribution to the skin overlying the spinous processes; the medial branch courses over the base of the transverse process where it joins with the superior articular process of the facet joint and courses along the articular process to supply sensation to the joint. Each facet joint receives sensory innervation from the medial branch nerve at the same vertebral level as well as from a descending branch from the vertebral level above; thus, two medial branch nerves must be blocked to anesthetize each facet joint (e.g., medial branch blocks at the base of the L4 and L5 transverse processes are needed to anesthetize the L4–5 facet joint). The specific course of the medial branch nerves and cannula position for radiofrequency treatment at specific spinal levels is discussed in the following sections.

Anatomy of the Sympathetic Nervous System

Because we will discuss sympathetic nerve block techniques, a brief review of the anatomy is warranted. The sympathetic nervous system is part of the autonomic nervous system. It innervates cardiac, smooth muscle, and glandular tissues, mediating a variety of reflexes. In certain pathologic pain states, neuronal activity in the sympathetic nervous system may be involved in the maintenance of chronic pain.[10] Anatomically, the peripheral sympathetic system arises as efferent preganglionic fibers that leave their cell bodies in the intermediolateral column of the spinal cord, which extends from the first thoracic spinal segment to approximately the second lumbar segment. These axons leave the spinal cord within the ventral root and initially proceed as part of the spinal nerve. They separate from the somatic motor neuron, forming the white rami communicantes, and project to the sympathetic chain, located at the side of the vertebral bodies. Within the sympathetic nerve trunk, the preganglionic fibers can transverse variable distances cephalad and caudad, forming synapses with many postganglionic neurons in different ganglia at other levels in the chain. The ratio of preganglionic sympathetic fibers to postganglionic fibers is estimated to be 1:10, permitting coordinated activity at several spinal levels.[10] The axons of the postganglionic neurons are predominantly unmyelinated and exit the ganglia as the gray rami communicantes, which join the spinal nerves en route to their peripheral targets. In addition to the multiple ganglia located in the thoracolumbar chain, there are classically 3 cervical ganglia, 4–5 lumbar ganglia, 4 sacral ganglia, and 1 coccygeal ganglion (the ganglion impar).

In the cervical region, the chain lies at the anterolateral aspect of the vertebral bodies. Most sympathetic fibers traversing to and from the head, neck, and upper extremities pass through the stellate ganglion. Classically, the stellate ganglion is formed by fusion of the inferior cervical and first thoracic sympathetic ganglia. The ganglion is commonly found just lateral to the longus colli muscle, anterior to the neck of the first rib and the transverse process of the seventh cervical vertebra. In this position, the ganglion lies posterior to the first portion of the subclavian artery at the origin of the vertebral artery posterior to the dome of the lung. Although several approaches to stellate ganglion block have been described, the most common is the anterior paratracheal approach at C6 using surface landmarks. Performing the block at C6 reduces the likelihood of pneumothorax, which is more likely when the

block is carried out close to the dome of the lung at C7. The anterior tubercle of the transverse process of C6 (Chassaignac's tubercle) is readily palpable in most individuals.

Sympathetic innervation to the abdominal viscera arises from the anterolateral horn of the spinal cord between the T5 and T12 levels. Nociceptive information from the abdominal viscera is carried by afferents that accompany the sympathetic nerves. Pain transmitted via the celiac plexus originates from the upper abdominal structures, including the pancreas, diaphragm, liver, spleen, stomach, small bowel, ascending and proximal transverse colon, adrenal glands, kidney, abdominal aorta, and mesentery. The celiac plexus is composed of a diffuse network of nerve fibers and individual ganglia that lie over the anterolateral surface of the aorta at the T12–L1 vertebral level. Presynaptic sympathetic fibers travel from the thoracic sympathetic chain toward the ganglion, traversing over the anterolateral aspect of the inferior thoracic vertebrae as the greater (T5–9), lesser (T10–11), and least (T12) splanchnic nerves. Presynaptic fibers traveling via the splanchnic nerves synapse within the celiac ganglia, over the anterolateral surface of the aorta surrounding the origin of the celiac and superior mesenteric arteries at approximately the L1 vertebral level. Postsynaptic fibers from the celiac ganglia innervate all of the abdominal viscera with the exception of the descending colon, sigmoid colon, rectum, and pelvic viscera.

The lumbar sympathetic chain consists of 4–5 paired ganglia that lie over the anterolateral surface of the second through fourth lumbar vertebrae. The cell bodies that send projections to the lumbar sympathetic ganglia lie in the anterolateral region of the spinal cord from T11 to L2, with variable contributions from T10 and L3. As in the thoracic area, the lumbar preganglionic fibers leave the spinal canal with the corresponding spinal nerve, join the sympathetic chain as white communicating rami, and then synapse within the appropriate ganglion. Postganglionic fibers exit the chain to join either the diffuse perivascular plexus around the iliac and femoral arteries or via the gray communicating rami to join the nerves that form the lumbar and lumbosacral plexus. Sympathetic fibers accompany all of the major nerves to the lower extremities. The majority of the sympathetic innervation to the lower extremities passes through the second and third lumbar sympathetic ganglia, and blockade of these ganglia results in near-complete sympathetic denervation of the lower extremities.

The superior hypogastric plexus is composed of a flattened band of intercommunicating nerve fibers that descend over the aortic bifurcation. The plexus carries sympathetic afferents and postganglionic efferent fibers from the lumbar sympathetic chain as well as parasympathetic fibers that arise from S2–S4. The plexus is retroperitoneal in location and lies over the anterior surface of the fourth and fifth lumbar and the first sacral vertebrae. Sympathetic nerves passing through the plexus innervate the pelvic viscera, including the bladder, uterus, rectum, vagina, and prostate.

Interlaminar Epidural Injection Steroids and Transforaminal Injection of Steroids

Overview

The theoretical background supporting the use of epidural steroids is based on the existence of inflammation as the basic pathophysiologic process. Nerve root edema has been demonstrated surgically and with computed tomography (CT) in patients with herniated disks.[11] Inflammation of nerves in the presence of a herniated disk has further been confirmed during surgery,[12] myelography,[13] and histologic examinations.[14,15] More recently, phospholipase A_2 (PLA_2), the rate-limiting enzyme in the conversion of arachidonic acid to prostaglandins and leukotrienes, has been found in high levels in the extruded disc material of patients undergoing discectomy for herniated disk.[16] Other inflammatory mediators such as prostaglandins have also been shown to produce hyperalgesia.[17] Clinically, improvement of pain has been shown to coincide with resolution or decrease in nerve root edema, despite a persistent herniated disk.[7]

In laboratory animals, PLA_2 has been implicated as a primary inflammatory mediator. Its administration in lumbar nerve roots produces motor weakness and decreased mechanical withdrawal thresholds.[18] Histologic examination shows reversible demyelination, vacuolar degeneration in the nerve roots, and unclear axonal margins.[14] In another animal model of radiculopathy, Hayashi et al.[19] ligated the left L4 and L5 nerve roots while surgically placing an epidural catheter with the tip between the ligated nerve roots. All rats demonstrated reversible motor weakness that resolved completely in 4 weeks, and all of the animals exhibited thermal hyperalgesia. The rats were separated into groups and treated with epidural betamethasone alone, normal saline, or epidural betamethasone plus bupivacaine. All treatment groups demonstrated a transient reduction in thermal hyperalgesia, but both betamethasone groups showed prolonged benefit lasting 3–4 weeks.

Steroids decrease inflammation by inducing the biosynthesis of a PLA_2 inhibitor, preventing prostaglandin generation.[20,21] Steroids also suppress ongoing discharge in chronic neuromas and prevent the development of ectopic neural discharges from experimental neuromas, which has been attributed to direct action on the membrane.[22] Steroids may block nociceptive input. Local application of methylprednisolone was found to reversibly block transmission in the unmyelinated C-fibers but not in Aβ-fibers.[23]

Patient Selection

Many investigators have attempted to identify which patients are most likely to benefit from epidural steroid injections. In 1960, Goebert et al.[24] administered three consecutive epidural hydrocortisone and procaine injections in 239 patients with low back pain. Fifty-eight percent of the patients had >60% relief for 3 months or longer, and 8% of patients claimed 40–60% pain relief.

In a prospective study, White et al.[25] followed the response to epidural steroid injection of 304 patients with low back pain. They found longer pain relief in patients with <2 weeks of pain and in those patients without "psychological overlay." Eighty-seven percent of the patients reported good short-term success, without significant differences between the acute and chronic pain groups, whereas 34% of patients in the acute pain group still reported pain relief at 6 months compared to 12% in the chronic pain group. Twenty-four percent of patients without psychological overlay were still relieved of their pain at 6 months compared to only 1.5% of patients with psychological overlay.

One prospective randomized study of lumbar epidural steroid injections followed 36 patients younger than 50 years with radicular pain, positive straight-leg raising test, and a prolapsed disk at L4–L5 or L5–S1 confirmed by magnetic resonance imaging (MRI).[26] These patients were randomized to two groups; both received identical conservative therapy and one of the groups also received a series of three epidural steroid injections. At 2-week followup, patients in the epidural steroid injection group had a significantly greater increase in straight-leg raise measurements compared to the control group. In addition, a trend in pain relief favoring the epidural steroid group was noted but did not reach significance. This study was not blinded, and all injections were given within 14 days of randomization, such that the interval from onset to injection was very brief.

The effectiveness of epidural steroids in the relief of radicular pain attributable to herniated disk has been documented by many studies.[27–34] Based on these and many other published studies, it is currently believed that epidural steroid injections are indicated in acute lumbosacral radicular pain or in radiculopathies secondary to herniated or bulging disks.[35] Although their usefulness has not been clearly documented by controlled studies, epidural steroid injections also have been used to treat back pain secondary to degenerative disk disease,[27,31,32] spinal stenosis,[36] trauma,[24] spondylolysis or spondylolisthesis,[25,27,29] and in pain following laminectomy.[24,37]

In a large observational study on the frequency of epidural steroid injections and patient characteristics, Fanciullo et al.[38] collected information on 25,479 patients seen at 23 specialty spine centers in the United States from 1995–1998. Surprisingly, epidural steroid injection formed part of the treatment plan for only 2002 patients (7.9%). As expected, lumbar problems were far more likely in patients who had an epidural steroid injection (12.6%) than in patients with cervical (3.7%), thoracic (1.8%), or sacral problems (2.4%). The most frequent diagnoses in patients who were offered epidural steroid injection were spinal stenosis (40.1%) and herniated disk (34.3%), followed by spondylolisthesis (7.8%) and compression fractures (1.6%). Evidence supports the use of epidural steroids in patients with disk herniations and other presumed inflammatory conditions, such as nerve irritation secondary to spinal stenosis or spondylolisthesis, but the efficacy of epidural steroids is undocumented in patients with compression fractures. These results show that patient selection for epidural steroid injections is not always consistent with existing data, and concordance between clinical practice and reported evidence of efficacy is variable.

Drug Selection for Epidural Steroid Injection

Most studies reported in the literature used a mixture of local anesthetic and steroid, saline with steroid, or steroid alone. The steroids most commonly used are either methylprednisolone acetate (Depo-Medrol) or triamcinolone diacetate (Aristocort). The doses of methylprednisolone most widely used vary from 80–120 mg, and the doses of triamcinolone most commonly used vary from 50–75 mg.[31,32,39,40]

Methylprednisolone acetate has been approved for intramuscular, intrasynovial, soft-tissue, and intralesional injection. It is a glucocorticoid with an elimination half-life of 139 hours and a range from 58–866 hours.[41] Triamcinolone diacetate, which has an elimination half-life of 18–36 hours, possesses glucocorticoid properties while being essentially devoid of mineralocorticoid activity, thus causing little or no sodium retention. It has been approved for administration by intramuscular, intraarticular, and intrasynovial routes.[42]

In a review of the literature, Kepes and Duncalf[43] found that methylprednisolone was the least irritating, the most beneficial, and the longest acting, although Delaney et al.[44] prefer triamcinolone because of its excellent antiinflammatory effect and low potential for sodium retention. No study has compared the effectiveness of triamcinolone and methylprednisolone, which probably are equally effective. Both of these preparations contain polyethylene glycol, which has been found to impair nerve transmission in rabbit vagus nerve and cause degenerative lesions in rat sciatic nerves.[45,46] Both preparations also contain benzyl alcohol, which is potentially toxic when administered locally to neural tissue.[31] Neither of these preparations should be used intrathecally.

Most practitioners dilute the steroid with local anesthetic or sterile saline, and the results are apparently comparable with either diluent.[30] Some authors have recommended use of local anesthetics "in the presence of muscle spasms".[26,47] However small the dose, use of local anesthetic carries some risks, including hypotension, arrhythmias, and seizures from intravascular injections. Brown[1] suggests that because the results are comparable, use of saline probably is sufficient. Some investigators have combined epidural methylprednisolone with morphine. In an initial study, Cohn et al.[48] showed encouraging results in postlaminectomy patients; however, a subsequent study was unable to repeat such beneficial effects.[49]

Traditionally, the volume of diluent has depended on the site of injection, whether lumbar, caudal, or transforaminal. When using a caudal approach, 20–25 mL of a solution has been recommended in order to assure epidural spread cephalad to the desired level.[27,30] When using a lumbar interlaminar approach, a volume of 5–10 mL has been recommended to reach the areas most commonly involved in the lumbar region.[25] Other practitioners use smaller volumes (2–3 mL), especially when using the transforaminal approach. Some authors have suggested that several nerve roots may be inflamed in addition to those adjacent to the herniated or bulging disk, and they recommend against using a small volume of diluent.[50] Wood et al.[46] suggested diluting the steroid after their study showed degenerative lesions in rat sciatic nerves attributable to the polyethylene glycol vehicle in the steroid preparation. The optimal volume of injectate and site of epidural placement remain unresolved.

Epidural steroids have been associated with glucose intolerance and pituitary–adrenal axis suppression for up to 3 weeks after repeated administration.[51–53] Ward et al.[54] measured insulin sensitivity and fasting blood glucose, fasting plasma insulin, and fasting serum cortisol levels in 10 healthy individuals 24 hours before and 1 week after epidural administration of triamcinolone 80 mg via a caudal route. They found that 24 hours after epidural steroid injection, insulin sensitivity had decreased to nearly half the baseline, fasting insulin levels increased 1.4-fold, and fasting glucose levels had increased 1.1-fold. All of these values normalized by 1 week after injection,

and they demonstrate the marked changes in insulin sensitivity occurring in nondiabetic healthy individuals after epidural steroid injection.

Technique

The epidural space can be approached through the interlaminar space (median or paramedian), intervertebral foramen (transforaminal), or sacral hiatus (caudal). The approach selected depends on patient selection, indication for injection, practitioner's experience, and availability of imaging. The patient can be positioned in the lateral decubitus position, sitting or prone, depending on the technique to be used.

Interlaminar Technique for Epidural Steroid Injection

The term *interlaminar* has been given to the traditional posterior approach to the epidural space in order to easily differentiate it from the transforaminal or caudal approach. The interlaminar approach can be either midline or paramedian. Correct epidural placement with this technique is facilitated by the use of imaging guidance. As reported by Sharrock et al.,[55] anesthesiologists have a high success rate of epidural anesthesia using loss-of-resistance; however, use of image guidance can confirm proper placement in all cases. When using the midline approach, the point of insertion depends on the level of entry and angle of the corresponding spinous processes. For the cervical and lumbar midline approach, the needle should be almost perpendicular to the neuraxis, in line with the corresponding spinous process. This is also true with the low thoracic approach below T9. In the midthoracic region, the spinous processes are sharply angled caudad, such that the tip of the spinous processes lies opposite the lamina of the inferior vertebral body. In this region, the midline approach requires that the needle be inserted with a steep cephalad angle, often approaching 130°. Many practitioners prefer the paramedian approach in the midthoracic region. The choice of needles when using the interlaminar approach is similar to those available for anesthesia; the most common type is the 18- or 20-gauge Tuohy needle.

For cervical interlaminar epidural injections, most practitioners place the patient in a sitting or prone position. When in the sitting position, the patient is asked to sit comfortably and flex the neck anteriorly. The forehead can be leaned against a sturdy, but padded, horizontal surface in order to minimize involuntary movement. This position avoids rotation of the spine and widens the lower cervical epidural space. Because of its large interlaminar distance, the most common approach is C6–7 or C7–T1, especially because the long spinous process of C7 (the vertebra prominens) serves as a reliable surface marker.

When the prone position is used for the cervical interlaminar approach, most practitioners prefer to use imaging guidance. This allows for good visualization of the interlaminar space and needle advancement between adjacent spinous processes.

Cervical Epidural Steroid Injection Technique Classically, the epidural space has been identified using loss of resistance to saline. Regardless of the approach, sterile technique must be strictly observed. The skin and subcutaneous tissues overlying the interspace where the block is to be performed are anesthetized with local anesthetic. The cervical interspaces with the largest interlaminar distance typically are found at C6–7 and C7–T1. Because of the ease of entry, many practitioners place the needle via one of these larger interspaces, regardless of the level of pathology, and rely on the flow of steroid in the epidural space to reach the level of pathology. The same technique can be used in all cervical interspaces below C3–4. Interlaminar injections above the C2–3 level have not been described.

An 18- or 20-gauge Tuohy needle is placed through the skin and advanced several centimeters until the needle is firmly seated in the interspinous ligament. An anteroposterior (AP) image is taken, and the needle is redirected toward midline. We use the loss-of-resistance technique with saline to find the epidural space. Repeat images taken after every 1–1.5 cm of needle advancement will assure that the needle direction does not stray from midline. A firm grasp of the adjacent structures and the proximity of the spinal cord is essential during cervical interlaminar epidural injection. After the needle tip enters the epidural space, the position is confirmed by injecting nonionic radiographic contrast, and adequate spread is verified in the AP and lateral planes. If lateral imaging of the cervicothoracic junction and low cervical spine is hindered by the adjacent structures of the torso and arms, a second lateral image taken just above the shoulders often can be much simpler to interpret when trying to confirm epidural contrast flow. Once epidural needle position has been confirmed, a solution containing steroid diluted in preservative-free saline is injected. In our practice, we routinely use 80 mg of methylprednisolone acetate or the equivalent diluted in 5 mL of total volume.

Midthoracic Epidural Steroid Injection Because of the steep angulation of the spinous processes at this level, image guidance is often used. The patient lies prone, with the head turned to one side. The C-arm is rotated 40–50° caudally from the axial plane without any oblique angulation. This allows for good visualization of the interlaminar space and needle advancement between adjacent spinous processes.

The skin and subcutaneous tissues approximately 1 cm lateral and 2–3 cm caudad to the interspace where the block is to performed are anesthetized. An 18- or 20-gauge Tuohy needle is placed through the skin and advanced several centimeters until the needle is firmly seated in tissue. An AP image is taken, and the needle is directed toward the superior margin of the lamina below the interspace that is to be entered, near the junction of the spinous process and the lamina. Although a midline approach can be used at low thoracic levels, the spinous processes are angled too steeply to allow for true coaxial needle placement at the midthoracic levels. Thus, the needle is best directed toward the superior margin of the lamina. While advancing, repeat images are taken and care must be taken to keep the needle tip over the lamina until bone is gently contacted. The periosteum is then anesthetized, and the needle is slowly advanced over the superior margin of the lamina until loss of resistance occurs. Because the needle is unlikely to lie within the interspinous ligament when using a paramedian approach, there will be little resistance to injection until the needle enters the interlaminar space and traverses the ligamentum flavum. A firm understanding of the adjacent structures and the prox-

imity of the spinal cord is essential for thoracic interlaminar epidural injection. After the needle tip enters the epidural space, the position is confirmed by injecting nonionic radiographic contrast, and spread is verified in the AP and lateral planes. Once epidural needle position has been confirmed, a solution containing steroid diluted in preservative-free saline is injected, and the needle is removed.

Lumbar Epidural Steroid Injection Epidural injection at the lumbar level can be administered with the patient in a sitting or prone position. The patient is asked to sit comfortably with his or her back to the anesthesiologist, curving the spine posteriorly and pushing the lumbar region against the examiner's fingers in an attempt to separate the spinous processes. If the procedure is to performed in the prone position under fluoroscopic imaging, a pillow is placed under the mid and lower abdomen to reduce the lumbar lordosis and increase the separation between adjacent spinous processes. The C-arm is rotated 15–20° caudally from the axial plane without any oblique angulation. This allows for good visualization of the interlaminar space and needle advancement between adjacent spinous processes.

The skin and subcutaneous tissues overlying the interspace where the block is to be performed are anesthetized. An 18- or 20-gauge Tuohy needle is placed through the skin and advanced 1–2 cm until the needle is firmly seated in the interspinous ligament. If the patient is prone, an AP image should be taken as the needle is advanced, until loss of resistance occurs. If the patient is sitting, adequate positioning will allow a proper midline approach. A firm knowledge of the adjacent structures and the proximity of the thecal sac and cauda equina is essential for lumbar interlaminar epidural injection (Fig. 93–4). After the needle tip enters the epidural space and aspiration is negative for CSF or blood, the position is confirmed by injecting nonionic radiographic contrast, and spread is verified in the AP and lateral planes. Lateral imaging of the lower lumbar spine is hindered by the overlying iliac crests, and visualization can be difficult in the obese patient. Once epidural needle position has been confirmed, a solution containing steroid diluted in preservative-free saline is injected, and the needle is removed. In the lumbar region, we usually use 80 mg of methylprednisolone acetate or the equivalent diluted in 5–10 mL of total volume. When larger injectate volumes are used, the solution spreads extensively in both the anterior and posterior aspects of the epidural space. In patients with significant lumbar pathology, the injectate tends to follow the path of least resistance, often flowing toward the side opposite the pathology.[2]

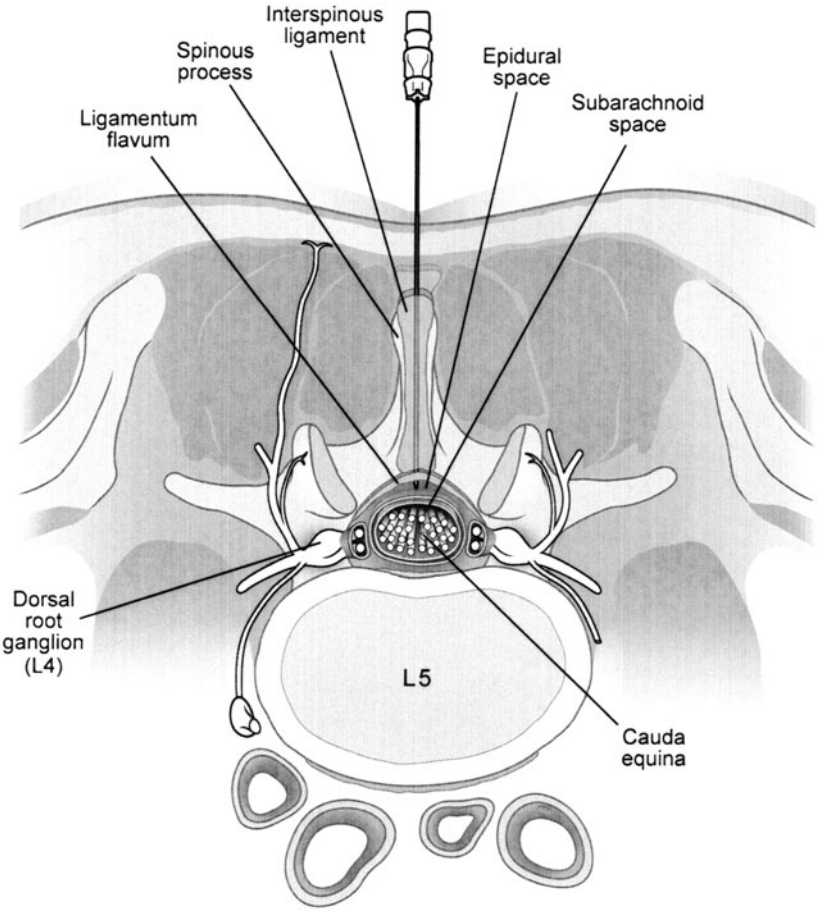

FIGURE 93–4. Axial diagram of interlaminar lumbar epidural injection. The epidural needle is advanced in the midline between adjacent spinous processes to traverse the ligamentum flavum and enter the dorsal epidural space in the midline. The normal epidural space is approximately 4–6 mm wide (from the ligamentum flavum to the dura mater in the axial plane). Note the proximity of the underlying cauda equina during lumbar epidural injection. (Adapted from Rathmell JP. Atlas of Image-Guided Intervention in Regional Anesthesia and Pain Medicine. Philadelphia: Lippincott Williams & Wilkins, 2006:47, with permission.)

Caudal Epidural Steroid Injection Anesthesiologists will be familiar with caudal injections administered to pediatric patients in the operating room. Because of difficulty identifying the sacral hiatus clinically in adults, these procedures usually are performed under fluoroscopy. The patient lies prone with the head turned to one side. The C-arm is rotated 20–30° caudally from the axial plane without any oblique angulation. This allows for good visualization of the sacrum, sacral hiatus, and coccyx.

Once the sacral hiatus is identified radiographically, the overlying skin and subcutaneous tissues are anesthetized. The sacral hiatus can be difficult to visualize radiographically. The approximate location can be identified by palpating the paired sacral cornua in the midline, near the superior extent of the gluteal cleft. An 18- or 20-gauge Tuohy needle can be used, but a smaller 22-gauge, 3.5-inch spinal needle is adequate. The needle is placed through the skin and advanced directly through the sacrococcygeal ligament. Once the needle has passed through

the sacrococcygeal ligament and is within the caudal spinal canal, the angle of the needle is decreased to lie closer to the plane of the sacrum, and the needle is advanced into the spinal canal an additional 1–2 cm. A firm grasp of the anatomy of the sacral hiatus and the caudal epidural space is essential for caudal epidural injection. AP and lateral imaging confirm the needle's position within the caudal epidural space. The caudal epidural space is generously supplied with veins, and intravascular needle placement is ruled out by injecting nonionic radiographic contrast under live fluoroscopy. Once caudal epidural needle position has been confirmed, a solution containing steroid diluted in preservative-free saline is injected, and the needle is removed. The caudal epidural space is distant from the usual sites of nerve root inflammation near the lumbosacral junction; thus, a significant volume of injectate usually is required to affect spread to the level of the lumbosacral junction. For this approach, we use 80 mg of methylprednisolone acetate or the equivalent diluted in at least 10 mL of total volume.

Complications of the interlaminar approach include dural puncture with subsequent postdural puncture headache, which can occur when this technique is used at any level of the spine. Although in a different patient population, the incidence of dural puncture in parturients undergoing lumbar epidurals ranges between 0% and 2.6%.[56] Postdural puncture headaches occur frequently after unintended dural puncture with large epidural needles. The incidence of headache following cervical dural puncture is lower than that following lumbar puncture, likely because of the diminished column of CSF cephalad to the point of dural puncture.

Although cervical and thoracic epidural blood patches using small volumes of autologous blood have been described, most practitioners manage postdural puncture headaches following cervical or thoracic epidural injection conservatively with fluids and oral analgesics. Dural puncture also can occur during caudal epidural injection but usually only if the needle is advanced several centimeters cephalad within the caudal spinal canal. The thecal sac extends to the level of approximately S2, and the position can be approximated by palpating the adjacent posterior superior iliac spines, which lie at the same level. Epidural blood patch using autologous blood is a safe and effective treatment that relieves headache symptoms promptly in 70–98% of patients who fail to improve after 24–48 hours of conservative treatment and oral analgesics.[57] The incidence of unintentional dural puncture may be higher in patients with previous lumbar surgery because of scarring within the epidural space and adhesion of the dura to the posterior elements.

Although direct neurologic needle trauma is rare (<0.6%),[58] injury to the spinal cord with catastrophic consequences, including quadriplegia, has been described, particularly in heavily sedated patients.[59–61] The level of sedation during this procedure should allow for direct conversation between the practitioner and the patient to assure that the patient can report contact with neural elements before significant traumatic injury occurs. Caution should be taken to avoid interlaminar epidural injection at any level where there is effacement of the epidural space.[62] Complete effacement of the epidural space as well as the CSF column surrounding the spinal cord within the thecal sac occurs in high-grade spinal stenosis, particularly that due to a large central or paramedian disk herniation. Direct trauma to the cauda equina or exiting nerve roots is unlikely during lumbar epidural injection when disciplined use of radiographic guidance is used to assure that the needle tip does not stray from the midline. Direct trauma to the cauda equina or the exiting nerve roots is unlikely with the caudal approach.

Regardless of the level of injection, epidural bleeding or infection can occur. Epidural hematoma or abscess can lead to significant compression of the spinal cord or cauda equina. Interlaminar epidural injection should be avoided or postponed in patients receiving anticoagulants.[63]

Transforaminal Technique for Epidural Steroid Injection

Transforaminal epidural steroid injection and selective nerve root injection can be performed using similar techniques. The distinction between the two techniques is questionable because the fascial sheath surrounding the spinal nerves is contiguous with the dura mater within the epidural space. A solution injected around a spinal nerve may well enter the epidural space, whether or not the needle tip is advanced through the intervertebral foramen prior to injection. Nonetheless, many practitioners reserve the term *selective nerve root injection* for injections that are performed with the needle tip adjacent to the spinal nerve, *outside* of the intervertebral foramen and the term *transforaminal injection* for injections that are performed with the needle tip *within* the intervertebral foramen. Unlike the interlaminar technique, the transforaminal approach *requires* the use of radiographic imaging to proceed with safety.[64]

Several important anatomic aspects are unique to transforaminal epidural and selective nerve root injections. At cervical levels, the ventral and dorsal roots of the spinal nerves descend in the vertebral canal to form the spinal nerve in the intervertebral foramen. The foramen faces obliquely anterior and laterally. Its roof and floor are formed by the pedicles of the articulated vertebrae. Its posterolateral wall is formed largely by the superior articular process of the lower vertebra and in part by the inferior articular process of the upper vertebra and the capsule of the zygapophysial joint. The anteromedial wall is formed by the lower end of the upper vertebral body, the uncinate process of the lower vertebra, and the posterolateral corner of the intervertebral disk. Immediately lateral to the external opening of the foramen, the vertebral artery ascends within the *foramen transversarium* in close proximity to the spinal nerve and anterior to the articular pillars of the zygapophysial joint. The spinal nerve, in its dural sleeve, lies in the lower half of the foramen, whereas the upper half is occupied by epiradicular veins. Arterial branches arise from the vertebral arteries to supply the nerve roots (radicular arteries) or the spinal cord via the anterior and posterior spinal arteries (medullary arteries). Medullary and radicular arterial branches also may arise from the deep or ascending cervical arteries and traverse through the entire length of the foramen adjacent to the spinal nerve. It is these spinal segmental arteries that are at risk for penetration during cervical transforaminal injection.

At the lumbar levels, the ventral and dorsal roots of the spinal nerves descend within the vertebral canal to

form the spinal nerve in the intervertebral foramen. Its roof and floor are formed by the pedicles of consecutive vertebrae. Its posterior wall is formed largely by the superior articular process of the lower vertebra and in part by the inferior articular process of the superior vertebra and the capsule of the zygapophysial joint. The anterior wall is formed by the vertebral body and the intervertebral disk. The spinal nerve, in its dural sleeve, lies in the anterior and superior portions of the foramen, just inferior to the pedicle.

The most common indication for a transforaminal approach or selective nerve root injection is for placing the corticosteroid immediately adjacent to the inflamed nerve root causing the radicular symptoms. Nerve root inflammation may stem from an acutely herniated intervertebral disk causing nerve root irritation or other causes of nerve root impingement, such as isolated foraminal stenosis due to spondylitic spurring of the bony margins of the foramen. However, currently no evidence shows better clinical outcome with the transforaminal approach versus interlaminar approach.[64] Selective nerve root injection with local anesthetic has been used diagnostically to determine which nerve root is causing symptoms when pathology exists at multiple vertebral levels. This information can prove invaluable in planning surgical intervention.

Cervical Transforaminal Steroid Injection The patient lies supine, facing directly forward. The C-arm is rotated 45–55° lateral oblique until the neural foramina are clearly visualized. The patient may also be asked to rotate the head away from the side of injection. Although this position facilitates access to the side of the neck, the neural foramina and bony elements of the cervical spine will no longer be aligned, which may prove confusing to the inexperienced practitioner.

A 25-gauge, 1.5-inch, blunt-tipped needle is sufficient in length for all but the most obese patients. To avoid the vertebral artery and the spinal nerve, the needle is advanced toward the posterior and middle aspect of the intervertebral foramen. Care is taken ensure that the needle tip remains superimposed on the bone of the facet column during advancement. In this way, the superior articular process of the facet just posterior to the foramen is contacted first, preventing needle advancement through the foramen and into the spinal canal. Once the needle contacts the facet, it is walked anteriorly into the foramen and advanced no more than another 2–3 mm. The depth is assessed by obtaining an image in the direct AP plane. To avoid direct trauma to the spinal cord and intrathecal injection, the needle should be advanced no further than halfway across the facet column. Nonionic radiographic contrast is injected under "live" or real-time fluoroscopy (or digital subtraction cineradiography) to assure that the needle tip lies in close proximity to the nerve root without any intravascular or intrathecal spread. The solution containing the steroid then can be injected safely. In our practice, we typically use 40 mg of triamcinolone acetonide or the equivalent diluted in 0.5–1 mL of 1% lidocaine.

Lumbar Transforaminal Steroid Injection The patient lies prone on the fluoroscopy table. The C-arm is rotated 20–30° lateral oblique to allow direction of the needle toward the superolateral aspect of the intervertebral foramen. A somewhat less oblique approach will result in a final needle position slightly lateral to the intervertebral foramen and has been advocated by some practitioners as a means of limiting spread of the injectate to a single nerve root. However, even small volumes of injectate will often be seen to track along the exiting nerve root to enter the lateral epidural space.

A 22- or 25-gauge, 3.5-inch spinal needle is sufficient in length for patients of average build, whereas a 5-inch needle may be needed in obese patients. To avoid the spinal nerve, the needle is advanced coaxially toward the superior aspect of the intervertebral foramen, just inferior to the pedicle and inferolateral to the pars interarticularis. This serves as an effective depth marker. Once this bony margin is contacted, the C-arm is rotated to a lateral view and the needle is slowly advanced toward the anterior and superior aspect of the foramen. If the patient reports paresthesia at any time during needle advancement, the needle should be withdrawn slightly and the position confirmed with radiographic contrast. With the needle in final position, nonionic radiographic contrast is injected under real-time fluoroscopy (or digital subtraction cineradiography) in the AP position to assure that the needle tip lies in close proximity to the nerve root without any intravascular or intrathecal spread. Obtaining a final lateral image will allow assessment of the extent of spread of the injectate.

Complications of the transforaminal technique can be catastrophic. A firm grasp of the anatomy of adjacent vascular and neural structures is essential to avoid complications during cervical and lumbar approaches (Fig. 93–5). Direct intravascular injection into the vertebral artery may produce generalized seizures when local anesthetic is used or cerebral ischemia when particulate steroid solutions are used.[64,65] Direct injection of particulate steroid into a medullary or radicular artery supplying the spinal cord at the cervical or lumbar level, respectively, can lead to catastrophic spinal cord infarction. Needle positioning toward the posterior aspect of the foramen and advancing the needle in a plane parallel to the nerve root reduces the risk of entering a vascular structure. Again, particular care should be taken when performing transforaminal injection on the left between T8 and L3, as the artery of Adamkiewicz lies between these levels. However, use of radiographic contrast injected during "live" or "real-time" fluoroscopy (or digital subtraction cineradiography) to visualize final needle position and detect any hint of intravascular injection is the only means to accurately verify that injectate is not located within an artery.

Subarachnoid injection may occur if the needle is advanced too far medially and pierces the dural cuff as it extends laterally onto the exiting nerve root. Direct trauma to the exiting nerve root or the spinal cord itself also may occur. Intradiscal placement of the needle during attempted transforaminal epidural steroid injection has been reported but usually is without sequelae.[66]

Sympathetic Blocks

Overview

The sympathetic nervous system is involved in the pathophysiology of a number of different chronic pain conditions, including complex regional pain syndrome (CRPS) and ischemic pain. These chronic pain states often are referred to as *sympathetically maintained pain* because they share the characteristic of pain relief following

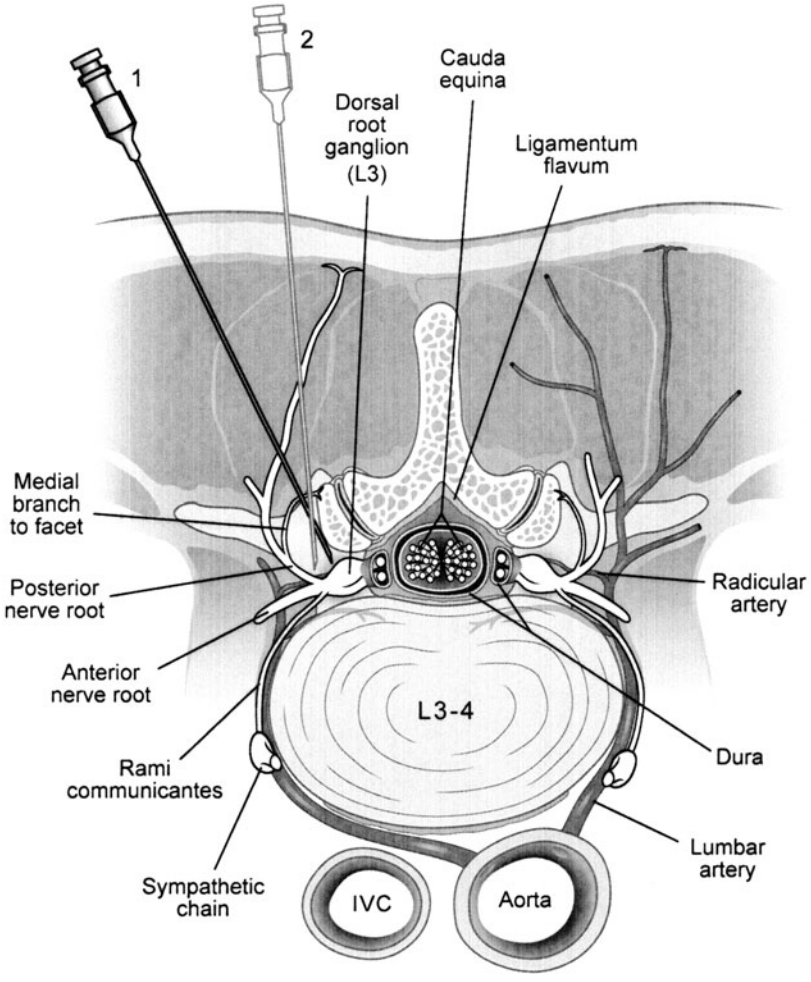

FIGURE 93–5. Axial view of lumbar transforaminal and selective nerve root injection. The anatomy and proper needle position (axial view) for right (1) L3–4 transforaminal injection and (2) L3 selective nerve root injection. (Adapted from Rathmell JP. Atlas of Image-Guided Intervention in Regional Anesthesia and Pain Medicine. Philadelphia: Lippincott Williams & Wilkins, 2006:58, with permission.)

blockade of the regional sympathetic ganglia.[67,68] In an extensive review, Cepeda et al.[69] questioned the efficacy of sympathetic blockade in the diagnosis and treatment of CRPS. In a review of 29 studies that included 1144 patients, only 29% of patients reported "full positive response" and 41% had a "partial positive response." According to these authors, most of the studies were retrospective and of poor quality. Sympathetic blockade is still widely used despite the scant evidence supporting its diagnostic and therapeutic role.[68,69] Many practitioners continue to use sympathetic blockade as a part of a multidisciplinary approach to treating CRPS; sympathetic blocks are one tool that can reduce pain and facilitate functional recovery. Blockade of the stellate ganglion has been used in the diagnosis and treatment of sympathetically maintained pain of the head, neck, and upper extremity, and 2nd lumbar sympathetic block is used for diagnosis and treatment of sympathetically maintained pain of the lower extremities.[67,70] Celiac plexus block has been used for malignant and nonmalignant pain involving the upper abdominal viscera, and several techniques have been described.[71] Celiac plexus neurolysis has been used successfully to treat pain from pancreatic cancer.[72,73] Superior hypogastric block for treatment of chronic pain arising from the bladder, uterus, rectum, vagina, and prostate has been well described.

Stellate Ganglion Block

Stellate ganglion block has long been the standard approach to diagnosis and treatment of sympathetically maintained pain syndromes involving the upper extremity, such as CRPS.[74] Other neuropathic pain syndromes, including ischemic neuropathies, herpes zoster (shingles), early postherpetic neuralgia, and postradiation neuritis also may respond to stellate ganglion block. Blockade of the stellate ganglion has proven successful in reducing pain and improving blood flow in vascular insufficiency conditions such as intractable angina pectoris,[75] Raynaud disease,[76] frostbite,[77] vasospasm, and occlusive and embolic vascular disease.[78] The sympathetic fibers control sweating; thus, stellate ganglion block can be quite effective in controlling hyperhidrosis.[79]

Patients with signs and symptoms of CRPS of the upper extremities may gain significant pain relief from stellate ganglion block.[74] Unfortunately, the duration and magnitude of the pain relief are unpredictable.[69] This led to the use of repeated sympathetic blocks, sometimes as often as daily or weekly over an extended period of time in attempt to improve the duration of pain relief. No controlled studies have ever verified this practice, and experts currently agree that repeated sympathetic blocks alone rarely eliminate the pain and disability associated with CRPS. Incorporating sympathetic blockade into a coordinated, multidisciplinary rehabilitation plan is essential for effective treatment of patients with CRPS. This treatment plan typically includes physical therapy, oral neuropathic pain medications, and supportive psychotherapy. Neuroablation has been used to destroy the sympathetic chain in patients who attain excellent pain relief of temporary duration with local anesthetic blocks. Few data evaluating the success of sympathetic ablation are available, and expert opinion regarding the usefulness of this approach in the long-term treatment of CRPS is varied.

The patient is placed supine, facing directly forward with a pillow under the upper back and lower neck to hold the neck in a slight extension. To perform the block without radiographic guidance, the operator palpates the cricoid cartilage and then slides a finger laterally into the groove between the trachea and the sternocleidomastoid muscle, retracting the muscle and adjacent carotid and jugular vessels laterally. Chassaignac's tubercle typically is palpable in this groove at the C6 level. Once the tubercle has been identified, a needle is advanced through the skin

and seated on the tubercle, where local anesthetic is injected. The local anesthetic spreads along the prevertebral fascia in a caudal direction to anesthetize the stellate ganglion, which lies just inferior to the point of injection in the same plane. In practice, marked variations in the size and shape of the Chassaignac's tubercle reduce the rate of successful block. The adjacent vertebral artery and C6 spinal nerve must be avoided to optimize conduct of this block. A simple modification of technique in which the needle is directed medially toward the base of the transverse process using radiographic guidance is a simple means of improving the reliability of stellate ganglion block and is described here.

When using fluoroscopic imaging, the C-arm is centered over the lower cervical spine without angulation. The position of the vertebral bodies and transverse processes of C6 and C7 are identified. The skin and subcutaneous tissues overlying the base of the transverse process of C6 or C7 on the affected side are anesthetized. The transverse processes are often difficult to distinguish from the underlying facet columns, but the transverse process joins the vertebral body just inferior to the uncinate process of the vertebral body, a structure that is easy to identify on the posteroanterior (PA) radiograph. The block can be carried out at either the C6 or C7 level when using radiographic guidance. However, it is important to realize that the vertebral artery overlies the base of the transverse process at C7, and many individuals lack a bony foramen transversarium at this level. Thus, at C7, care must be taken to keep the needle tip in line or medial to a line connecting the uncinate process of C7 and T1. Straying more lateral will risk penetration of the vertebral artery. The overlying carotid artery must be retracted laterally to perform the classic technique for stellate ganglion block over the C6 transverse process, but this is unnecessary when the needle is directed toward the base of the transverse process, as the needle passes medial to the great vessels of the neck.

A 25-gauge, 3-inch needle is placed through the skin and advanced coaxially until it is seated in the tissues. The needle is adjusted to remain coaxial as it is directed toward the base of the transverse process, just inferior to the uncinate process using repeat PA images after every 2–4 mm of needle advancement. Once the surface of the vertebral body is contacted, the needle is in final position. Intravascular placement is ruled out and proper position is assured by injecting radiographic contrast. The contrast should spread along the anterolateral margin of the vertebral bodies in both PA and lateral radiographs. Thereafter, 10 mL of local anesthetic (0.25% bupivacaine) is injected incrementally. Repeat radiographs following local anesthetic injection should show dilution of the contrast and spread of the solution inferiorly to the T1 level where the stellate ganglion lies. Sympathetic block should ensue within 20 minutes following injection and is assured by seeing a 1 °C or greater rise in temperature of the ipsilateral hand. Signs of successful stellate ganglion block are listed in Table 93–1.

Many important structures lie within the immediate vicinity of the needle's tip once it is properly positioned for stellate ganglion block. Commonly, diffusion of local anesthetic blocks the adjacent recurrent laryngeal nerve. This often leads to hoarseness, a feeling of having a lump in the throat, and subjective feelings of shortness of breath and difficulty swallowing. Bilateral stellate ganglion block should not be performed because bilateral recurrent laryngeal nerve blocks may lead to loss of laryngeal reflexes and respiratory compromise. The phrenic nerve is also commonly blocked by direct spread of local anesthetic and leads to unilateral diaphragmatic paresis. Diffusion of local anesthetic as well as direct placement of local anesthetic adjacent to the posterior tubercle result in somatic block of the upper extremity. This may take the form of a small area of sensory loss due to diffusion of local anesthetic or a complete brachial plexus block when the local anesthetic is placed within the nerve sheath.

Major complications associated with stellate ganglion block include neuraxial block (spinal or epidural) and seizures. Extreme medial angulation of the needle from a relatively lateral skin entry point may lead to needle placement into the spinal canal through the anterolaterally oriented intervertebral foramen. In this manner, local anesthetic can be deposited in the epidural space or, if the needle is advanced far enough, it may penetrate the dural cuff surrounding the exiting nerve root and lie within the intrathecal space. Medial angulation will direct the needle toward the trachea and esophagus and risk penetration of these structures. More likely is placement of the needle tip on the posterior tubercle and spread of local anesthetic proximally along the nerve root to enter the epidural space. In this case, partial or profound neuraxial block, including high spinal or epidural block with loss of consciousness and apnea, may ensue. Airway protection, ventilation, and intravenous sedation should be promptly administered and continued until the patient regains airway reflexes and consciousness. Because the maximal effect of epidural local anesthetic may require 15–20 minutes to develop when longer-acting local anesthetics are used, it is imperative that patients be monitored for at least 30 minutes after stellate ganglion block.

Intravascular injection during stellate ganglion block likely will result in immediate onset of generalized seizures. The carotid artery lies just anteromedial to the Chassaignac tubercle, whereas the vertebral artery lies within the bony transverse foramen just posteromedial to the tubercle. If injection occurs into either structure, the local anesthetic injected enters the arterial supply traveling directly to the brain, and generalized seizures begin rapidly and after small amounts of local anesthetic. However, because the local anesthetic rapidly redistributes, the seizures typically are brief and do not require treatment. In the event of seizure, halt the injection, remove the needle, and begin supportive care.

TABLE 93–1.

Signs of Successful Stellate Ganglion Block

- Horner Syndrome
  - Miosis (papillary constriction)
  - Ptosis (drooping of the upper eyelid)
  - Enophthalmos (recession of the globe within the orbit)
  - Anhidrosis (lack of sweating)
- Nasal congestion
- Venodilation in the hand and forearm
- Increase in temperature of the blocked limb by at least 1 °C

Celiac Plexus Block

Neurolytic celiac plexus block is among the most widely applicable of all neurolytic blocks. Neurolytic celiac plexus

block has a long-lasting benefit for 70–90% of patients with pancreatic and other intraabdominal malignancies. A meta-analysis by Eisenberg et al.[80] concluded that adequate-to-excellent pain relief can be achieved in 89% of patients in the first few weeks following the block. From 70–90% of patients still had complete pain relief during the 3-month interval prior to their death.[80] Although encouraging, interpretation of these data requires caution, as this meta-analysis is based on retrospective studies.

Several techniques for localizing the celiac plexus have been described. In the classic technique, a percutaneous posterior approach uses surface and bony landmarks to position needles in the vicinity of the plexus. Numerous reports have described new approaches for celiac plexus block using guidance from plain radiographs, fluoroscopy, CT, or ultrasound.[81–83] No single methodology has proven clearly superior with regard to safety or success rate. In recent years, general agreement has arisen that radiographic guidance is necessary to perform celiac plexus block. Many practitioners have turned to routine use of CT, taking advantage of the ability to visualize adjacent structures when performing this technique.[84]

The transcrural approach to the celiac plexus (Fig. 93–6) places the local anesthetic or neurolytic solution directly on the celiac ganglion, anterolateral to the aorta. The needles pass directly through the crura of the diaphragm en route to the celiac plexus. In contrast, splanchnic nerve block (Fig. 93–6) avoids the risk of penetrating the aorta and uses smaller volumes of solution, and the success is unlikely to be affected by anatomic distortion caused by extensive tumor or adenopathy within the pancreas. Because the needles remain posterior to the diaphragmatic crura in close apposition to the T12 vertebral body, this has been termed the *retrocrural technique.* Splanchnic nerve block is a minor modification of the classic retrocrural celiac plexus block; the only difference is that, for splanchnic block, the needles are placed more cephalad. In most cases, celiac plexus (transcrural or retrocrural) and splanchnic nerve block can be used interchangeably, with the same results. Although some strongly advocate one approach or the other, there is no evidence that either approach results in superior clinical outcomes.[71]

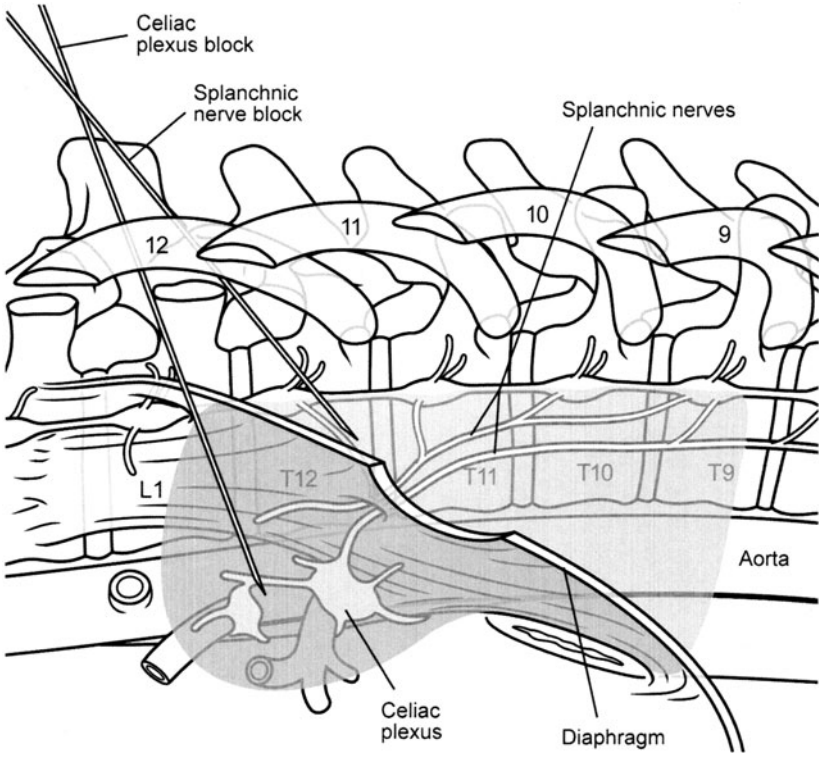

FIGURE 93–6. Anatomy of the celiac plexus and splanchnic nerves. The celiac plexus is composed of a diffuse network of nerve fibers and individual ganglia that lie over the anterolateral surface of the aorta at the T12–L1 vertebral level. Presynaptic sympathetic fibers travel from the thoracic sympathetic chain toward the ganglion, traversing over the anterolateral aspect of the inferior thoracic vertebrae as the greater (T5–9), lesser (T10–11), and least (T12) splanchnic nerves. Celiac plexus block using a transcrural approach places the local anesthetic or neurolytic solution directly on the celiac ganglion anterolateral to the aorta. The needles pass directly through the crura of the diaphragm en route to the celiac plexus. In contrast, for splanchnic nerves block, the needles remain posterior to the diaphragmatic crura in close apposition to the T12 vertebral body. Shading indicates the pattern of solution spread for each technique. (Adapted from Rathmell JP. Atlas of Image-Guided Intervention in Regional Anesthesia and Pain Medicine. Philadelphia: Lippincott Williams & Wilkins, 2006:124, with permission.)

Celiac plexus and splanchnic nerve block are used to control pain arising from intraabdominal structures. These structures include the pancreas, liver, gallbladder, omentum, mesentery, and alimentary tract from the stomach to the transverse colon. The most common application of neurolytic celiac plexus block is treatment of pain associated with intraabdominal malignancy, particularly pain associated with pancreatic cancer.[72,85] Neurolysis of the splanchnic nerves or celiac plexus can produce dramatic pain relief, reduce or eliminate the need for supplemental analgesics, and improve quality of life in patients with pancreatic cancer and other intraabdominal malignancies.[85] The long-term benefit of neurolytic celiac plexus block in patients with chronic nonmalignant pain, particularly those with chronic pancreatitis, is debatable.

Transcrural Technique Once the C-arm is aligned over the thoracolumbar junction, the skin and subcutaneous tissues overlying the superior margin of the L1 vertebral body are anesthetized. The aorta lies to the left of midline over the vertebral bodies. By routinely placing the left-sided needle first, a single needle can often be used for the block. If the aorta is penetrated en route, a transaortic technique is used. A 22-gauge, 5-inch spinal needle is advanced just caudal to the margin of the 12th rib and cephalad to the transverse process of L1 to contact the anterolateral surface of the L1 vertebral body. The C-arm is then rotated to a lateral projection and the needle advanced to lie 2–3 cm anterior to the anterior margin of L1 in the lateral view. Continuous aspiration should be applied as the needle is advanced past the anterior border of L1. If blood ap-

pears, the needle has penetrated the aorta and should be advanced through the anterior wall of the aorta until blood can no longer be aspirated. The needle tip should be medial to the lateral border of the L1 vertebral body in the AP view. Final needle position is confirmed by injecting radiographic contrast under live fluoroscopy. The contrast should layer over the anterior surface of the aorta and appear pulsatile. If the contrast spreads to both sides of midline over the anterior surface of the aorta, then only a single needle is necessary for the block. If the contrast remains to the left of midline over the anterolateral surface of the aorta, a second needle is placed from the contralateral side using the same technique described for the left-sided block. Diagnostic celiac plexus block prior to neurolysis is performed using 10–15 mL of 0.25% bupivacaine per side. The dose should be given in increments of 5 mL, aspirating periodically to assure that the needle has not moved to an intravascular location.

Splanchnic Nerve Block or Retrocrural Technique Once the C-arm is aligned, the skin and subcutaneous tissues overlying the anterolateral margin of the midportion of the T12 vertebral body are anesthetized. For splanchnic nerve block and neurolysis, needles must be placed on both sides. A 22-gauge, 5-inch spinal needle is advanced just caudal to the margin of the 12th rib and cephalad to the transverse process of L1 to contact the anterolateral surface of the T12 vertebral body. This requires 20–30° of cephalad angulation of the C-arm. The C-arm is then rotated to a lateral projection and the needle advanced 1–2 cm to align with the anterior third of the T12 vertebral body in the lateral view. The needle tip should be just medial to the lateral border of the T12 vertebral body in the AP view. Final needle position is confirmed by injecting radiographic contrast under live fluoroscopy. The contrast should layer over the anterolateral surface of the T12 vertebral body. A second needle is placed from the contralateral side using the same technique described for the left-sided block. Diagnostic splanchnic nerve block prior to neurolysis is performed using 5–8 mL of 0.25% bupivacaine per side. The dose should be given in increments of 5 mL, aspirating periodically to assure that the needle has not moved to an intravascular location.

Celiac Plexus and Splanchnic Neurolysis The technique for needle placement is identical for diagnostic local anesthetic block of the celiac plexus or splanchnic nerves and for neurolysis. The two commonly used neurolytic solutions are ethyl alcohol and phenol. Phenol is a combination of carbolic acid, phenic acid, phenylic acid, phenyl hydroxide, hydroxybenzene, and oxybenzene. There is no commercially available phenol preparation, but a solution can be prepared by a compounding pharmacist from anhydrous phenol crystals.

Phenol is highly soluble in glycerin and radiographic contrast solutions. Phenol has local anesthetic properties at lower concentrations and is neurolytic at higher concentrations. Concentrations <5% cause protein denaturation, whereas higher concentrations produce protein coagulation and segmental demyelination. Poorly myelinated and unmyelinated nociceptive fibers are destroyed at concentrations of 5–6%. Higher concentrations can produce axonal damage, spinal cord infarction, arachnoiditis, and meningitis. Large systemic doses of phenol cause effects similar to those seen with local anesthetic overdose, such as seizures and cardiovascular collapse. A 10–12% solution of phenol can be prepared in radiographic contrast. This allows radiographic monitoring of the spread of neurolytic solution as it is injected.

For celiac plexus neurolysis, 10–15 mL per side is injected. If the neurolytic solution spreads to both sides of midline over the anterior surface of the aorta, then only a single needle is necessary for the block. If the neurolytic solution begins to spread posteriorly toward the intervertebral foramen, the injection should be halted to avoid nerve root injury. During splanchnic neurolysis, the contrast should layer over the anterolateral surface of the T12 vertebral body. A second needle is placed from the contralateral side using the same technique described for the left-sided block. For splanchnic neurolysis, 5–8 mL per side is injected. The needles should be flushed with saline or local anesthetic before they are removed to avoid depositing the neurolytic solution along the needle track.

Neurolysis also can be performed using 50–100% ethyl alcohol in similar volumes. Alcohol in excess of 33% results in extraction of cholesterol, phospholipids, and cerebrosides from neural tissues. It produces nonselective destruction of neural tissue. Unlike phenol, the degree of neural blockade increases over the first several days following neurolysis; however, it is intensely inflammatory and has been associated with persistent or worsened pain and neuritis. Phenol has a direct local anesthetic effect and is associated with minimal pain on injection. Because of the intense burning pain on injection, ethyl alcohol is best diluted with local anesthetic prior to injection or injected after placing a small volume of local anesthetic.

Although the majority of cases can be carried out using fluoroscopic guidance alone, CT allows excellent visualization of the anatomic structures that lie in close proximity to the target site during neurolytic celiac plexus block.[86] To directly ablate the celiac plexus, the needles must be advanced through the diaphragm until they lie adjacent to the anterolateral surface of the aorta. This can be accomplished by advancing two separate needles adjacent to the anterolateral surface of the aorta or using a single needle advanced through the aorta.

CT-guided celiac plexus block is carried out with the patient positioned prone in the CT scanner gantry. A radiographic marker is placed on the skin surface 1 cm inferior to the inferior margin of the 12th rib and 7 cm from midline, and axial CT images extending from T12 through L1 are taken in 3-mm intervals. In this way, the position of the needle entry site on the skin's surface can be adjusted to form a direct path to the anterolateral surface of the aorta, without passing through adjacent structures. The skin is anesthetized, and a 22-gauge, 5-inch spinal needle is seated in a plane that corresponds to the axis seen on CT. With the needle seated in the subcutaneous tissue, but still superficial, a repeat CT image is obtained through the tip of the needle, and the angle of the needle is redirected toward the anterolateral surface of the aorta. The needle is advanced, and repeat CT images are obtained after every 1–2 cm of needle advancement. Once the needle is in position, a small volume of radiographic contrast is injected to

confirm needle position. A solution of neurolytic drug in radiographic contrast allows radiographic monitoring of the spread of neurolytic solution as it is injected. A repeat CT image is obtained after every 5 mL of injection. If the neurolytic solution spreads to both sides of midline over the anterior surface of the aorta, then only a single needle is necessary for the block.

Following celiac plexus block, several physiologic side effects are expected, including diarrhea and orthostatic hypotension. Blockade of the sympathetic innervation to the abdominal viscera results in unopposed parasympathetic innervation of the alimentary tract and may produce abdominal cramping and diarrhea. Likewise, the vasodilatation that ensues often results in orthostatic hypotension. These effects are invariably transient but may persist for several days after neurolytic block. The hypotension seldom requires treatment other than intravenous hydration.

Complications of celiac plexus and splanchnic nerve block include hematuria, intravascular injection, and pneumothorax. CT allows visualization of the structures that lie adjacent to the celiac ganglion as the block is being performed and may help to avoid these complications.[86] The kidneys extend between T12 and L3, with the left kidney slightly more cephalad than the right. The aorta lies over the left anterolateral border of the vertebral column. The celiac arterial trunk arises from the anterior surface of the aorta at the T12 level and divides into the hepatic, left gastric, and splenic arteries. Using the transaortic technique, caution must be used to avoid needle placement directly through the axis of the celiac trunk as it exits anteriorly. The inferior vena cava lies just to the right of the aorta over the anterolateral surface of the vertebral column.

Neurolytic celiac plexus block carries a small but significant additional risk. Intravascular injection of 30 mL of 100% ethanol will result in a blood ethanol level well above the legal limit for intoxication but below the danger limit of severe alcohol toxicity. Intravascular injection of phenol is associated with clinical manifestations similar to those of local anesthetic toxicity: CNS excitation, followed by seizures and, in extreme toxicity, cardiovascular collapse. The most devastating complication associated with neurolytic celiac plexus block is paraplegia. The actual incidence of this complication is unknown but appears to be <1:1000. The theoretical mechanism is spread of the neurolytic solution toward the posterior surface of the aorta to surround the spinal segmental arteries, specifically, the artery of Adamkiewicz.

Lumbar Sympathetic Block

Lumbar sympathetic blockade has been used extensively in the diagnosis and treatment of sympathetically maintained pain syndromes involving the lower extremities.[74] Patients with peripheral vascular insufficiency due to small-vessel occlusion also can be treated effectively with lumbar sympathetic blockade. If local anesthetic block improves blood flow and reduces pain, these patients often will benefit from surgical or chemical sympathectomy.[87]

Other patients with neuropathic pain involving the lower extremities have shown variable response to lumbar sympathetic block. In those with acute herpes zoster and early postherpetic neuralgia, sympathetic block may reduce pain.[88] However, after 3–6 months, once postherpetic neuralgia is well established, sympathetic blockade is rarely helpful. Likewise, deafferentation syndromes such as phantom limb pain and neuropathic lower extremity pain following spinal cord injury have shown variable and largely disappointing responses to sympathetic blockade.[89]

Lumbar sympathetic block typically is carried out using a single-needle technique and a large volume of local anesthetic to spread cephalad and caudad to bathe adjacent ganglia. The patient lies prone with a pillow under the lower abdomen and iliac crest to reduce lumbar lordosis. The C-arm is centered over the midlumbar region. The final needle position for lumbar sympathetic block is over the anterolateral surface of the lumbar vertebral body. The C-arm is rotated obliquely 20–30° until the tip of the transverse process of L3 overlies the anterolateral margin of the L3 vertebral body.

The ganglia of the lumbar sympathetic chain vary in number and location among individuals. The ganglia lie between L2 and L4, and in most humans the ganglia lie over the inferior portion of L2 and the superior portion of L3.[90] Thus, the optimal location for a single needle is over the anterolateral margin of the inferior portion of L2, the L2–3 interspace, or the superior margin of L3.

After the skin and subcutaneous tissues are anesthetized, a 22-gauge, 5-inch spinal needle is advanced using a coaxial technique toward the anterolateral surface of the L3 vertebral body to gently contact bone. The needle is then walked laterally off the bony margin. The C-arm is rotated to a lateral projection, and the needle is advanced until the tip lies over the anterior third of the vertebral body. Proper needle position is verified in the AP projection where the needle tip should lie medial to the lateral margin of the vertebral body.

Once the needle is in position, aspiration to detect intravascular needle placement is carried out, followed by administration of nonionic radiographic contrast. Contrast spread should be seen anterior to the L3 vertebral body. From 15–20 mL of 0.25% bupivacaine is injected incrementally. Signs of successful sympathetic blockade in the lower extremities include venodilation and temperature rise. Skin temperature should be monitored in the contralateral foot to assess for changes unrelated to the block. A rise in temperature of at least 1°C without a rise in temperature of the contralateral limb should occur with successful sympathetic block.

Lumbar Sympathetic Neurolysis

Neurolytic lumbar sympathetic block has been used in efforts to provide long-term sympathetic blockade in patients who receive only short-term pain relief with local anesthetic blocks. Lumbar sympathetic neurolysis can be accomplished using either injection of a neurolytic solution or radiofrequency lesioning. Because the locations of the lumbar sympathetic ganglia are variable, injection of neurolytic solution that spreads to encompass an area beyond the needle tip may produce more reliable neurolysis than radiofrequency treatment. Nonetheless, when the needle tips are positioned accurately, the discrete lesions resulting from radiofrequency treatment can produce effective neurolysis.[91] Although the techniques are well described, few data are available to guide the choice among chemical neurolysis, radiofrequency neurolysis, and open surgical sympathectomy.

Chemical Neurolysis Chemical neurolysis of the lumbar sympathetic chain is carried out by placing three separate needles at the L2, L3, and L4 levels, as described for local anesthetic block. The needles should be directed to the mid or inferior aspect of L2, the superior aspects of L3, and L4 to correlate with the most frequent anatomic locations of the lumbar sympathetic ganglia. Three needles are placed so that the smallest volume of neurolytic solution can be injected to treat the ganglia at each level. Once proper needle position has been confirmed in the AP and lateral projections, a small volume of radiographic contrast is placed through each needle to assure that the needles are not located intravascularly and that the injectate will layer in close apposition to the anterolateral margin of the vertebral bodies. Thereafter, 2–3 mL of neurolytic solution is placed through each needle.

Radiofrequency Neurolysis Similar to chemical neurolysis, radiofrequency neurolysis of the lumbar sympathetic chain is carried out by placing three separate 15-cm radiofrequency cannulas with 10-mm active tips over the anterolateral surface of the L2, L3, and L4 vertebral bodies. Once proper needle position has been confirmed, sensory and motor stimulation are conducted. When the cannulas are in proper position over the sympathetic ganglia, the patient typically will report vague back or abdominal discomfort with < 1.0 V of output and sensory stimulation at 50 Hz. However, the report of any sensation during sensory testing is more variable than during sensory testing before radiofrequency treatment of the facet joints. Motor stimulation is then carried out to assure that the cannulas do not lie along the course of the anterior primary ramus of one of the spinal nerve roots. There should be no muscle movement in the lower extremities during stimulation at 2 Hz at an output of at least 3V. Our practice has been to place the lesions if the cannulas appear to be in proper anatomic position even if the patient reports no pain or discomfort during sensory stimulation. Local anesthetic is added and lesions are created at 80 °C for 90 seconds.

Significant and potentially toxic levels of local anesthetic can result from direct needle placement into a blood vessel and intravascular injection during lumbar sympathetic block. Hematuria can follow direct needle placement through the kidney but usually is self-limited. Nerve root, epidural, or intrathecal injection can arise when the needle is advanced through the intervertebral foramen and usually is avoided entirely with proper use of radiographic guidance. Following neurolytic lumbar sympathetic block, significant postsympathectomy pain arises in the L1 and L2 nerve root distribution over the anterior thigh in as many as 10% of treated patients. This observation stems from results following open surgical sympathectomy, but such postsympathectomy neuralgia also has been reported after both chemical and radiofrequency sympathectomy. Postsympathectomy neuralgic pain in the anterior thigh has been postulated to result from partial neurolysis of adjacent sensory fibers, most often the genitofemoral nerve.[92]

Facet Joint Injections: Intraarticular Injections, Medial Branch Blocks, and Radiofrequency Treatment

Overview

Intraarticular facet injection has been largely supplanted by radiofrequency techniques for treatment of facet-related pain. Clinical experience and a limited number of published observational studies suggest that intraarticular injection of local anesthetic and steroid leads to relief of facet-related pain that is limited in duration.[93,94] In contrast, radiofrequency treatment is safe and modestly effective in producing longer-term pain relief in the same group of patients. Nonetheless, an understanding of facet-related pain syndromes and the methods for placing medication directly within the facet joint may still prove useful for those practitioners who are unable to provide radiofrequency treatment.

Osteoarthritis of the spine is ubiquitous and an inevitable part of aging. The degenerative cascade that leads to degeneration of the intervertebral disks causes progressive disk dehydration and loss of disk height. Typically starting in the third decade of life, disk degeneration leads to increased mobility of adjacent vertebrae and increased shear forces on the facet joints themselves. This can lead to a pattern of pain over the axis of the spine that increases with movement, particularly with flexion and extension, but produces little or no pain radiating toward the extremities. In the past, the only treatment available for those with debilitating facet-related pain was segmental fusion of the spine to completely arrest motion within the painful portion of the spine.[95]

The majority of patients have pain that is gradual in onset and can be localized only to a general region of the spinal axis.[96] However, a subgroup of patients present with sudden onset of pain, often associated with trauma in the form of sudden flexion or hyperextension of the spine in the affected region. Diagnostic studies are invariably unrevealing, showing either no abnormalities or facet arthropathy at multiple levels. In those with pain of sudden onset, it may be possible to isolate one or more facets that are causing the pain. It is in these patients with sudden onset of well-localized pain that intraarticular facet injection with local anesthetic and steroid can prove most beneficial.

Patients with facet-related pain are difficult to distinguish from those with other causes of axial spinal pain. Some patients present with sudden onset of pain following a significant flexion–extension (whiplash) injury, but more commonly the onset is insidious over months to years. Patients with myofascial or discogenic pain as well as those suffering from sacroiliac dysfunction present with similar symptoms. Nonetheless, certain features can be helpful in differentiating facet-related pain from other causes of spinal pain. The pain caused by facet arthropathy is most pronounced over the axis of the spine itself and typically is maximal directly in the region of the most affected joints. The pain tends to be exacerbated by movement, particularly extension of the spine, which forces the inflamed articular surfaces of the facet joints together. However, axial spinal pain at rest or worsening with forward flexion or rotation of the spine is another common feature. The most important historical feature is a predominance of axial spinal pain; patients who report that the predominance of their pain is in the extremities are more likely to have acute or chronic radicular pain than facet-related pain. The quality of the pain typically is deep and aching, with the pain waxing and waning with activity. Burning or stabbing qualities

suggest neuropathic pain rather than facet arthropathy.

Diagnostic studies often are unrevealing. Patients with significant facet-related pain may have unremarkable plain x-ray film and/or imaging studies of the spine, or they may show facet arthropathy at multiple levels. Patient selection for facet injection or radiofrequency treatment is empiric and relies on excluding other causes of pain and a pattern of pain that corresponds to facet-related pain.

The patterns of pain caused by abnormalities in specific facet joints have been established by injecting a mild irritant into a specific facet joints in healthy volunteers and then recording the pattern of pain produced[97–99] The levels treated are chosen by correlating the patient's report of pain to these pain diagrams. Occasionally a patient presents with evidence of facet arthropathy and a pattern of pain that corresponds to a single level, but this is uncommon. Most patients have more diffuse pain that can only be narrowed to a specific region. Treatment should be directed toward the joint(s) that most closely matches the pattern of referred pain that has been established for each joint and that typically requires treatment at more than one level.

Intraarticular Facet Joint Injections versus Radiofrequency Treatment

Choosing between intraarticular facet injection and diagnostic medial branch blocks followed by radiofrequency treatment is a frequent clinical scenario. Limited outcome studies of intraarticular injection, particularly at the cervical level, have demonstrated only transient pain relief lasting from days to weeks in most patients.[93,94,100] In a randomized trial, Marks et al.[101] showed equal pain relief in patients receiving facet joint injections and medial branch blocks. Patients who obtain significant pain relief from diagnostic blocks of the medial branch nerves may attain significant pain reduction from radiofrequency treatment that is longer lasting. Two randomized controlled trials have shown that radiofrequency ablation provides prolonged pain relief up to 6 months.[102,103] Based on this improved efficacy and a long track record of safety, increasingly more practitioners are beginning immediately with radiofrequency treatment rather than intraarticular injection. Intraarticular injection remains valuable in patients with recent-onset pain that is discrete in location and suggests involvement of a single facet joint. Intraarticular injection also is a reasonable alternative when the expertise or equipment for radiofrequency treatment is not available, but it will provide only transient symptomatic relief in patients with facet-related pain who have not responded to conservative treatment.

Intraarticular Facet Injection

Cervical Intraarticular Facet Injection The patient lies prone, facing directly toward the table with a small headrest under the forehead to allow for air flow between the table and the patient's nose and mouth. The C-arm is rotated 25–35° caudally from the axial plane without oblique angulation. This brings the axis of the x-ray path in line with the axis of the facet joints and allows for good visualization of the joints. Although the cervical facet joints also can be entered from a lateral approach with the patient lying on his or her side, advancing a needle using radiographic guidance in the AP plane allows the operator to directly see the position of the spinal canal at all times and avoid medial needle direction that could lead to spinal cord injury.

The skin and subcutaneous tissues overlying the facet joint where the block is to be carried out are anesthetized. The cervical level is easily identified by counting upward from the T1 level, where the T1 vertebra is easily distinguished by the presence of a large transverse process that articulates with the first rib. A 22-gauge, 3.5-inch spinal needle is placed through the skin and advanced until it is seated in the tissues in a plane that is coaxial with the axis of the x-ray path. The needle is then advanced in increments of 0.5–1 cm using repeat images to redirect the needle toward the facet joint. Once the surface of the joint space is contacted, a lateral radiograph is obtained, and the needle is advanced slightly to penetrate the posterior joint capsule. The needle should not be advanced into the joint between articular surfaces; this serves no purpose and is likely to abrade the articular surfaces and lead to worsened pain once the local anesthetic block subsides. Although intraarticular location of the needle tip can be confirmed with radiographic contrast, this is unnecessary if the needle location is correct in both AP and lateral planes.

Thoracic Intraarticular Facet Injection Thoracic intraarticular facet injection is not commonly used. The plane of the thoracic facet joints is steeply angled, nearing the frontal plane. Even with steep angulation of the C-arm, the joint space cannot be visualized directly but must be inferred from the position of adjacent structures. The patient is positioned prone with the head turned to one side. The C-arm is angled 50–60° in a caudad direction from the axial plane. The plane of the mid and lower thoracic facet joints lies at an angle of 60–70° from the axial plane, but further angulation of the C-arm is impractical without the image intensifier resting against the patient's back. This angle allows visualization of structures adjacent to the facet joint from which the position of the joint can be inferred. The inferior articular process (superior aspect of the joint) lies posteriorly, directly over the superior articular process (inferior aspect of the joint). The needle tip is advanced toward the inferior aspect of the joint.

The thoracic level is easily identified by counting upward from the T12 level where the 12th and lowest rib joins the T12 vertebra. A 22-gauge, 3.5-inch spinal needle is placed through the skin and advanced until it is seated in the tissues in a plane that is coaxial with the axis of the x-ray path. The needle is adjusted to remain coaxial and advanced toward the inferior margin of the joint space. Because of the joint's steep angle, the needle can be advanced only into the inferior and posterior most extent of the joint. Lateral radiography is difficult to interpret because of the overlying structures of the thorax.

Lumbar Intraarticular Facet Injection The anatomy of the lumbar facet joint and surrounding structures is illustrated in Fig. 93–7. The patient is positioned prone with the head turned to one side. The C-arm is angled obliquely 25–35° from the sagittal plane and without caudal angulation. This angle allows direct visualization of the facet joint. The skin and subcutaneous tissues overlying the facet joint where the block is to be carried out are anesthetized. The lumbar level is easily identified by counting upward from

the sacrum. A 22-gauge, 3.5-inch spinal needle is placed through the skin and advanced until it is seated in the tissues in a plane that is coaxial with the axis of the x-ray path. The needle is adjusted to remain coaxial and advanced toward the joint space.

Whether the intraarticular injection is done at the cervical, thoracic, or lumbar level, the facet joint itself holds only limited volume, typically <1.5 mL. Placing contrast in the joint will limit the ability to place local anesthetic and steroid within the joint. Intraarticular injections are commonly carried out at the lumbar levels. At this level, the articular space is Z-shaped, with the superior recess extending slightly lateral to the axis of the articular surfaces and the inferior recess extending slightly medial to the axis of the articular surfaces. Once needle position has been confirmed, a solution containing steroid and local anesthetic is placed. A total dose of 80 mg of methylprednisolone acetate or the equivalent should be divided over all of the joints to be injected, but >40 mg per joint probably is unnecessary. Using concentrated steroid (40 or 80 mg/mL) allows 1:1 mixture with local anesthetic (0.5% bupivacaine) to provide some immediate pain relief.

Complications associated with intraarticular facet injection are uncommon. The most likely adverse effect is an exacerbation of pain. This is frequent when intraarticular cervical facet injection is carried out and the needle is advanced within the joint space. The joint space is narrow, and advancing the needle within the joint can abrade the articular surfaces, causing increased pain. This exacerbation usually is self-limited. Infection can occur, leading to abscess within the paraspinous musculature, but the incidence is exceedingly low.[104] Bleeding complications have not been associated with intraarticular facet injection.

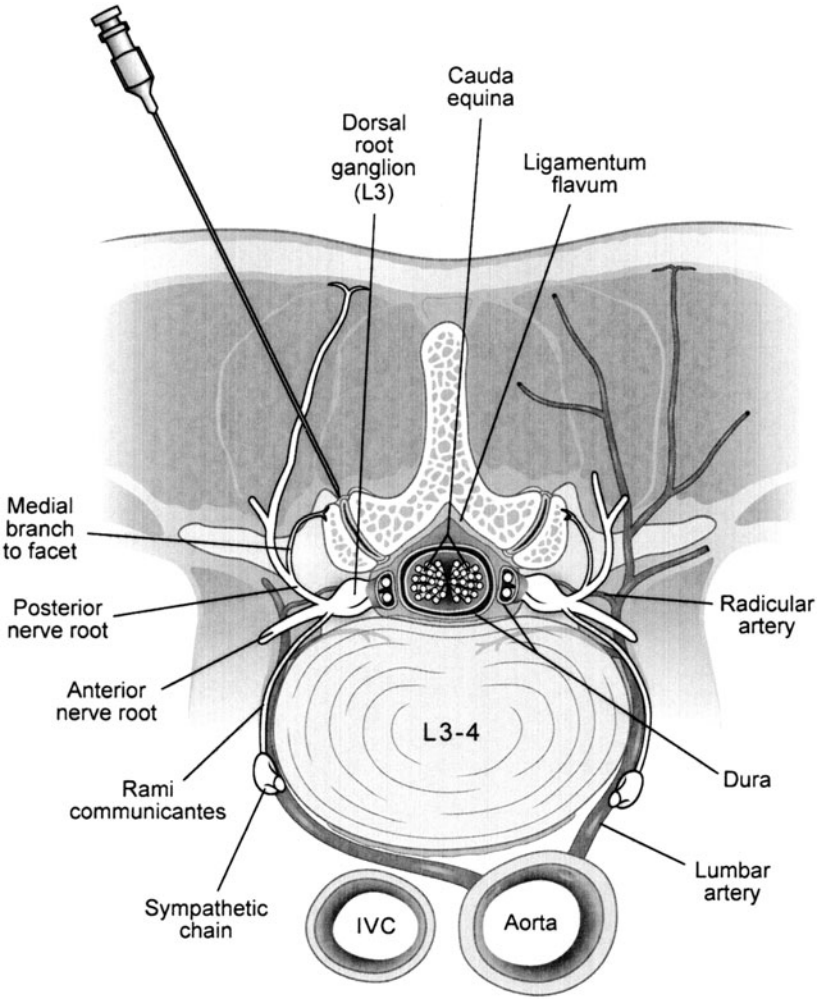

FIGURE 93–7. Axial diagram of intraarticular lumbar facet injection. The axis of the facet joint lies 25–35° from the sagittal plane. Note the innervation to the facet joint. (Adapted from Rathmell JP. Atlas of Image-Guided Intervention in Regional Anesthesia and Pain Medicine. Philadelphia: Lippincott Williams & Wilkins, 2006:76, with permission.)

Facet Medial Branch Blocks and Radiofrequency Treatment

In patients who receive only temporary relief from therapeutic intraarticular facet injections or have pain that is more diffuse, requiring treatment at numerous levels, radiofrequency treatment can produce significant, enduring pain relief. Many investigators have pointed to the need for controlled diagnostic injections to determine who will respond to radiofrequency treatment. Despite the value of placebo-controlled injections, they are impractical in most clinical settings. Most practitioners rely on a single set of diagnostic local anesthetic blocks to the medial branch nerves at the levels of suspected pathology to determine who should receive radiofrequency treatment. Patients who report significant pain relief, usually defined as ≥ 50% pain reduction lasting the average duration of the local anesthetic, go on to radiofrequency treatment. Similar, transient pain relief with intraarticular injection of local anesthetic can be used as a reasonable prognostic test before proceeding with radiofrequency treatment.

Conventional radiofrequency treatment produces a small area of tissue coagulation surrounding the active tip of an insulated cannula. When the tip of the radiofrequency cannula is placed in close proximity to a neural structure, the lesion encompasses the nerve, causing denervation. The most commonly used cannulas for facet treatment are 22-gauge SMK (Sluijter-Mehta) cannulas, which come in lengths of 5, 10, and 15 cm. These radiofrequency cannulas have a noninsulated area where coagulation occurs, called the *active tip,* which may be 4, 5, or 10 mm in length. Conventional radiofrequency damages neural tissue by creating an electrical field between the active tip of the needle connected to a voltage generator and an inactive or dispersion electrode at a distance. This induces the movement of a tissue ionic current that follows the alternating current, generating friction and, therefore, creating heat surrounding the needle tip. Radiofrequency power produces heat by current flow and not through heat transfer from the tip.[105] The lesion,

although variable, is well circumscribed and reproducible when the physical parameters are properly controlled. The size is mostly dependant on needle diameter, length of the active tip, tissue vascularization, tip temperature, and time of exposure. Lesions are characterized by a central core filled with blood related to electrode placement surrounded by an area of coagulation necrosis and separated by a wall of neuroglial proliferation from a zone of liquefaction necrosis. The lesion is surrounded by an area of demyelination.[106,107] For all but the most obese patients, the 10-cm cannulas with 5-mm active tips are used.

In recent years, pulsed radiofrequency treatment has come into frequent use. Studies that investigated the effects of nonheated tissues exposed to the electromagnetic field showed that the so-called *isothermal (42–45°C) radiofrequency procedure* induced physiologic changes in tissues.[108] Van Zundert et al.[109] showed increase in expression of c-fos in the dorsal horn of experimental animals up to 7 days after pulsed radiofrequency treatment, which suggests sustained activation of a pain-inhibiting process. Although the concept of long-lasting pain reduction without neural destruction is appealing, as yet, little clinical evidence supports the efficacy of this new technique.[110]

The key concept when using conventional versus pulsed radiofrequency is understanding where the lesion or pulse radiofrequency energy will occur relative to the active tip. The lesion produced by conventional radiofrequency is along the shaft of the needle surrounding the active tip. There is scant tissue destruction at the tip of the needle; thus, the active tip of the cannula must be placed along the course of the nerve. In contrast, the highest density of voltage change during pulsed radiofrequency emanates directly from the tip of the radiofrequency cannula; thus, the tip of the needle should be directed perpendicular to the course of the nerve to be treated. Techniques for both conventional and pulsed radiofrequency treatment are discussed here.

Cervical Facet Medial Branch Block and Radiofrequency Treatment

The medial branch nerves to the cervical facets course across the articular pillar, midway between the superior and inferior articular processes. The nerves can be anesthetized by placing a needle from a posterior or lateral approach. For the patient, the lateral approach is more comfortable because he or she can lie on one side rather than face down, and the needle must traverse less tissue en route to the target. However, when the needles are inserted from a lateral approach, they are directed toward the spinal cord; even slight rotation of the neck can lead to confusing the left and right articular pillars and result in needle entry into the spinal canal. For performing diagnostic medial branch blocks, either approach is adequate because the local anesthetic will be deposited in the same location in both approaches. For conventional radiofrequency treatment, the cannulas should be placed using a posterior approach, as this will allow the entire length of the 5-mm active tip to be placed along the course of the nerve on the articular pillar. For pulsed radiofrequency treatment, the cannulas can be placed from a lateral approach, as the voltage fluctuations are maximal at the tip of the cannula.

Posterior Approach The patient lies prone, facing directly toward the table with a small headrest under the forehead to allow for air flow between the table and the patient's nose and mouth. The C-arm is rotated 25–35° caudally from the axial plane without any oblique angulation. This brings the axis of the x-ray path in line with the axis of the facet joints and allows for good visualization of the articular pillars.

Lateral Approach The patient lies in the lateral decubitus position with a pillow under the head in order to keep the neck horizontal and minimizes lateral flexion of the neck to either side. The C-arm is placed directly over the patient's neck without rotation or angulation. Care must be taken to assure that the left and right articular pillars are aligned directly over one another. This is a point of great confusion among practitioners who are inexperienced with radiographic anatomy of the cervical spine. Even small degrees of rotation can place the left and right facet joints in significantly different locations on lateral radiographs. It is difficult to discern the left side from the right, and if a needle is advanced toward the contralateral facet target in error, the needle can easily penetrate into the spinal canal.

Diagnostic Medial Branch Blocks The cervical level can be identified by counting upward from T1 or downward from C2. Radiographically, T1 is identified in the AP view by its large transverse process that articulates with the head of the first rib, and C2 can be identified by its odontoid process in the AP view and its large spinous process in the lateral view. The skin and subcutaneous tissues overlying the facet target where the block is to be carried out are anesthetized. A 22-gauge, 3.5-inch spinal needle is placed through the skin and advanced just until it is seated in the tissues in a plane that is coaxial with the axis of the x-ray path. The needle is adjusted to remain coaxial and advanced toward the facet target in the middle of the articular pillar, midway between superior and inferior articular surfaces of the vertebra. This appears as an invagination or "waist" on AP radiographs and as a trapezoid on lateral radiographs. From the posterior approach, the needle is gently seated on the lateral margin of the facet column in the middle of the "waist"; from a lateral approach, the needle tip is seated in the middle of the trapezoid. Needle position is confirmed with AP and lateral radiographs. Once needle position has been confirmed, a small volume of local anesthetic is placed at each level and the needles are removed. The patient is instructed to assess his or her degree of pain relief in the hours immediately after the diagnostic blocks.

Radiofrequency Treatment Radiofrequency cannulas are placed using a technique identical to that described for medial branch blocks. For conventional radiofrequency treatment, 5-cm SMK cannulas with 5-mm active tips are used and placed from a posterior approach. Once the lateral margin of the facet column is contacted, the needle is walked laterally off of the facet and advanced 2–3 mm to position the active tip along the course of the medial branch nerve. Proper testing for sensory–motor dissociation is conducted. For sensory testing, the patient is asked to report pain or tingling during stimulation at 50 Hz at output < 0.5 V. Motor testing is carried out at 2 Hz, slowly

increasing the output to three times the sensory threshold. There should be no motor stimulation to the affected myotome throughout the testing period. We routinely increase the output to 3 V to rule out stimulation of the nerve root before we proceed with radiofrequency procedure. Thereafter, great care must be taken to prevent any movement of the cannulas. Each level is anesthetized prior to ablation, and lesions are created at 80°C for 60–90 seconds.

For pulsed radiofrequency treatment, 5-cm cannulas with 5-mm active tips are inserted from a lateral approach. The tip is placed in the center of the trapezoid of the target facet, midway between articular surfaces and midway between the anterior and posterior extents of the facet column. Proper testing for sensory thresholds is conducted as for conventional radiofrequency treatment. Each level then is treated with pulsed radiofrequency adequate to maintain voltage fluctuations of 40–45 V for 120 seconds, without exceeding a tip temperature of 42°C. Local anesthesia is not needed for pulsed radiofrequency treatment but can be placed before the cannulas are removed.

Thoracic Facet Medial Branch Block and Radiofrequency Treatment

The medial branch nerves to the thoracic facets course over the base of the transverse processes where they join with the superior articular processes. The patient lies prone, with the head turned to one side. The C-arm is positioned over the thoracic spine, rotated 25–35° caudally from the axial plane without any oblique angulation. The transverse processes of the thoracic vertebrae are best seen from this angle at both high and low thoracic levels.

Diagnostic Medial Branch Blocks The thoracic level can be identified by counting downward from T1 or upward from T12. The skin and subcutaneous tissues overlying the facet target where the block is to be carried out are anesthetized. A 22-gauge, 3.5-inch spinal needle is placed through the skin and advanced just until it is seated in the tissues in a plane that is coaxial with the axis of the x-ray path. The needle is adjusted to remain coaxial and advanced toward the base of the transverse process where it joins the superior articular process and seated just on the bony margin. Once the needle is in position, a small volume of local anesthetic is placed at each level and the needles are removed. The patient is instructed to assess his or her degree of pain relief in the hours immediately after the diagnostic blocks.

Radiofrequency Treatment Radiofrequency cannulas are placed using a technique identical to that described for medial branch blocks. For conventional radiofrequency treatment, 5- or 10-cm SMK cannulas with 5-mm active tips are used. Once the needle is seated against the superior margin of the transverse process where it joins the superior articular process of the facet, the cannula is walked superolaterally off of the transverse process and advanced 2–3 mm to position the active tip along the course of the medial branch nerve. Proper testing for sensory–motor dissociation is conducted as previously described. Thereafter, great care must be taken to prevent any movement of the cannulas. Each level is anesthetized and lesions are created at 80°C for 60–90 seconds. Cannula placement for thoracic pulsed radiofrequency treatment is carried out in the same manner.

Lumbar Facet Medial Branch Blocks and Radiofrequency Treatment

The medial branch nerves to the lumbar facets course over the base of the transverse process where they join with the superior articular processes (Fig. 93–8). The medial branch nerve lies in the groove between the transverse process and the superior articu-

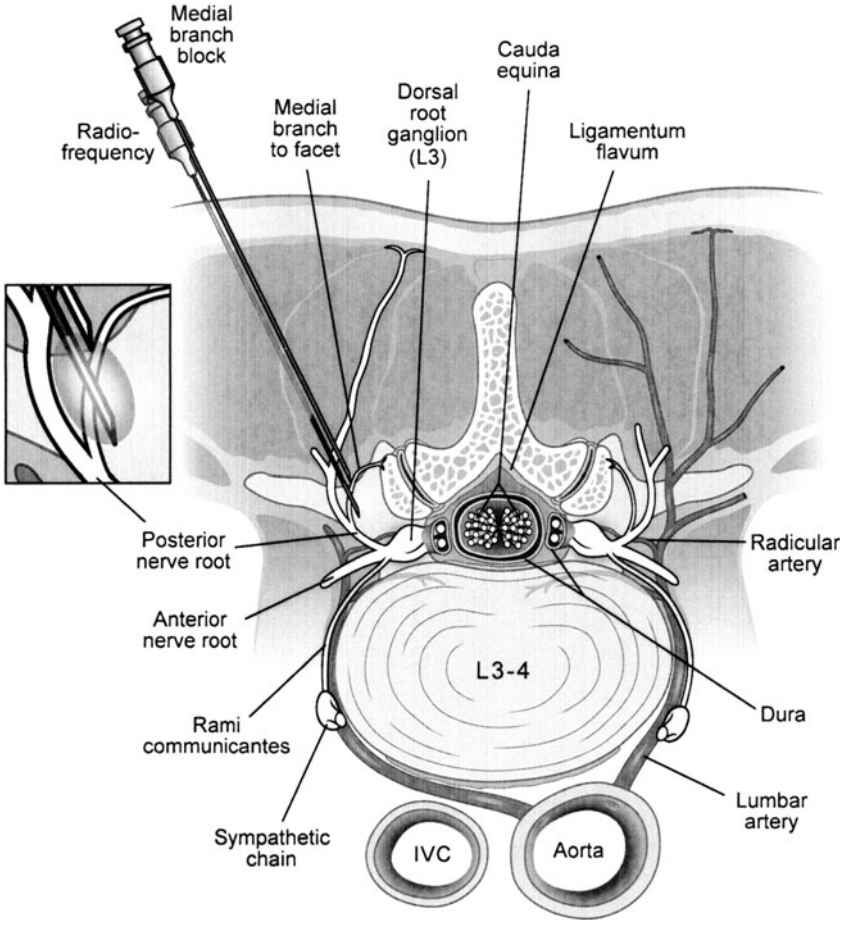

FIGURE 93–8. Axial diagram of lumbar medial branch nerve blocks and radiofrequency treatment. A 22-gauge, 3.5-inch spinal needle (or 22-gauge, 10-cm SMK radiofrequency cannula with 5-mm active tip) is advanced toward the base of the transverse process where it joins with the superior articular process. Placement of cannulas for conventional radiofrequency treatment should be carried out with 25–30° of caudal angulation of the C-arm to bring the axis of the active tip parallel to the course of the medial branch nerve in the groove between the transverse process and the superior articular process. (Adapted from Rathmell JP. Atlas of Image-Guided Intervention in Regional Anesthesia and Pain Medicine. Philadelphia: Lippincott Williams & Wilkins, 2006:89, with permission.)

lar process, which slopes inferolaterally. The patient lies prone, with the head turned to one side. A pillow is placed under the lower abdomen in an effort to tilt the pelvis backward and swing the iliac crests posteriorly away from the lumbosacral junction. The C-arm is positioned over the lumbar spine with 25–35° of oblique angulation so that the facet joints themselves and the junction between the transverse process and the superior articular process are clearly seen. For medial branch blocks, the needle can be advanced in the axial plane without caudal angulation. However, for radiofrequency treatment, the C-arm should be angled 25–30° caudal to the axial plane so that the active tip of the radiofrequency cannulas will be parallel to the medial branch nerve within the groove between the transverse process and the superior articular process as it slopes inferomedially.

Diagnostic Medial Branch Blocks The lumbar level can be identified by counting upward from the sacrum. The skin and subcutaneous tissues overlying the facet target where the block is to be carried out are anesthetized. A 22-gauge, 3.5-inch spinal needle is placed through the skin and advanced until it is gently seated in the tissues in a plane that is coaxial with the axis of the x-ray path. The needle is adjusted to remain coaxial and advanced toward the base of the transverse process where it joins the superior articular process and seated just on the bony margin. Once the needle is in position, a small volume of local anesthetic is placed at each level and the needles are removed. The patient is instructed to assess his or her degree of pain relief in the hours immediately after the diagnostic blocks.

Radiofrequency Treatment Radiofrequency cannulas are placed using a technique identical to that described for medial branch blocks; however, the C-arm is angled 25–30° caudal to the axial plane so that the active tip of the radiofrequency cannulas will be parallel to the medial branch. For conventional radiofrequency treatment, 10-cm SMK cannulas with 5-mm active tips are used. Once the needle is seated against the superior margin of the transverse process where it joins the superior articular process of the facet, the cannula is walked off of the superior margin of the transverse process and advanced 2–3 mm to position the active tip along the course of the medial branch nerve. Proper testing for sensory–motor dissociation is conducted as previously described, assuring there is no stimulation of the motor nerves to the lower extremities. Thereafter, great care must be taken to prevent any movement of the cannulas. Each level is anesthetized and lesions are created at 80°C for 60–90 seconds. Cannula placement for lumbar pulsed radiofrequency treatment is carried out in the same manner, except that the active tip need not be parallel to the medial branch nerve.

Complications of Medial Branch Block and Radiofrequency Treatment Complications associated with diagnostic medial branch nerve blocks are uncommon and similar to those following intraarticular facet injections. Unlike intraarticular injection, it is unusual for medial branch blocks to cause an exacerbation of pain. Patients should be warned to expect mild pain at the injection site lasting 1 or 2 days after the procedure. Radiofrequency treatment of the facets also is associated with few complications. Despite the fact that conventional radiofrequency produces actual tissue destruction, injury to the spinal nerve roots is uncommon, perhaps because of sensory and motor testing. Injury to the spinal nerve root has been reported following radiofrequency treatment and could present with new-onset radicular pain with or without radiculopathy. The importance of physiologic testing before each lesion should be emphasized, because this will reduce the chance that the active tip of the cannula is close enough to the anterior nerve root to cause injury.

Exacerbation of pain following conventional radiofrequency treatment is common, and patients should be instructed to expect an increase in pain, similar in character to their usual pain, that will last from several days to a week or more. A smaller group of patients will report uncomfortable dysesthesia, usually in the form of a sunburn-like feeling of the skin overlying the spinous processes and often accompanied by allodynia. This adverse effect is more common following cervical radiofrequency treatment and usually subsides over several weeks. These dysesthesias likely stem from partial denervation of the lateral branch of the posterior primary ramus, which supplies a variable region of cutaneous innervation overlying the spinous processes. Likewise, some patients will report a small patch of complete sensory loss in this same region.

Pulsed radiofrequency treatment does not produce tissue destruction, so it is not surprising that most patients will have no worsening of their pain following treatment or will have a transient, mild exacerbation that is short lived. Painful dysesthesia and other consequences of nerve injury do not occur with pulsed radiofrequency treatment. It is precisely because of this lack of neural destruction and associated adverse effects that pulsed radiofrequency treatment has become popular among practitioners. If controlled trials emerge to support the efficacy of pulsed radiofrequency treatment, it may rapidly replace conventional radiofrequency.[110]

Lumbar Discography and Intradiscal Treatments

Overview

Discography is a diagnostic test in which radiographic contrast is injected into the nucleus pulposus of the intervertebral disk. Although originally developed for the study of disk herniation, discography now is used most commonly to identify symptomatic disk degeneration. The two components of discography are (1) the anatomic appearance of contrast spread within the disk (using plain radiographs and/or CT) and (2) the presence or absence of typical pain during contrast injection within the disk (pain provocation). The usefulness of discography remains controversial. Some clinicians routinely use discography to identify symptomatic disks prior to surgical fusion or intradiscal thermal annuloplasty, whereas others believe the test is of unproven benefit in identifying symptomatic disks.[111,112] Discography remains the only test available that attempts to correlate pain response from the patient during provocation with abnormal disks discovered on imaging studies. Improved surgical outcomes following lumbar fusion have been reported when guided by the use of discography.[112–115] Intradiscal electrothermal therapy (IDET) is a minimally invasive procedure that offers an

alternative treatment to a subset of those patients with discogenic low back pain. Much like its use prior to fusion, discography is used to identify symptomatic intervertebral disks prior to IDET.[116]

The patient with low back or neck pain originating from the vertebral disk often presents with deep, achy, axial midline pain. Pain can be referred to the buttocks and posterior thigh from lumbar disks but does not extend to the distal extremities. Patients with discogenic pain often are young and otherwise healthy. Discogenic pain is common in those with jobs that require repetitive motion of the affected spine segment (e.g., package handlers) or which expose the spine to excessive vibration (e.g., long-distance truck drivers, helicopter pilots, and jack-hammer operators). Onset of symptoms usually is gradual. Pain is experienced with prolonged sitting (sitting intolerance), standing, and bending forward. The referred pain usually remains in the proximal part of the extremity. Results of physical examination usually are nonspecific, with limited range of motion at the affected segment or pain with movement, particularly on flexion.

Proponents of discography argue that MRI and CT reveal only nonspecific findings, such as loss of disk height and/or hydration. Jensen et al.[117] showed that >50% of asymptomatic patients have abnormal findings on MRI scans, in at least one intervertebral disk. The presence of a high-intensity zone on MRI at the posterior aspect of the disk indicates that a radial tear of fissure may be present in the annulus fibrosis, again a nonspecific finding common in individuals without back pain.

Treatment for discogenic pain starts with conservative therapy, including physical therapy and oral nonsteroidal antiinflammatory drugs. In those with prolonged or disabling pain that is suspected to be of discogenic origin, provocative discography can help to identify the affected level and guide targeted therapy.

Diagnostic Lumbar Discography

Lumbar discography is a painful procedure, even when performed by the most skilled practitioners. Intravenous sedation can facilitate the procedure; however, caution must be used to avoid oversedation, which could impede ongoing communication with the patient. The patient must be able to report paresthesias before neural injury occurs. Discography relies on the patient reporting the location and severity of symptoms during provocation, and excessive sedation can make interpretation of the results difficult.[118]

The patient lies prone, with the head turned to one side. A pillow is placed under the lower abdomen, above the iliac crest in an effort to reduce the lumbar lordosis. Having the patient rotate the inferior aspect of the pelvis anteriorly toward the table will tip the iliac crest posteriorly and often is key to successfully performing discography at the L5–S1 level. The C-arm is rotated 25–35° obliquely centered on the disk space to be studies. The C-arm is then angled in a caudad–cephalad direction; the degree varies among patients, depending on the disk to be studied and each patient's degree of lumbar lordosis. In general, the L3–4 disk lies close to the axial plane and requires no cephalad angulation to align the vertebral end plates; the L4–5 disk requires 0–15° of cephalad angulation; and the L5–S1 disk requires 25–35° of cephalad angulation (Fig. 93–9). Proper alignment of the C-arm is critical to the safety and success of discography.

The skin and subcutaneous tissues overlying the disk space where discography is to be carried out are anesthetized, and additional local anesthetic is instilled liberally as the needle is advanced. A 22-gauge, 5-inch spinal needle is placed through the skin and advanced just until it is seated in the tissues in a plane that is coaxial with the axis of the x-ray path. A 7- or 8-inch spinal needle is often required in obese patients and is often needed at the L5–S1 level because of the long and oblique trajectory to the disk space. Without careful use of a coaxial technique throughout the entire course of needle advancement, discography will require multiple repositionings of the needle, if it can be done successfully at all. The direction of the needle should

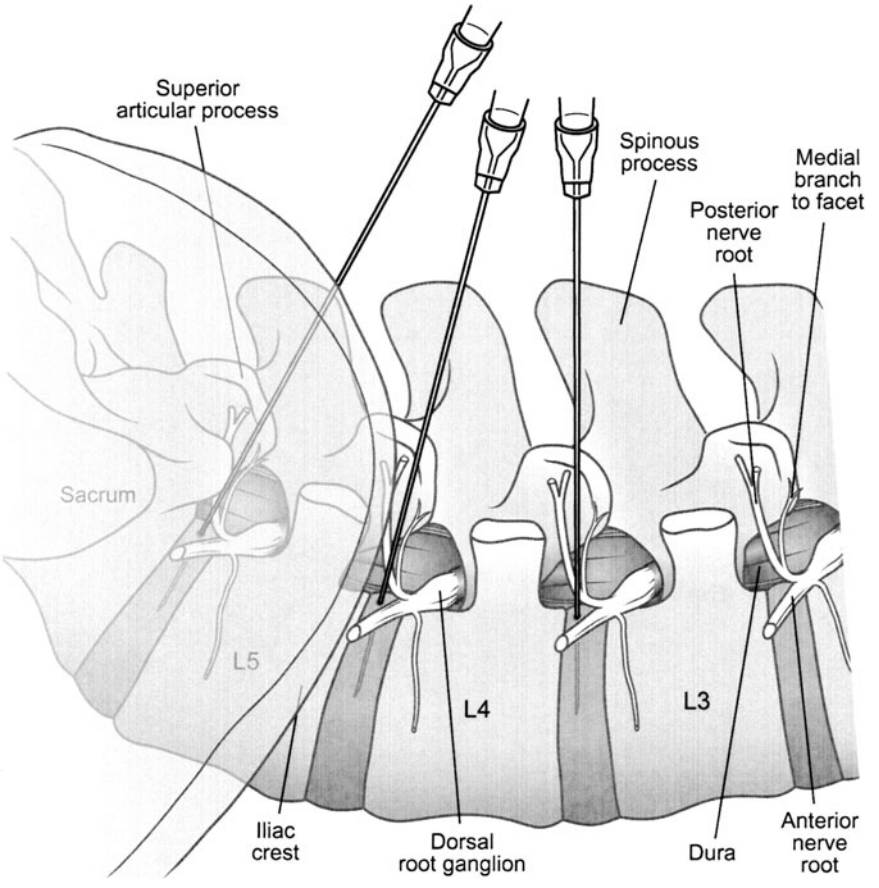

FIGURE 93–9. Anatomy of the lumbar intervertebral disks. In general, the L3–4 disk lies close to the axial plane, the L4–5 disk is angled caudally 0–15°, and the L5–S1 disk is angled caudally 25–35°. Needles can be safely inserted into each disk through the posterolateral aspect of the annulus fibrosis, just caudal to the exiting nerve root. (Adapted from Rathmell JP. Atlas of Image-Guided Intervention in Regional Anesthesia and Pain Medicine. Philadelphia: Lippincott Williams & Wilkins, 2006:102, with permission.)

be rechecked after every 1–1.5 cm of needle advancement and adjusted to remain coaxial. The position of the exiting nerve root beneath the pedicle should be kept in mind at all times, and efforts to assure that the needle does not stray cephalad or lateral to the intended point over the middle of the disk will reduce the likelihood of striking the nerve root en route to the disk.

Once the needle is in contact with the surface of the disk, there will be a notable increase in resistance to needle placement. At this point, the C-arm should be rotated to a lateral position and the needles advanced halfway from the anterior to the posterior margin of the disk. Proper final placement is then checked in the AP plane, where again the needle should be in the midportion of the disk space. The nucleus pulposus occupies the central third of the disk space, and placement of the needle tip anywhere within the nucleus should suffice. The final needle path lies just inferior to the exiting nerve root, and in many patients it is difficult or impossible to position the needle exactly in the center of the disk.

Once the needles are in final position at all levels to be tested, provocative testing is carried out. A small volume of radiographic contrast containing antibiotic is placed at each level (<1.5 mL of iohexol 180 mg/mL containing 1 mg/mL of cefazolin). The contrast material is injected under live fluoroscopy to observe the pattern of contrast spread within the disk. As the contrast is injected, the resistance to injection is noted and the patient is questioned about his or her symptoms. Some practitioners use an inline pressure monitoring device to assure that excess pressure is not delivered during the provocative test. Some evidence indicates that pain reproduction using small volumes without excessive pressure during injection correlates most closely with symptomatic discogenic pain; injection under high pressure or with large volumes may well produce pain even in normal disks.[119]

A concordant discogram result occurs when the patient reports his or her typical pattern of severe pain during injection at the level of suspected pathology and the same patient reports no pain on injection of an adjacent disk that is normal in appearance.[118,120] After injection of all levels, final AP and lateral radiographs should be obtained to document the levels tested and the patterns of contrast spread during injection. Some practitioners advocate for subsequent CT to assess the patterns of disk disruption using axial imaging, but the usefulness of CT discography in planning subsequent therapy is unclear.

Complications of Lumbar Discography The majority of patients experience a marked exacerbation of their typical back pain in the days following discography. They should be warned to expect this pain and given a short course of oral analgesics for treatment of the exacerbation. Less commonly, injury to the exiting nerve roots occurs. The position of the nerve roots is in close proximity to the needle's path. Care must be taken to advance the needle slowly as it passes over the transverse process en route to the posterolateral margin of the disk. If the patient reports a paresthesia to the lower extremity, the needle should be withdrawn and redirected. Paresthesia will occur in a small proportion of patients, even with good technique. Persistent paresthesiae are uncommon and typically ensue only after repeated paresthesias occur during the procedure.

Infection can occur, leading to abscess within the presacral musculature, but the incidence is exceedingly low. Infection within the disk space (discitis) is the most feared complication of discography, with an incidence <1:1000. Treatment of discitis may require long-term administration of intravenous antibiotics and/or surgical removal of the infection. No cases of discitis occurring in patients who received intradiscal antibiotics during discography have been reported. Bleeding complications have not been associated with intradiscal injection.

Intradiscal Electrothermal Therapy

Spinal fusion has been reserved for patients with advanced disk degeneration, with clinical results varying between 46% and 82%.[95,114] Patients who have early degenerative disk disease with preservation of near-normal disk height (>75% of normal disk height remaining) but severe ongoing back pain that does not improve with conservative therapy may be adequate candidates for intradiscal thermal coagulation (Intradiscal Electrothermal Therapy, Smith & Nephew, Andover, MA).[121] The mechanism of action of IDET is unclear, but thermal energy has been shown to coagulate neural tissue[122] and induce collagen denaturation,[123] thereby addressing both nociceptive and mechanical aspects of discogenic pain.[124] Early prospective studies demonstrated significant pain reduction and improvement in physical function in 30–50% of patients treated with IDET.[121,124] However, two randomized controlled trials comparing IDET to placebo have reached conflicting conclusions.[125,126]

Patients suitable for IDET present with concordant pain on discography at one or two spinal levels and no pain during provocation of an adjacent control disk. IDET makes use of a navigable thermal resistance wire that is placed percutaneously and positioned along the posterior aspect of the of the annulus fibrosis. Once in position, the disk is heated using a standardized protocol. Like discography, IDET is a painful procedure, even when performed by the most skilled practitioners. Intravenous sedation can facilitate the procedure, but a level of sedation that allows for ongoing communication with the patient is essential. The patient must be able to report paresthesias or excess discomfort during intradiscal treatment before neural injury occurs. Placement of cannulas for IDET is identical to that for needle placement during discography. The patient lies prone, with the head turned to one side. A pillow is placed under the lower abdomen, above the iliac crest in an effort to reduce the lumbar lordosis. The C-arm is rotated 25–35° degrees obliquely centered on the disk space to be studies. The C-arm is then angled in a caudad–cephalad direction that varies among patients, depending on the disk to be studied and the degree of lumbar lordosis.

Like discography, the L3–4 disk lies close to the axial plane and requires no cephalad angulation to align the vertebral end plates; the L4–5 disk requires 0–15° of cephalad angulation; and the L5–S1 disk requires 25–35° of cephalad angulation. Proper alignment of the C-arm is critical to the safety and success of IDET. The technique for placing the cannulas through which the IDET catheter is introduced into the disk is similar to that for needle placement for discography. However, the best final position of the introducer is in the anterolateral aspect of the nucleus rather than the central portion of the

nucleus. This allows for a more gradual angle as the IDET catheter exits the introducer and curves around the inner aspect of the annulus. The skin and subcutaneous tissues overlying the disk space where IDET is to be carried out are anesthetized, and additional local anesthetic is instilled liberally as the cannulas are advanced. A 17-gauge introducer supplied by the manufacturer is placed through the skin and advanced just until it is seated in the tissues in a plane that is coaxial with the axis of the x-ray path. The IDET introducer is stiff and easy to redirect and advance. The direction of the cannula should be rechecked after every 1–1.5 cm of needle advancement and adjusted to remain coaxial. The position of the exiting nerve root beneath the pedicle should be kept in mind at all times, and efforts to assure that the needle does not stray cephalad or lateral to the intended point over the middle of the disk will reduce the likelihood of striking the nerve root en route to the disk.

Once the needle is in contact with the surface of the disk, there will be a notable increase in resistance to needle placement. At this point, the C-arm should be rotated to a lateral position and the needles advanced halfway from the anterior to the posterior margin of the disk. Proper final placement is then checked in the AP plane, where again the needle should be in the midportion of the disk space.

Once the IDET introducer is in satisfactory position, the navigable thermal resistance wire (SPINECATH, Smith & Nephew) is introduced. The tip of the wire slides along the medial circumference of the annulus and can be guided by gently rotating the proximal end of the catheter. The catheter is first advanced beyond the tip of the introducer and into the disk space using lateral radiography. When the tip of the catheter passes to the posterior aspect of the annulus and begins to traverse along the posterior annulus, the C-arm is rotated to the AP view, and the catheter is advanced to final position across the entire posterior annulus. The catheter has two radiopaque guides that indicate the active treatment portion of the catheter. These markers should be positioned to either side of the disk to indicate that the entire posterior annulus will be treated.

This brief description is simplistic; guiding the IDET catheter to final position can be quite challenging and requires delicate manipulation of the catheter to keep the tip from advancing into radial tears within the annulus. Overaggressive handling of the catheter will cause it to kink, and, once kinked, the catheter will be difficult or impossible to steer.

Once the catheter is in final position, heat is introduced using a specific protocol designed to gradually raise the temperature within the disk to 80–90°C and maintain that temperature for a minimum treatment period, typically 14–16 minutes. It is important that the patient is not overly sedated during the actual heat treatment so that he or she can report discomfort due to excess heat, before neural injury occurs.

Complications of IDET Patients should be warned of the typical postprocedural flareup in pain symptoms that occurs after IDET. This results in an exacerbation of typical axial back pain, often lasting several days to weeks. Less commonly, injury to the exiting nerve roots occurs. The position of the nerve roots is in close proximity to the needle's path. Care must be taken to advance the needle slowly as it passes over the transverse process en route to the posterolateral margin of the disk. If the patient reports a paresthesia to the lower extremity, the needle should be withdrawn and redirected. Paresthesia occurs in a small proportion of patients, even with good technique. Persistent paresthesias are uncommon and typically ensue only after repeated paresthesias occur during the procedure.

Cauda equina syndrome, with severe neuropathic pain in the lower extremities as well as bowel and bladder dysfunction, has been reported to occur from IDET.[127,128] Injury to the cauda equina is more likely to occur when there is an insufficient posterior annulus and the thermal catheter lies in close proximity to the thecal sac. The catheter can exit the disk space to enter the epidural space; however, this should be evident before treatment on lateral radiographs. Assuring that the patient is sufficiently awake to report excessive discomfort during the IDET treatment should reduce the chances of significant neural injury. Finally, overaggressive handling of the IDET catheter leads to kinking of the catheter near the point where it exits the tip of the introducer within the intervertebral disk. Repeated attempts to reposition the catheter once it is kinked can lead to shearing of the catheter tip. Catheter breakage and migration of the tip have been described.[129]

A key to successful outcome following IDET is strict adherence to a structure rehabilitation program that guides the patient through gradual increases in physical activity over a 6-week to 3-month time period. Rehabilitation following IDET is similar to the programs used following lumbar fusion.

Implantable Drug Delivery Systems and Spinal Cord Simulation

Implantable Drug Delivery Systems

Intrathecal morphine and other opioids are now widely used as useful adjuncts in the treatment of acute and chronic pain. A number of agents show promise as analgesic agents with spinal selectivity. Continuous delivery of analgesic agents at the spinal level can be carried out using percutaneous epidural or intrathecal catheters, but vulnerability to infection and the cost of external systems typically limit them to short-term use (<6 weeks). Reliable implanted drug delivery systems are available that make long-term delivery of medications to the intrathecal space feasible. These systems consist of a drug reservoir/pump implanted within the subcutaneous tissue of the abdominal wall, which is refilled periodically through an access port. The pump may be a fixed-rate, constant-flow device or a variable-rate pump that can be programmed using a wireless radiofrequency transmitter similar to those used for implanted cardiac pacemakers.

The intrathecal catheter is placed directly within the CSF of the lumbar cistern by advancing a needle between vertebral laminae at the L2–3 level or below. Direct delivery of the opioid at the spinal level corresponding to the dermatome in which the patient is experiencing pain may improve analgesia, particularly when local anesthetics or lipophilic opioids (e.g., fentanyl or sufentanil) are used. Thus, in the past, some practitioners advocated threading the catheter cephalad to the appropriate dermatome. Unfortunately, cases of inflammatory mass formation surrounding the catheter tip of some indwelling intrathecal catheters

have been reported.[130–134] These inflammatory masses often present with gradual neurologic deterioration caused by spinal cord compression. Currently, many physicians recommend that implanted intrathecal catheters be placed only within the lumbar cistern below the conus medullaris, where the appearance of an inflammatory mass is less likely to directly impinge on the spinal cord.[135]

Patient selection for intraspinal pain therapy is empiric and remains the subject of debate. In general, intrathecal drug delivery is reserved for patients with severe pain that does not respond to conservative treatment.[135] Most patients with cancer have ongoing pain despite appropriate oral opioid therapy, or they develop intolerable side effects related to these medications. Randomized controlled trials comparing maximal medical therapy with intrathecal drug delivery for cancer-related pain have demonstrated improved pain control and reduction in opioid-related side effects in patients who received intrathecal pain therapy.[136] Intrathecal drug delivery has been widely used for noncancer pain, particularly for treatment of chronic low back pain.[137] However, use of this therapy in noncancer pain has not been subject to controlled trials and remains controversial.[138]

Once a patient is selected for intrathecal therapy, a trial is performed. Most physicians now conduct trials by placing a temporary percutaneous intrathecal catheter and infusing the analgesic agent over several days to judge the effectiveness of this therapy *before* a permanent system is implanted. Some carry out the trial of intrathecal therapy using a single dose or a continuous epidural infusion. The most common analgesic agent used for spinal delivery is morphine, which remains the only opioid approved by the FDA for intrathecal use.

It is important to discuss the benefits and risks involved in the procedure with the patient and his or her family. Before the procedure, discuss with the patient the location of the pocket for the intrathecal pump. Most devices are large, and the only region suitable for placement is the left or right lower quadrant of the abdomen. Once the site is determined, mark the proposed skin incision with a permanent marker while the patient is in the sitting position. The position of the pocket on the abdominal wall is deceptively difficult to determine once the patient is lying on his or her side. If the location is not marked, the pocket is often placed too far lateral within the abdominal wall.

Implantation of an intrathecal drug delivery system is a minor surgical procedure that is performed in the operating room using aseptic precautions, including skin preparation, sterile draping, and use of full surgical attire.[139] The procedure can be conducted under either local anesthesia or general anesthesia using dedicated anesthesia personnel. Performing the initial spinal catheter placement under general anesthesia is controversial, and concerns about neural injury are similar to those associated with any neuraxial technique performed under general anesthesia.[140]

The patient is positioned on a radiolucent table in the lateral decubitus position with the patient's side for the pump pocket nondependent. The arms are extended at the shoulders and secured in position so that they are well away from the surgical field. The skin is prepared, and sterile drapes are applied. The radiographic C-arm is positioned across the lumbar region to provide a cross-table AP view of the lumbar spine. Care must be taken to assure that the x-ray view is not rotated by observing that the spinous processes are indeed in the midline, halfway between the vertebral pedicles.

Surgical Technique

The L4–5 or L5–S1 interspace is identified using fluoroscopy. The spinal needle supplied by the intrathecal device manufacturer must be used to assure that the catheter will advance through the needle without damage. The needle is advanced using a paramedian approach starting 1–1.5 cm lateral to the spinous processes and just inferior to the superior margin of the lamina that forms the inferior border of the interspace you plan to enter. The needle is directed to enter the spinal space in the midline. After dural penetration, the stylette is removed to assure adequate flow of CSF. Using fluoroscopic guidance, the spinal catheter is advanced through the needle until the tip is well into the spinal space but below L2. Position of the catheter tip is verified using fluoroscopy in the AP and lateral planes. The needle is then withdrawn slightly (~1–2 cm) but left in place around the catheter within the subcutaneous tissues to protect the catheter during the subsequent dissection. The catheter is secured to the surgical field using a small clamp to assure that it does not fall outside of the sterile field.

A 5- to 8-cm incision parallel to the axis of the spine is extended from just cephalad to just caudad to the needle, extending directly through the needle's skin entry point. The subcutaneous tissues are divided using blunt dissection until the lumbar paraspinous fascia is visible surrounding the needle shaft. A pursestring suture is created within the fascia surrounding the needle shaft. This suture is used to tighten the fascia around the catheter and prevent backflow of CSF, which may lead to a chronic subcutaneous CSF collection. The needle is removed, taking care not to dislodge the spinal catheter. Free flow of CSF from the catheter should be evident after the needle is removed; if no CSF flows from the catheter, a blunt needle can be inserted within the end of the catheter and gentle aspiration used to assure that the catheter remains within the thecal sac. If CSF cannot be aspirated from the catheter, it should be removed and replaced. Once the provider is certain that the catheter is adequately placed, it is then secured to the paraspinous fascia using a specific anchoring device supplied by the manufacturer.

Attention is now turned to creating the pocket within the patient's abdominal wall. A 10- to 12-cm transverse incision is made along the previously marked line, and a subcutaneous pocket is created using blunt dissection. The pocket should always be created caudad to the incision. If the pocket is placed cephalad to the incision, the weight of the device on the suture line is likely to cause wound dehiscence. In many patients, the blunt dissection can be accomplished using gentle but firm pressure with the fingers. It is simpler and less traumatic to use a small pair of surgical scissors to perform the blunt dissection. After the pocket is created, the pump is placed in the pocket to assure that the pocket is large enough. The pump should fit completely within the pocket without any part of the device extending beneath the incision.[139] With the device in place, the wound margins must fall into close apposition. There should be no tension on

the sutures during closure of the incision or the wound is likely to dehisce.

After pocket creation is completed, a tunneling device is extended within the subcutaneous tissues between the paraspinous incision and the pocket. The catheter is then advanced through the tunnel (most tunneling devices place a hollow plastic sleeve in the subcutaneous tissue through which the catheter can be advanced from the patient's back to pump pocket). The catheter is trimmed to a length that allows for a small loop of catheter to remain deep to the pump and attached to the pump. The pump is placed in the pocket, with a loop of catheter deep to the device. This loop allows for patient movement without placing tension on the distal catheter and causing it to be pulled from the thecal sac. Two or more sutures should be placed through the suture loops or mesh enclosure surrounding the pump and used to secure the pump to the abdominal fascia. These simple retaining sutures prevent the pump from rotating or flipping within the pocket. The skin incisions are then closed in two layers: a series of interrupted subcutaneous sutures to securely close the fascia overlying the pump and the catheter, followed by a skin closure using suture or staples.

Surgical Technique for Permanent Epidural Catheter Placement

For placement of a permanent epidural catheter, patient positioning and use of fluoroscopy are similar to those described for intrathecal catheter placement. The interspace of entry varies with the dermatomes that are to be covered, particularly if local anesthetic solution is to be used. A typical loss-of-resistance technique is used to identify the epidural space, and a Silastic catheter is threaded into the epidural space. A paraspinous incision is created, and the catheter is secured to the paraspinous fascia as described for intrathecal catheter placement.

Two types of permanent epidural systems are available: (1) a totally implanted system using a subcutaneous port that is accessed by a needle placed into the port through the skin and (2) a percutaneous catheter that is tunneled subcutaneously but exits the skin to be connected directly to an external infusion device.

To place a permanent epidural with a subcutaneous port, a 6- to 8-cm transverse incision is made overlying the costal margin halfway between the xiphoid process and the anterior axillary line. A pocket is created overlying the rib cage using blunt dissection. The catheter is then tunneled from the paraspinous region to the pocket as described for intrathecal catheter placement and secured to the port. The port must then be sutured securely to the fascia over the rib cage. Care must be taken to assure that the port is secured firmly in a region that overlies the rib cage. If the port migrates inferiorly to lie over the abdomen, it becomes difficult to access. The rigid support of the rib cage holds the port firmly from behind, allowing for easier access to the port. The skin incisions are then closed in two layers: a series of interrupted subcutaneous sutures to securely close the fascia overlying the catheter, followed by a skin closure using suture or staples.

To place a permanent epidural without a subcutaneous port, a tunneling device is extended from the paraspinous incision to the right upper abdominal quadrant, just inferior to the costal margin. A small incision (~0.5 cm) is made to allow the tunneling device to exit the skin. Percutaneous epidural catheters are supplied in two parts: the distal portion of the catheter that is placed within the epidural space, and the proximal portion of the catheter that enters the abdominal wall and connects with the distal portion of the catheter. The proximal portion of the catheter is secured to the tunneling device and pulled through the incision in the abdominal wall subcutaneously to emerge from the paraspinous incision. Many catheters are supplied with an antibiotic-impregnated cuff that is designed to arrest entry of bacteria along the track of the catheter. This cuff should be placed approximately 1 cm from the catheter's exit site along the subcutaneous catheter track. The proximal and distal portions of the catheter are trimmed, leaving enough catheter length to assure that there is no traction on the catheter with movement. The two ends of the catheter are connected using a stainless steel union supplied by the manufacturer and sutured securely. The paraspinous skin incision is closed in two layers with a series of interrupted subcutaneous sutures to securely close the fascia overlying the catheter, followed by a skin closure using suture or staples. The skin incision at the epidural catheter's exit site in the right upper quadrant is closed around the base of the catheter using one or two simple interrupted sutures.

Complications

Bleeding and infection are risks inherent to all open surgical procedures. Bleeding within the pump pocket can lead to a hematoma surrounding the pump that may require surgical drainage. Bleeding along the subcutaneous tunneling track often causes significant bruising in the region but rarely requires treatment. Similar to other neuraxial techniques, bleeding within the epidural space can lead to significant neural compression. Infection of drug delivery devices is infrequent (range 2.5–9%), and the majority of infections involve the pump pocket site.[139] Signs of infection within the pump pocket typically occur within 10–14 days of implantation but may occur at any time. Some practitioners have reported successful treatment of superficial infections of the area overlying the pocket with oral antibiotics aimed at the offending organism and close observation alone. However, infections within the pocket or along the catheter's subcutaneous course almost universally require removal of all implanted hardware and treatment with parenteral antibiotics to eradicate infection. Catheter and deep-tissue infections can extend to involve the neuraxis and result in epidural abscess formation and/or meningitis. Although meningitis is rare, each time a pump is refilled provides an opportunity for the drug to become contaminated during preparation or for the pump reservoir to become contaminated during needle penetration.[139] Permanent epidural catheters without subcutaneous ports have a higher infection rate than those with ports in the first weeks after placement, but both systems have a similar high rate of infection when left in place for more than 6–8 weeks.[141]

Spinal cord injury during initial catheter placement has been reported.[142,143] Most practitioners recommend placing the catheter only in the awake patient so that the patient can report paresthesia during needle placement. However, this is a topic of some debate, and placement of the intrathecal catheter under general anesthesia using radiographic guidance below the level of the conus med-

ullaris (~L2) is considered appropriate by some physicians. The catheter can be placed incorrectly within the subdural compartment or the epidural space. In both cases, free flow of CSF will not follow, indicating improper location of the catheter tip.

Wound dehiscence and pump migration are infrequent problems. Assuring that the size of the pocket is sufficient to prevent tension on the suture line at the time of wound closure is essential to minimize the risk of dehiscence. Pump migration usually occurs because retaining sutures were omitted at the time of pump placement. Placing two or more sutures through the suture loops or mesh on the pump and securely fastening them to the abdominal fascia will minimize the risk of pump migration.

Subcutaneous collection of fluid surrounding the pump (seroma) can be problematic and typically follows pump replacement. Percutaneous drainage of the sterile fluid collection often is successful in resolving the problem. Subcutaneous collection of spinal fluid, particularly in the paraspinous region, can develop, even many months after pump placement. This complication can be managed with observation alone unless the fluid collection is large or painful; in these instances, neurosurgical exposure of the spinal catheter as it enters the dura and placement of a pursestring suture around the catheter to eliminate the spinal fluid leak may be needed.

Spinal Cord Stimulation

The idea that direct stimulation of the ascending sensory tracts within the spinal cord might interfere with the perception of chronic pain is founded in everyday observations. We all are familiar with the fact that rubbing an area that has just been injured seemingly reduces the amount of pain coming from that injured region. The advent of transcutaneous electrical stimulation (TENS) whereby a light, pleasant electrical current is passed through surface electrodes in the region of ongoing pain reinforced the observation that stimulation of sensory pathways reduces pain perception in chronic pain states. In 1965, Patrick Wall, a neurophysiologist exploring the basic physiologic mechanisms of pain transmission, and Ronald Melzack, a psychologist working with patients who had chronic pain, together proposed the Gate Control Theory to explain how non-noxious stimulation can reduce pain perception.[144] In their theory, they proposed that second-order neurons at the level of the spinal cord dorsal horn act as a "gate" through which noxious stimuli must pass to reach higher centers in the brain and be perceived as pain. If these same neurons receive input from other sensory fibers entering via the same set of neurons within the spinal cord, the non-noxious input can effectively close the gate, preventing simultaneous transmission of noxious input. Thus, the light touch of rubbing an injured region or the pleasant electrical stimulation of TENS closes the gate to the noxious input of chronic pain. From this theory, investigators developed the concept of direct activation of the ascending fibers within the dorsal columns that transmit nonpainful cutaneous stimuli as a means of treating chronic pain.

We have learned much about the anatomy and physiology of pain perception since the gate control theory was first proposed. It is unlikely that the simplistic notion of a gate within the dorsal horn is responsible for our observations, but the theory served as a useful concept in the development of spinal cord stimulation. Both the peripheral nerve fibers and second-order neurons within the dorsal horn transmitting pain signals become sensitized after injury, and anatomic changes, cell death, and altered gene expression all likely have a role leading to chronic pain.[145] Direct electrical stimulation of the dorsal columns, known as *spinal cord stimulation* (SCS) or *dorsal column stimulation,* has proved effective, particularly in the treatment of chronic radicular pain.[146] North et al.[146] reported a prospective, randomized, crossover trial comparing SCS to reoperation in patients with persistent radicular pain after lumbosacral spine surgery. Patients randomized to SCS were considered more "successful" and less likely to cross over than those randomized to surgery. Although the sample was small, there was no difference in activities of daily living and work status. The mechanisms behind SCS remain unclear, but direct electrical stimulation within the dorsal columns may produce retrograde changes within the ascending sensory fibers that modulate the intensity of incoming noxious stimuli.

The epidural SCS lead is placed directly within the dorsal epidural space just to one side of midline using a paramedian, interlaminar approach. Entry into the epidural space is performed several levels below the final intended level of lead placement. Typically, leads for stimulation of the low back and lower extremities are placed via the L1–2 interspace and those for upper extremity stimulation are placed via the C7–T1 interspace. Investigators have mapped the patterns of electrical stimulation of the dorsal columns and the corresponding patterns of coverage reported by patients with leads in various locations.[147] In general, the epidural lead must be positioned just 2–3 mm to the left or right of midline on the same side as the painful region to be covered.

For lower extremity stimulation, successful coverage usually is achieved by placing the lead between the T8 and T10 vertebral levels, although upper extremity stimulation usually requires lead placement between the occiput and C3 vertebral levels. If the lead ventures too far from midline, uncomfortable stimulation of the exiting nerve roots will result. If the lead is placed too low, overlying the conus medullaris (at or below L1–2), unpredictable patterns of stimulation may result. In the region of the conus, the fibers of the dorsal columns do not lie parallel to the midline; rather, they arc from the corresponding nerve root entering the spinal cord toward their eventual paramedian location several levels cephalad.

Patient selection for SCS is empiric and remains a subject of debate. In general, SCS is reserved for patients with severe pain that does not respond to conservative treatment. The pain responds best when relatively well localized because success of SCS is dependent on the ability to cover the entire painful region with electrical stimulation Attaining adequate coverage is more difficult when pain is bilateral, often requiring two leads, one to each side of midline.[148,149] When the pain is diffuse, it may be impossible to get effective coverage with stimulation using SCS. Among the best-established indications for SCS is chronic radicular pain with or without radiculopathy in either the upper or lower extremities. Use of SCS for treatment of chronic axial low back pain has been less satisfactory, but results seem to be improv-

ing with the advent of dual-lead systems and electrode arrays that allow for a broad area of stimulation.[150] Randomized controlled trials comparing SCS with repeat surgery for patients with failed back surgery syndrome have demonstrated greater success in attaining satisfactory pain relief in those treated with SCS.[146,151] A small randomized controlled trial by Kemler et al.[152] also suggested significant improvement of pain relief in patients with CRPS who were treated with SCS in conjunction with physical therapy compared with physical therapy alone. Functional status did not improve in either group.[152] The usefulness of psychological screening prior to SCS remains controversial; some investigators have suggested that screening for patients with personality disorders, somatoform disorder, or hypochondriasis may improve the success rate of SCS.[150,153]

Once a patient is selected for therapy with SCS, a trial is carried out by placing a temporary percutaneous epidural lead. The screening is conducted using an external device as an outpatient procedure to judge the effectiveness of this therapy *before* a permanent system is implanted. Some carry out the trial of SCS using a surgically implanted lead that is tunneled using a lead extension that exits percutaneously. The strictly percutaneous trial lead is simpler to place and does not require full operating room setup for placement. The surgically implanted trial lead requires placement in the operating room and surgical removal if the trial is unsuccessful. If the trial is successful, the implanted trial lead can remain, and the second procedure to place the impulse generator is brief, not requiring placement of a new epidural lead. In either case, after successful trial stimulation, a permanent system is placed and the lead is positioned to produce the same pattern of stimulation that afforded pain relief during the period of trial stimulation.

Placement of a percutaneous trial spinal cord stimulator lead can be carried out in any location that is suitable for epidural catheter placement. This may be done in the operating room but also can easily and safely be carried out in any location that allows for adequate sterile preparation of the skin and draping of the operative field. Fluoroscopy must be available to guide anatomic placement. Using a strictly percutaneous trial, the trial lead is placed in the same fashion used for permanent lead placement, but the lead is secured to the skin without any incision for the trial period.

Before permanent spinal cord stimulator implantation, discuss with the patient the location of the pocket for the impulse generator. The regions most suitable for placement are the lower quadrant of the abdomen and the lateral aspect of the buttock. Once the site is determined, mark the proposed skin incision with a permanent marker while the patient is in the sitting position. As with the pump reservoir, the position of the pocket is deceptively difficult to determine once the patient is lying on his or her side. If the location is not marked, the pocket is often placed too far lateral within the abdominal wall. Placement of the impulse generator within the buttock allows for the entire procedure to be carried out with the patient in the prone position and simplifies the operation by obviating the need to turn from the prone to lateral position halfway through implantation. If the impulse generator is placed in a pocket overlying the buttock, it must remain well below the superior margins of the iliac crest.

Implantation of a spinal cord stimulator lead and impulse generator is a minor surgical procedure that is carried out in the operating room using aseptic precautions, including skin preparation, sterile draping, and use of full surgical attire. The procedure must be conducted using local anesthesia and light enough sedation that the patient can report where he or she feels the electrical stimulation during lead placement.

The patient is positioned on a radiolucent table in the prone position. Initial lead placement can be carried out with the patient in a lateral decubitus position, but even small degrees of rotation along the spinal axis can make positioning of the lead difficult. The arms are extended upward so that they are in a position of comfort well away from the surgical field. The skin is prepared and sterile drapes are applied. For stimulation in the low back and lower extremities, the radiographic C-arm is positioned directly over the thoracolumbar junction to provide an AP view of the spine. Care must be taken to assure that the x-ray view is not rotated by observing that the spinous processes are in the midline, halfway between the vertebral pedicles.

Surgical Technique

The L1–2 interspace is identified using fluoroscopy. The epidural needle supplied by the device manufacturer must be used to assure that the lead will advance through the needle without damage. The needle is advanced using a paramedian approach starting 1–1.5 cm lateral to the spinous processes and somewhat caudad to the interspace to be entered. The needle is directed to enter the epidural space in the midline with an angle of entry not $>45^\circ$ from the plane of the epidural space. If the angle of attack of the needle on initial entry into to the epidural space is too great, the epidural lead will be difficult to thread as it negotiates the steep angle between the needle and the plane of the epidural space. The epidural space is identified using a loss-of-resistance technique. The electrode is then advanced through the needle and directed to remain just to one side of midline in the dorsal epidural space as it is threaded cephalad under fluoroscopic guidance. The electrode contains a wire stylette with a slight angulation at the tip. Gentle rotation of the electrode as it is advanced allows the operator to direct the electrode's path within the epidural space. For stimulation in the low back and lower extremities, the electrode initially is positioned 2–3 mm from the midline on the same side as the patient's pain between the T8 and T10 vertebral levels.

Final electrode position is attained by connecting the electrode with an external impulse generator and asking the patient where the pattern of stimulation is felt. In general, cephalad advancement will result in stimulation higher in the extremity and caudad movement will lead to stimulation lower in the extremity. However, if the lead is angled even slightly from medial to lateral, the pattern of stimulation may change less predictably with movement of the electrode (e.g., cephalad advancement can lead to stimulation lower in the extremity under these circumstances). Final electrode position should be recorded using radiography so that a permanent lead can be placed in the same position. For trial stimulation, the needle is then removed, the electrode is secured to the back, and a sterile occlu-

sive dressing is applied. The patient is instructed on the use of the external pulse generator and scheduled to return in 5–7 days for assessment of his or her response and for removal of the trial lead.

During permanent implantation, the procedure for initial lead placement is identical to that for trial stimulation. Once final lead position is attained and the optimal pattern of stimulation is confirmed, the lead must be secured, a pocket for the impulse generator created, and the lead tunneled beneath the skin to connect with the impulse generator. Following initial lead placement, the epidural needle is withdrawn slightly (~1–2 cm) but left in place around the lead within the subcutaneous tissues to protect the lead during the subsequent incision and dissection. A 5- to 8-cm incision parallel to the axis of the spine is extended from cephalad to caudad to the needle, extending directly through the needle's skin entry point. The subcutaneous tissues are divided using blunt dissection until the lumbar paraspinous fascia is visible surrounding the needle shaft. The stylette is then removed from the lead and needle is withdrawn, taking care not to dislodge the electrode. The lead is secured to the paraspinous fascia using a specific anchoring device supplied by the manufacturer.

If lead placement has been carried out in the prone position and the impulse generator is to be placed over the buttock, this site is included in the initial skin preparation and draping, assuring that it is below the superior margins of the iliac crest. If the generator is to be placed in the abdominal wall, the lead must be coiled beneath the skin, the paraspinous incision temporarily closed using staples, and a sterile occlusive dressing applied. The sterile drapes are then removed, and the patient is repositioned in the lateral decubitus position with the side where the abdominal pocket will lie upward. After repeat preparation of the skin and application of sterile drapes, attention is turned to creating the pocket within the patient's abdominal wall or overlying the buttock. An 8- to 10-cm transverse incision is made along the previously marked line, and a subcutaneous pocket is created using blunt dissection. The pocket should always be created caudad to the incision. If the pocket is placed cephalad to the incision, the weight of the impulse generator on the suture line is likely to cause wound dehiscence. Blunt dissection is accomplished using gentle but firm pressure with the fingers or using a small pair of surgical scissors. After the pocket is created, the impulse generator is placed in the pocket to assure that the pocket is large enough. With the device in place, the wound margins must fall into close apposition. As with the pump reservoir, there should be no tension on the sutures during closure of the incision or the wound is more likely to dehisce.

After the pocket creation is completed, a tunneling device is extended within the subcutaneous tissues between the paraspinous incision and the pocket. The electrode is advanced through the tunnel (tunneling devices vary and are specific to each manufacturer). The means with which the electrode is connected to the impulse generator also varies by manufacturer. Some devices use a lead extension that connects the impulse generator and the lead; others use a one-piece lead that is connected directly to the impulse generator. After tunneling, the lead and/or lead extension are connected with the impulse generator. Any excess lead is coiled and placed behind the impulse generator within the pocket. This loop allows for patient movement without placing tension on the distal electrode and causing it to be pulled from the epidural space.

The skin incisions are closed in two layers: a series of interrupted subcutaneous sutures to securely close the fascia overlying the impulse generator within the pocket and the electrode over the paraspinous fascia, followed by a skin closure using suture or staples.

Complications

Bleeding and infection are risks inherent to all open surgical procedures. Bleeding within the impulse generator pocket can lead to a hematoma surrounding the device that may require surgical drainage. Bleeding along the subcutaneous tunneling track often causes significant bruising in the region but rarely requires treatment. Similar to other neuraxial techniques, bleeding within the epidural space can lead to significant neural compression. According to Follett et al.,[139] the complexity of lead implantation, including the trial period and a second-stage implant operation, may contribute to the higher multiple-site infection rate observed for SCS patients in postmarket surveillance data. Signs of infection within the impulse generator pocket also appear within 10–14 days after implantation but may occur at any time. Infections within the pocket or along the lead's subcutaneous course almost universally require removal of all implanted hardware and treatment with parenteral antibiotics to eradicate infection. Lead and deep tissue infections can extend to involve the neuraxis and result in epidural abscess formation and/or meningitis.

There is a significant risk of dural puncture during initial localization of the epidural space using the loss-of-resistance technique. The epidural needle used for electrode placement is a Tuohy needle that has been modified by extending the orifice to allow the electrode to pass easily. This long bevel often results in equivocal loss of resistance; it is not uncommon to have minimal resistance to injection along the entire course of needle placement. To minimize the risk of dural puncture, the needle tip can be advanced under fluoroscopic guidance and first seated on the margin of the vertebral lamina. In this way, the depth of the lamina is certain and the needle need be advanced only a small distance over the lamina, through the ligamentum flavum, and into the epidural space. Loss of resistance is used only during the final few millimeters of needle advancement over the lamina. If dural puncture does occur, there is no clear consensus on how to proceed. Some practitioners abandon the lead placement and allow 1–2 weeks before reattempting placement; this approach allows the practitioner to watch and treat postdural puncture headache, which is nearly certain to occur. Other practitioners proceed with lead placement through a more cephalad interspace; if postdural puncture headache ensues and does not respond to conservative treatment, an epidural blood patch is placed at the level of the dural puncture. Spinal cord and nerve root injury during initial lead placement have been reported. Placing the epidural needle and lead in the awake, lightly sedated patient who is able to report paresthesias should minimize the risk of direct neural injury.

The most frequent complication following spinal cord stimulator placement is lead migration. The first line of defense is ensuring that the lead is

firmly secured to the paraspinous fascia. Suturing the lead to loose subcutaneous tissue or fat is not adequate. Postoperatively, the patient must be clearly instructed to avoid bending and twisting at the waist (lumbar leads) or bending and twisting the neck (cervical leads) for at least 4 weeks after lead placement. Placing a soft cervical collar on those who had a cervical lead placed provides an easy reminder to avoid movement. Lead fracture may occur, often months or years after placement. Avoiding midline placement or tunneling the lead across the midline will reduce the incidence of fracture caused by compression of the lead on bone. Lead fracture is signaled by a sudden loss of stimulation and is diagnosed by checking lead impedance using the spinal cord stimulator programmer.

TRAINING IN INTERVENTIONAL PAIN MEDICINE

In our rapidly changing world of modern healthcare, new technologies are appearing at a dizzying rate. Many of these new treatments require physicians to acquire detailed new knowledge and technical skills. Interventional pain medicine is evolving as a distinct discipline that requires detailed new knowledge and expertise. Familiarity with radiographic anatomy for the conduct of image-guided injection and the minor surgical skills needed to place implanted devices such as spinal cord stimulators and implanted drug delivery systems are just a few of the techniques that practitioners must master. As we set out to introduce new interventional techniques to our own pain practices, we must be properly trained to conduct these techniques to ensure safety and success.

FUTURE DIRECTIONS

The field of evidence-based medicine has emerged as a new paradigm to guide practicing physicians.[154] This field endeavors to educate practitioners about how to frame specific questions based on the clinical problems they are faced with every day. They then venture to the published scientific literature with focused questions about prevention, treatment, and diagnosis of specific clinical conditions. Many evidence-based medicine centers offer concise and periodically updated summaries about specific clinical conditions. The idea is to get the best information available to the practicing clinician. It describes the best available evidence, and if there is no good evidence, it says so. In pain medicine, we are faced with an expanding array of treatment options that strike us as logical developments that *should* provide pain relief for our patients. However, there is a dearth of clinical evidence to guide rational choice and application of the majority of these emerging treatments.

Merrill[155] has presented a detailed analysis of the current state of evidence guiding the use of interventional treatments in the field of pain medicine. He points out the frequent flaws in existing studies, including the lack of valid comparators (e.g., no treatment) and concludes that "...the practice of invasive pain medicine teeters at a particularly critical juncture...crippled by a lack of vigorous self-evaluation of its role in the treatment of chronic pain." Merrill goes on to detail the means by which we, as scientists and clinicians, can proceed to build a better body of evidence for the treatments we are using.

The field of pain medicine is young and early in development, and it is perhaps unreasonable to expect an accumulation of randomized clinical trials just yet. The evidence-based medicine movement gives little guidance to practitioners whose tools are still under development. It simply reminds us that no evidence regarding many of our techniques exists. As individual practitioners, we must monitor our own outcomes using valid measures, be more reflective and systematic in studying our own outcomes and patterns of care, and provide this information to our patients as part of the decision-making process. As pain practitioners we have an expanding range of treatment options available to us, few with convincing evidence of efficacy superior to alternate treatments. We must evaluate each patient and use the limited evidence available to us today to guide compassionate and rational, if not evidence-based, use of therapy for our patients.

CHAPTER 94

Palliative and Cancer Pain Care

Phillip C. Phan, MD, and
Allen W. Burton, MD

EPIDEMIOLOGY

Cancer

In 2004, 1.4 million Americans were newly diagnosed with cancer, approximately 4000 per day.[1] In the same year, 564,000 U.S. deaths were attributed to cancer, accounting for approximately 22% of all deaths. It is estimated that more than 10 million people in the United State (approximately 3% of the population) are living with cancer in 2004. The demographic of cancer continues to evolve, with the overall number of cases slowly trending upward, and the number of long-term survivors, including those with chronic pain issues, continuing to grow.

Cancer Pain and Related Symptom Burden

The diagnosis of cancer is distressing to the patient in many ways. First, the patient fears that cancer will shorten his or her life. Second, the patient is apprehensive that the cancer will bring significant pain and suffering with disease progression. Pain is already experienced by 20–50% of cancer patients at the time of diagnosis. With cancer progression, 75% of patients with advanced cancer experience pain.[2] Up to 80% of cancer patients described their pain as having moderate-to-severe intensity.

According to the World Health Organization (WHO), an estimated 6.6 million people worldwide die of cancer every year.[3] WHO studies point out that cancer-related pain continues to be a significant source of global health concern. With advances in therapeutic modalities, approximately 80% of cancer pain can be readily controlled.[4] Unfortunately, even with these advances, cancer pain remains widely undertreated, even in developed countries.[5] In the United States, the reasons for undertreatment of cancer pain are complex and encompass many barriers (Table 94–1).

In recent years, there has been a growing awareness that pain control is an essential part of comprehensive cancer care. Some studies have shown a direct correlation between good pain control and the cancer patient's length of survival as well as responsiveness to timely oncologic treatment.[6,7] In addition to problems stemming from immobility (deep venous thrombosis, pneumonia), uncontrolled pain has proved to be major risk factor in cancer-related suicides.[8,9]

ASSESSMENT

Pain is always subjective and is experienced only by the patient. Over the past 20 years, the assessment of pain has been the subject of much research and refinement of techniques and instruments. A brief review is presented in here; the reader is directed to the references for more details on the assessment of cancer pain. In addition to evaluating the pain symptom, the physician must focus on a myriad of related symptoms. The cancer patient often experiences fatigue, insomnia, depression, anxiety, somnolence, and even cognitive impairment. The psychosocial symptoms, such as anxiety and depression, often can have a large impact on the patient's perception and

KEY POINTS

1. Cancer pain remains a significant problem. Studies show approximately 30% of ambulatory cancer patients suffer moderate-to-severe pain. With progressive disease, the incidence is far higher. Breakthrough pain or episodic severe pain often is problematic for cancer patients.
2. Elucidation of the painful syndrome will help guide effective treatment. In most cases, cancer pain stems from the tumor itself. Tumors cause pain due to invasion of bone, soft tissues, muscle, and nervous structures. A less frequent cause of cancer pain is treatment-related pain, including postchemotherapy neuropathic pain, postsurgical pain syndromes, and postradiation pain syndromes.
3. Neuropathic pain states usually are more difficult to treat. Neuropathic pain is seen with chemotherapy-induced painful peripheral neuropathies, postherpetic neuralgias, phantom limb pain, and others. Nociceptive pain syndromes typically are opioid responsive, whereas in neuropathic pain states, adjuvant analgesics may be needed to obtain adequate analgesia.
4. Treat opioid-related side effects aggressively. In some patients, opioid doses are limited by intolerable side effects, including sedation, confusion, constipation, nausea, and pruritus. These side effects are best managed by changing opioids, adding agents to treat the side effect, or using neuraxial, neural blockade, or other interventional pain techniques to lower systemic opioid doses.
5. Stick with the basic tenets of cancer pain management. These include the use of oral opioids whenever possible, often with combinations of long-acting opioids for constant pain with short-acting opioids for "breakthrough" pain. It also includes the use of adjuvant coanalgesics, including nonsteroidal antiinflammatory drugs, anticonvulsants, antidepressants, and topicals to minimize opioid doses and concomitant opioid-related side effects.
6. Prophylactically treat constipation and nausea.
7. Advance to interventional therapies when the risk-to-benefit ratio is favorable. Interventional options for pain control include nerve blocks, parenteral infusions, neuraxial infusions, palliative radiotherapy, palliative chemotherapy, and surgery in combination for optimal patient quality of life. The optimal blend of these techniques currently is empirical and based largely on availability of services.
8. Cancer pain management is rewarding. In most cases, adequate pain and symptom control can be obtained through regular assessment and application of the relatively straightforward principles outlined.

TABLE 94–1.

Barriers to Effective Cancer Pain Control

I. Barriers by healthcare providers
  A. Inadequate assessment by physicians
  B. Lack of knowledge regarding current treatments by providers
  C. Outdated beliefs by practitioners
    1. Cancer pain expected with disease progression
    2. Opioids prescribed only for dying patients
    3. Patient's pain complaints unreliable
  D. Reluctance to prescribe opioids by physicians
    1. Fear of regulatory controls
    2. Fear of increasing liability for overprescribing
    3. Increased work and effort for opioid management
II. Patient and family-related barriers
  A. Fear of developing addiction to "narcotics"
  B. Reluctance to discuss pain with physician
  C. Fear of acknowledging pain as disease progression
III. Barriers from healthcare system
  A. Lack of coordination for effective treatment of pain
  B. Inadequate resource for dedicated pain treatment

expression of pain. Furthermore, the patient can develop symptoms from side effects of therapeutic intervention, such as nausea, vomiting, and headaches. Thus, the cancer patient commonly presents with a constellation of symptoms that has a profound impact on the patient's psychological well-being, functional status, and quality of life.

Screening Instruments

Many pain clinics use a questionnaire to aid in and standardize assessment. The Wisconsin Brief Pain Inventory (BPI) and Memorial Pain Assessment Card are well-accepted, standard tools for evaluating cancer pain.[10,11] At The University of Texas MD Anderson Cancer Center, an institutionally approved MD Anderson questionnaire (modified BPI) is used for initial and followup assessment of patients (Fig. 94–1).

Advantages to the Wisconsin BPI include the following:

1. It is a 15-minute questionnaire, which can be self-administered.
2. It includes several questions about the characteristics of the pain and associated symptoms, including the origin of the pain and the effects of prior treatments.
3. It incorporates two valuable features of the McGill Pain Questionnaire, a graphic representation of the location of pain and groups of qualitative descriptors. Severity of pain is assessed by a series of scales from 0–10 (11-point numerical rating scale [NRS]) that score pain at its best, worst, and on average. The perceived level of interference with normal function is also quantified with an NRS.
4. Consistent evidence suggests that the BPI is cross-culturally valid and is useful, particularly when patients are not fit to complete a more through or comprehensive questionnaire.[12,13] Further evidence shows its validity and usefulness in documenting outcomes and health status of noncancer pain patients.[14]

Pediatric cancer pain assessment is a complex topic beyond the scope of this chapter, but pain assessment in the child should be organized in an age-appropriate manner using the proper tool. Examples of pediatric assessment tools include Beyer's The Oucher, Eland's color scale-body outline, Hester's poker chip tool, and McGrath's faces scale.[15]

Pain History

Objective observations of grimacing, limping, and vital signs (tachycardia) may be useful in assessing the patient, but these signs often are absent in patients with chronic pain. Pain evaluation should be integrated with a detailed oncologic, medical, and psychological history. The initial evaluation should include determination of the patient's feelings and attitudes about the pain and disease, family concerns, and the premorbid psychological history. A comprehensive but objective approach to assessment instills confidence in patients and family that will be valuable throughout treatment.

A comprehensive evaluation of the patients with cancer pain includes the following:

- The *chief complaint* is obtained to ensure appropriate triage (i.e., may need to send patient who has severe pain with a bowel obstruction to the emergency center for urgent treatment).
- The *oncologic history* is obtained to gain the context of the pain problem. The oncologic history includes diagnosis and stage of disease, therapy and outcome (including side effects), and patient's understanding of the disease process and prognosis.
- The *pain history* should include information on any premorbid chronic pain and the following data for each new pain site: onset and evolution, site and radiation, pattern (constant, intermittent, or unpredictable), intensity (best, worst, average, current) using NRS from 0–10, quality, exacerbating and relieving factors, pain interference with usual activities, neurologic and motor abnormalities (including bowel and bladder continence), vasomotor changes, and current and past analgesics (use, efficacy, side effects). Prior analgesic use, efficacy, and side effects should be cataloged. Prior treatments for pain should be noted (radiotherapy, nerve blocks, physiotherapy, etc.)
- *Review of medical record and radiologic studies.* Many treatments of cancer themselves can cause pain (e.g., chemotherapy- and radiotherapy-induced neuropathies or postoperative pain syndromes; Table 94–2).[16] Many specific cancers can cause well-established pain patterns as a result of known likely sites of metastasis: (1) breast to long bones, spine, chest wall, brachial plexus, and spinal cord; (2) colon to pelvis, hips, lumbar plexus, sacral plexus, and spine; and (3) prostate to long bones, pelvis, hips, lung, and spine.[17]
- *Psychological history* should include marital and residential status, employment history and status, educational background, functional status, activities of daily living, recreational activities, support systems, health and capabilities of spouse or significant other, and past history of (or current) drug or alcohol abuse.[18]

FIGURE 94–1. MD Anderson modified brief pain inventory (BPI) assessment form.

- *Medical history* (independent of oncologic history) should include coexisting systemic disease, exercise intolerance, allergies to medications, previous and current medication use, prior illness and surgery, and thorough review of systems including the following:
  - General (including anorexia, weight loss, cachexia, fatigue, weakness, insomnia)
  - Neurologic (including sedation, confusion, hallucination, headache, motor weakness, altered sensation, incontinence)
  - Respiratory (including dyspnea, cough, pneumonia)
  - Gastrointestinal (including dysphagia, nausea, vomiting, dehydration, constipation, diarrhea)
  - Psychological (including irritability, anxiety, depression, dementia, suicidal ideation)
  - Genitourinary (including urgency, hesitancy, hematuria)

Physical Examination

The physical examination must be thorough, although at times a focused examination may be appropriate. In patients with spinal pain and known or suspected metastatic disease, a complete neurologic examination is mandatory. Gonzales et al.[19] found new evidence of metastatic disease in 64% of patients, which resulted in new antitumor therapy for 18% of patients evaluated by their pain service.[19]

FIGURE 94–1. (Continued)

Clinical Plan of Care

- It is important to formulate a clinical impression *(Diagnosis)*. Multiple diagnoses usually apply, and it is optimal to use the most specific known diagnosis. For example: 1. T11 compression fracture (pathologic versus osteoporotic) with severe pain. 2. Metastatic breast carcinoma (with known bony metastasis). 3. Nausea with dehydration. 4. Constipation.
- It also is important to formulate recommendations *(Plan)* and alternatives for each problem. For example (related to the above problem list): 1. MRI of the T-spine with consideration of vertebroplasty if appropriate. 2. Oxycodone slow-release 10 mg twice daily, with oral transmucosal fentanyl citrate for breakthrough pain. 3. Management including further chemotherapy, radiotherapy, or bisphosphonates as deemed appropriate by the patient's oncologist. 4. Metoclopramide 10 mg orally 30 minutes prior to meals and as needed for nausea. 5. Addition of Senokot-S twice daily for constipation.
- A call to the referring oncologist and/or primary care provider helps ensure good communication among all of the patient's physicians. An exit interview with the patient, ideally conducted by the physician, but any trained professional can be designated for this important duty. The exit interview may include the following:
  - Explaining the probable cause of symptoms in terms the patient can understand.

- Discussing the prognosis for symptom relief, management options, and specific recommendations. In addition to writing prescriptions, oral and written instructions should be provided. Educational material regarding medications, pain management strategies, procedures, or others should be provided. Potential side effects should be discussed.
- Arranging for followup with clinic contact information.
- A dictated summary (in addition to the phone call) should be sent to referring and consulting physicians to keep them apprised of the patient's present status and treatment offered.

ETIOLOGY AND CLASSIFICATION OF CANCER PAIN SYNDROMES

Pain in the cancer patients can have many causes. Most cancer pain syndromes are tumor related, but an increasing array of treatment-related painful syndromes are being seen now with increasing life expectancy. Numerous schema for classification of cancer pain syndromes have been explored. This chapter explores time course and pathophysiology as relevant classifications as they relate to treatment strategies.

Pain Syndrome Time Course

Acute

The large majority of cancer pain is due to tumor invasion of pain-sensitive structures. The invasion causes a derangement of physiologic processes, including inflammation, edema, acidosis, and necrosis of pain-sensitive tissues. Other pathologic processes may include invasion of bone or soft tissues, obstruction of lymphatic or vascular vessels, distension of hollow organs, distortion of solid organs, and compression of nervous system structures.[20] All of these processes cause typical acute cancer pain syndromes, most of which are diagnosed during the oncologic workup. Many of these same pains improve with successful treatment of the tumor, so reassessment is important given the dynamic nature of tumor-related pain.

TABLE 94–2.

Incidence of Developing Chronic Postoperative Pain by Type of Surgery

Type of Surgery	Reported Incidence of Chronic Pain
Limb amputation	30–80%
Thoractomy	22–70%
Cholecystectomy	3–56%
Inguinal hernia	0–37%

Data from Perkins FM, Kehlet H. Chronic pain as an outcome of surgery. Anesthesiology 2000;93:1123–1133.

Chronic

A significant source of pain can be related to the cancer treatments. Most times, the pain is more chronic with a gradual onset and often delayed diagnosis and treatment. Certain types of chemotherapy often cause painful peripheral neuropathy, including the taxanes, platinum compounds, vincristine and its analogues, and some newer agents such as bortezomib.[21] Often, the neuropathy is dose related and resolves with lowering of the dose of the offending agent in subsequent courses of chemotherapy. However, in some patients, the painful neuropathy is permanent and very disabling. It can lead to problems with gait or fine motor tasks of the hands in addition to severe pain. Radiation treatment also may cause neural injury in the form of plexopathy, chronic radiation myelopathy, chronic radiation enteritis and proctitis, as well as nonspecific postradiation head and neck pain, most likely involving a myofascial pain syndrome.[22]

Surgical treatment can lead to chronic postoperative pain syndromes. For example, the postradical mastectomy patient often has pain to the posterior upper arm, axilla, and anterior chest wall secondary to damage of the intercostobrachial nerve.[23] Similarly, nerve damage during thoracotomy and radical neck dissection can cause pain in the distribution of the affected nerves.[24] Phantom limb pain is especially common after amputation procedures, with burning and cramping sensation in the area of amputated limb.[25]

As the pain syndromes become chronic, that is, lasting beyond the expected healing time course, the treatment algorithms become similar to treatments of noncancer chronic pain. Many confusing issues are developing in this patient population, such as patients with very slowly progressive cancer and associated pain that may last many years. In many cases, the "lines" between treating cancer pain or so-called "malignant" versus "nonmalignant" pain syndromes are blurring.[26]

Cancer Pain Pathophysiologic Classification

In assessment of cancer pain, an understanding of pain classification is helpful in delineating both the mechanism of pain and its responsiveness to therapeutic interventions. Pain can be broadly classified into nociceptive and neuropathic pain.

Nociceptive Pain

Somatic Nociceptive pain occurs when nonneurologic tissues suffer insult or injury. However, the associated neurologic structures are not injured and remain functional. Consequently, the injuries of the damaged tissues are detected as noxious stimuli, which are transmitted along the classic pain pathways. The pain perceived by the central nervous system (CNS) is proportional to the degree of tissue damage caused by the cancer. The pain experienced by the patient often is responsive to nonsteroidal antiinflammatory drugs (NSAIDs) because tissue damage from cancer inevitably initiates activation of cellular phospholipase A_2 to release arachidonic acids from cell lipid membrane. Cyclooxygenase (COX) enzymes then act on arachidonic acids to produce potent inflammatory mediators such as thromboxanes, prostaglandins, and leukotrienes. NSAIDs, including the COX inhibitors, attenuate this initial inflammatory reaction at the site of the tissue damaged by cancer and thus reduce the initial pain signals. The physician must be aware of the growing concerns about the cardiovascular side effects of this group of compounds.[27]

Opioid therapy also is effective in helping to control nociceptive pain. Opioid analgesics act on pain receptors at the level of spinal cord and in the brain to modulate pain pathways in the CNS. Nociceptive pain responds to opioids in a scaled manner, such that pain control is generally proportional to opioid dosage.[28]

Nociceptive Visceral Pain Nociceptive pain can be subcategorized into nociceptive somatic pain and nociceptive visceral pain. Nociceptive somatic pain results from activation of nociceptive receptors in somatic tissues. These nociceptors are sensitive to mechanical, chemical, and thermal stimuli. They are located in skin, bone, muscle, tendon, joint, and connective

tissues. The pain signals from these nociceptors are carried along sensory nerve fibers. The patient's perception of nociceptive somatic pain typically is characterized as aching, dull, sharp, throbbing, and well localized to the injured tissue site.

Nociceptive visceral pain, in contrast, is poorly localized. It originates typically from solid organs of the chest, abdomen, and pelvis. The nociceptive receptors in these solid organs typically do not respond to cutting or burning stimuli. However, they are extremely sensitive to any mechanical stress or torsion of organs as well as tension or traction on mesenteric or vascular attachments to organs. The visceral nociceptive pain signals are carried by autonomic sympathetic fibers. The pain is poorly localized by the patient and often described as vague, dull, aching, or pressure-like.[29] The patient often perceives this nociceptive visceral pain as a referred pain that is falsely localizing to a distant site. For example, pancreatic cancer pain often presents as a referred midback pain, and cancer involvement of diaphragm causes pain in the right shoulder.

Neuropathic Pain

The second major class of cancer pain is neuropathic pain. This pain differs from nociceptive pain in that the cancer causes direct injury to the neural tissues. Tumor destruction of peripheral nerves will cause abnormal and exaggerated pain signal transmission. Tumor invasion of peripheral or central nervous system results in abnormal pain signal processing, integration, and perception. The cancer patient often reports extraordinary pain perception, with the pain feeling different from the usual pain sensation. Neuropathic pain often is described as diffuse and excessively sensitive (hyperesthesia), even with nonnoxious stimuli (allodynia). Neuropathic pain is thought to be less responsive to opioid analgesics and instead requires adjuvant medications and interventional therapy for effective pain control.[30]

TREATMENT MODALITIES

Pharmacologic Therapy

WHO Guidelines

As discussed earlier, the barriers to effective pain control are multifold. As a result, clinicians have traditionally undertreated cancer pain. A growing recognition of this health issue has led to the development of numerous guidelines for treating cancer pain, including most famously the WHO stepladder approach to treating cancer pain. Although too simple to serve as a comprehensive treatment algorithm, the principle of treating more resistant cancer-related pain with stronger doses of opioids is generally sound (Table 94–3).

Nonopioid Analgesics

The nonopioid class of analgesics includes both acetaminophen and NSAIDs. Nonopioids are commonly used for mild cancer pain, as directed by the WHO analgesic ladder. Even in the patient with advanced cancer, nonopioid analgesics combined with opioid analgesics are effective in treating pain at both central and peripheral sites. Nonopioids help to reduce the requirement for opioids, thus decreasing the opioid-associated side effects of nausea, constipation, somnolence, and cognitive impairment. Nonopioid analgesics must be used with caution, if at all, in cancer patients who are immunosuppressed. Both acetaminophen and NSAIDs can suppress a fever response indicative of a mounting infection in the immunocompromised patient.

Adjuvant Medications

This heterogeneous class of adjuvant medications has a defined role in the WHO three-step analgesic ladder. They fall into five general categories: antidepressants, anticonvulsants, local anesthetics, corticosteroids, and miscellaneous (Table 94–4).

TABLE 94–3.

World Health Organization (WHO) Three-Step Analgesic Ladder for Cancer Pain

Step 1: Mild cancer pain	→	Nonopioid analgesics ± Adjuvant medications
Step 2: Moderate cancer pain	→	"Weak" opioids ± Nonopioid analgesics ± Adjuvant medications
Step 3: Severe cancer pain	→	"Strong" opioids ± Nonopioid analgesics ± Adjuvant medications

These adjuvant medications act to promote certain desirable effects (or prevent opioid-related side effects) in the cancer patient. Tricyclic antidepressants are useful for certain types of neuropathic pain, especially burning dysesthetic pain. They have the significant side effect of sedation at high doses. Consequently, they can be helpful in cancer pain patients with insomnia and depression. Anticonvulsants and local anesthetics have a membrane-stabilizing effect and are effective for neuropathic pain secondary to nerve injury in both peripheral and central nervous systems. Cortico-

TABLE 94–4.

Adjuvant Drugs for Treatment of Cancer Pain

- I. Antidepressants
  - Amitriptyline
  - Nortriptyline
  - Imipramine
  - Desipramine
  - Duloxetine
  - Maprotiline
  - Paroxetine
  - Venlafaxine
- II. Anticonvulsants
  - Gabapentin
  - Carbamazepine
  - Oxcarbazepine
  - Pregabalin
  - Clonazepam
  - Topiramate
- III. Local Anesthetics
  - Mexiletine
  - Transdermal lidocaine
- IV. Corticosteroids
  - Dexamethasone
  - Methylprednisolone
  - Prednisolone
  - Cortisone
- V. Miscellaneous
  - Psychostimulants: Dextroamphetamine, Methylphenidate, Modafinil
  - GABA agonist: Baclofen
  - α_2 antagonist: Clonidine
  - NMDA antagonist: Ketamine, dextromethorphan
  - Antiemetics[a]: Metoclopramide, ondansetron, dronabinol
  - Laxatives/stool softeners[a]: Senna, docusate

[a]Recommended in all patients receiving opioids.
GABA, γ-Aminobutyric acid; NMDA, N-methyl-D-aspartate.

steroids have a potent antiinflammatory effect and are helpful in cancer patients with spinal cord compression, intracranial tumors, organ capsule distension, and bone infiltration. Steroids also have CNS effect in improvement of mood and sense of well being in the cancer patient. Antiemetics and stool softeners should routinely be prescribed along with opioids. The other miscellaneous adjuvant medications have variable effects and are tailored to the patient's individual pain and associated symptoms.

Opioid Analgesics

Opioid analgesics are a mainstay for treatment of cancer pain. In the WHO three-step analgesic ladder, "weak" opioids are recommended for treatment of moderate cancer pain, whereas "strong" opioids are prescribed for severe cancer pain. The "weak" opioids have less potency and fewer side effects. Some common oral "weak" opioids are listed in Table 94–5.

The "weak" opioids are produced containing acetaminophen or aspirin. They are "weak" because of the limitation of their ceiling dose of acetaminophen or aspirin, above which the patient has a higher risk of renal and hepatotoxicity.

The "strong" opioids are more potent because they are made in pure form, without addition of aspirin or acetaminophen. Thus, these opioids do not have a maximum ceiling dose. However, with higher dosages of the "strong" opioids, the patient tends to experience more significant side effects of nausea and vomiting, constipation, pruritus, somnolence, and cognitive impairment. Some common "strong" opioids are listed in Table 94–6.

Failure of Noninterventional Therapies

It has been estimated that up to 70–90% of patients with cancer pain have satisfactory pain relief from pharmacologic therapies alone, following the WHO guidelines for cancer pain.[31] However, this means that 10–30% of patients have pain that cannot be treated with medications alone. The reasons for this failure of pharmacologic treatment are variable.[32] They vary from physician-related factors to patient-related factors. The physician-related reasons for pharmacologic failure include inaccurate assessment of pain and deficiency in knowledge of current analgesics and adjuvant medications. Patient-related reasons range from fear of addiction to adverse side effects.[33,34] Most commonly, the patient cannot tolerate adverse side effects of the medication regimen, especially opioid use.[34] Failure of pharmacologic control of cancer pain is commonly seen with progression of cancer. Patients with advanced disease can present with intractable pain from multiple metastases and multiple pain sites.

TABLE 94–5.

"Weak" Opioids for Treatment of Moderate Cancer Pain

Generic Name	Examples
Hydrocodone	Lortab, Vicodin, Lorcet, Norco
Codeine	Tylenol #3, #4
Propoxyphene	Darvon, Darvocet

Interventional Therapies

Goal of Intervention

Patients who fail to respond to conservative pharmacologic treatments may be candidates for interventional therapies. A large armamentarium of invasive procedures is available to achieve better control of cancer pain. However, the role of interventional therapies must be placed in the proper context. They cannot be used as the sole treatment of cancer pain, especially for advanced cancer patients. Rather, they should be used as part of a multimodality approach in the treatment of cancer pain.[35,36] The etiologies of cancer pain are diverse, and the pain symptom is interrelated with the constellation of symptoms experienced by cancer patients. Consequently, a global multimodal approach to treatment of cancer pain is necessary. It includes appropriate antineoplastic therapy, management of analgesics and adjuvant pain medications, behavioral and psychiatric support, and finally interventional therapies. Interventional pain procedures will not completely eliminate the need for pain medications. The therapeutic goal of such procedures is to help alleviate cancer pain and reduce the overall analgesic need, thereby minimizing associated opioid-related side effects.

TABLE 94–6.

"Strong" Opioids for Treatment of Severe Cancer Pain

Generic Name	Examples
Morphine/ MS-CR	MSIR, MS Contin, Oramorph, Kadian, Avinza
Oxycodone/ oxycodone	CR Roxicodone, OxyContin
Fentanyl	Duragesic (time-released transdermal), Actiq (PO immediate-release)
Hydromorphone	Dilaudid
Methadone	Dolophine
Oxymorphone	Nuromorphan

Communication

Prior to proceeding with any invasive pain procedure, communication between the pain physician and the relevant parties is absolutely essential. The patient must first be educated on risks and benefits of the interventional procedure. He or she must be allowed an opportunity to have questions about procedure extensively and satisfactorily answered. At the same time, the patient must be grounded in realistic expectations for outcomes of this procedure. The patient should be made aware of the efficacy of the procedure, duration of effectiveness, and possibility of failure of the procedure to provide complete or even partial pain relief. All potential complications from procedure are explained to patient. He or she must understand that the interventional procedure is part of a multimodal approach for pain control.

With cancer patients, especially those critically ill or preterminal, family members and caregivers often are involved in decision-making process. Family support helps the patient to cope emotionally with cancer disease as well as undergo the procedural intervention. Like the patient, family members and caregivers must be educated and have realistic expectations about the procedure.

Effective communication with other professional members of the care team is important. They include the patient's oncologists, primary care providers, and all relevant consultants. Treatment of cancer is a multidisciplinary effort. The interventional procedure should be planned in coordination with the overall cancer treatment. For example, the cancer patient may undergo chemotherapy with resultant thrombocyto-

penia. In such cases, interventional procedure must be carried out prior to chemoinduction or afterward when the patient's platelet count has normalized. Typically, other members of the patient's care team are informed about the planned interventional procedure and given a chance to voice their input or concerns.

Detailed Physical Examination

A thorough physical examination of the patient prior to the procedure is critical. This entails a complete neurologic evaluation. Interventional procedures for pain control are invasive and involve neurologically sensitive tissues such as peripheral nerves or CNS structures. The objective of intervention is to disrupt or modulate pain pathways involved in nociception. Interventional procedures such as neurolysis of peripheral nerves will block not only pain transmission but also sensory and motor innervations. Consequently, it is important to document before and after the procedure a complete and thorough physical examination, with focus especially on pain and neurologic changes. Changes such as sensory and motor blockade are closely monitored after procedures.

Categories of Interventional Techniques

Interventional therapies can be categorized into three groups: neurolytic techniques, neuromodulation techniques, and surgical techniques. *Neurolytic* or *neuroablation techniques* are procedures that target destruction of nerves or neural structures that are involved in generation or transmission of pain signals. Neurolytic lesions can be created by a variety of agents. Lysis is achieved with chemicals (glycerol, alcohol, or phenol), heat (radiofrequency coagulation), or cold (cryotherapy).

Neuromodulation techniques have as their basis the original Wall and Melzack[37] gate control theory of pain. This theory proposes that all nerve fiber endings except those that innervate hair cells are alike and that suprathreshold stimulation of these nonspecific receptors initiates pain signals. According to Melzack and Wall,[37] substantia gelatinosa functions as a primary gatekeeper in the transmission of pain from the periphery to the CNS. Neuromodulation techniques aim at modulation of pain signals along the transmission pathway. These techniques include local anesthetic blockade; regional infusion of drugs at epidural, intrathecal, intraventricular, or perineural sites; and electrical stimulation of the CNS.

Surgical techniques are the third class of interventional pain procedures. Surgical procedures range from the minimally invasive percutaneous vertebroplasty to extremely invasive neurosurgical destructive techniques. Neurosurgical techniques include percutaneous cordotomy, thalamotomy, cingulotomy, hypophysectomy, and trigeminal tractomy. Most of these procedures are performed stereotactically under monitored anesthesia care and fluoroscopy or CT guidance.

Neurolytic Procedures

Over the past century, many chemical and physical ablative techniques have been developed with goal of disrupting the transmission of pain signals along the neural pathways. Chemical neurolysis is achieved with alcohol (50–100%), phenol (5–15%), and glycerol. These agents produce nerve injury resulting in degeneration of nerve fiber distal to the lysis lesion (wallerian degeneration).[38] The injury disrupts nerve cell transmission of pain and results in a nociceptive block. However, with wallerian degeneration, the nerve axon can begin to regenerate within 3 months. Thus, chemical neurolysis provides a temporary block of nociception for approximately 1–3 months.[39]

Alcohol is the chemical that classically has been used for neurolysis.[40] Today many clinicians favor use of phenol for peripheral neurolysis because it is less neurotoxic than alcohol.[41] Alcohol is used in concentration up to 100%. It causes nonselective destruction of all nerves as well as surrounding soft tissues. Alcohol is rapidly soluble in blood and is hypobaric relative to cerebrospinal fluid (CSF). If injected into intraspinal space, the alcohol will rise rapidly, diffusing away from initial injection site. Specifically, it damages nerves by extracting fatty substances and precipitating proteins in the nerve axon, resulting in wallerian degeneration.[42] The injury is proportional to both the concentration and volume of alcohol used. A higher risk of neuritis is associated with alcohol injection compared to phenol.[43] Patients often experience intense burning pain initially with alcohol injection.

Phenol, which now is more commonly used, is associated with a lower risk for neuritis.[43] Phenol 5% is equivalent to alcohol 40% concentration in neurolytic potency.[44] Phenol is less water soluble than alcohol, so it tends to concentrate more around the injection site. It is diffusible and is able to penetrate neural axon and denature proteins, causing wallerian degeneration.[43] Many clinicians prefer phenol because the intensity and duration of neural blockade are less with phenol, theoretically providing a wider margin of safety.

Glycerol is less commonly used in peripheral neural blockade. It is used primarily for treatment of trigeminal neuralgia. It is injected directly into the trigeminal cistern (Meckel cave), with good efficacy in blocking trigeminal neuralgia. Other neurolytic chemicals that have been attempted include ammonium salt compounds and hypertonic and hypotonic saline solutions, with variable results.[43]

Radiofrequency thermocoagulation is also used to produce a physical nociceptive block.[45] The lesion created by radiofrequency heating is discreet, and lesion size is controlled by the temperature of the probe and the duration of application. Some studies have shown that radiofrequency ablation can produce a longer-lasting block.[46]

Cryotherapy can be used to achieve neurolytic lesioning. Applying extreme cold to the nerve will result in long-lasting nerve blockade. Cryoneurolysis of intercostals nerves intraoperatively has been reported to have good efficacy in controlling postthoracotomy pain.[47] Wide application of cryoablation has been hindered by the large probe size and the relative complexity of the equipment involved.

Patient selection for chemical neurolysis, radiofrequency ablation, and cryoneurolysis techniques is extremely important to achieving the desired outcome. The patient should have an advanced progressive cancer with a limited life expectancy (6–12 months). The pain should be severe, persistent, refractory to conservative treatment, and consistent with a nociceptive somatic or visceral pain. Neuropathic pain usually does not respond well to neuroablation therapy. The potential risks associated with neuroablation are listed in Table 94–7.

Despite the inherent risks of neuroablation, patients with advanced can-

TABLE 94–7.

Potential Risks of Neuroablation Techniques

Dysesthetic pain: Painful neuralgia due to deafferentation, neuritis, or neuroma formation
Tissue damage: Accidental injury to nontargeted neurologic and non-neurologic tissues
Motor paralysis: Especially with intrathecal neurolysis
Sensory deficit: Areas of paresthesia or numbness
Failure to relieve pain: Due to incomplete ablation or incorrect nerve target
Short-term pain relief: Due to central nervous system plasticity, axonal regrowth, or tumor progression

cer and well-localized nociceptive pain can benefit greatly from neurolytic blockade. Peripheral neurolysis has been proven to alleviate the suffering of cancer patients with intractable pain.[48] Regional blocks are extremely useful in disrupting pain signals transmitted along the sympathetic and parasympathetic nerves.

Neural Blockade in Head and Neck More than 40,000 patients are diagnosed with head and neck cancer each year in the United States, and more 500,000 patients are diagnosed worldwide.[49] Cancer of the head and neck constitutes approximately 5% of all malignant diseases in the United States and affects approximately 6.6 million patients worldwide.[50] Because of dense facial and neck innervations, cancer commonly causes not only disfiguring facial lesions but also disabling pain in face and neck. Blocking relevant trigeminal nerve or cervical nerve branches can control the pain. However, the efficacy of interventional nerve block can be affected by tumor distortion of anatomy, radiation-induced fibrosis of local tissues, and possible overlapping sensory innervations of neighboring cranial nerves V, VII, IX, and X and upper cervical nerves. Careful evaluation of facial pain and proper selection of nerve block will provide patients with relief.

Trigeminal Nerve Block *Indications:* Blockade of trigeminal ganglion or specific branches of trigeminal nerves will alleviate somatic and neuropathic pain from cancer.

Anatomy: The trigeminal or gasserian ganglion is formed from two nerve roots that arise from the ventral pons of the brainstem. These roots fuse anteriorly and enter the Meckel cave, a recess in the middle cranial fossa. Three sensory divisions then exit anteriorly as the ophthalmic nerve (V1), maxillary nerve (V2), and the mandibular nerve (V3). Destruction of the gasserian ganglion is useful for intractable pain from invasive tumors of the orbit, maxillary sinus, and mandible.[51] Conversely, each individual sensory nerve can be blocked separately if selective blockade is desired.

Techniques: The patient is placed in a supine position, with the cervical spine extended on a foam pad or pillow. The cheek skin is aseptically prepped and then anesthetized with 1% lidocaine, 2.5 cm just lateral to the corner of mouth. Using C-arm fluoroscopic guidance, a 3.5-inch, 20-gauge spinal needle is advanced slowly through the anesthetized skin area, 2.5 cm lateral to the corner of the lips. The direction of the spinal needle should be cranial, dorsal, and medial, with the foramen ovale as the target (Fig. 94–2). It may be easier to have the patient gaze straight ahead and then aim the needle in the cephalad direction, perpendicular to midpupillary line. The needle is directed through the pterygopalatine fossa until the needle reaches the skull base. The needle then is walked posteriorly into the foramen ovale. Once the needle enters the foramen ovale, its tip should be located within the Meckel cave. Careful aspiration of needle is important to ensure that the needle tip is not in a vascular structure. A sterile solution of 100% alcohol (0.5 mL) is used to achieve neurolysis.

Complications: Unintentional dural puncture can lead to neurotoxicity, including seizures and death. When the needle is directed through the pterygopalatine fossa, injury to vessels can result in facial hematoma or ocular subscleral hematoma. Postprocedural neuritis can cause significant dysthetic pain in trigeminal sensory areas. Masticator weakness is possible with trigeminal block.

Occipital Nerve Block *Indications:* Occipital nerve block is effective for treatment of oncologic pain in the posterior scalp and occipital region.

Anatomy: Most of the posterior scalp is innervated by the greater occipital nerve, which arises from the dorsal rami of the C2 nerve root. It emerges subcutaneously in the posterior scalp just slightly inferior to the superior nuchal line and 2–3 cm lateral to the greater occipital protuberance. At this point of emergence, it is just medial to the occipital artery.[52]

Techniques: The patient is placed in a sitting position, with the neck slightly flexed. The greater occipital protuberance and the mastoid process are palpated. In addition, one third the distance between these two structures, the greater occipital artery can be palpated (3–4 cm lateral to the greater occipital protuberance on the superior

FIGURE 94–2. Submental oblique radiograph of classic approach to trigeminal nerve block.

nuchal line). The greater occipital nerve lies just medial to the greater occipital artery. It can be blocked at this site with local anesthetic or neurolytic injection.

The skin is aseptically prepped, and a short 1-inch, 25-gauge needle is introduced after the skin is infiltrated with local 1% lidocaine. Bony contact is made at a minimal depth approximately 2–3 mm. A diagnostic block with 1–2 m L of local anesthetic (1% lidocaine) can be injected. For neurolytic block, a volume of 3–5 mL is used.

Complications: Because of the superficial location of the greater occipital nerve and the relative ease of this block, complications are minimal. The close proximity of the greater occipital artery may increase the risk of intravascular injection, which can be avoided by frequent aspiration while the neurolytic solution is slowly injected. Neuritis also can occur with neurolytic agents, especially with alcohol.

Superficial Cervical Plexus Block

Indications: Superficial cervical plexus block is often used to treat cancer pain in the neck in areas innervated by the cervical plexus.

Anatomy: The superficial and deep cervical plexus arises from the first four cervical nerves. The cervical plexus begins just lateral to the first cervical vertebrae. It is located anterior to the levator scapulae and middle scalene muscles and posterior to the sternocleidomastoid (SCM) muscle. The plexus gives off both superficial sensory branches and deep motor branches. This anatomic division of sensory and motor nerves allows for selective sensory blockade of the superficial sensory branches of the cervical plexus without compromising the motor function of the neck muscles.

These superficial branches arise from the plexus and pierce the deep fascia of the neck at the posterior border of the SCM muscle. It is at this point where the bundle of the superficial cervical plexus emerges that sensory innervation to the plexus can be blocked easily.[53] The superficial cervical plexus gives rise to the sensory nerves that supply sensation to the skin and superficial fascia of the head, neck, and shoulder. These nerves include the lesser occipital, greater auricular, accessory, anterior cervical nerve, and suprascapular nerves.[54]

Techniques: The patient is placed in a supine position, with the head turned away from the site to be blocked. The mastoid process is identified with the attached SCM muscle. The patient may have to raise the head slightly to allow for identification of SCM muscle. The neck is aseptically prepped. Just lateral to the SCM midpoint, a 1-inch, 25-gauge needle is inserted subcutaneously. A 5-mL volume of local anesthetic (1% lidocaine) is injected subcutaneously at this point. The needle then is directed superiorly and inferiorly along the posterior border of the SCM. A total volume of 10–20 mL of local anesthetic can be injected to achieve a diagnostic block. This block, if successful, can be followed with neurolytic agents to achieve a longer blockade. As a note of caution, the external jugular vein crosses the midpoint of the lateral border of the SCM. Careful aspiration prior to infiltration is helpful to avoid intravascular injection.[55]

Complications: Few complications are associated with this superficial cervical block. The most common complication is intravascular injection into the external or internal jugular vein, with resulting systemic toxicity. Placement of the needle into jugular vein may result in hematoma or even air embolism.

Neural Blockade in Upper Extremity

Brachial Plexus Block

Indications: Malignancy can involve the upper extremity. Such cancers includes sarcomas, both of bone and soft tissue. In the United States, almost 13,000 new cases of bony sarcoma and 7000 new cases of soft-tissue sarcomas are diagnosed each year.[56] In most cases, surgical resections of sarcomas with limb-sparing procedures are performed with good results. However, these patients often have severe pain from direct tumor invasion of neurovascular bundle or as a consequence of surgical resection of tumor. Neural blockade of the brachial plexus is effective in controlling somatic nociceptive pain in upper extremity cancer.

For short-term palliation of cancer pain, brachial plexus block can be performed with a catheter left in place for continuous infusion of local anesthetic. In cases of severe intractable pain from invasive tumors of brachial plexus or soft tissues and bone of shoulder and upper extremity, destruction of the brachial plexus is indicated. The patient should be made aware of the full consequences of neurolysis of brachial plexus, including paralysis of upper extremity.

Anatomy: The brachial plexus is formed from fusion of ventral rami of C5–T1 nerve roots. These nerve roots, with possible contribution from C4 and T2, emerge from the lateral aspect of the vertebral bodies and run laterally and inferiorly, in the interscalene compartment. These nerves of the brachial plexus run down the interscalene compartment and pass behind the clavicle, cephalad to the first rib and then into the axilla.

Techniques: Multiple approaches to brachial plexus blockade include interscalene block, and supraclavicular, infraclavicular, and axillary blocks. For cancer pain from tumor involvement of shoulder, interscalene block is preferred.[57]

The patient is placed in a supine position, with the head turned away from the site to be blocked. The posterior border of the SCM muscle is identified. The patient can cooperate by slightly flexing his or her head. The groove between the posterior border of SCM muscle and the anterior scalene muscle can be palpated by rolling fingers posteriorly off the edge of SCM muscle. The neck is then aseptically prepped. At the level of the cricoid cartilage (C6) in the interscalene groove, a 1.5-inch, 25-gauge needle is inserted in a slightly caudal, medial, and posterior angle. The skin is infiltrated with local anesthetic. The needle is inserted as described until paresthesia of shoulder, arm, or hand is obtained. Such paresthesia is encountered at a needle depth of 1 cm. Once a paresthesia is achieved or a motor response is obtained via verve stimulator, the needle is known to be near the brachial plexus. If aspiration is negative for CSF and blood, 30–40 mL of local anesthetic solution is injected incrementally, with frequent aspiration. Throughout injection, the patient is monitored for signs of local anesthetic toxicity and subarachnoid injection.

Once the efficacy of local anesthetic blockade in relieving cancer pain has been proven, the patient may wish to proceed with a longer-lasting neurolytic block with phenol. A 20-mL volume of 6% phenol is slowly injected into the

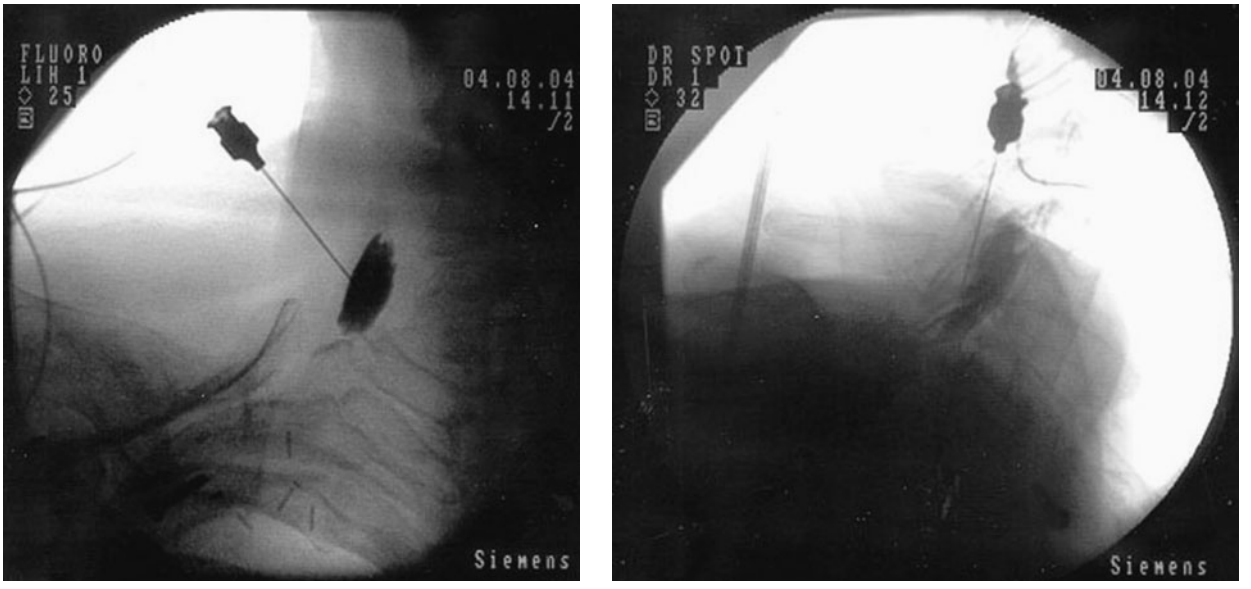

FIGURE 94–3. Two radiographic views of neurolytic brachial plexus block with 20 mL of 6% phenol solution.

intrascalene compartment of the brachial plexus (Fig. 94–3). Motor paralysis of upper extremity can be expected with this neurolysis of brachial plexus.

If a shorter prolonged blockade of brachial plexus is desired, a continuous local anesthetic infusion of the brachial plexus can be performed. The infraclavicular approach for brachial plexus block is preferred because the catheter can remain in the same position for 3 weeks or more.[58] The infraclavicular entry site permits easy catheter threading near the plexus, and the catheter's position is minimally affected with patient movement. For the infraclavicular approach, the patient is placed in a supine position with the head turned away from the site to be blocked. The clavicle is identified by palpation and fluoroscopy. The axillary artery also is palpated and marked. The ipsilateral neck, anterior shoulder, and axillary region are prepped with povidone iodine (Betadine) in a sterile manner. At the inferior border of the clavicle at the midpoint, local anesthetic (1% lidocaine) is generously infiltrated subcutaneously. A 16-gauge spinal needle is introduced at this midclavicular point and directed laterally toward the marked axillary artery location. The needle is directed at a 45° angle to the skin and then connected to a nerve stimulator by an alligator clip. As the needle advances, fluoroscopy will allow for visualization of the needle tip. Once the tip nears the brachial plexus, muscles innervated by the plexus will be stimulated, with visible flexion and extension of the elbow, wrist, and fingers. At this point, 2–3 mL of contrast dye is injected to confirm under fluoroscopy the spread along axillary sheath. The catheter then is threaded through the spinal needle and 3–5 cm beyond the tip. The needle is withdrawn, and the catheter is sutured in place. Infusion of 0.125% or 0.25% bupivacaine is used to provide continuous brachial plexus analgesia. It is effective in controlling somatic pain for several days and sympathetically mediated pain for up to a few weeks.

Complications: Complications of interscalene block are possible because of proximity to many structures in the neck. Intravascular injection, as mentioned earlier, will lead to systemic toxicity. Subarachnoid injection can cause sensory, motor, or total spinal anesthesia and even death. Phrenic nerve block is an expected side effect of interscalene block.

Complications of infraclavicular brachial plexus block are similar to those of interscalene block. Proximity to the subclavian artery and vein increases the potential for intravascular injection.

Neural Blockade in Thorax *Intercostal Nerve Block*

Indications: Lung cancer is the number one cancer killer among both males and females.[56] It accounts for 15% of malignant disease in males and 13% in females. Patients diagnosed with lung cancer often require thoracotomy with surgical biopsy or resection of tumor mass. Many patients experience chest wall pain from either direct tumor involvement of the chest wall or surgical trauma to intercostal nerves. In addition to lung cancer, aggressive breast cancer may invade the ribs and intercostal nerve bundles, causing pain.

Tumor invasion of lung parenchyma and visceral pleura does not cause pain because these structures are nociceptive insensitive. However, cancer involvement of the parietal pleura does elicit a pain response. Pain is transmitted from parietal pleura along somatic nerve, including the intercostals nerves from T1–12. Intercostal nerve blockade is effective in blocking this somatic pain.[59]

Anatomy: The intercostal nerves are formed from ventral rami of thoracic nerves from T1–12. Each nerve, joined by intercostal vein and artery, runs in a neurovascular bundle in the subcostal groove. It gives off four branches as it runs anteriorly in the intercostals space. The first is the gray rami communicantes, which joins the sympathetic ganglion. The second branch is the posterior cutaneous nerve, which innervates the paravertebral region. The third branch is the lateral cutaneous nerve, which innervates the axilla and lateral chest wall. The fourth branch is the anterior cutaneous nerve, which innervates anterior thorax. There is considerable sensory overlap between those branches as well as between the intercostal nerves themselves. Thus pain from one area may require blockade of multiple adjacent intercostal nerves.[60]

Techniques: For neurolytic block, the procedure should be performed under

fluoroscopic guidance. The patient is placed in a prone position. The relevant ribs are identified by palpation and under fluoroscopy. The inferior border of each rib is indicated with a marking pen. The intercostal block is classically performed at the angle of the rib, just lateral to the paraspinal muscle groups. The relevant paraspinal area is prepped aseptically. Using a 1-inch, 25-gauge needle, the skin is infiltrated subcutaneously with local anesthetic. The clinician should palpate to obtain a gross estimation of the depth from skin to bone of rib. The needle is slowly advanced perpendicular to the skin, with fluoroscopic guidance. The C-arm should be in the anteroposterior projection with a caudal tilt. The needle tip should hit the body of the rib and then walk inferiorly off the lower border of rib into the subcostal groove. Water-soluble contrast dye injected into this groove should show a nice spread along the inferior border of rib. A neurolytic solution of 10% phenol can be injected with 3–5 mL for each intercostal block.

Complications: Common complications of intercostal nerve blockade include pneumothorax and systemic toxicity. Pneumothorax results from needle puncture through parietal and visceral pleura. This will create an air leak from lung into pleural space. A simple pneumothorax may infrequently progress into a tension pneumothorax with its life-threatening implications. The patient should be closely monitored after the procedure, and a postprocedural chest radiograph is recommended.

Another complication of intercostal nerve blockade is systemic toxicity from absorption of anesthetic or neurolytic solution into the intercostal neurovascular bundle. Because of the close proximity of intercostal artery and vein to the nerve, rapid absorption of injected solution into the circulation is common. However, systemic toxicity is infrequent because of the small volume used for neurolysis. A less likely complication is neuroaxial spread of the anesthetic or neurolytic solution.

Instead of chemical neurolysis, cryoanalgesia and radiofrequency ablation have been used for intercostal nerve blockade. Cryoanalgesia or "freezing" of intercostal nerves has been shown to control pain in postthoracotomy patients if performed under direct visualization of intercostal nerve at termination of surgery.[47] After surgery, percutaneous intercostal cryolysis has not been shown to be as effective.[61]

Intercostal nerve radiofrequency ablation can be used for long-lasting blockade. A blunt-tipped, 100-mm, 22-gauge radiofrequency electrode with a 5-mm active tip is inserted into the intercostal space. One milliliter of 2% lidocaine is injected into the electrode cannula. Lesioning is accomplished by coagulation at 80°C for 60 seconds. The technique of proximal intercostal nerve radiofrequency lesioning, including ablation of the dorsal root ganglion, is being used with favorable preliminary results (Fig. 94–4).

Sympathetic Blockade for Cancer Pain Visceral pain arises from cancer involvement of sympathetically mediated organs. Insults to these organs can result from abnormal distension of organ wall or viscus, tension or torsion on mesenteric vessels, and ischemia. Such visceral pain is commonly seen with gastrointestinal malignancies, such as hepatic metastases, intestinal tract tumors, and pancreatic cancers. Sympathetically mediated pain can involve neuropathic pain, as occurs with direct injury to nervous tissue such as brachial plexopathy and lumbosacral plexopathy. Blockade of sympathetic chain has been shown to be effective in controlling sympathetically mediated pain.[62,63]

The sympathetic axis is made up primarily of a pair of ganglionated paravertebral chains that run from base of skull to the tip of coccyx. It also consists of several major vertebral plexuses, including celiac, cardiac, and hypogastric plexuses. Table 94–8 lists major sympathetic structures and the corresponding tissues innervated.[64]

These sympathetic structures are attractive targets for blockade of sympathetically mediated pain. Interruption of pain pathways at these discrete sites has been demonstrated to have a useful role in controlling oncologic pain.[65,66]

Stellate Ganglion Block *Indications:* Stellate ganglion block helps control sympathetically mediated pain in the head, neck, and upper extremity. Sympathically mediated pain is commonly seen in tumor invasion of brachial plexopathy as in Pancoast tumors.[67]

Anatomy: Stellate or cervicothoracic ganglion is formed from fusion of the inferior cervical and the first sympathetic ganglia. This ganglion controls sympathetic afferent nociceptive signals to head, neck, and upper extremity. The ganglion is located at the base of the neck and anterior to the neck of the first rib. It is bounded anteriorly by subclavian artery and the origin of vertebral artery, posteriorly by the vertebral body and longus colli muscle, laterally by the scalene muscles, and inferiorly by the dome of the pleura.

Techniques: Because of many important structures in the neck adjacent to stellate ganglion, fluoroscopic imaging is recommended. The patient is placed in a supine position with the neck

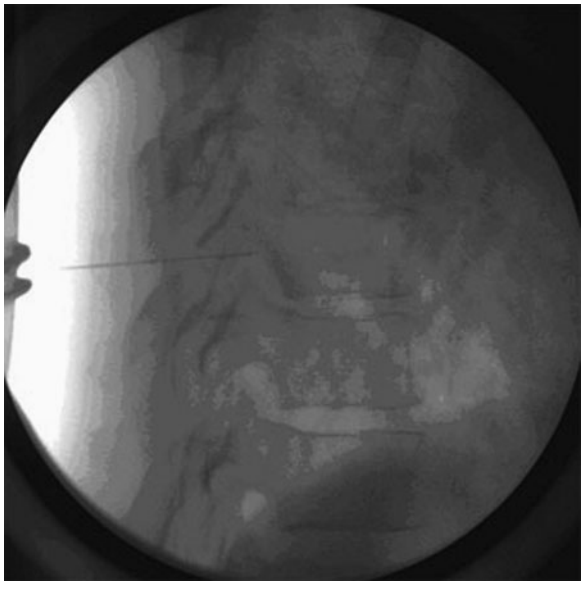

FIGURE 94–4. Lateral view of intercostal dorsal root ganglion radiofrequency ablation.

TABLE 94–8.

Sympathetic Structures

Sympathetic Structures	Innervated Tissues
Stellate ganglia	Brain, ear, tongue, pharynx, larynx, skin of neck, head, and upper extremity
Thoracic ganglia	Mediastinal contents, esophagus, trachea bronchus, pericardium, heart, lung
Celiac plexus	GI tract (from distal esophagus to mid-transverse colon), liver, adrenals, ureters, abdominal vessels
Lumbar ganglia	Skin and vessels of lower extremity, kidneys, ureters, transverse colon, testes
Hypogastric plexus	Descending and sigmoid colon, rectum, vaginal fundus, bladder, prostate, prostatic urethra, testes, seminal vesicles, uterus, and ovaries
Ganglion impar	Perineum, distal rectum and anus, distal urethra, vulva and distal third of vagina

slightly extended. The classic technique is to identify the Chassaignac tubercle at C6 and insert the needle at this site. However, many clinicians recommend the Racz technique for possible improved safety margin.[52] The patient's neck is aseptically prepped, and the skin over body of C7 vertebral body is anesthetized with 1% lidocaine. The nondominant hand is used to palpate the carotic artery at the level of C7 and retract it laterally. The dominant hand introduces a 1.5-inch, 22-gauge needle just medial to the palpated carotid artery and directs the needle in a medial direction. The target of the needle tip is the ventrolateral aspect of the C7 vertebral body, not the transverse process as seen in the classic approach. Once the needle tip contacts the C7 vertebral body, it is withdrawn slightly approximately 1 mm. The needle then is aspirated for CSF or blood. From 1–2 mL of contrast dye is injected to confirm the caudocephalad spread anterior to the prevertebral facia. For gangliolysis, a mixture of 3% phenol, local anesthetic, and steroid is used (i.e., 5 mL of 6% phenol in saline, 5 mL of 0.5% bupivacaine, and 80 mg of methylprednisone).

The volume of this mixture injected is dependent on the extent of blockade desired. Ten milliliters of neurolytic mixture is adequate for stellate ganglion blockade of sympathetically mediated pain to head and upper extremity. If blockade of pain from thoracic viscera is desired, a volume of 15–20 mL of neurolytic mixture is necessary. During injection, the clinician must exercise caution to minimize intravascular injection. Even 1 mL of local anesthetic injected into the carotid or vertebral artery can cause loss of consciousness and seizure. An initial test dose, frequent aspiration, and slow injection are good suggested measures.

Efficacy: Evidence of sympathetic blockade in the head can include a myriad of signs of Horner, syndrome such as miosis, ptosis, enophthalmos, facial anhidrosis, and nasal congestion. Sympathetic blockade to upper extremity results in visible engorgement of veins in the hands and forearm.

Complications: Because of anatomic proximity to critical structures, serious complications of stellate ganglion block can include pneumothorax, anesthetic-induced seizure from intravascular injection, and total spinal anesthesia from subarachnoid injection. Other less serious problems include localized hematoma, infection, and neck muscle tenderness. Many clinicians fear a permanent Horner syndrome with neurolysis. However, Racz and Holubec[68] did not observe any long-term Horner syndrome with their modified technique.

Celiac Plexus Blockade *Indications:* Celiac plexus blockade continues to be an extremely effective intervention for pain from pancreatic cancer and malignancies involving the upper and midabdomen.[65,69] Pancreatic cancer carries a poor prognosis, and palliation of pain symptom is a priority in these patients, with survival rates typically < 6 months. Patients often present initially with upper abdominal pain with referred pain to the back.[70] The pain is described as severe, increasing with disease progression, and poorly relieved by opioids or other medications. Celiac plexus block is the treatment of choice for pain control in pancreatic cancer patients.

Anatomy: Sympathetic innervations of abdominal organs arise in the anterolateral horn cells in the spinal cord. Preganglionic fibers from T5–12 leave ventral roots of spinal cord to join with white rami communicans. These fibers do not synapse at the sympathetic chain; instead they pass onward through to the celiac plexus. Passing from the sympathetic ganglia to the celiac plexus, the preganglionic fibers travel along the discrete splanchnic pathways. Preganglionic fibers from T5–9 coalesce to form the greater splanchnic nerve. This greater splanchnic nerve passes through the diaphragm and synapse onto the celiac plexus. Preganglionic nerves from T10–11 join to form the lesser splanchnic nerve before synapsing within the celiac plexus. The least splanchnic nerve arises from the T12 sympathetic ganglion and courses through anteriorly to join the celiac plexus. Blockade of sympathetically mediated pain in this region is accomplished by neurolysis of either the celiac plexus or the splanchnic nerves that became the plexus.

The celiac plexus is located anterior to the aorta at the level of the L1 vertebral body and anterior to the crura of the diaphragm. This plexus contains two large discrete ganglia on either side of aorta. The left celiac ganglion is slightly lower than the right ganglion.

Techniques: Multiple techniques (up to 13 approaches) have been described for sympathetic blockade at the level of celiac plexus.[71,72] Posteriorly, clinicians can use the classic retrocrural, transcrural, or transaortic technique. Anteriorly, percutaneous gangliolysis with CT guidance or direct intraoperative celiac gangliolysis can be used.

For the posterior classic retrocrural approach, the patient is placed in a prone position with a pillow under the lower abdomen to minimize lordosis. The midback is prepped aseptically. Using fluoroscopy, the relevant landmarks are identified and marked. These landmarks are relevant: the spinous processes of T12 and L1, and the

inferior border of the 12th rib. It is extremely important to correctly identify the T12 spinous process by following the 12th rib medially and by counting cephalad from the L5 spinous process. The skin is infiltrated with local anesthetic at a distance 8 cm lateral to the L1 spinous process and inferior to the 12th rib. The underlying muscle tissue also is infiltrated with local anesthetic. Five-inch, 22-gauge needles are inserted bilaterally. Each needle is advanced slowly initially oriented at a 45° angle toward midline and approximately 15° cephalad, using fluoroscopic guidance. The initial target is the L1 vertebral body. Once bony contact is made, the depth of needle is noted. The needle is then withdrawn and redirected at a steeper angle (60° from midline) so that the needle tip is walked off the L1 vertebral body. The left needle is advanced approximately 2 cm beyond bony contact, slowly with frequent aspiration. The right needle is advanced further approximately 4 cm past the vertebral body anteriorly. The goal is for the left needle tip to position posterior to aorta and the right needle tip to position anterolateral to aorta. These positions approximate the location of the celiac ganglia.

A small amount of contrast is injected into both needles to confirm localized dye spread in the proper anatomic location. Local anesthetic solution (12–15 mL of 1% lidocaine) is injected into each side to achieve an initial diagnostic block. The patient is awakened from light sedation to confirm pain relief and no adverse motor blockade of lower extremities. The patient is again sedated, and neurolysis can be performed with 10–12 mL of 50% alcohol or 6% phenol to each side.

The splanchnic nerve block (or so-called retrocrural celiac plexus block) is similar to the classic retrocrural technique. However, the needles are aimed more cephalad to the anterolateral margin of the T12 vertebral body (Fig. 94–5). The goal is neurolysis of the splanchnic nerves feeding into the celiac plexus.

Efficacy: Celiac plexus blockade has proved to provide significant relief of pancreatic cancer pain. Pain relief has been reported between 70% and 94% of patients.[73] Studies have shown a higher success rate, corresponding to better patient selection and technologic advances.

Complications: Although not strictly a complication, sympatholysis with its side effects should be considered in celiac blockade. Orthostatic hypotension may occur and should be anticipated. Unopposed parasympathetic activity will lead to GI hypermotility. The consequent diarrhea is transient and does not last more than 2 days. Serious complications can include visceral injury, renal trauma with hematoma, and intravascular or subarachnoid injection. Pneumothorax is possible.

Lumbar Sympathetic Block *Indications:* Lumbar sympathetic blockade has been used to treat sympathetically mediated cancer pain due to tumor invasion or metastases to the lumbosacral region, chemotherapy- or radiation therapy-induced lumbar plexopathy, phantom limb pain, and lower extremity neuropathy secondary to malignancy.[74]

Anatomy: Lumbar sympathetic chain is variable in size and location. The sympathetic ganglia usually are located between L2 and L4 vertebral bodies. Classically, the sympathetic chain lies in the fascial plane anterolateral to lumbar vertebral bodies, just anterior and medial to psoas muscles.

Techniques: The patient is placed in a supine position, with a pillow under the lower abdomen to minimize lordosis. The back is prepped aseptically. Using fluoroscopy, surface landmarks of L2, L3, and L4 spinous processes are identified and marked. At a distance 8 cm lateral to each spinous process, the skin and underlying muscle tissue are generously infiltrated with local anesthetic. A 7-inch, 22-gauge needle is introduced at the selected site and directed at a 45° angle with the midline. The needle is advanced until vertebral body is confirmed. The depth of the needle is noted, and the needle is withdrawn and redirected at a steeper angle (60° with midline) to walk off the vertebral body. Once the needle slides past vertebral body, it is advanced approximately 1 cm further into the prevertebral fascial plane. This sequence is repeated bilaterally for L2, L3, and L4 levels. Contrast dye, 1–3 mL, at each needle site can be used to visualize the spread radiographically. A diag-

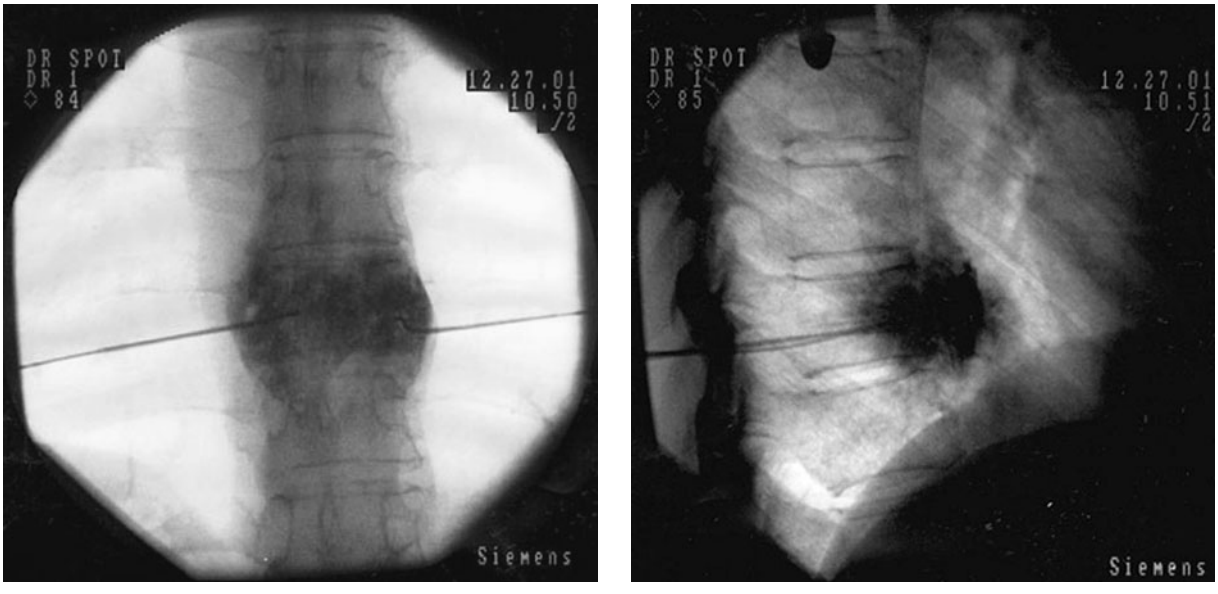

FIGURE 94–5. Anteroposterior and lateral views of retrocrural celiac plexus block.

nostic block with 20–30 mL of bupivacaine 0.25% can be performed, with the patient awakened to evaluate any neurologic sequelae. Neurolysis then can be performed with 6% phenol for a volume of 5 mL at each needle site.

Complications: Side effects of lumbar sympatholysis include hypotension and diarrhea. Intestinal hypermotility is self-limited.[75] Other complications include psoas muscle necrosis and renal or visceral damage. The most common complication with lumbar sympatholysis is genitofemoral neuralgia. Most cases are transient and resolve in a few weeks.

Superior Hypogastric Plexus Block *Indications:* Pelvic malignancies can affect multiple organs in the pelvis and include gynecologic and prostate cancers. Each year in the United States, 18,400 new cases of gynecologic cancer of the uterine cervix, vulva, and vagina are diagnosed, resulting in approximately 6300 deaths.[49] Patients with pelvic malignancy often experience initial visceral pelvic pain. The pain often is described as vague, poorly localized in pelvic region, and colicky in character. Surgical destruction of the hypogastric plexus has been shown to relieve pelvic pain.[76,77] Plancarte et al.[79] have reported a technique for hypogastric blockade with good results for controlling pelvic pain secondary to cancer. In that study, all 28 cancer patients with intractable pelvic pain reported good pain relief after the procedure.

Anatomy: The superior hypogastric plexus arises from the coalescence of nerve branches descending from the celiac plexus and lumbar sympathetic chains. This hypogastric plexus is a bilateral retroperitoneal structure located usually anterolaterally, extending from the level of the L5 vertebral body to upper third of the S1 vertebral body. The plexus is just medial to the bifurcation of iliac arteries and veins on each side.

Techniques: The patient is placed in a prone position. A pillow is placed under the lower abdomen to minimize lumbar lordosis. The back is prepped aseptically. Under fluoroscopy, the spinous processes of L4 and L5 are identified and marked. The entry point is 5–7 cm off midline at the level of the L4–5 interspace. The skin and underlying tissue at this point are well anesthetized with local anesthetic (1% lidocaine). A 7-inch, 22-gauge needle is introduced at an orientation 30° caudal and 45° mesiad off midline. Under fluoroscopy in anteroposterior and lateral views, the needle is slowly advanced, with the target being the anterolateral aspect of the L5 vertebral body. The iliac crest and L5 transverse process can be obstacles along the needle trajectory. The needle may have to be reoriented slightly to bypass these anatomic structures. Once bony contact is made with the L5 vertebral body, the needle is reoriented to a more mesiad angle to walk the needle tip off the body of the L5 vertebra. The tip of the needle should be advanced approximately 1 cm past the anterolateral border of the L5 vertebral body. A loss of resistance may be felt as the needle tip passed beyond the psoas muscle fascia and into the retroperitoneal space where the hypogastric plexus lies. Because of close proximity to the bifurcation of iliac vessels, careful aspiration is helpful to ensure the needle tip is not intravascular. Contrast dye can be injected to visualize even dye spread to the paramedian space at L5, anterior to the psoas fascia (Fig. 94–6). Each side can be injected with 10 mL of 0.25% bupivacaine for diagnostic block, and neurolysis can be achieved with 10 mL of 10% phenol at each site.

Complications: Because of close proximity to the iliac vessels, the clinician should be cautious about intravascular injection. Vascular puncture may lead to hemorrhage. Other less likely complications include subarachnoid injection, sacral nerve injury, and bladder or bowel injury.

Ganglion Impar Block *Indications:* In the perineum, there is a diffuse network of mixed sympathetic and somatic innervations. Thus, perineal pain usually involves both somatic and sympathetic pathways. In cancer patients with perineal pain, cancer can involve the lower colon, rectum, bladder, cervix, and endometrium. Blockage of ganglion impar with the goal of disrupting sympathetically mediated pathways has been shown to be effective in managing some intractable perineal cancer pain.[79]

Anatomy: Ganglion impar is a solitary retroperitoneal structure located at the level of sacrococcygeal junction. The two parallel sympathetic chains fuse together anterior to superior borders of the coccyx, forming the ganglion impar or ganglion of Walther.

Techniques: The patient is placed in a supine position, with a pillow placed under the lower abdomen. The buttock area and midsacral to anus area are prepped in an aseptic manner. In the midline and just posterior to the anus, the skin over the anococcygeal ligament is anesthetized with local anesthetic.[79] A 3.5-inch, 22-gauge spinal needle is bent 1 inch from the hub to form a 30° angle. This bent needle will allow the tip of the needle to maneuver anterior to the concavity of the coccyx and sacrum. Under fluoroscopy, the needle is advanced inferior to the tip of the coccyx and then

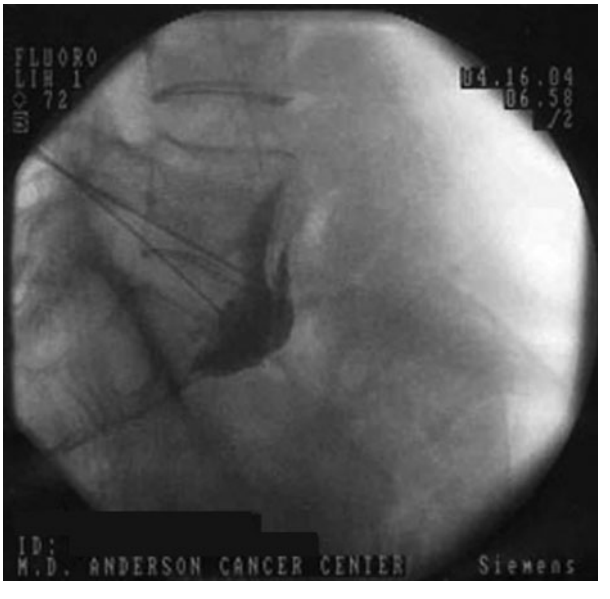

FIGURE 94–6. Lateral radiograph of superior hypogastric plexus block.

upward and anterior to the coccyx. The target is the anterior sacrococcygeal junction. A 5-mL volume of 0.25% bupivacaine is injected for diagnostic block, and 5 mL of 10% phenol is used for neurolysis.

Complications: This block of ganglion impar may cause rectal perforation because of proximity to the rectum. Because most of this region is dually innervated by both somatic and sympathetic fibers, complete pain relief may be difficult to achieve by this block alone.

Neuromodulation Techniques

Intraspinal Drug Delivery Significant side effects from systemic high-dose opioid administration can be minimized with intraspinal delivery of opioids. Deposition of opioids in close proximity to spinal cord receptors provides for more potent analgesia and fewer side effects.[7] If the opioid dose is delivered into epidural location, only 20–40% of the systemic dose is required to achieve similar analgesia.[80,81] The intrathecal dosage is even lower, requiring only 10% of the systemic dose.

In cancer patients, the intraspinal opioid dose can be delivered by percutaneously tunneled epidural catheters, tunneled epidural or spinal catheters connected to subcutaneously implanted injection ports, or fully implanted spinal infusion pump systems (Fig. 94–7).[82] The SynchroMed pump system (Medtronic Inc., Minneapolis, MN) is an example of a fully implantable system that is sophisticated yet easy to use. The pump can easily be reprogrammed to meet the patient's changing pain condition. Advantages of a fully implantable intrathecal pump include effective pain control, increased independence and mobility of the patient, and a reduced risk of infection with an internalized pump system. However, the initial cost of system hardware and implantation surgery can be prohibitive and hard to justify for patients with predicted survival <3 months.[83,84] With survival time <3 months, a simple tunneled epidural catheter or subcutaneous infusion is more economically feasible and beneficial for the patient. The epidural space is further from the spinal cord and thus requires a higher dose or rate of infusion, usually mandating an external pump.

Other Techniques

Vertebroplasty Neurosurgical procedures can be used to treat intractable pain. Vertebroplasty is one procedure that provides significant pain relief in patients with vertebral compression fractures secondary to malignant diseases. Malignant tumors include metastasis, lymphomas, and myeloma. Vertebroplasty involves injection of polymethylmethacrylate (PMMA) cement into diseased vertebral body.[85,86]

Palliative Care

Palliative care is defined as comprehensive care of the terminally ill patient. In overall oncologic care, much effort and treatment is used in the palliative treatment mode. Many patients have meaningful life-extending and life-enhancing palliative (as distinct from "curative") treatments. Treatments include chemotherapy, radiotherapy, tumor ablative procedures, surgery, and the interventional treatments outlined in this chapter.

Effective palliation in the patient with advanced cancer always starts with complete assessment and appropriate pharmacologic management. In some patients in whom the risk-to-benefit ratio is favorable and more conservative therapies are failing, interventional pain techniques may be helpful. When treating the advanced cancer patient, it is important to keep in mind some tenets of palliative medicine, such as these adopted from Field et al.[87,88] Symptom control is a paramount concern. It is critical to discuss openly and compassionately the patient's goals of care and to tailor your treatments in accordance with the patient's wishes. The patient's overall well-being directly impacts on the caregiver's quality of life. Be honest with patients and family members while being cautious not to extinguish hope.

FIGURE 94–7. Implantable programmable pump.

CONCLUSION

Cancer pain management is a complicated challenge. It requires a thorough understanding of the cancer disease process, pain diagnosis, and treatment modalities available to treat the pain condition. In addition to pain, the patient often presents with a constellation of symptoms arising from the cancer and the oncologic treatment. Both pharmacologic and interventional modalities of treatment are necessary to help the patient control pain and reach a satisfactory quality of life. In carefully selected cases, diverse interventional techniques help the physician and patient to achieve effective control of cancer pain, thereby optimizing quality of life.

PART 9

PRACTICE RELATED ISSUES

CHAPTER 95

Legal Issues in Anesthesiology

C. Lee Parmley, MD, JD

LEGAL ISSUES IN ANESTHESIOLOGY

Legal System

The American legal system is composed of federal and state court systems, the latter of which is the usual forum for matters pertaining to anesthesia practice.[1] State courts are established to adjudicate civil and criminal actions. Many consider our legal system to be cumbersome, overburdened, and often ineffective and unfair. Despite this reputation, it is our route to dispute resolution and protection of interests both personal and public. When contracts are formed by private parties, the legal system is called upon to interpret language and hold parties to their contractual obligations. When one party is injured by another, the legal system is expected to resolve the matter and make whole the injured party to the extent possible. When criminal actions are taken, punitive action is imposed by the legal system.

Criminal

Criminal courts deal with violation of criminal and other statutes and regulations for which penalties beyond those available in the civil system can be imposed. Penalties include fines and loss of privileges, including liberty. Anesthesia practitioners hopefully will have little need to interface with the criminal court system. Violation of criminal statutes and some state regulations represent the possibility of being indicted as a criminal defendant. Legal representation in such proceedings is seldom provided through malpractice insurance coverage, and effective representation is necessary and usually quite costly. Occasionally healthcare providers, including those in the field of anesthesia, will be needed to testify as witnesses in criminal proceedings that involve patients who were the victims of criminal activity. Participating in such proceedings represents a considerable inconvenience, although often the court will make every effort to accommodate scheduling needs. Although in this situation the witness usually is called to provide factual evidence, the attorneys also may rely on the witness' expertise and ask for explanations and opinions, which ordinarily are in the realm of the expert witness.

Civil

Civil courts impose financial penalties and at times require or prevent a particular action of an individual. Most frequently the practice of anesthesiology interfaces with the civil court system, which is the forum for resolution of disputes based in contract and tort law, which includes actions in medical malpractice or medical negligence cases.

Evidentiary Standards

For legal proceedings, evidence is offered to establish the factual basis of the case. The finder of fact is ordinarily a jury but in some cases may be a judge. Evidence is presented to the finder of fact, who then weighs the evidence and determines what actually is the factual basis. How convincing the evidence must be in order to make a determination is thought of as the burden of proof. For criminal cases, the evidence must be sufficient to eliminate reasonable doubt. Civil cases, such as medical malpractice, ordinarily rely on a preponderance of the evidence standard. Language frequently applied is "more likely than not" or "with a reasonable degree of medical probability." Medical practitioners are trained to look at evidence supporting a P value of .01 or .05 or a confidence of 95–99%. The preponderance of the evidence standard is much lower, just enough to tip the evidentiary scale at –51%.

Burden of Proof

For civil and criminal cases, the party bringing the case has the burden of proof, which means the responsibility to provide evidence sufficient to meet the evidentiary standard. There is a presumption of innocence until the evidence is sufficient to establish facts

KEY POINTS

1. Elements of Negligence: To succeed in a medical malpractice action, the plaintiff must prove four elements by preponderance of the evidence. (1) Duty: The defendant owed a duty of care to the plaintiff. (2) Breach of Duty: The defendant failed to act consistent with the standards of care. (3) Causation: The injury suffered by the plaintiff is linked to or caused by the defendants breach of duty. (4) Damages: There is actual compensable loss resulting from the defendant's breach of duty.
2. Exclusive Contracts: Exclusive arrangements used by hospitals to contract for anesthesiology service and may be challenged on allegation of antitrust and restraint of trade.
3. National Practitioner Data Bank: Information contained in this data bank is protected from unrestricted public inquiry but is queried when medical staff application is made.
4. HIPAA (Health Insurance Portability and Accountability Act): Protects healthcare information while asking acknowledgment that it may be released for uses related to medical treatment, payment, and/or healthcare operation, such as auditing performance evaluation and training program.
5. Informed Consent: Process by which a patient chooses to accept or refuse treatment offered once there has been exchange of information sufficient to establish an understanding of potential risks and benefits of both treatment and nontreatment options.
6. Do Not Resuscitate Orders: Should be reconsidered when patients with these orders are taken for surgery and anesthesia. A patient-oriented approach requires an individualized look at goal-directed and procedure-directed option.
7. Parents are the natural guardian of their children and are expected to seek care that is in their children's best interest when needed. Courts usually will appoint a guardian other than the parent and support decisions for medical care deemed to be clearly in the child's best interest.

that are legally sufficient to prove otherwise. For medical malpractice, the plaintiff brings the case and has the burden of proving with the preponderance of evidence that every element of the tort claim is present.

Occasionally there are cases where the burden of proof shifts to the defendant, who must prove that he or she is not negligent. With *res ipsa loquitur* (meaning "the things speaks for itself"), the plaintiff's case is much easier to prove. Surgery on the wrong part of the body would be such a case. For *res ipsa* to apply, (1) the injury must ordinarily not occur in the absence of negligence, (2) the instrumentalities involved in the injury must be under the exclusive control of the defendant, (3) the plaintiff must be free of any contribution to the injury, and (4) the evidence or factual details must be more readily available to the defendant that the plaintiff. When *res ipsa loquitur* applies, there exists a rebuttable presumption that negligence exists, making it the defendants' burden to prove otherwise.[2]

Medical Liability

Elements of Negligence

Humans owe each other a duty of ordinary care to avoid injury to each other. When one individual is injured due to the failure of another to exercise ordinary care, a case in negligence can arise. For the medical arena, the injury involves the care provided by a healthcare practitioner or institution. Four elements must be proven.

The first of the elements is referred to as "Duty." Usually considered to be established through the development of a doctor–patient relationship, the duty is the requirement to provide care, although ordinary or standard care is all that the duty requires. The second element of negligence is a "Breach" of the established duty. The breach occurs when the individual with a duty fails to provide ordinary care or act within the standards of care.

"Causation" is the third element and is the causal link between the breach of duty and the injury sustained by the plaintiff. At times a patient may suffer an injury, and there may be one or more breaches of the standards of care. Unless the breach can be shown to have caused the injury sustained, the case will lack causation. Causation can be proven by two legal tests, the "but for" test and the "substantial factor" test. The plaintiff may succeed if he or she can show by a preponderance of the evidence that "but for" the defendant(s)' breach of duty the injury would not have occurred. Alternatively, the plaintiff may succeed if it can successfully be shown that the defendants' breach of duty represented a substantial factor in causing the plaintiff's injury, despite the presence of other factors, which may include ones introduced through action or inaction of the plaintiff.

The fourth element of negligence is called "Damages." This is the economic value assigned to the injury sustained by the plaintiff. Although losses may be physical, economic, and emotional, damages will be calculated to compensate the plaintiff such as to make him or her whole. The calculated damages will include medical expenses (current and future), loss of earnings, and earning capacity as well additional amounts added for pain, suffering, and loss of consortium, all of which will be computed in economic terms. Punitive damages intended to punish the defendant may be sought and awarded for gross negligence, that is, willful and wanton disregard for the well-being of the plaintiff.

Standards of Care and Expert Testimony

The duty to provide ordinary care is basic tort law and is expressed in the terms of doing what would be done by the reasonably prudent person in the same or similar circumstances. Ordinary care requires a slightly different perspective for purposes of establishing standards of care in medical negligence litigation. For that purpose, standards of care are those actions that would be taken by physicians of similar training and experience in the same of similar circumstances. For anesthesia cases, the defendant can expect to face the practice parameters and guidelines promulgated by the American Society of Anesthesiologists (ASA). It seems that the introductory language of these guidelines expressing their appropriate application seeks to limit their application as standards of care. Nonetheless, the finder of fact likely will be influenced by the fact that these guidelines have been developed by practitioners of apparently similar training and experience within the national society, which makes it seem a reasonable expectation that practitioners within the specialty would follow them.

In addition to published information that can be used to help establish standards of care, expert witnesses will be called by both parties to testify as to the appropriate action that was or should have been taken by the defendant practitioner. Expert testimony will seek to establish the existence of a physician–patient relationship, with associated duty of care, and breach of that duty, being a violation of the standards of care. Exert testimony also will be required to establish that, in fact, the breach of duty was a causative factor that resulted in the plaintiff's injury. Interestingly, it seems always possible to find expert opinion sufficiently diverse to support both the plaintiff's and the defendant's position.[3]

Anesthesia Malpractice Claims

Medical negligence cases involving anesthesia have declined over the past several decades. In fact, in 1999 the Institute of Medicine recognized anesthesia as an area in which very impressive improvements in safety have been made.[4] Historically, adverse outcomes related to respiratory events were the single largest class of injury, and consequences of brain damage and death led to high-damage claims. This is true across adult, pediatric,[5] and obstetric[6,7] populations. Most commonly, the respiratory adverse events resulting in significant injury were inadequate ventilation, esophageal intubation, and difficult tracheal intubation.[8] Advances in technology with the development of oximetry and capnography in conjunction with the creation and implementation of practice guidelines appear significant when considering factors that have both improved patient safety and reduced anesthesia malpractice cases.[9]

Despite the reduction in the number and cost of claims against anesthesia practitioners, medical malpractice cases continue to be filed and likely will continue despite the efforts made to curb them through tort reform. The process is initiated by a notice letter, which establishes the intent of the injured party or plaintiff to take legal action. This must be done within the statue of limitations and begins with filing a complaint or petition in state court and serving notice on the defendants being sued. The defendants thereafter file a responsive pleading,

which answers the allegations in the original petition.[10]

Discovery

Once filed, the case enters the discovery phase, where both plaintiff and defendants acquire evidence to be used to prove their case. This involves requests for production of documents such as medical records and other written or recorded information that may reflect facts pertaining to the plaintiff's injury and the economic loss associated with it. Discovery also includes depositions whereby sworn testimony from parties as well as fact and expert witnesses is taken and preserved in preparation for trial. Discovery allows the plaintiff and defendants to develop their cases and possibly enter settlement negotiations and avoid trial.

Trial

At trial, the plaintiff will be required to prove all elements of the negligence case against each defendant with sufficient evidence to meet the burden of proof. Defense of the medical practice case requires that the defendant defeat only one of the elements of the plaintiff's case. Although attack is made on multiple elements, failure of the plaintiff on only one element results in a verdict for the defendant. The trial concludes with a verdict for the plaintiff or defendant. An award of damages in some dollar amount for the plaintiff will be divided such that costs of litigation and the attorney's contingency fee are paid prior to money going to the injured party. A verdict for the defendant puts an end to the experience, although the memories will remain.

Avoiding and Surviving Lawsuits

The most effective protection against a medical malpractice lawsuit is the rapport a healthcare provider develops with the patient.[11] If the provider is personable, available, and trustworthy, the injured patient will want to keep him or her out of the defendant pool, even if there is reason to be included. By contrast, poor bedside manner and distrust increases the likelihood of being named in malpractice cases. Angry patients and those who sense they are getting less than the whole truth often resort to the legal system for resolution. Those who have generated the anger and distrust can expect to participate in the legal action.

Although provider apology for medical error does not decrease the number of lawsuits filed, it does tend to expedite settlement of claims for fewer dollars.[12] In the past, standard practice was to adopt a policy of total silence,[13] believing that disclosure would increase the incidence of litigation.[14] The older approach now faces one of counterintuition in which disclosure and apology are made when adverse events and medical errors occur. The process helps fulfill needs of both physician and patient,[15] should be undertaken as close to the time of error as possible when the patient is capable of full comprehension, and after consultation with legal counsel that does not have power of veto. The truth-based apology may eliminate the perception that details are being withheld and is consistent with the recommendations of several professional societies and associations.[16]

When involved in a case with an undesired outcome, it is wise to anticipate the possibility of adverse legal action. Notifying ones insurance carrier and the hospital risk management officer are appropriate early steps, soon after the event and long before legal action is initiated. It is crucial to avoid discussing the matter with others, and never alter medial records. Records kept in the ordinary course of business, with the exception of those generated as part of the peer review and quality improvement processes, are discoverable and will end up in the hands of the plaintiff's attorney.[10]

Protected from discovery are products generated in anticipation of litigation and communications between the attorney and client. Liability insurance policies ordinarily provide legal counsel for the insured healthcare provider, and their recommendations should be heeded. If there is reason to believe that the attorney provided by the insurance company is not zealously representing the case filed against one, it is best to ask for alternative representation or to employ individual counsel. Individual counsel is also recommended when the damages sought exceed the coverage afforded by the liability policy.

Economic Relationships and Contracts

Corporations

It is common for groups of anesthesia practitioners to join forces in order to provide services for hospitals, outpatient centers, and clinic operations. The legal entity that frequently does this is the professional corporation, which is formed and regulated under state law.[17] The corporation is a separate entity, which in many ways has attributes of a person in that it can enter into contracts, employ workers, earn and lose money, and be a party to litigation. Such corporations may be owned by one or more individuals, often those who form the practice together and thereafter employ others who eventually become shareholders.

Medical practice corporations take on numerous expenses, including billing and other costs of business, malpractice insurance premiums, educational expenses, and at times the costs of travel and transportation. Earnings of the group practice are pooled, overhead expenses paid, and salaries to shareholders and other employees paid. The corporation is also the entity with which a hospital might contract to obtain coverage for anesthesia services needed to maintain business operations. Corporations file returns and pay taxes on profits, so they may pay out bonuses to employees and stockholders at the end of each fiscal year.

Hospitals

Hospitals, also legal entities, often enter into explicitly exclusive supplier arrangements for the provision of "hospital-based physician" services, which includes anesthesiology.[18] Typically this contract will be made between a hospital and a corporation. The contract spells out compensation, billing, minimum services, and management responsibilities; at the same time it excludes other anesthesiologists or groups from providing services at the hospital.[18] For the hospital, this provides an assurance that necessary services will be provided and is an alternative to hiring anesthesia providers as employees salaried by the hospital. For the corporation and anesthesia group, it prevents others from entering the practice area and capturing revenue, which will be theirs and protected by the exclusivity clause of the contract.

The bargaining power of the hospital compared with the practice groups is seldom equal, and at times the group may find itself in the position of being controlled by the hospital's business plan and driven to cut costs and corners. Patient care problems may also arise

when qualified practitioners are excluded by the contract, which may also circumvent peer review activities.[19]

At times, exclusive contracts are legally challenged based on allegations of restrain of trade and antitrust.[20] Often the plaintiff to such action is a practitioner who is not a party to the contract or employed by the contracting entity and therefore cannot practice in the defendant hospital. The pleadings will cite violations of procedural due process, not unlike those involving the termination of staff privileges,[21] and also allege that the exclusive contract seeks to monopolize the market and is a restraint of trade. Although the contracts usually are upheld at trial, the courts have not been totally insensitive to the argument.

Courts have concluded that certain types of provisions in exclusive contracts are unreasonable "per se," and if these exist the contract imposes an unreasonable restriction on competition. The per se violations include agreements to fix prices, agreements between competitors to divide markets, and, in some cases, group boycotts and tying arrangements. Short of per se violations, contracts may be found unlawful if they are not supported by the "rule of reason," which states that contracts are lawful if the participants lack market power or the results are significant efficiencies that outweigh the anticompetitive effects.[22]

When patients can easily travel to an alternative hospital to receive care, the institution and contracting group lack market power as considered under the rule of reason. On the other hand, exclusive contracts have been found unlawful when a hospital has high market share, and the contract tends to insulate the physician group from competition. At times, courts have upheld exclusive contracts when they allow hospitals and physician groups to control cost or quality of services provided to patients.[22]

Supervision

Anesthesiologists who supervise certified registered nurse anesthetists (CRNAs) and/or residents are held accountable for the actions of those under their supervision. Although there is really not an alternative to direct supervision of residents, CRNA supervision is somewhat different.

A substantial portion of the total number of anesthetics administered in the United States is performed by CRNAs either with or without the supervision of anesthesiologists. This supervisory relationship, when it exists, is known as the *anesthesia care team.* The distribution of anesthesia providers in this country is highly skewed toward metropolitan areas, where supervision in the anesthesia care team is more prevalent.[23] CRNAs working in the anesthesia care team model are found to be more limited in their scope of practice when employed by the anesthesiology group rather than the hospital, and many find their practice to be noncollaborative.[24] The scope of practice of CRNAs in rural hospitals[25] is broader than in metropolitan practice.

To date no studies have shown a difference in anesthesia quality of care or outcomes based solely on the distinction of the provider being a CRNA or anesthesiologist. In 2001, the Centers for Medicare and Medicaid Services (CMS)[26] published its ruling allowing state governments exemption from the requirement for CRNA supervision. This required written notification of CMS by the state governor after consultations with the boards of medicine and nursing, determination that opting out was consistent with state law and that, upon decision, was in the best interests of the citizens of the state.

In addition to being seen as favorable to CRNAs, this allowed an option to relieve supervising physicians of liability, which concerned some, especially supervising physicians who were not anesthesiologists.

Private and Public Information

National Practitioner Data Bank

The National Practitioner Data Bank (NPDB) was established in 1986 through the Health Care Quality Improvement Act.[27] Seeking to improve the quality of healthcare, the NPDB was intended to restrict the ability of incompetent physicians to move from state to state without disclosing their incompetence. The NPDB is a flagging system to facilitate a review of healthcare practitioners credentialing. Hospitals, medical boards, professional societies, and others that take adverse actions against professional licensure, as well as those that make payments as a result of medical malpractice actions, are required to report to the NPDB. Any actions taken to reduce, restrict, suspend, revoke, or deny clinical privileges or membership are to be reported, as are monetary payment and adverse judgments resulting from medical malpractice law suits.

When healthcare practitioners apply for clinical privileges, a hospital must query the NPDB and repeat the query every 2 years thereafter. Information obtained through this query is restricted to use only for the purpose for which it was obtained. Civil penalties can be imposed for violation of the confidentiality of the NPDB information. Although the general public cannot obtain information regarding a particular practitioner from the NPDB, a plaintiff's attorney can request information pertaining to a practitioner against whom he or she has filed suit, if through discovery it is disclosed that the hospital failed to do so. Defense attorneys cannot query the NPDB, but a practitioner may make a query to obtain information concerning himself to see which, if any, incidents have been reported.

In general, those involved in the credentialing of healthcare practitioners enjoy qualified immunity. They cannot be held liable for providing information regarding the healthcare practitioner unless the information provided is false and the individual providing the information actually knew it to be false. Courts have held that hospitals are immune for reporting peer review information to the NPDB, as long as the reports are made without knowledge of falsity.

Health Insurance Portability and Accountability Act

Whereas the regulations under the Health Insurance Portability and Accountability Act of 1996 (HIPAA) are new, the underlying concept of privacy of medical information is not.[28,29] In fact, some consider the HIPAA regulations to be unduly complex, long, and laden with excess commentary, while the underlying principle is quite simple. The recognized right for a patient's personal medical information to be kept private has been present from the time of Hippocrates.[30,31] Understandably, patients are willing to disclose to their physician the information required for diagnosis and treatment when they understand that the information will remain confidential.

In the era of electronic communications, management of healthcare information has become more complex and protection of privacy more prob-

lematic. Some computer experts believe that, for all practical purposes, privacy is dead, and that personal control of private information is a mere illusion in the computer age. Apparently denying the legitimacy of this perception, HIPAA regulations seek to inform and educate patients as to their privacy rights. Patients are to receive a notice of privacy, setting forth who will be able to use their medical information and for what purposes. Patients are asked to acknowledge that they have been informed that their information may be disclosed for uses related to medical treatment, payment, and/or healthcare operations such as auditing, performance evaluations, training programs, and the like. Some providers still obtain authorization to disclose medical information, which is necessary when the disclosure is for reasons other than treatment, payment, or operations, for example, medical research.

Patients have a right to access and copy their entire medical history with limited exception, and parents have rights to access the medical records of their minor children unless precluded through court action. Emergency treatment need not be delayed while HIPAA notice is provided, but once the emergency condition has stabilized, privacy notice is to be provided. HIPAA regulations stipulate that the information to be disclosed is to be the minimum necessary and specifically include the conducting of training programs where healthcare trainees learn under supervision. Significant penalties can be imposed for violations of HIPAA regulation. Civil monetary penalties up to $25,000 annually[32] may be imposed for violations, and criminal penalties for those who knowingly obtain to disclose identifiable health information can be has high as 10 years' imprisonment and $250,000 if the intent is to use the information for commercial advantage.[33]

Consent

Among the legal documents most frequently seen by anesthesia providers are those associated with the process of informed consent.[34,35] In general, patients come to the healthcare industry seeking care, and it would be presumed that they would agree to receive the care they are seeking. That presumption is incorrect if there are aspects of the care they would consider sufficient to make them think it over and perhaps choose not to be treated. The process of informed consent in essence represents the foundation of the physician–patient relationship. The patient seeks diagnosis and treatment; the physician makes a diagnosis and offers options for treatment. The patient cannot compel the physician to treat contrary to his or her will, just as the physician cannot compel the patient to accept treatment that he or she does not want. A full disclosure and comprehension of treatment risks and benefits is necessary if the consent is to be truly informed.

Treatment

In order for there to be informed consent, there must be exchange of information. This requires a patient competent to understand the nature of the treatment being discussed and the implications of accepting the treatment as well as the nontreatment option. It also requires a physician to disclose the potential benefits of treatment as well as the risks represented by the treatment or nontreatment. The extent of risk disclosure has been a topic of disagreement over the years. The physician-based standard, requiring disclosure of risks deemed appropriate by physicians, has largely been replaced by the "reasonable person" standard.

This standard requires disclosure of risks that a reasonable person would need to consider in determining whether or not to accept an offered treatment. Considering the frequency and severity of risk is important. Death as a risk of anesthesia is very unlikely, yet its severity is such that it should be disclosed. At the other end of the spectrum might be a sore throat following use of an endotracheal tube, which, although quite inconsequential, may be frequent enough in occurrence to make its disclosure appropriate. The reasonable person standard is now widely accepted in most jurisdictions.

Blood Products

Although many standard surgical consent forms include provision for blood product administration, it is common practice in some areas to have separate consent documents pertaining to their administration. This is in part due to the inherent risks, although small, of transmitting infectious disease, as well as to allow those who might refuse administration of blood products for religious reasons to engage in meaningful informed consent dialogue. The refusal of blood products, as is frequently encountered when Jehovah's Witnesses undergo anesthesia and surgery, may present an ethical conflict for practitioners. Although uncommon, being asked to stand by and allow a patient to die for lack of a lifesaving blood transfusion generates a conflict of conscience for healthcare providers involved.[36] Nonetheless, it is well recognized that patients do have the right to refuse treatment even when that treatment is necessary to sustain life.

Frequently the issue is made far complex when individual Jehovah's Witness patients will allow administration of some blood components, such as albumin and immune globulins, but not red blood cells; each individual is allowed to make decisions regarding these matters.[37] When minor children are involved and the need for administration of blood product arises, courts routinely intervene to require treatment for children whose parents deny consent for lifesaving medical interventions.[38]

Emergency

There are exceptions to the duty to disclose. The legal system recognizes the rights of a physician in a true emergency to act without patient consent, so long as his or her actions are consistent with those customarily done in the particular emergency. In emergency situations, there may be a presumption of consent; that patients would want treatment that would be lifesaving. There are rare occasions when the mere discussion of treatment risks may be detrimental to a patient's health. When discussion of risks generate emotional distress, such as to foreclose a rational discussion, a physician may exercise what is know as *therapeutic privilege*, and forego full risk disclosure to the patient. Careful documentation and discussion with family members regarding the situation is appropriate in this case.

Surrogacy and Family Consent

Incompetent patients requiring surgery and anesthesia traditionally have family members in attendance who can be engaged in the consent process. This long-standing practice has gained legal acceptance and is based on the presumption that the family is generally most concerned about the good of the patient and ordinarily will be most

knowledgeable about the patient's preferences, goals, and values. Since the 1980s, many states have enacted family consent statutes, which set forth the hierarchy of family members and close friends who are to be looked to for medical decision making. Ordinarily the hierarchy runs in descending order from the spouse, parents, majority of reasonably available adult children, and nearest living relative. Some states have freestanding statutes, although others incorporate this into their statutes addressing living will, advance directive, and healthcare decision making.[39]

Ethical Issues

Busy anesthesia practice usually is conducted without undue attention to biomedical ethics for its own sake. Although daily activities are filled with a balancing of risks and benefits and providing care consistent with the patient's wishes, the ethical principles of autonomy, beneficence, and nonmaleficence are not necessarily the terminology commonly applied. These principles are more in focus when dealing with end-of-life decisions, as may be faced when terminally ill patients are brought to the operating room, when life-sustaining treatment is to be withdrawn, and when transplantable organs are retrieved from the cadaveric donor.

End-of-Life Care

The past several decades have been characterized by tremendous advances in technology, pharmacology, and healthcare in general. Populations are aging, and medical conditions that once were terminal have found treatments that prolong life considerably. Prior years saw deaths in hospital occur despite every effort that could be made. More frequently today we see hospital deaths when decisions are made that not everything that can be done really should be done.[40] Decisions to limit care by either withholding or withdrawing treatments are commonly made in the process of caring for patients at the end of life.

Do Not Resuscitate Orders

Probably the most basic of decisions regarding end of life care is a decision to withhold advanced cardiac life support in the event of a cardiac arrest. In 1974, the American Heart Association and American Medical Association stated that the purpose of cardiopulmonary resuscitation is to prevent sudden, unexpected death; it is not indicated in cases of terminal illness where death is expected.[41] Although conceptually this was not difficult to grasp, early on orders to withhold cardiopulmonary resuscitation, or "do not resuscitate (DNR)" orders, were often spoken rather than written.[42] But with time there evolved a more sound recognition that continuation of life-sustaining treatments[43] as well as cardiopulmonary resuscitation may not always be appropriate, and the distinction between sustaining life and prolonging the dying process emerged.

There are really two reasons to withhold cardiopulmonary resuscitation: when it is medically inappropriate and when a patient refuses to have such treatment,[44] even if it might be deemed medically appropriate by the healthcare team. Ethically speaking, there is no obligation to provide care that is of no benefit to the patient, especially if such treatment could be considered harmful or cause pain. Likewise, treatment offered and considered appropriate can be refused by the patient whose autonomy we must respect.

Conflict has arisen when patients with DNR orders are brought to the operating room to undergo surgical procedures and anesthesia.[45] Cardiac arrest is among the recognized risks of anesthesia, and practitioners would choose to have every opportunity to correct problems caused by their care. For some time, there was a pattern of universal suspension of DNR orders when patients were in the operating room and under the effects of anesthesia. Currently such practices are being reconsidered and replaced by more patient-oriented and individualized policies and practices with goal-directed and procedure-directed options.[46] This reevaluation process regarding DNR orders prior to surgery is appropriate for the pediatric population as well.[47] The ASA recommends the development of a policy that provides four options and requires a reconsideration of the decision for the DNR and the implications of the procedure and anesthetic to be undertaken.[48]

Withdrawal of Treatment

Life-sustaining treatment is ordinarily initiated when organ failure is sufficient to risk loss of life. When underlying conditions are corrected and organ function restored, life-sustaining treatment is no longer needed and can be discontinued. This is commonly seen when patients require mechanical ventilation postoperatively while temporary pulmonary insufficiency would put them at risk of death without such support. However, if organ function is not restored or the patient's condition deteriorates further, it may become apparent that survival can no longer be expected. At this time, it will be appropriate to entertain the option of withdrawing life-sustaining treatment that is merely delaying the moment of death or prolonging the dying process.[49] Even when life-sustaining treatment is withdrawn, physicians have a duty to care for the dying patient, administering medications to provide comfort and assuring the continuation of other care for preservation of dignity. Often medications administered for comfort also have depressant effects that could hasten death, a double effect. Such medications are to be administered to provide comfort even if they may also hasten death.[49]

Some patients have executed a directive to physicians, or a living will, which specifies desire regarding the application of life-sustaining treatment in the event they have a terminal or irreversible condition and they are incompetent to express their desire at that point in time. Most frequently the directive asks that treatments be discontinued so that the individual may die naturally, although other instructions may also be given. A directive to withdraw or withhold life-sustaining treatments can be considered a statement of refusal of treatment in the process of informed consent.

Even without a written directive, decisions to limit life-sustaining treatment are frequently made for the incompetent patient. Family members who would otherwise be involved in the consent process can engage in discussions regarding the discontinuation of life-sustaining treatment. At times they may be aware of the specific desire of the patient in this regard, but even if this was never clearly expressed, the decision can be made based on the patient's values and what is in his or her best interest.[39]

Futility

At times patients, or more often families, demand administration or continuation of treatment that is medically inappropriate.[50] When there is no ex-

pectation for survival, treatment directed at cure can be considered futile.[51,52] Although there is no obligation to provide futile care, there is reluctance to discontinue such treatment demanded by families, when to do so would soon be followed by the patient's death. Consultation of clinical ethics is appropriate and may help resolve such situations. Some institutions and state laws provide a due process means by which discontinuation of futile life-sustaining treatment, even contrary to the demands of the patient or family, can be accomplished with protection from legal liability.[53,54]

Organ Donation after Cardiac Death

Although historically organs for transplantation were retrieved from patients immediately following cardiac death, this practice was largely abandoned with the evolution of the concept of brain death. Anesthesia practitioners are commonly called upon to provide intraoperative management for the brain-dead cadaveric organ donor.[55] The procedure, unlike most cases, is somewhat unique in that administration of anesthetic is not necessary to render the patient insensitive to pain, and once the heart is arrested the intraoperative management of the anesthesia provider is essentially complete despite continuation of the surgical procedure.

With the high demand for transplantable organs and the increased public awareness of organ donation, there is rekindled interest in organ donation after cardiac death. Such an option at times occurs when there is a decision to discontinue life-sustaining treatment for a patient who will die soon and who has preserved function of transplantable organs such as kidney and liver. The end-of-life process usually occurs in the ICU and includes administration of medications to provide comfort at the time life-sustaining treatment is removed. Moving this process to the operating room allows control of the circumstances surrounding death and the possibility for retrieval of transplantable organs.[56]

Understandably, some who work in the operating room environment are troubled by this practice. They may need to reconsider what really is taking place and, if necessary, be excluded from the process. Although withdrawal of life-sustaining treatment and administration of medications for comfort predictably will be followed by death, the death is not caused for purposes of obtaining transplantable organs. The "dead donor rule," which applies here as well as for the brain-dead donor, prohibits the practice of causing death to obtain organs.[57]

Anesthesiologists have resisted the opportunity to participate in this practice. Rather than bringing in the anesthesia provider solely for participation in the end-of-life process, this is often done with providers who have cared for the patient in the ICU. Regardless of whether or not anesthesiologists directly participate in these procedures, their involvement in the development of hospital policies and procedures is appropriate, and they should seek to ensure that the protection of patient dignity and comfort is paramount throughout.[58]

Pediatric Issues

Consent

Generally, speaking the legal system will protect individual rights regardless of a person's age. The ability of some individuals to comprehend the nature of medical care and its impact on their person is limited, which is the case in the pediatric population. Cognitive development throughout childhood as well as developments of emotional reactions based on a broadening experiential foundation leads eventually to the competencies associated with adulthood. Ethical arguments that consent of the pediatric patient should not be based on an arbitrary age but rather on the development of personhood place high value on the child's input in the consent process.[59]

The ability to consent for and refuse treatment requires a level of maturity and understanding. Certainly a child may refuse to be subject to the pain of an injection despite the fact that immunization may have an effect in prolonging life. Clearly the consent for a surgical procedure is even more complex, and with younger children it would be unrealistic to expect an understanding of a procedure and its inherent risks and potential benefits. A progressive is recommended for use in obtaining consent from or for children; this allows involvement of the child based on age and developmental maturity. For ages 6 years and younger, in whom decision-making capacity is highly limited, consent is made on the child's behalf and in his or her best interest. With increasing age and development of decision-making capacity, the child's participation and contribution to the process increase through informed permission and assent to informed consent at maturity.[60] Even though the capacity to truly give consent may be present with older children and teenagers, parents still are ordinarily asked to execute consent documents on their children's behalf.

Parents are the natural guardian of their children and are expected always to seek care that is in the best interest of the children. When there is question as to whether on not the consent for treatment or refusal of treatment is truly in the child's best interest, it may be necessary to seek intervention by the legal system. Every state has a statutory framework set up to protect abused or neglected children, and statutes allow any person to petition the court for guardianship for the protection of a person lacking legal capacity.[61] Courts traditionally support decisions for medical care deemed to be clearly in the child's best interest and ordinarily will not appoint a guardian other than the parent unless there is good reason.

Neglect and Abuse

Child protective services are established by state governments to all the state to take custody of children who are being denied the necessities of life, such as housing, clothing, food, education, and medical care. There is some variation among the states, but most allow the state to take custody of the child upon little or nothing more than a verified petition alleging neglect or abuse.[62] Temporary custody may be sufficient to allow provision of medical care, but ultimately unless the state shows by clear and convincing evidence that all statutory requirements are met, there is little chance of terminating parental rights and maintaining custody.

Children are commonly the victims of injury, with trauma and accidents being the leading causes of death between the ages of 1 and 14 years.[63] At times, patterns of injury may be of concern, especially with acute injuries seen in conjunction with signs of prior trauma, such as bruises, contusions, and healing fractures, which may be suggestive of the "battered child syndrome."[64] Abuse may be sexual or may take the form of neglect, with failure to meet a child's needs for shelter,

clothing, food, and healthcare.[65] Stories telling the sequence of events leading to the current and prior injuries may seem inadequate to explain the degree of trauma, and details related may change over time.[66]

The immediate matter of consent for treatment when a child requires treatment that a parent declines is directed to the court, where a judge can and almost always will issue a court order that permits the healthcare provider to care for the child. A more long-term plan is activated when child protective services intervenes in the situation.

CHAPTER 96

Substance Dependence and Abuse in Anesthesia Care Providers

Raymond C. Roy, PhD, MD

> *…there is always* soma*, delicious* soma*, half a gramme for a half-holiday, a gramme for a weekend…A gramme is better than a damn…I wish I had my* soma.
> Aldous Huxley
> *Brave New World*, 1932

SUBSTANCE ABUSE: A NATIONAL PROBLEM

The United States manifests a significant ambivalence toward drugs. While the federal government wages war against the illicit drug industry and organized medicine campaigns against the nonmedical use of prescription drugs, the entertainment and advertising industries, in the spirit of Lieutenant Milo Minderbinder in Joseph Heller's *Catch-22*, bombard its citizens daily with prodrug references. Lyrics from Toby Keith's popular country music song "Get Drunk and Be Somebody" reflect a common mantra:

> *All week long, we're real nobodies,*
> *But we just punched out: it's paycheck Friday.*
> *Weekend's here, good God Almighty:*
> *People, let's get drunk an' be somebody*
> Toby Keith, Get Drunk and Be Somebody
> *White Trash with Money*, 2006

Comedians receive knowing laughs and applause from their audiences when they reference or parody recreational drug use. Television, Internet, and movie advertisements suggest that life is more enjoyable in social settings involving alcohol and more manageable with medications ("Ask your doctor if this medication is right for you."). Helping people who misuse drugs to "pass" drug tests also is a big business. For example, if "urine luck" is entered into an Internet search engine, almost two million citations are offered. Physicians and major pharmaceutical companies tout the benefit of medications to relieve pain. Anesthesia providers make their living daily demonstrating that drugs of high abuse potential can be safely administered. Even a brochure for the Wood Library Museum of Anesthesiology proclaims "Thank Goodness They Inhaled." Drug and alcohol misuse is commonly associated with youthful experimentation. However, misuse also is triggered by internal and external pressures to improve self-confidence and performance on the athletic field, in the classroom, on competitive examinations, in the workplace, and in the bedroom, to achieve a better body image, to feel more comfortable socially, to cope with the stresses of highly competitive work and study environments, and to escape from dysfunctional social relationships and unsatisfactory living situations. College students call this "pharming."[1]

The economic costs of drug misuse are staggering. If healthcare, law enforcement, prosecution, incarceration, and loss of productivity are taken into account, the annual cost associated with drug misuse, excluding nicotine and caffeine, is $465 billion, an amount greater than that linked to heart disease ($290 billion), cancer ($187 billion), or obesity ($123 billion).[2] From the perspective of a private insurer, the annual direct cost of healthcare for patients with claims associated with codes for opioid abuse in the *International Classification of Diseases, Ninth Revision, Clinical Modification* (ICD-9-CM; copyright by the World Health Organization in 1999) is more than eight times higher than for patients without such claims: $15,884 versus $1830. The higher costs are driven by a greater prevalence of costly comorbidities, such as nonopioid poisoning, hepatitis, psychiatric illnesses (especially depression), AIDS, and pancreatitis, increased utilization of the emergency room and in-patient services, and a greater number of drug prescriptions.[3]

The number of people who misuse drugs is staggering. According to the 2003 National Survey on Drug Use and Health sponsored by the Substance Abuse and Mental Health Services Administration (SAMHSA), 9.1% of the population of the United States over the age of 12 years, an estimated 21.6 million people, has a substance misuse disorder.[2] Substance misuse disorders run the gamut from smoking marijuana to driving under the influence to chemical dependency. According to the National Institute of Mental Health National Comorbidity Survey Replication (NCS-R), the prevalence of substance misuse disorders in the U.S. English-speaking population is 14.6%.[4] Of the 47,403 nonfederally employed physicians licensed since 1980 in the state of Florida 3604 (7.6%) had a substance misuse disorder serious enough to require treatment monitored by the Florida Professionals Resource Network, a physicians health program (PHP).[5] A PHP is an impaired provider program recognized by the state medical board as the primary agency to monitor compliance with substance abuse treatment programs and fitness to retain a license to practice medicine.

KEY POINTS

1. The incidence of opioid abuse among anesthesia trainees is 1%.
2. Addiction is a treatable chronic, relapsing disease.
3. Vulnerability to addiction has a genetic component.
4. Seventy-five percent of addicts declare themselves by age 27 years.
5. Most addicts have psychiatric comorbidities.
6. The addicted brain is a reorganized brain.
7. The key to detection of dependence is recognition of subtle changes in behavior and performance.
8. Interventions must be carefully researched, planned, and rehearsed.
9. The earlier the intervention, the greater the chance for successful treatment.
10. Improvements in the treatment of addiction have reduced relapse rates.
11. Reentry requires a contract between the dependent colleague and the employer.

When reading the literature, it is important not to confuse the terms *incidence* and *prevalence* and to be clear whether the terms refer to misuse, abuse, chemical dependence, or addiction (defined later in the chapter). *Incidence* refers to the number of persons who develop or are recognized to have a medical condition, such as chemical dependence, within a given, usually shorter, period of observation (e.g., the duration of a training program). *Prevalence* refers to the total number of persons who have a condition for a longer period of time, such as a professional lifetime. Because chemical dependence now is viewed as a lifelong relapsing disease, its prevalence includes those who have undergone successful treatment and reentry and are drug free but not those who have died as a consequence of their addiction. Prevalence is always greater than incidence.

If the incidence and lifetime prevalence for physicians is the same as it is for society as a whole, then 9.1% of physicians are wrestling with substance misuse issues at any given time, and 14.6% at sometime during their career will have a problem with drug misuse, abuse, dependence, or addiction. An argument can be made that the incidence and prevalence among physicians is less than for society as a whole. Because 50% and 75% of addicts declare themselves by age 27 years,[4] they may be less likely to enter or complete medical training. Supporting this premise is a 1992 study that determined the lifetime prevalence of substance abuse among all physicians, regardless of specialty, to be 7.9%, which is lower than the 14.6% for the population in general.[6] However, there should be no solace in the possible lower prevalence among physicians. Even accepting this lower prevalence, the lives of thousands of physicians are adversely affected by this affliction, more than 3600 in the state of Florida alone since 1980.[5] Although the incidence of substance abuse is greater than the incidence of malignant hyperthermia, prolonged QT syndrome, aortic stenosis, untreated hyperthyroidism, or a host of other medical conditions about which anesthesia providers are rightfully concerned, most anesthesia texts, training curricula, and continuing medical education (CME) meeting programs give it far less content exposure.

SUBSTANCE ABUSE AMONG ANESTHESIA PROVIDERS

There are no solid data for the incidence or prevalence of substance misuse or abuse specific to anesthesia providers. However, there are reasonable data for the incidence of chemical dependence specific to anesthesia residents and student registered nurse anesthetists (SRNAs): between 1% and 2% for the 2–3 years specifically involved in anesthesia training when alcohol and marijuana are excluded.[7] In the most recent survey of 169 anesthesiology residency programs active in 2001, 111 responded. Eighty percent of these programs reported at least one chemically dependent resident from their respective program between 1991 and 2001, with an average of 2.1 residents per program over the decade studied. Fatality before intervention was reported by 19% of the programs.[8]

Anesthesiologists are consistently overrepresented in analyses of data from PHPs.[9] In the previously cited Florida survey, more anesthesiologists are in treatment than would be predicted by their representation in the total physician workforce: 12% versus 4.7%.[5] It is tempting to say that there are four obvious explanations for this finding. (1) Drug abusers seek opportunities. Substance-abusing medical trainees and professionals seek to practice anesthesia in order to gain access to opioids and other anesthesia drugs for abuse. (2) Opportunity creates abusers. Anesthesia providers have a greater risk for becoming addicted than other physicians because they have ready access to drugs that they personally can either administer to patients or divert for their own abuse. (3) The stress of administering anesthesia can become overwhelming. Susceptible anesthesia providers seek relief from the pressure of administering drugs every day, which can lead to patient death or injury. (4) Environment creates abusers. Chronic inhalation of trace amounts of anesthetic drugs in the operating room increases the susceptibility to abuse. Even though each of these hypotheses has face validity, no studies specifically designed to test the first three have been performed. Gold et al.,[10] exploring the fourth environmental hypothesis, propose that "second-hand" exposure may produce changes in the brain that predispose susceptible anesthesia providers to chemical dependence. They have detected propofol and fentanyl in air sampled from cardiac surgery operating rooms. The highest concentrations were in samples from air around the patient's head.[10]

Many people have jumped to the conclusion that anesthesiologists have a greater problem with substance abuse than other physicians based on their greater relative enrollment in PHPs. There are several strong reasons not to do so *at this time.* First, the percent enrollment in PHPs has not been verified as a valid cross-sectional sample for addicted physicians. The percent of individuals enrolled in treatment programs is less than those who need such treatment. The cumulative lifetime probability of patients with substance abuse disorders receiving any treatment is 52.7–76.9%.[11] Second, the effect of the drug abused on admission to an PHP has not been well studied. Anesthesia providers could have the same lifetime prevalence of substance misuse disorders as other medical practitioners, but the time span over which they are diagnosed and treated may be compressed into a younger age range. This proposed compression effect would occur because they are more likely to abuse drugs with a higher addictive potential (e.g., fentanyl versus alcohol). Third, the effect of the preferred drug of abuse (e.g., opioids versus alcohol) on peer assistance and the legal pressure to enroll in treatment programs has not been well studied. Alcohol is a legal substance, is socially acceptable if consumed without causing intoxication, and is legally acceptable if blood alcohol levels while driving are below a certain threshold. Persons who abuse alcohol may seek counseling but enroll in surveyed treatment programs only if they become dependent. "An estimated 8 million adults in the United States have alcohol dependence. Of this number, only a minority ever receive treatment for the disorder, even when treatment is defined broadly to include participation in Alcoholics Anonymous."[12] Fourth, the effect of the diagnosis of abuse versus dependence, made according to the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision* (DSM-IV-TR; published by the American Psychiatric Association in 2000), is not taken into account in most of these

analyses. Colleagues with a dependence on drugs may not demonstrate behavior associated with abuse, such as hazardous use, irresponsibility in their social or work roles, or legal problems. In the National Epidemiologic Survey on Alcohol and Related Conditions (NESARC), which included 42,392 respondents, 22% of those who met the DSM-IV-TR definition of drug dependence did not meet the DSM-IV-TR definition of drug abuse (Table 96–1).[13,14] It is possible that a high percentage of dependent individuals who avoid behaviors associated with abuse may escape detection and not be enrolled in PHPs. Fifth, the effectiveness of specialty-dependent substance abuse awareness efforts has not been determined. Educational initiatives have not reduced the incidence in training programs over the last 3 decades, perhaps because most of the trainees who manifest their chemical dependence during training actually develop addictive behavior prior to the start of their residency. But awareness programs may have increased the detection and intervention rates for anesthesiologists more than for other physicians with substance misuse disorders.

TABLE 96–1.

Outline of Substance-Related Disorders: DSM-IV-TR General Criteria

- I. Intoxication: Reversible substance-specific syndrome
- II. Abuse
  - A. Recurrent use associated with ≥1 of the following within 12 months:
    1. Failure to fulfill major role obligations at work, school, or home
    2. Use in hazardous situations
    3. Use-related legal problems
    4. Use despite recurrent social or interpersonal problems caused or exacerbated by effects of intoxication
  - B. Symptoms have never met criteria for substance dependence for this substance class
- III. Dependence: Recurrent use with ≥3 of the following manifestations:
  - A. Tolerance
  - B. Self-treatment to relieve or avoid withdrawal symptoms
  - C. Overdoses
  - D. Persistent unsuccessful efforts to stop
  - E. High percent of time devoted to drug acquisition, use, recovery
  - F. Reduction in social , occupational, or recreational activities in order to use
  - G. Use despite acknowledging threat to physical or mental health

Data from Fauman.[13]

SUBSTANCE MISUSE TERMINOLOGY

Terms associated with appropriate drug use include tolerance, physical dependence, and withdrawal. Each represents normal physiologic adaptations seen in all patients after repeated administration of certain drugs. Although these terms also apply to drug misuse syndromes, they should not automatically imply substance abuse, substance dependence, or addiction. The American Academy of Pain Medicine (AAPM), the American Pain Society (APS), and the American Society of Addiction Medicine (ASAM) issued a consensus document in 2001 defining physical dependence and tolerance.[15] "Tolerance is a state of adaptation in which exposure to a drug induces changes that result in a diminution of one or more of the drug's effect over time." Either a given dose of a drug yields a decreased effect after repetitive administration, or an increasingly larger dose of the drug is required to produce an effect of intensity comparable to the first dose. "Physical dependence is a state of adaptation that is manifested by a drug class specific withdrawal syndrome that can be produced by abrupt cessation, rapid dose reduction, decreasing blood level of the drug, and/or administration of an antagonist." Although withdrawal signs and symptoms tend to be associated with the discontinuance of opioids, they can be seen in other categories of drugs, such as clonidine and β-adrenergic blocking agents. All chronic pain patients who are treated with opioids develop tolerance and physical dependence.

The five terms associated with inappropriate drug use are abuse, intoxication, dependence, withdrawal, and addiction. Note that dependence and withdrawal are terms associated with both appropriate and inappropriate drug use. Addiction is not a term used in the DSM-IV-TR or the ICD-10. These two systems classify all substance misuse disorders with the terms abuse, intoxication, withdrawal, and dependence. The 2001 AAPM, APS, and ASAM consensus statement defines addiction as "a primary, chronic, neurobiologic disease, with genetic, psychosocial, and environmental factors influencing its development and manifestations. It is characterized by behaviors that include one or more of the following: impaired control over drug use, compulsive use, continued use despite harm, and craving."[15] Similarly, the National Institute on Drug Abuse (NIDA) defines addiction as "a chronic, relapsing disease characterized by compulsive drug seeking and use, despite harmful consequences, and by neurochemical and molecular changes in the brain."[16] NIDA and the National Institute on Alcohol Abuse and Alcoholism (NIAAA) differentiate dependence and addiction as follows. "Physical dependence refers to adaptations that result in withdrawal symptoms when drugs such as alcohol and heroin are discontinued. Those are distinct from the adaptations that result in addiction, which refers to the loss of control over the intense urges to take the drug even at the expense of adverse consequences."[17] A person moves from misuse to abuse to addiction when craving, drug seeking, and compulsive use dominate his or her life and behavior.

Pseudoaddiction is a diagnosis made in chronic pain patients who develop drug-seeking behaviors because their pain is inadequately treated.[18] The diagnosis requires four conditions: (1) an appropriately diagnosed and documented pain condition; (2) inadequate pain treatment unrecognized by the medical staff; (3) analgesia-seeking behavior misinterpreted by the medical staff as inappropriate non–pain-related drug seeking; and (4) resolution of drug-seeking behavior when sufficient analgesia is provided. If the drug seeking is not pain related, then the diagnosis becomes either substance (opioid) abuse or dependence.

All substance-related disorders involve adverse social, behavioral, psychological, and physiologic effects caused by seeking, ingesting, injecting, or inhaling an abused substance.

The DSM-IV-TR recognizes 12 classes of these substances: (1) alcohol, (2) inhalants, (3) amphetamines, (4) nicotine, (5) caffeine, (6) opioids, (7) cannabis, (8) phencyclidine, (9) cocaine, (10) sedatives, hypnotics, or anxiolytics, (11) hallucinogens, and (12) other or unknown substances.[13] These abused substances have different molecular structures, different sites and mechanisms of action, and different physiologic effects. However, they all initiate a common series of adaptations that will, with repeated use, evolve to the brain lesion associated with addiction, starting with an increase in dopaminergic activity in the nucleus accumbens core (NAc).[19,20]

Although the terms narcotic, opiate, and opioid are frequently used interchangeably, *opioid* actually refers to any agent that binds to opioid receptors. There are four classes of opioids: (1) endogenous peptides, such as endorphins, enkephalins, and dynorphins; (2) opiates, such as morphine and codeine, which are naturally occurring alkaloids derived from the opium poppy *(Papaver somniferum);* (3) semisynthetic derivates of opiates, such as heroin, hydrocodone, hydromorphone, oxycodone, and oxymorphone; and (4) synthetic drugs, such as meperidine, methadone, fentanyl, sufentanil, alfentanil, remifentanil, butorphanol, nalbuphine, and buprenorphine. *Narcotic* is a general term that refers to substances that induce a sleep state or narcosis. Before the 20th century, opium was used to create a "daydreaming" state of drowsiness rather than the "high" or "rush" now sought from heroin, cocaine, and methamphetamine. Thus, the term narcotic was more appropriate then than now. Narcotic is also a legal term that applies to drugs identified in the Harrison Narcotics Tax Act of 1914, the Controlled Substances Act of 1970, and the United Nations Single Convention on Narcotic Drugs of 1961. Cannabis, cocaine, and methamphetamine are referred to as narcotics even though they are not opioids.

TRADITIONAL VIEWS OF ADDICTION

In their 1993 review of opioid addiction among anesthesiologists in *Anesthesiology,* Silverstein et al.[21] made several key points (Table 96–2). Ten of these points are discussed in a more current context. First, addiction is a disease. In 1956, the American Medical Association (AMA) declared that alcoholism met the definition of a disease. In 1987, the AMA extended disease status to dependence on any drug of abuse. In doing so it recognized that dependence and addiction satisfy all the criteria for a disease: (1) identified vector—the drug of abuse; (2) typical signs and symptoms; (3) predictable natural course; and (4) recommended treatments. The early editions of the DSM from the 1950s regarded alcoholism and drug abuse as sociopathic personality disturbances. In the DSM-III, published in 1987, and in all subsequent editions, substance misuse disorders were reclassified as axis 1, or clinical disorders, as opposed to axis, 2, 3, 4, or 5 disorders, which include personality disorders, general medical conditions, psychosocial, and environmental problems.

Three questions must be answered in sequence before any disorder is assigned a DSM code.[13] Is the disorder due to the direct effects of a substance? Is the disorder due to the direct effects of a medical condition? Does the disorder cause significant distress or impaired function? Thus, all medical professionals should be programmed to consider substance use or abuse first as an explanation for any abnormal behavior or physical complaints. However, few primary care physicians screen for alcohol or drug dependence during routine examinations.[22] The value of preoperative screening for alcohol or drug dependence in select patients has not been established. The success of preemployment, recredentialing, random, or suspicion-based drug screening programs to identify anesthesia providers with substance misuse problems are limited at best.[23]

TABLE 96–2.

Traditional Views of Addiction: Key Points from Silverstein et al.[21]

1. Alcohol and drug dependence are diseases, not character flaws.
2. The pathogenesis of chemical dependence is incompletely understood.
3. Denial is a major system of the disease.
4. Significant behavioral changes are associated with addiction.
5. Federal laws create mandates for healthcare employers regarding substance abuse.
6. The Americans with Disabilities Act provides limited protection to addicts in treatment.
7. Impaired Provider Programs provide rehabilitation safety nets for physicians.
8. Intervention requires evidence and preparation.
9. Reentry for selected individuals requires written contracts.
10. Drug testing must be performed under the auspices of medical review officer.

Data from Silverstein et al.[21]

Second, the pathogenesis of chemical dependence and addiction was unclear in 1993. It was known that drugs of abuse increased the amount of dopamine released in the reward center of the brain. However, this observation was viewed more as an end point to explain why people "enjoyed" the drug rather than a starting point for the "hard wiring" of neural pathways that leads to cravings for drugs, compulsive drug acquisition behavior, and loss of the ability to "just say no." Although the public was still locked into the view of addiction as a character flaw, physicians were moving closer to accepting the disease model for addiction. But even physicians tended to view addiction more like an acute illness with typical signs and symptoms associated with the self-limited states of intoxication and withdrawal rather than a chronic condition with signs and symptoms of drug craving and compulsive drug use. A popular misconception was that once detoxification and withdrawal were complete, that is, the drug was completely eliminated from the body, the illness was successfully treated. Now all the patient had to do was use will power to prevent a reoccurrence. Before more physicians would accept the concept of addiction as a chronic disease, they needed both the identification of an actual brain lesion and medications specific for treatment of addiction. A brain lesion has now been identified, and specific medical therapies are emerging (see Pathophysiology of Addiction and Treatment of Opioid Addiction).

Third, the inability of the addict to initiate the request for help is one of the hallmarks of the addictive process. In the early stages of addiction, denial can be defined as a failure to recognize

the problem or to accept the inability to control the problem. There are two sides to the denial problem: denial by the sufferer of his or her illness, and denial by those close to the chemically dependent individual of any responsibility to recognize and address suspicious behavior. It is uncommon for the drug-dependent individual to seek help on his or her own volition. Varying degrees and types of pressure must be exerted by relatives, colleagues, or employers to achieve "voluntary" enrollment in treatment programs. Attempts to create statutory mandates for healthcare workers to report colleagues suspected of substance abuse to state medical or nursing boards or professional societies, with immunity for reporting and with disciplinary action for failing to report, have been difficult to codify or enforce. In later stages of addiction, the definition of denial changes. The addict knows and may freely admit he or she has an addiction. But the cravings and compulsion are too strong to resist. Here denial is defined as a perversion of "just saying no." The "no" is not to drugs but to abstinence.

Fourth, significant behavioral changes are associated with addiction. Recognition of chemical dependence in a colleague occurs when an index of suspicion reaches a threshold that demands investigation. This threshold varies from one observer to another. It should be lowest among those with the longest and closest contact and highest among those with infrequent or casual contact because the key is recognizing changes in behavior. Most dependent anesthesia providers are clever enough to avoid manifesting signs of intoxication and withdrawal at work. It is common for dependent providers to come early to work to acquire and inject opioids, not to achieve a "high" but to control withdrawal symptoms. They strive to protect their jobs to protect their sources of drugs. Behavior changes associated with addiction can be divided into five categories: (1) drug acquisition, (2) withdrawal symptom control, (3) disguising or covering injection sites, (4) gradual elimination of nondrug acquisition activities, and (5) psychiatric comorbidities, especially depression. Behavioral changes should be noticed first by family members in the same household, but they also are the most likely to exhibit denial because of fear of consequences, shame, or just hope of some quiet resolution. Unfortunately, many of the behavioral changes are similar to, and mistaken for, those associated with stress and sleep deprivation.

Fifth, the Health Care Quality Improvement Act (HCQIA) of 1986, the Drug-Free Work Place Act (DFA) of 1988, and the Drug-Free Schools and Communities Act Amendments (DRFSCA) of 1989 require medical societies, licensing boards, healthcare organizations, and training programs to address substance abuse in the workplace and on campus. The HCQIA mandates the following: (1) establishment of the National Practitioner Data Bank (NPDB), which opened in 1990, as a central repository for adverse actions taken against physicians with regard to restriction, suspension, or withdrawal of privileges or licensure, professional conduct, or malpractice decisions; (2) mandatory reporting of adverse actions to the NPDB by institutions; (3) mandatory query by institutions of the NPDB prior to granting or renewing licenses privileges; and (4) immunity to the reporting individuals or organizations. The DFA and DRFSCA stipulate that entities which are recipients of federal grants and contracts must provide a drug-free workplace as a necessary condition for receiving these funds. Most large hospitals and all academic medical centers must comply. The DFA does not apply to Medicare third-party reimbursements. The seven actions required by the DFA (Table 96–3) are the same actions any anesthesia group should consider taking. In 1992, the American Hospital Association recommended that all healthcare institutions adopt a policy that mandates preemployment drug screening, for-cause testing, and postaccident testing.

Entry into drug rehabilitation may not require reporting to the NPDB,[12] but several big "ifs" must be satisfied: (1) if no patient is placed at risk or harmed by drug-influenced behavior; (2) if no hospital privileges are suspended; (3) if no license is suspended or revoked; (4) if the employer is "sympathetic"; (5) if the investigation, intervention, rehabilitation, and reentry are carried out through an employee assistance program and a PHP approved by the state medical board; and (6) if the employee "voluntarily" agrees to enroll in a detoxification and rehabilitation program.

The DRFSCA requires "(1) the annual distribution to each student and employee of – (A) standards of conduct that clearly prohibit, at a minimum, the unlawful possession, use, or distribution of illicit drugs and alcohol by students and employees on its property or as part of any of its activities; (B) a description of the applicable legal sanctions under local, State, or Federal law for the unlawful possession or distribution of illicit drugs and alcohol; (C) a description of health risks associated with the use of illicit drugs and alcohol; (D) a description of any drug or alcohol counseling, treatment, or rehabilitation or reentry programs that are available to employees or students; and (E) a clear statement that the institution will impose sanctions on students and employees (consistent with local, State, and Federal law), and a description of those sanctions, up to and including expulsion or termination of employment and referral for prosecution, for violations of the standards of conduct required by paragraph (1)(A); and (2) a biennial review by the institution of its program to – (A) determine its effectiveness and implement changes to the program if they are needed; and (B) ensure that the sanctions required by paragraph(1)(E) are consistently enforced."[24]

TABLE 96–3.

Institutional Actions Mandated by the Drug-Free Work Place Act of 1988

1. Publish declaration that institution will comply with act.
2. Establish drug-free awareness program with 3 components:
   A. Education regarding dangers of drugs
   B. Counseling, rehabilitation, and employee assistance
   C. Policy and procedures
3. Create a substance abuse policy.
4. Require compliance with substance abuse policy as condition for employment.
5. Notify appropriate federal agencies of drug-related offense by employee.
6. Take disciplinary action or require rehabilitation when drug-related offense occurs.
7. Document efforts to maintain drug-free workplace.

TABLE 96–4.

Americans with Disability Act of 1992 (ADA)

Exempted from ADA Protection

Employers:
With <15 employees working ≥ 20 weeks during calendar year for whom allowing
- dependent employee to return to work creates
  - Undue hardship
    - Accommodations too onerous
    - Cost of monitoring for relapse too high
  - Direct threat to health and safety of others if relapse
    - Cannot be eliminated by reasonable accommodation
    - Can be construed from history plus opportunity
      - Little supervision plus drug availability

Employees who:
- Currently use illicit drugs
- Currently use licit drugs illegally, e.g., abusing prescription drugs
- Directly violate company policy
  - Under the influence of a drug while on the job

Protection by ADA is Accorded Employees Who Are:

Qualified to do the job if not abusing drugs
- Able to perform essential functions of their job
  - Without accommodation, or
  - With reasonable accommodations
- Maintain same performance standards as nondependent employees
- Are not a direct threat to health and safety if relapse

Abstinent
- Determined by monitoring program

Dependent
- Currently in employee assistance program or physicians health program sponsored or approved treatment program
- Rehabilitated

Disabled, i.e., otherwise unable to work because of history of dependence
- Disability is an impairment limiting a major life activity
- Working may be defined as a major life activity
  - Not yet recognized by U.S. Supreme Court
  - Recognized by lower courts

Data from Meyer.[25]

Sixth, the Americans with Disabilities Act (ADA) of 1992 defines a history of drug dependence as a disability and provides limited protection to qualified individuals as described in Table 96–4 who satisfy three criteria: (1) documented participation in or graduation from a rehabilitation program; (2) documented participation in an active monitoring program, including drug testing; and (3) abstinence. An employer is not required to make an accommodation if it creates undue hardship. The terms "qualified individual" and "undue hardship" are very subjective. The intentions of the HCQIA, DFA, and DRFSCA frequently collide with the intentions of the ADA. The concern for patient safety or institutional liability has more legal support than the responsibility for the health of the employee disabled by chemical dependency.[25] It still is not clear "at what point does the safety of a third party takes priority over accommodating an employee with a chemical dependency disability. Chemical dependency disabilities enjoy less protection than other disabilities under the ADA, and policies prohibiting such workers from safety-sensitive positions have been upheld as a business necessity in other circuits... Whether such an expansive policy of prohibiting all workers with chemical dependencies from treating patients would be accepted remains to be seen. Therefore, until the ADA [is] clarified through either further legislation or judicial interpretation, hospitals and employers remain in the untenable position of weighing the risk of tort liability for accidents resulting from a relapsed employee versus the risk of discrimination liability under the ADA."[25]

Seventh, most states have established PHPs to help physicians confidentially work through substance dependence problems, manage their treatment, monitor their remission, and reenter the workforce. Intervention with the goal of detoxification, treatment, and monitored reentry into the workforce is called *diversion.* Cooperation between the state medical boards and the PHPs is essential to enable the practitioner with a problem to walk the bureaucratic tightrope between confidentiality and ability to return to work versus public safety issues and loss of ability to practice medicine. These programs have a common purpose but a variety of names, such as the California Diversion Program, the Florida Professionals Resource Network, the Idaho Physicians Recovery Network, the Kentucky Physicians Health Foundation, the Montana Professional Assistance Program, the New Mexico Monitored Treatment Programs, the North Carolina Physicians Health Program, the Ohio Physicians Effectiveness Program, the Oklahoma Professionals Recovery Program, the South Carolina Physicians' Advocacy and Assistance Committee, the Utah Recovery Assistance Program, and the Virginia Health Practitioners Intervention Program, to name a few. Unfortunately, the protection afforded by PHPs tends not to extend to certified registered nurse anesthetists (CRNAs).[26]

Eighth, it is the goal of all substance awareness efforts to intervene as early as possible on a colleague's substance misuse/abuse–dependency–addiction pathway so that he or she will have the best chance for disease control and reentry into the workforce. Intervention is an "advocacy-oriented" confrontation of a colleague whose behavior has suggested that he or she *may* have a problem with chemical dependence.[21] Its goal is to convince a colleague with documented detrimental changes in behavior to voluntarily enter an evaluation program. Treating a colleague for apparent signs of intoxication, side effects of the abused drug or its adulterants, or withdrawal and resuscitating a colleague from an over-

dose are acute emergency medical treatments. These actions are not included in the scope of the term *intervention,* although they should trigger a subsequent intervention. More commonly intervention is required in the absence of these medical issues. It is divided into three phases: (1) investigation of suspicious behavior, (2) preparation of a plan for confronting the suspect, and (3) the confrontation itself. These phases are discussed later in the chapter (see Intervention on Colleague Misusing Drugs). Each phase of intervention should be conducted with the assistance of specifically trained personnel who are not members of the anesthesia department. Intervention does not include diagnosis or treatment. It is important to remember that most interventions are prompted by documented observations of inappropriate behavior, which could have many causes, and not the witness of actual drug administration.

Ninth, reentry is controversial because of the tension among patient safety, perceived protection of the ADA, and degree of employer tolerance with regard to relapse. Sympathetic employers and groups, who hold the door open for colleagues to come back to work if their substance abuse problems manifest after they have been hired, insist that returning anesthesiologists, CRNAs, and anesthesia assistants (AAs) not only remain drug free but also take aversive or antagonist drugs (e.g., naltrexone) if opiates or alcohol were the substances abused. Colleagues enrolled in methadone maintenance programs are not permitted reentry as anesthesia providers. As more experience with buprenorphine maintenance programs accumulates, it is plausible to suggest that opioid-dependent anesthesia providers may be able to reenter if they faithfully take the buprenorphine–naltrexone combination. Whether anesthesia providers being treated with opioids for chronic pain syndromes are allowed to practice currently depends on the group and is handled locally on a case-by-case basis. Of concern in this setting is the observation that when chronic pain patients are screened for signs of abuse using urine testing and behavioral monitoring, 20–50% provided urine samples positive for illicit drugs, demonstrated addictive behavior, or both.[27,28] Reentry should involve a work reentry contract stipulating what is expected of the reentering individual by the employer and what the reentering individual should expect from the employer if he or she meets the contractual obligations. Becoming increasingly common are *last chance agreements,* which clearly describe how substance abuse has affected the employee's performance in the past, how the employee's performance has put the employer at risk, what is expected of the employee if employment is to continue, and what the employee can expect if his or her performance does not meet expectations.

Tenth, most people think testing for drugs is straightforward. Nothing could be farther from the truth. It is so complex from physiologic, pharmacologic, analytical, sampling, legal, economic, and outcomes perspectives that all hospitals are required to have a specially trained medical review officer who is a physician accountable for the integrity of the sampling, testing, and interpretation processes.[21,23,29] Four general indications for drug testing, in order of increasing required specificity, are (1) emergency screening to facilitate treatment of suspected overdose, (2) nonurgent screening, (3) monitoring for abstinence during rehabilitation or for compliance during methadone maintenance, and (4) diagnostic testing following up on a positive result from nonurgent drug screening. The highest specificity is required for diagnostic testing to avoid the consequences of false-positive results. Not only must the laboratory test for drugs of abuse, it also must test for adulteration of the sample by the substance abuser whose goal is a false-negative result. Finally, although a positive drug test may permit a definitive decision on hiring or firing or compliance versus noncompliance, reliance on a positive drug test will miss a high percentage of noncompliance with treatment or rehabilitation programs or substance abuse, and vice versa. Drug testing must be combined with behavioral assessment to meet the goals of any monitoring program.[21,27,28]

NEW PERSPECTIVES OF ADDICTION

Since the 1993 review by Silverstein et al.,[21] 10 major advances in the understanding and treatment of substance misuse disorders have been made (Table 96–5). First, both NIDA and NIAAA, which are members of the National Institutes of Health (NIH), now promote the concept that addiction is a disease with severity based on DSM-IV-TR and ICD-9-CM definitions of dependence and abuse. NIDA and NIAAA clearly view addiction not as an acute disorder that resolves after withdrawal symptoms subside but as a chronic relapsing disease that must be managed, just like diabetes mellitus or coronary heart disease. However, many are still reluctant to view it as a chronic medical illness as evidenced by the following observation: "...relapse among patients with diabetes, hypertension, and asthma following cessation of treatment has been considered evidence of the effectiveness of those treatments and the need to retain patients in medical monitoring. In contrast, relapse to drug or alcohol use following discharge from addiction treatment has been considered evidence of treatment failure."[22] As post-detoxification treatments have expanded to include aggressive followup, use of anticraving drugs, and lifelong monitoring, treatment success has improved. The discouraging data from

TABLE 96–5.

New Perspectives of Addiction

1. Treatment success improves if addiction is treated as a chronic relapsing disease.
2. Drug relapse in addicted colleagues is not voluntary.
3. Characteristic irreversible changes in the brain are associated with addiction.
4. Dopamine *and* glutamate are the major neurotransmitters involved in addiction.
5. Vulnerability to addiction has a strong genetic component.
6. Addiction is a developmental disorder.
7. Addicted colleagues have high prevalence of psychiatric comorbidities.
8. Polypharmacy is common for control of withdrawal symptoms.
9. Buprenorphine is the approved drug for office-based treatment of addiction.
10. The Joint Commission on Accreditation of Health Care Organizations and the American Board of Anesthesiology support the Americans with Disabilities Act.

more than a decade ago regarding unsuccessful reentry need to be replaced with more optimistic data from recent efforts.[9]

Second, the addict craves, seeks, or uses drugs involuntarily.[30–32] What starts out as voluntary substance misuse (*"Just say no"*) concludes as either a lifelong management of craving (*"Can't say no"*) if successful intervention occurs in the early phase of addiction or involuntary compulsive behavior with multiple unsuccessful interventions in the late phase of addiction. Changes in the brain either predispose or force the abstinent chemically dependent individual to relapse. Thus, relapse must be considered part of the disease. Treatments now are being aimed toward controlling craving and compulsive drug-seeking behavior.[33]

Third, sustained drug abuse leads to irreversible changes in the brain. Positron emission tomography (PET) and functional magnetic resonance imaging studies in nonusers, recreational drug users, and addicts have identified five key areas in the brain where changes associated with addiction take place: the ventral tegmental area (VTA) in the midbrain; the nucleus accumbens core (NAc), amygdala (AMG), and dorsal striatum (DSt) in the forebrain; and in the prefrontal cortex (PFC), the orbitofrontal cortex. The initial drug experience in the nonaddicted brain involves dopaminergic projections from the VTA to the NAc. In the addicted brain, the drug experience involves dopaminergic projections to the DSt and glutamatergic projections from the PFC to the NAc.[11–14,31–38] Thus, a clear brain "lesion" is associated with the disease of addiction (Fig. 96–1).

Fourth, dopamine is no longer viewed as the mediator of pleasure but as the primary neurotransmitter for learning from experience what is pleasurable, aversive, novel, and predictable.[32,34,38] Initially, all experience and all drugs of abuse increase firing of dopaminergic neurons in the VTA. How the brain determines which experiences to seek and which to avoid is not clear. One theory is that a pleasurable experience increases the dopamine concentration in the NAc above one threshold; an aversive one, above an even higher threshold. The difference between the two thresholds depends on the density of dopamine D2 receptors or the ratio of D1 to D2 receptors. Eventually, cues that predict a pleasurable or aversive

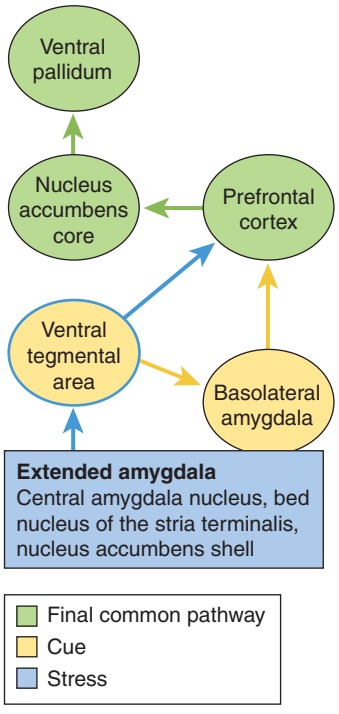

FIGURE 96–1. Neural circuitry mediating the activation of goal-directed behavior. Kalivas PW, Volkow ND. The neural basis of addiction: a pathology of motivation and choice. Am J Psychiatry 2005;162:1403–1413. Reprinted with permission from the American Psychological Association.

experience or a drug high cause firing of these neurons rather than the actual experience or the drug itself. Finally, the specificity and sensitivity of these various cues as predictors of experience or drug availability are evaluated, and the dopamine firing pattern is changed.

Fifth, addiction has a strong genetic component, with up to 60% of the vulnerability attributed to either specific phenotypes or gene–environmental interactions.[39,40] Genes affect how an individual responds to drugs. Genes associated with addiction affect the expression of receptors, such as the μ-opioid, κ-opioid, dopamine D2, D3, and D4, serotonin 1B and 2A, γ-aminobutyric acid (GABA receptor subunits α_1, α_6, and β_1), muscarinic M_2, and cannabinoid 1. Humans whose genotype includes the dopamine D2 receptor Taq1 A1 allele have a deficiency in dopamine D2 receptors. The absence or deficiency of this receptor is associated with an increased risk of addictive, compulsive, or impulsive behavior.[39,40] Genes associated with addiction affect the expression of enzymes that are involved in drug synthesis or metabolism, such as dopamine β-hydroxylase, tryptophan hydroxylase, monamine oxidase A, catechol-*O*-methyltransferase, alcohol dehydrogenase, and cytochrome P450 (CYP). Not only do genes affect drug disposition and addiction vulnerability, but the reverse also is true. Drugs affect how genes are expressed, and this in turn affects the transcription, translation, and trafficking of proteins. It is in this area of research where the mechanisms of neural adaptations associated with addiction are being sought.[41–43] Environmental influences and drug availability determine whether genetically vulnerable individuals avoid addiction or genetically resistant individuals become addicted.

> *Too often blame is laid on those with addictions as though they sought and intended to become addicted. Perhaps they made poor choices about drug use, but all too frequently the choice was made during adolescence or before.*
>

Sixth, addiction may actually be a developmental disorder. The greater neuroplasticity in the immature adolescent brain makes it more vulnerable than the mature brain to the creation of neural circuits associated with addiction.[44] The average age of onset for substance use disorders is 20 years, with the range for 25th to 75th percentiles of 18 to 27 years and 5th to 95th percentiles of 15 to 41 years.[4] The median duration of delay between onset of abuse or dependency and first treatment contact is 5–9 years.[11] Thus, it is easy to hypothesize that most anesthesia trainees, who are diagnosed as chemically dependent on opioids during their training, either are so or meet the DSM-IV-TR criteria for abuse of a substance not typically used for anesthesia before they start their training. There is a strong positive correlation between the degree of impulsiveness and the age of the first alcohol or drug experience.[45] The seeds of addiction are frequently sown while the brain is still developing and before its defense mechanisms are in place. Maturation of the human PFC, the area of the brain that inhibits risky behavior, occurs around 25 years of age.[46] The length of time between the initial use of cocaine and the diagnosis of cocaine dependence is inversely proportional to the age of the first co-

caine experience.[47] The majority of addicts declare themselves during adolescence and early adulthood. NIAAA and NIDA now feel that if addictive behavior can be prevented in teenagers, the incidence and prevalence of chemical dependence for the entire population will be reduced dramatically.[48,49]

Seventh, an anesthesia provider who becomes chemically dependent on an anesthetic drug during or after his or her anesthesia training is very likely to have a significant psychiatric comorbidity, such as bipolar disorder, depression, anxiety disorder, attention deficit hyperactivity disorder, schizophrenia, or abuse or dependence on a nonanesthetic drug.[9] A preexisting DSM-IV-TR diagnosis of abuse or dependence on a nonanesthetic drug of abuse (e.g., alcohol, marijuana, cocaine, methamphetamine, or prescription drugs) may be the comorbidity most commonly associated with development of an addiction to an anesthetic drug.[48] Not all depressed individuals are or become substance abusers, but >50% of substance abusers become depressed.[50] This information may be useful in recognizing an endangered colleague and definitely important in establishing a therapeutic regimen.

Eighth, addicted individuals tend to abuse more than one drug. This observation is not new. But in the context of the first seven insights, the explanation for it is new. Most anesthesia providers develop their addiction to anesthetic drugs at an age that is beyond the age range associated with the primary addiction. They come into training with brain changes associated with early addiction as a consequence of abusing nonanesthetic drugs. They enter training with the comorbidity of drug abuse or dependence that has gone unrecognized in the recruiting process. There is also evidence that some of the polypharmacy associated with substance abuse is an effort to control withdrawal symptoms when the drugs of choice are not available. Anesthesia trainees have diverted potent inhaled agents, benzodiazepines, ketamine, and propofol for this purpose because they are not as tightly controlled in many operating rooms as are opioids. Hair analysis for drugs revealed this polypharmacy in anesthesiologists who displayed addictive or abusive behavior but had negative urine drug screens during interventions. Hair that grows approximately 1 cm per month can provide an historic record of abuse.[51]

Ninth, the signing of the Drug Addiction Treatment Act of 2000 approved the treatment of addicted individuals with schedule III, IV, or V narcotic medications in an office-based setting as long as the drugs used are approved by the Food and Drug Administration (FDA) specifically for medically supervised tapering toward detoxification or for maintenance therapy, and the physicians involved received 8 hours of approved training.[52] This act amends the Harrison Narcotic Drug Act of 1914, which made it illegal for physicians to prescribe opioid medication for treatment of opioid dependence. The only approved exception was methadone dispensed through tightly regulated programs. In 2002, the FDA approved the use of buprenorphine, a schedule III partial μ-opioid receptor agonist, alone or in combination with naltrexone. The purpose of naltrexone is to prevent the abuse of buprenorphine, not to block the effects of other opiates.

Tenth, both the Joint Commission on Accreditation of Health Care Organizations (JCAHO) and the American Board of Anesthesiology (ABA) support the intent of the ADA. The JCAHO now mandates that hospital medical staffs have "a process to identify and manage matters of individual health for licensed independent practitioners... The purpose of this process is to help with rehabilitation, rather than discipline, to aid a practitioner in retaining and regaining optimal professional functioning that is consistent with protection of patients."[53] The ABA accepts into the examination system qualified applicants with a history of alcohol or illicit drug use if it receives "acceptable documentation" that "they do not pose a direct threat to the health and safety of others" and "are not currently engaged in the illegal use of drugs." After a candidate for ABA certification satisfies the examination requirements, "the ABA will determine whether it should defer awarding its certification to the candidate for a period of time," usually several years after the candidate enters a rehabilitation program, to assure a reasonable period of abstinence, monitored compliance with reentry contracts, and safe care of patients. The ABA receives notifications of actions by state medical boards from the Federation of State Medical Boards and "will initiate proceedings to revoke certification(s) of diplomates with a medical license that is revoked, suspended, or surrendered in lieu of revocation or suspension" because of substance abuse issues.[54]

The rest of this chapter follows the new evidence that most anesthesia residents, SRNAs, CRNAs, AAs, and anesthesiologists who become chemically dependent will have a strong history of risk taking or substance misuse prior to entering their training, that is, they will already have a history of binge drinking, disorderly behavior, reckless driving, arrests for driving under the influence, or recreational drug use, or they will have a psychiatric comorbidity that creates a vulnerability. Much of this information is not available to recruitment committees. Fortunately, not everyone with this background becomes an addict, but between 10% and 20% of individuals move from abuse to dependence.[55] But those who do already have some of the brain changes to be discussed. Thus, the focus will be on the behavior of a chemically dependent colleague in the workplace and not on acute intoxication, which most often occurs away from the workplace, initially in groups but progressively in isolation. It will deal with issues of recognition, detection, intervention, rehabilitation, reentry, and drug testing. PHPs help with rehabilitation, monitoring, and reentry into practice, but the burden of recognizing there is a problem in the first place, and subsequently intervening, still falls on family members, friends, colleagues, or employers of the impaired colleague. Despite the fact that alcohol, marijuana, cocaine, and methamphetamine are commonly abused substances, this chapter focuses primarily on the intravenous opioids. These are drugs that are both more likely to be abused by anesthesia providers than by nonproviders[5,9] and are associated with a very short time line from initial misuse to addiction.[56]

PATHOPHYSIOLOGY OF ADDICTION

Addiction is a disease of the learning and motivation centers of the brain.[31–38] It can be prevented, but once established it can only be controlled, not

cured. The goal of addiction research is a clearer understanding of how the normal processes are distorted by drugs of abuse so that better prevention, detection, and treatment options can emerge. Prevention of the initial drug experience ideally is the best strategy, but societal influence is stronger than physician input in this area. Pediatricians are discussing this stage and the phenotyping and screening of adolescents.[48,49] The public health approach of screening, diagnosis, intervention, and treatment during the early repetitive drug experience stage offers the next best strategy for limiting the irreversible brain changes, but the research underlying this approach is in its infancy. The logistics and costs for implementation are formidable. Again, societal influence is still very strong at this level. The current, most likely point of intervention for successful treatment and reentry is in the early addiction stage. The late addiction stage is associated with a high relapse rate, unlikely reentry, and premature death from overdose, suicide, or drug-related crime. This section describes the brain lesion that makes addiction a disease.

Normal Brain

The VTA is the primary sensor in the brain circuits designed to evaluate the quality and importance or salience of any experience. It does this by quantifying the intensity of the pleasure or displeasure from the experience and by assessing the reliability of environmental predictors that the experience will be repeated. The first task involves changes in the activity of its dopaminergic projections to the NAc. At baseline, neurons in the VTA demonstrate a continual or tonic pattern of firing that leads to dopamine release in the NAc. Phasic bursts of dopaminergic activity occur in association with the appearance of a natural reward, such as a taste of good food or a sexual stimulus, or an environmental threat. These phasic bursts increase the dopamine concentration in the NAc to a greater extent than that associated with basal activity—the greater the synaptic concentration of dopamine, the more intense the pleasure or pain from the experience.

The VTA accomplishes its second task through dopaminergic projections to the AMG and DSt. These circuits establish associations, called *cues,* between previously neutral stimuli and the rewarding or aversive experience. When a cue appears, a phasic burst occurs in the VTA neurons in advance of the pleasurable or painful experience. If the experience appears at the predicted time after the cue is detected and the experience meets the expected intensity, the cue imprinted in the AMG and DSt is validated. If the experience does not occur at the predicted time or the pleasure is not as great as expected, there is a pause in the basal firing and the salience of the cue is downgraded. Eventually the appearance of cues of potential rewards or threats causes the release of as much or more dopamine than does the actual experience itself.

The pleasure–pain assessment and validation–invalidation process takes place in the PFC with information obtained via dopaminergic projections from the VTA and glutamatergic projections from the AMG and DSt. It is also the job of the PFC to "process information related to reinforcing properties of a stimulus in the context of alternative competitive stimuli".[40] The orbitofrontal cortex portion of the PFC is where prioritization occurs and motivation is centered. In the case of drug abuse, the PFC should evaluate the opportunity for a drug experience, decide it is not in the best interest of the individual, and encourage alternate behavior to avoid environmental threats and seek natural pleasures or alternative learned pleasures.

Addicted Brain

Despite the considerable diversity in their molecular structures, all drugs of abuse either increase dopaminergic transmission from the VTA or exaggerate the effects of normal dopamine released into the NAc, AMG, DSt, and PFC. Dopaminergic neurons in the VTA form a synaptic cleft with neurons in the NAc. Cocaine, methamphetamine, amphetamine, and methylphenidate directly increase the concentration of dopamine in the synaptic cleft by blocking the reuptake of dopamine into the presynaptic VTA neuron. They accomplish this by interfering with the ability of the dopamine transporter (DAT), a carrier protein, to move extracellular dopamine intracellularly. Evidence suggests that the probable mechanism for this reduced DAT activity is reduction in the expression of the DAT on the cell surface through an intracellular mechanism.[57] To induce a "high," 50% of DAT must be blocked. Above this threshold the intensity of the "high" is increased with increasing percent of DAT blocked.[38] Opiates increase dopamine indirectly by acting on GABAergic interneurons in the VTA. By binding to opioid receptors on GABAergic cells, they stop the inhibitory action of GABAergic neurons on dopaminergic cells. The activity of dopaminergic neurons increases, and more dopamine appears in the synaptic cleft in the NAc. The actions of alcohol are more complex. What is known is that ethanol is a potent inhibitor of interneuronal effects of GABAergic neurons[58] and increases dopamine in the NAc indirectly, like the opiates. But it also may reverse dopamine uptake through DATs.[59]

Because of their pharmacokinetic profiles, drugs of abuse produce a longer and stronger "dopamine high" than do natural rewards or threats. The sustained high concentrations of dopamine in the synapses of the NAc exaggerate the value or perceived importance of the drug experience. In the synapses in the AMG, DSt, and PFC, the sustained high concentrations of dopamine more strongly imprint cues for repeating the drug experience than do cues for seeking natural rewards. Individuals become chemically dependent by "overlearning of the motivational significance of cues that predict the delivery of drugs."[34] Over the same time period, the sustained high concentrations of dopamine with repeated drug intake lead to a downregulation of dopamine receptors, which devalues natural rewards and creates a "reward deficiency syndrome."[59] Changes in the PFC lead to an increase in glutamatergic output to the NAc in response to drug cues, drug reinstatement, or stress that direct the addict to restrict the focus of his or her activity to drug acquisition and administration. The addict will respond either impulsively or compulsively, depending on how the PFC processes cues related to past drug experiences and how the PFC perceives the level of stress. An addict will seek drugs despite intellectually knowing and openly acknowledging that doing so will jeopardize marriage, career, health, or life. There is an actual or relative decrease in descending inhibitory influences due to a di-

rect loss of neural traffic saying "do-not-do-this" behavior, an increase in neural traffic insisting on "got-to-have-it" behavior, or a combination of the two.

The addicted brain is a reorganized brain.[32] Three key elements in the reorganization are the development of hypofrontality, the conversion of the NAc from a dopaminergic responsive center to a glutamatergic responsive center, and the shift in VTA dopaminergic activity from the NAc to the DSt and PFC. Frontal lobe volume losses occur in cocaine-, alcohol-, and heroin-dependent subjects, with a negative correlation between normalized prefrontal volumes and years of abuse. The pyramidal neurons in the PFC decrease in size and show diminished baseline glutamatergic activity. But presented with drug cues or the drug itself, the amount of glutamate they release in the NAc is exaggerated. Similarly, the size of dopaminergic neurons in the VTA decrease and their baseline activity diminishes. But when stimulated by drug administration or drug cues, the amount of dopamine they release in the DSt and PFC is exaggerated. Finally, the number and density of dendritic spines on the medium spiny cells in the NAc and pyramidal neurons in the PFC increase when the drugs of abuse are cocaine or amphetamine but not opioids. These changes in neuron morphology are long-lasting. Synapses and postsynaptic dopamine and glutamate receptors are located on these spines. The increase in dendritic arborization appears to be mediated through induction of the transcription factor ΔFosB and its set of target genes.[41,42]

Three principles appear to govern the reorganization of the brain with addiction.[32] *Principle 1:* The final common pathway for drug-seeking behavior involves glutamatergic projections from the PFC to the NAc. Laboratory support for this principle comes from four key observations: (1) inactivation of the PFC prevents resumption of drug-seeking behavior in abstinent rats challenged by relapse stimuli; (2) injection of α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) glutamate receptor antagonists into the NAc prevents drug- or cue-induced relapse; (3) increased glutamate release occurs in the NAc following drug- or stress-induced relapse; and (4) treatments that prevent the release of glutamate prevent or reduce drug seeking in both animal and human subjects. *Principle 2:* Relapse may be triggered by cues from past drug abuse activity, stress, or a single dose of the drug of abuse (reinstatement). Each of these relapse stimuli involves a different neural circuit. *Principle 3:* Craving and relapse require dopaminergic transmission from the VTA, not to the NAc, as happens with initial or acute administration of a drug of abuse, but to the DSt and PFC. In humans, the greater the increase in dopamine concentration in the DSt, the greater the craving or desire for drugs. The more advanced the addiction, the greater the increase in dopamine concentration in the DSt with a given cue. In human addicts, there is no increase in dopamine concentration in the NAc with drug cues. Laboratory support for this principle comes from the following four observations: (1) inactivation of the VTA inhibits relapse from all stimuli in laboratory animals; (2) dopamine release in the PFC precedes glutamate release in the NAc; (3) if dopamine release into the PFC is prevented, glutamate release in the NAc is prevented, and relapse does not occur; and (4) if dopamine release occurs in the PFC after injection of glutamate antagonists in the NAc, relapse does not occur.

Dopamine and Glutamate Receptors

A molecule of dopamine released from VTA neurons into the synapses in the NAc, AMG, DSt, and PFC binds to one of five different dopamine receptor subtypes grouped into two families: the D1 family, which includes receptors D1 and D5, and the D2 family, which includes receptors D2, D3, and D4. The dopamine D2 receptor density and the ratio of the number of dopamine D2 receptors to D1 receptors in specific brain regions are important in determining an individual's perception of drug experience as pleasurable or aversive and his or her susceptibility to addiction. These measures may be useful in defining the stage of, and monitoring therapy for, addiction. The brain lesion associated with substance abuse manifests a greater of number D1 receptors and fewer D2 receptors. D1 receptors are responsive only to the strongest stimuli (e.g., those associated with drugs of abuse), whereas D2 are responsive to less intense stimuli (e.g., those associated with natural rewards). The density of dopamine D2 receptors decreases approximately 4–6% per decade, but advancing age is not associated with an increase in addiction risk. Within a given age range, there is wide individual variability in the density of dopamine D2 receptors. Those with a high density of dopamine D2 receptors are more likely to view a recreational drug experience as unpleasant and thus not develop behaviors that lead to addiction.[60] In the laboratory it is more difficult to induce chemically dependent behavior toward alcohol and morphine in dopamine D2 receptor knockout mice and in mice pretreated with dopamine D2 receptor antagonists. PET scans consistently demonstrate downregulation of dopamine D2 receptors in addicted patients. With increasing chemical dependence, the number of D2 receptors and the ratio of the number of D2 receptors to D1 receptors decreases in the NAc, DSt, and PFC. These findings indicate considerable plasticity in the expression of these receptors. High levels of dopamine D2 receptors protect against alcohol abuse. When an adenoviral vector is used to deliver the dopamine D2 receptor into the NAc of rats previously trained to self-administer alcohol, the rats reduce their alcohol intake.[61] Thus, focusing on means to increase the number of dopamine D2 receptors could produce new therapies to treat alcoholism and possibly other addictions.

Sustained exposure to cocaine or amphetamine causes endocytosis of the AMPA glutamate receptor in the postsynaptic cells of the NAc. A reduced density of postsynaptic AMPA-type subunit GluR2 in the NAc is associated with drug craving in addicts. When a viral protein vector was used to deliver a peptide decoy of the AMPA receptor into the NAc (but not the VTA) of addicted rats, the NAc cells retracted the receptor decoy rather than the receptor itself. Restoring the postsynaptic density of GluR2 in this manner extinguished craving-like behavior in the rats and suggests a new direction for treatment of addiction.[62] Another new direction may focus on the cystine–glutamate transporter mechanism.[63] Cystine is the oxidized dimeric form of cysteine. Administration of prodrugs for cysteine may increase the extracellular

glutamate in the NAc, decrease the amount of glutamate released into the NAc with PFC stimulation, and reduce drug-seeking behavior.

NATURAL HISTORY OF ADDICTION

The neuroadaptations that occur in the brain as it responds to abuse, and transitions to dependence and addiction, can be divided into four stages chronologically: (1) initial drug experience (hours to days); (2) repetitive drug exposure (weeks to months); (3) early addiction (months to years); and (4) late addiction (years). In the first two "recreational drug" stages, the abuser typically is sharing the drug experience with others. In the last two stages, the abuser tends to isolate himself or herself. The rate at which any one individual passes through these stages depends in part on the drug of abuse: slower (years) for alcohol and faster (months) for opioids, cocaine, and methamphetamine. Not only is the pathophysiology different for each stage, but the success rates for intervention, treatment, and reentry into anesthesia practice are different for each stage. The earlier the intervention, the greater the likelihood of successful treatment and reentry (Fig. 96–2).

RECOGNITION OF COLLEAGUE MISUSING DRUGS

The earlier a colleague misusing drugs can be identified, the earlier an intervention can be performed and the greater the chance of successful rehabilitation and reentry. An errant colleague will present in one of four different ways: (1) first-time or early misuser; (2) DSM-IV-TR–defined abuser; (3) individual who meets DSM-IV-TR–defined criteria for both abuse and dependence; and (4) DSM-IV-TR–defined dependent individual who does not meet DSM-IV-TR criteria for substance abuse. Unfortunately, inexperienced opioid misusers often present as an overdose or a death. Opioid abusers are identified primarily by their inappropriate and irresponsible behavior, first in social situations and then at work. Because of these behavioral changes, colleagues in categories 2 and 3 may be identified in the early stage of addiction. Unfortunately, it is very difficult to identify chemically dependent colleagues who do not meet the DSM-IV-TR criteria for abuse. They compose approximately 20% of the general population of persons with known drug dependence.[14] It is my opinion that this percent is likely to be much higher among dependent anesthesiologists. They remain outwardly competent and professional but inwardly miserable as they contrive to sustain their addiction while hiding it from family, friends, and colleagues and protecting their job and source of drugs. The story of William Steward Halsted, the famous surgeon at Johns Hopkins Hospital in the late 1880s and early 1900s, is worth reading from this perspective.[64] Only late in the addictive process, when the amount of opioid these dependent individuals require becomes too great to acquire at work and their drug-seeking behavior overcomes their ability to sustain their charade or when they give in to suicidal ideation, do they declare themselves.

Early identification of an errant colleague requires a surveillance system. The DFA requires employees to comply with the institution's substance abuse policy and employers to document efforts to maintain a drug-free workplace. However, the DFA does not mandate any specific surveillance system for healthcare organizations. One purpose of the DFA is to reassure the public that a system is in place for workers whose jobs put people at risk of serious injury from performing under the influence of alcohol or drugs, such as airline pilots and other transportation workers. Some non–healthcare businesses and institutions have adopted drug testing as their primary surveillance system. In alcohol and drug rehabilitation programs, drug testing alone misses many noncompliant participants. More accurate results in this setting are obtained when behavioral observations are combined with some form of drug testing. How well behavioral assessment and drug testing in a homogeneous population, 100% of whom are known to have a substance abuse problem, translates to the inhomogeneous population in surgical suites,

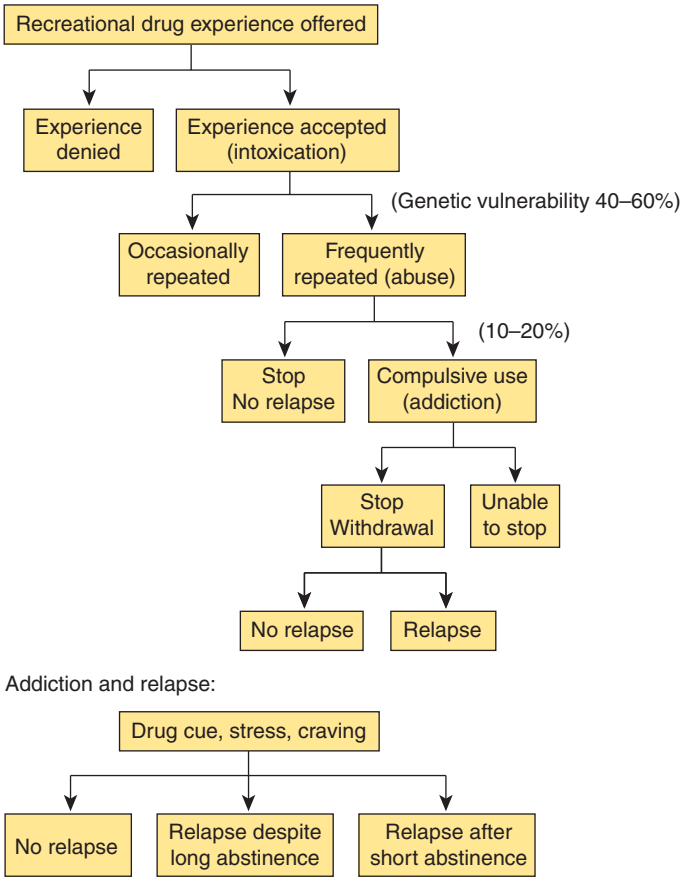

FIGURE 96–2. Natural history of exposure to drugs of abuse. (From Kalivas and Volkow[32] with permission.)

only 1% of whom may have a substance abuse problem, remains to be determined.

The primary purpose of drug and alcohol rehabilitation and methadone maintenance programs is observation and care of patients with known substance-related problems. Thus, a drug misuse surveillance system for patients is a primary component of their operation. The primary purpose of healthcare institutions is not to monitor their healthcare providers for drug misuse behavior. However, it is important for these institutions to monitor the quality of the care provided. When an assessment reveals an outcome on the wrong side of a benchmark, a system evaluation is instituted. Sometimes, but not always, this includes competence assessments of providers. Unlike the case for surgeons, few outcome data tend to be collated specific to individual anesthesia providers. Thus, surveillance systems that rely on quality assessments are unlikely to detect gradually deteriorating performance or subtle changes in behavior of anesthesiologists, CRNAs, or AAs (Table 96–6). Substance abuse is only one of many possible reasons for poor performance and frequently not the most likely one.

Inappropriate behavior of any kind must be addressed. However, early detection of substance misuse requires observation of more subtle changes in behavior, presumably precursors to overt inappropriate behavior that may be the result of acute effects of drug administration or the chronic effect of drug-induced brain changes. There is evidence of a considerable reluctance on the part of healthcare workers to report colleagues whom they only suspect of drug abuse.[65] Random drug testing has the potential to reveal a problem earlier than quality of care or behavioral assessments. The complexities of the collection process, the relative ease by which addicts can subvert the system, and the high cost-to-benefit ratio in large systems with low anticipated positive findings have deterred most programs from implementing random drug testing.[23] Thus, the three purported hallmarks of substance misuse surveillance systems—competence assessment, behavioral changes, and random drug testing—are unlikely to be implemented or are likely to be ineffective if put in place. Most large healthcare institutions have a drug awareness program and a response system rather than a true surveillance system. They rely on an alert, educated, concerned healthcare provider reporting very suspicious or obviously abnormal behavior to the department head, the professional advisory or wellness committee, or employee assistance for subsequent investigation. Thus, our current systems do not favor early detection of a colleague with a substance misuse problem, especially if he or she meets DSM-IV-TR criteria for dependence but not abuse.

The ideal surveillance system should not be created specifically to detect substance misuse. Rather, it should focus on anesthesia provider well-being in general. If behavioral changes are found to be due not to substance abuse but to some other cause, such as sleep deprivation, stress, a medical illness such as diabetes mellitus, or side effects of medications prescribed for a medical illness, they still must be addressed. The ideal system should have observers who can witness the behavior of the same providers frequently enough recognize a change. The observational standard should be a change in behavior, a more sensitive but less specific finding, rather than a specific behavior that has reached a certain threshold for inappropriateness or diagnosis. The ideal system collects and integrates different kinds of information from different sources (Table 96–6) on a frequent basis: (1) observation of signs and symptoms of drug intoxication or withdrawal; (2) behavioral changes related to dress, work habits, professionalism, personal life, competence, and drug acquisition; (3) signs and symptoms of psychiatric comorbidities associated with addiction, especially depression; (4) analyses of documentation systems and surveys; and (5) drug testing. An ideal system also has the "right" kind of person in charge who frequently asks "Is there anyone we should be concerned about?" and looks for "red flags." For example, do queries of automated anesthesia information management systems reveal (1) residents, CRNAs, AAs, or anesthesiologists whose opioid use is two standard deviations greater than others, especially if they also record high delivered concentrations of potent inhaled agents; or (2) anesthesia providers whose patients consistently have higher pain scores in the recovery room than expected. Without an aggressive surveillance system the barriers to recognition (Table 96–7) are formidable.

Most people have no difficulty recognizing the intoxicated individual. Alcoholics are more likely to come late to work intoxicated, but "experienced" users chemically dependent on intravenous opioids are more like to come early to work, check out drugs for the first case, and immediately divert opioids for acute self-administration to treat withdrawal symptoms. These same "experienced" users also request breaks during the day to sequester themselves to inject opioids to prevent

TABLE 96–7.

Barriers to Recognition of Colleague Misusing Drugs

- Continued competent performance until late in the addiction process
- Symptoms for abuse and addiction overlap with other common conditions
  - Stress, sleep deprivation
- Limited observations of single provider by same observer
  - Academic medical center: Multiple attendings and/or multiple trainees
  - Large practices: Multiple attendings and multiple certified registered nurse anesthetists or anesthesia assistants
  - Physician-only practice: No other anesthesia provider critiquing anesthetic
- Wide variability in acceptable anesthetic management
- No system that identifies outliers in opioid administration in the operating room
- No system that identifies outliers in pain scores in the postanesthesia care unit
- Limited substance abuse education of, or feedback from, nurses in operating room or postanesthesia care unit
- Easy to divert drugs with current drug accounting and monitoring systems
- Unwillingness to believe it could happen
- Fear of being bad guy, ruining career of colleague, or being wrong ("false alarm")
- Abuser feeling either he or she can control the addiction or that it is worth the risk
- Family fear loss of "face" or security and hope abuser overcomes problem on own

withdrawal symptoms. Signs and symptoms of withdrawal are listed in Table 96–8.[66–71] Most anesthesia providers dependent on opioids are clever enough to protect their source by avoiding suspicion, intoxication, and withdrawal at work. They discreetly divert drugs at work for intoxication away from the workplace. When experienced addicts run out of viable veins or when "inexperienced" addicts miss their veins, they frequently resort to subcutaneous or intramuscular injections. Because of poor sterile technique, the sites of this "skin popping" become infected. Abscesses, especially in the lower extremities of anesthesia providers, are red flags suggesting possible substance abuse.[67] Intravenous drug users who inject primarily in the upper extremity may develop the puffy hand syndrome.[68] Other red flags include keeping injection sites away from public eyes by wardrobe changes, such as switching to wearing long pants rather than short pants to and from work, wearing long sleeve shirts in clinical settings, or wearing operating room scrubs to and from work, or changing clothes in the privacy of their office or in dressing room stalls rather than out in the open.

The appearance of chest pain, malignant dysrhythmias (ventricular fibrillation, ventricular tachycardia, supraventricular tachycardia), or signs and symptoms of an acute coronary syndrome in a young colleague should include substance abuse in the differential diagnosis. The average age of patients presenting with cocaine-associated chest pain was 37.6 ± 9.3 years, considerably younger than the typical coronary heart disease population.[70] These individuals were identified by their acknowledgment in the emergency room of using cocaine during the week before presentation or by positive urine toxicology screen. Both cocaine and crystal methamphetamine reach peak blood concentrations within seconds to minutes after smoking or intravenous injection, minutes to hours after nasal insufflation or "snorting," and longer after oral ingestion. They increase the catecholamine concentration in the synaptic cleft by interfering with the ability of the catecholamine transporter, a carrier protein, to return extracellular catecholamines intracellularly to presynaptic neurons. The increased catecholamine residence time in the synapse leads to α-adrenergic effects, such as hypertension and coronary spasm, and β-adrenergic effects, such as tachycardia and dysrhythmias. The combined increase in oxygen demand and decrease in oxygen supply leads to anginal symptoms, frequently in the absence of occlusive coronary lesions, myocarditis, and dilated cardiomyopathy.[71] Chronic use accelerates atherosclerosis and produces hypertrophic cardiomyopathy. Although the risk of these myocardial infarctions is greatest within 1 hour of drug administration, they may occur up to 1–2 days later. Patients who present with drug abuse–associated chest pain that resolves shortly after presentation, who have normal levels of troponin and no new ischemic changes on ECG during a 9- to-12-hour observation period, and who do not develop cardiovascular complications (dysrhythmias, acute myocardial infarction, or recurrent symptoms) have a very low risk of

TABLE 96–8.

Signs and Symptoms of Withdrawal

- **Common to Non-stimulant Drugs of Abuse**
  - Central nervous system: Agitation, anxiety, dysphoria, irritability, panic
  - Autonomic nervous system: Tachycardia, hypertension
  - Gastrointestinal system: Nausea
- **Opioid**
  - Influenza-like symptoms: Fever, diaphoresis, myalgia, arthralgia, tearing, rhinorrhea, sneezing
  - Central nervous system: Tremors, yawning, insomnia, suicidal ideation
  - Autonomic nervous system: Piloerection, mydriasis
  - Gastrointestinal system: Stomach cramps, vomiting, diarrhea
- **Alcohol**
  - Central nervous system: Insomnia, tremors, delirium tremens, hallucinations, grand mal seizures, status epilepticus
  - Gastrointestinal system: Vomiting, poor appetite
- **Stimulant Drugs of Abuse (Cocaine and Methamphetamine)**
  - Central nervous system: Depression, exhaustion, fatigue, sleepiness, lack of motivation, cravings, psychotic reactions, suicidal ideation
  - Gastrointestinal system: Intense hunger

Data from Kosten and O'Connor.[66]

myocardial infarction during the 30 days following discharge. Patients presenting with chest pain in an age group younger than expected for coronary heart disease should be screened for recent cocaine or methamphetamine intake.

INTERVENTION ON COLLEAGUE MISUSING DRUGS

The three keys to a successful intervention are a thorough investigation, an experienced intervention team, and rehearsed intervention plan. These factors are well discussed in the review by Silverstein et al.[21] and summarized as follows. The investigation, which may take weeks, is ideally performed confidentially by an experienced team drawn from the human resources, employee assistance, or risk management departments or physician well-being committee of the medical center, with a representative from the anesthesia department. The purpose of the investigation is not to make the diagnosis of substance misuse, substance abuse, or chemical dependency but to gather sufficient evidence of behavioral changes, drug diversion, or drug use to mandate an evaluation. No intervention should be attempted based only on suspicion without evidence.

The intervention team should consist of two or more members with experience in confronting people who deny their problems. If behavioral changes are the only evidence of suspected drug misuse, the team cannot assume that drug misuse is the problem. Rather, the team should accept that the evidence suggests it is reasonable and necessary for the individual to have an evaluation before he or she is allowed to return to work. It is the purpose of the subsequent medical and psychiatric evaluation to determine the cause of the behavioral changes. There should never be a one-on-one intervention. The gender and cultural makeup of the team is important to avoid charges of harassment or assault. Ideally, one team member should be someone who is either a certified addictionologist or a former impaired professional. A spouse or family member could be motivated to either facilitate or sabotage the process. Advice from an experienced interventionalist is recommended to determine his or her suitability as a member of the intervention team. Interventions take time, sometimes hours, if diversion is to be successfully accomplished. It is important for team members to devote their full attention to the intervention by turning off their beepers and cell phones and canceling all other commitments until the intervention is completed.

The intervention plan should include preparation for immediate drug testing, inpatient admission to a hospital or treatment center, accompanied transfer to testing site and inpatient facility, and contingency plans if the suspect refuses to accept testing and evaluation. The purpose of the intervention is not to accuse the individual of a crime or to make the diagnosis of drug misuse. It is to convince the health professional colleague to submit to drug testing and an evaluation. Drug testing should be required as a routine part of institutional policy and procedure related to risk management of untoward events or inappropriate or unaccountable behavior. Because the suspect may become physically hostile, security personnel should be alerted to be in the vicinity of the intervention, but they should remain out of sight unless needed to avoid the perception of an impending arrest. Finally, an individual once confronted must be regarded as a suicide risk and not be left alone until he or she has been admitted to an evaluation center or accompanied by a responsible individual away from the medical center if he or she refuses evaluation and leaves against medical advice.

ULTRARAPID OPIOID DETOXIFICATION

Medically supervised opioid withdrawal, or detoxification, can be divided into four general approaches in order of decreasing duration of time required to complete the process: (1) substitution of abused opioid with an approved opioid, methadone, or buprenorphine, and a slow taper (weeks to months) of the approved opioid to minimize withdrawal symptoms; (2) complete discontinuation of any opioids and administration of medications, such as clonidine and benzodiazepines, to attenuate withdrawal symptoms (1–2 weeks); (3) precipitation of withdrawal by administration of antagonists, naloxone, or naltrexone, and the administration of medications to attenuate the withdrawal symptoms (rapid detoxification in 3–5 days); and (4) precipitation of withdrawal by administration of antagonists during general anesthesia or sedation (ultrarapid opioid detoxification [UROD] in 6–8 hours).[73] When clonidine-assisted, buprenorphine-assisted, and anesthesia-assisted detoxification were compared with naltrexone as preparation for antagonist therapy, no differences in the rate of retention in treatment programs or frequency of opioid-positive urine specimens were observed. There was a significant increase in morbidity blamed, perhaps somewhat questionably by nonanesthesiologists, on the use of general anesthesia.[74] The accompanying editorial by another nonanesthesiologist stated "anesthesia-assisted detoxification should have no significant role in the treatment of opioid dependence."[75] When UROD was combined with subcutaneous implantation of naltrexone pellets, pulmonary edema, aspiration pneumonia, prolonged debilitating withdrawal, delirium, and death occurred after discharge home.[76] There are experienced advocates in Europe for UROD use in select patients.[77–79]

Currently in the United States UROD should be considered only if it is part of a clinical study approved the institutional review board. The American Society of Addiction Medicine (ASAM) has published a public policy statement regarding opioid antagonist agent detoxification under sedation or anesthesia stating: (1) "ASAM does not support the initiation of acute opioid detoxification interventions unless they are part of an integrated continuum of services that promote ongoing recovery from addiction"; and (2) "[UROD] is a procedure with uncertain risks and benefits, and its use in clinical settings is not supportable until a clearly positive risk-benefit relationship can be demonstrated. Further research on UROD should be conducted."[80] It is unethical to provide general anesthesia or deep sedation for ultrarapid detoxification to patients who are not enrolled in approved treatment programs under the care of credentialed addictionologists and who just want to "get clean" to go back to work. Doing so facilitates illegal drug use, enables addictive behavior, and puts patients at risk for signif-

icant morbidity and mortality if they are discharged directly home from the recovery room.

TREATMENT OF OPIOID ADDICTION

Over the last decade, three major advances have been made in the treatment of addiction caused by any drug. First is the recognition that addiction is a chronic relapsing disease. This means that successful treatment requires more than detoxification and graduation from a rehabilitation program. It must include rest-of-life management. Second is the development of anticraving drugs to combat the changes in the neural circuitry in the brain that create the compulsion to repeat the drug experience. Third is the emergence of addictionologists, physicians who specialize in the treatment management of these complex patients. Additional advances have been made in the treatment of addiction specific to the drug of abuse.

The treatment of opioid addiction has evolved from detoxification and active participation in self-help programs to detoxification, long-term prescription of antagonist or agonists drugs, long-term prescription of anticraving drugs, care managed by an addictionologist, counseling, and active participation in self-help programs (Tables 96–9 and 96–10). Because the nonprescription use of opioids is illegal and because the prescription use of methadone for addiction treatment is not acceptable for actively practicing anesthesiologists or nurse anesthetists, the treatment regimens for anesthesia providers seeking reentry are designed to maintain abstinence with opioid antagonists (oral naltrexone or depot naltrexone) and control cravings with anticraving drugs prescribed by an addictionologist, active participation in PHP-endorsed behavioral health programs, and active treatment of psychiatric comorbidities, such as depression. If this approach is unsuccessful, as defined by short periods of abstinence, multiple relapses, or failure to remain enrolled in treatment programs, then administration of agonist drugs, such as methadone or buprenorphine, are considered. This approach replaces a licit drug illicitly administered with a legal drug legally administered. This substitution may enable a colleague to control his or her addiction but precludes him or her from returning to the practice of anesthesia.

There may come a time when anesthesia providers in buprenorphine maintenance programs are permitted reentry to practice at medical centers where buprenorphine is not used for pain management. Buprenorphine is a partial μ-opioid receptor agonist and a κ-opioid receptor antagonist.[81] It is available for administration by intramuscular injection, intravenous infusion, transdermal patch, or sublingual tablet. It is not administered orally because its first-pass metabolism is too rapid. It readily displaces most other opioids from the μ-receptor and precipitates withdrawal. From the perspective of reentry, it has three important characteristics. (1) It binds so tightly to opiate receptors that it is very difficult for patients adhering to the buprenorphine maintenance protocol to become high on other opioids. Thus, they may be less likely to divert drugs for their own use. (2) Patients do not develop tolerance with chronic administration, so there is no dose escalation with treatment over time. (3) There is a ceiling to both its respiratory depression and analgesic effects.[82] However, the tight binding also creates a problem. Respiratory depression or arrest from an overdose, which

    - Donepezil[88]
- Anticraving drug[33]
  - Acamprosate[a] (glutamate receptor antagonist)
  - Baclofen (GABA β receptor agonist)
  - Buproprion[a] (dopamine, norepinephrine reuptake inhibitor, nicotinic receptor antagonist)
  - Modafinil (increases glutamate)
  - Naltrexone[a] opioid receptor antagonist
  - Propranolol β-adrenergic receptor antagonist)
  - Rimonabant (cannabinoid receptor antagonist)
  - Topiramate (GABAergic)

[a]FDA approved for addiction therapy. The other drugs are in clinical trials.
[b]Disulfiram is aversive for alcohol and anticraving for cocaine in the absence of alcohol.
GABA, γ-Aminobutynic acid.

can occur when taken in combination with alcohol or benzodiazepines, is not reversed by customary doses of naloxone.[83] Two responses to this problem have been to recommend against the use of buprenorphine as an analgesic and to combine it with naloxone to limit its own abuse potential. Most studies of buprenorphine maintenance therapy have been performed in patients previously treated in methadone maintenance programs. When patients this far along in the addiction process are switched to buprenorphine–naloxone maintenance programs, there is still too much noncompliance and multiple drug use to support reentry.[84] However, in a more motivated patient population in which treatment is initiated with buprenorphine earlier in the addiction process, the results may be positive enough to consider reentry.

Because alcohol consumption outside the workplace is legal, treatment programs may be designed primarily to eliminate alcohol abuse symptoms as defined by DSM-IV-TR rather than to produce abstinence. Although abstinence still may be the most desired goal, successful treatment may be defined as a significant reduction in alcohol intake, a significant increase in the number of abstinent days, satisfactory work habits, competent work performance, the avoidance of intoxication at work, and continued active participation in PHP-endorsed behavioral health programs.[85–87] Whether complete abstinence *versus* satisfactory control is acceptable and whether aversive therapy *versus* anticraving therapy *versus* satisfactory control with just behavioral therapy or a combination of all three are acceptable for reentry are local issues.

RELAPSE

Addiction now is recognized as a chronic relapsing disease. Unfortunately most of the data regarding relapse comes from abstinence programs that are too short term in scope or support and from patients who are far less motivated than most healthcare providers or have been identified and treated too late in the addiction process. The reported relapse rates are so high that antagonist therapy with its goal of no relapse typically is rejected in favor of agonist therapy with methadone or buprenorphine with a goal of fewer relapses. However, there is a group of patients who do get close to optimum therapy, physicians in PHPs.[12] In this group, the results for abstinence programs are far more optimistic. In their study of relapse in the Washington Physician Health Program, Domino et al.[9] observed an overall relapse rate of 25% over 10 years. To express the results more positively, 75% of physicians did not relapse. Three factors predicted relapse: a family history of substance abuse, a second DSM-IV axis 1 diagnosis (coexisting psychiatric illness), and major but not minor opioid use. Major opioids included fentanyl, sufentanil, morphine, meperidine, methadone, heroin, and controlled-release oxycodone. Minor opioids included butorphanol, codeine, hydrocodone, pentazocine, propoxyphene, and tramadol. Relapsed rates decreased with increasing time in treatment. All who avoided relapse in the first 5 years successfully returned to the practice of medicine. With specific regard to anesthesiologists, the study had insufficient power to separate out a contribution of anesthesiology as a profession independent of the abuse of major opioids. However, the authors did refer to data from the New Jersey Physician Health Program and California Physicians Diversion programs that did not reveal a risk for anesthesiologists higher than for other specialists.

REENTRY

In a study of treatment outcomes among 199 residents in anesthesiology involved in drug misuse, 167 returned to medicine, 100 continued as anesthesia residents, 9 died, and 91 completed their anesthesia training, for a 79% overall reentry rate in medicine and a 46% reentry rate into anesthesia.[9] In the previously cited study from the Washington Physician Health Program, only five of 22 anesthesiologists who misused fentanyl were able to return to practice (23%), but no information about the 11 anesthesiologists whose drug of choice was not fentanyl was presented.[9] Presumably, they were less likely to relapse and more likely to have successfully reentered practice. Thus, successful reentry can occur. The question is when and how.

Ward, who has considerable experience in his large group private practice, does not permit even a discussion of reentry until an impaired colleague meets several prerequisites (Personal Communication, 2005). The colleague must be actively participating in an PHP-approved treatment program and completed at least 6 months of treatment. The colleague's addictionologist or approved therapist, not a member of the department of anesthesiology, must confirm his or her readiness to return to work. The treatment program must be an abstinence program with either aversive or antagonist therapy and probably anticraving therapy. The colleague's compliance must be monitored, and results of drug screening tests must be negative. Finally, any coexisting psychiatric comorbidities must be treated and well controlled. There may be a time when satisfactory performance in a laboratory simulating the operating room may be necessary to establish whether the impaired colleague can deal with common cues of previous drug acquisition that could trigger relapse.[89] Similarly, functional magnetic resonance imaging during tests of decision making may be required because activation patterns in the right insular, posterior cingulated, and temporal cortex now have been used to accurately predict relapse in patients in recovery programs.[90]

Once the prerequisites are met, then a reentry contract is prepared that describes his or her reorientation to the practice, the time line for gradual resumption of former work assignments, when call assignments will resume, performance expectations, the person to whom he or others should report concerns about his progress or compliance, agreement to be monitored for changes in behavior, drug testing indications, and consequences of failing to continue treatment, meet performance expectations, or pass drug tests. It should include indications for continuing on a prearranged schedule, slowing the schedule down (never speeding it up), or stopping practice. It is important for him to return, if possible, to the same hospital and operating rooms for reentry because this will enable him to work with people who know him and can be more sensitive to changes in his behavior. He should return to the cardiac surgery operating rooms if he is a

cardiac anesthesiologist even though this may be the place where higher opioid anesthetic techniques typically are administered. It is important for him to acknowledge to coworkers, operating room nurses, CRNAs, and surgeons, why he was away from work and ask them to be his safety net.

CALL TO ACTION

Substance abuse has gotten the attention of professional organizations in anesthesia. The Committee on Occupational Health for the American Society of Anesthesiologists (ASA) has prepared two useful documents, "Model Curriculum for Substance Abuse" and "Model Department Policy for Drug and Alcohol Testing as Part of a Comprehensive Intervention for Suspected Substance Abuse in Anesthesia Professionals." The Society of Academic Anesthesia Chairs and Academic Anesthesia Program Directors (SAAC/AAPD) has sponsored two instructional videos, the original *Wearing Masks* and *Collateral Damage: Drug Abuse and Anesthesiology*. The American Association of Nurse Anesthetist (AANA) has established an active wellness committee and sponsored the making of several instructional videos that are sequels to *Wearing Masks*. Anesthesiologists who have an interest in addressing the problems of substance abuse should become members of the Association of Medical Education and Research in Substance Abuse (AMERSA).[91]

> *I try to remember not to call people with addictions—drug addicts. I propose that you do the same. The word addict carries a very negative connotation and suggests that the person is the problem rather than the disease.*
> C. Everett Koop, MD, former United States Surgeon General
> McGovern Lecture, Hanover, New Hampshire, May 1, 2003

An anesthesia provider can take several important steps in helping a colleague and the profession deal with chemical dependency. First is to accept addiction as the disease it is. There is an organic lesion. There are medications and therapies to treat the disease. Now 50–75% of anesthesia residents and anesthesiologists with significant substance abuse or dependence issues return to the practice of anesthesiology. These statistics should only get better in the near future. Second is to pay attention to colleagues by caring about their well-being and addressing any possible signs and symptoms of substance misuse, stress, or sleep deprivation they may manifest. Like most diseases, chemical dependence is best treated as early as possible. Third is to establish a well-being committee in your department or group. This committee should make it easy to report worrisome changes in behavior without creating an overbearing or inherently suspicious environment. An active well-being committee is a sign of a department or group that cares for its members.

CHAPTER 97

The Economics of Healthcare and Anesthesia Practice

Franklin Dexter, MD, PhD, and Amr E. Abouleish, MD, MBA

This chapter focuses on the determinants of anesthesia labor productivity and costs in operating rooms. Although the concepts are the same worldwide, the specific examples and their relevance to daily practice focus on U.S. nonfederal facilities. Both productivity and the cost of providing operating room anesthesia care are inextricably linked to the choices of how many operating rooms to keep open simultaneously and how to schedule cases into those locations, that is, evaluation of anesthesia care (productivity, costs, efficiency) within an operating room is a surrogate for evaluation of operating room management (productivity, costs, efficiency) and vice versa. The principles and processes for the evaluation discussed can be used equivalently for anesthesia operating room care and operating room management.

For example, a surgeon operates at an outpatient surgery center every Monday starting at 8 AM. She always finishes sometime between 2:45 PM and 4:00 PM. Issues such as turnover time, surgical time, and/or anesthesia time are unlikely to have any influence on the use of one anesthesia team each Monday for the surgeon. Even if turnover, surgical, and/or anesthesia times were reduced, likely the surgeon's operating room would still be planned for that surgeon, with one operating room team including one anesthesia team. The costs for providing the anesthesia care would be the same.

DEFINITIONS

Scheduling and Assignment

Staff scheduling is the process of deciding which anesthesia providers work each shift on each day. Staff scheduling for a future date usually is performed before the surgical cases to be performed on that date have been scheduled.

For example, anesthesiologists create their work schedule every month. Betsy and Leslie are scheduled to work 8 AM to 4 PM on March 8.

Staffed hours are hours that an anesthesia group schedules its providers to cover when not on call (e.g., 8 AM to 4 PM).

Staff assignment is the process of deciding who will take care of a specific patient on a specific day.

For example, tomorrow Amr will be medically directing residents in operating room 11 and in operating room 12.

Elective, Urgent, and Emergent Cases

We are not aware of any one best answer as to what constitutes an elective, urgent, or emergent case.[1] Still, differentiating among such cases is necessary to plan staffing. The following is a set of reasonable definitions that provide for different operational decisions.

An *elective case* can be defined as one for which the patients can wait at least 3 days for surgery without sustaining additional morbidity.[2] The choice of 3 days corresponds to patients waiting from Friday to Monday. At a facility with patients scheduled for elective surgery on Saturdays, at least 2 days would be used.

For example, tonsillectomy is an elective case.

An *emergent case* can be defined as one for which the patient is likely to sustain additional morbidity and/or mortality unless surgical care is started in less time than needed for a team to be called in from home. In this context, "likely" to have a worse outcome means based on scientific studies, such as published observational studies. By using this definition, the relevant staffing decision can be made by reviewing data on prior emergent cases.[2]

For example, emergency cesarean section because of uterine rupture is an emergent case.

An *urgent case* is defined as one for which the safe waiting time lies between that of an emergency and an elective case.[2] Almost all nonelective cases are urgent cases.

For example, lung transplantation is an urgent case. It is not an emergency case, because the patient can wait long enough for an operating room team to come to the hospital from home.

Definitions Related to Service-Specific Staffing and Operating Room Allocation

Surgical service refers to a group of surgeons who share allocated operating room time (i.e., service-specific staffing). An individual surgeon, a group, a

KEY POINTS

1. Efforts to increase anesthesia group productivity are essentially indistinguishable from those to increase the efficiency of use of operating room time, and vice versa.
2. To describe operational reality, the mathematics of service-specific staffing is based on the surgeon and patient having open access to operating room time on the workday of their choosing.
3. Scheduling cases and making decisions on the day of surgery to increase operating room efficiency are worthwhile interventions to increase anesthesia group productivity. However, by far the most important step is the allocation of operating room time (i.e., the planning of service-specific staffing) appropriately 2–3 months before the day of surgery.
4. Reducing surgical and/or turnover times generally provides small increases in anesthesia group productivity, but results vary widely because they are highly sensitive to both the operating room allocations (i.e., staffing) and the appropriateness of those operating room allocations.
5. An individual anesthesia provider's productivity is influenced by surgical times, types of procedures, underutilized operating room time, and concurrency (i.e., staffing ratios). Thus, most anesthesia groups base compensation on work schedules, such as the shifts worked, rather than units billed, because the latter is influenced by factors that often are not controlled by the anesthesiologist.

specialty, or a department can represent a surgical service. *Service* simply refers to the unit of operating room allocation.

For example, all of the cardiothoracic surgeons practicing at a hospital are allocated operating room time. Then, "cardiothoracic surgery" is a service.

For example, two gynecologists are partners in one of three gynecology groups that practice at a hospital. If the two gynecologists are together allocated operating room time, then they represent a service.

For example, a busy surgeon is personally allocated 8 hours of operating room time every Friday. Then, from the perspective of allocating operating room time and scheduling cases on Fridays, that surgeon represents a surgical service. The service-specific staffing is that one operating room for 8 hours every Friday.

Even when a surgical suite does not have a formal organizational plan for allocating operating rooms (i.e., "block schedule"), there can be service-specific staffing (i.e., operating room allocations). In this regard, "services" need not be specific clinical disciplines in the medical staff organizational structure. Rather, they reflect the activities of individuals or groups of surgeons who use the operating room facilities and thus require organized staffing to support those activities.

For example, a 10-operating room surgical suite has the official policy that all of its cases are scheduled on a first-scheduled, first-served basis. However, in reality, cases of the same specialty usually are scheduled into the same operating rooms. In addition, there are specialty teams. Nurses and anesthesia providers care only for patients undergoing neurosurgery and otolaryngology cases, some only for gynecology or general surgery, and so forth. Then, the services correspond to the specialty teams.

Allocated operating room time is an interval of operating room time with a specified start and end time on a specified day of the week that is assigned by the facility to a surgical service for scheduling cases. Some facilities have operating room time that is staffed and available for cases but not allocated to a specific service. Such operating room time has been allocated to a pseudoservice, variably named the open, unblocked, first-scheduled, first-served, or "other" service.

For example, an academic department is allocated operating room time from 8 AM to 5 PM on Monday to Friday. This does not mean that the department's surgeons are limited to scheduling cases only if they can be completed by 5 PM. Instead, it means that staffing has been planned for the department's surgeons between 8 AM and 5 PM. The definition applies whether or not at that hospital it happens that the department's surgeons actually finish by 5 PM.

Operating room time of a case is defined as the time from when a patient enters an operating room until he or she leaves the operating room. This definition is used often because it has good interrater reliability. Future use of anesthesia information management systems to provide such data automatically may make operating room management easier.[3]

Turnover time is the time from when one patient exits an operating room until the next patient on that day's operating room schedule enters the same operating room.[4,5] Separating turnover time from the operating room time of a case permits the two to be studied statistically as separate processes (discussed below under Impact of Reducing Times on Productivity). Cleanup times and setup time are characteristically recorded separately from operating room times. In part, this is because it is hard to define when cleanup has ceased and setup has begun for the next case. Turnover times include cleanup times and setup times, but not delays between cases. Hospital surgical suites may consider times between cases that are longer than a defined interval (e.g., 1 hour) to be delays, not turnovers.[4]

For example, staffing is planned from 7 AM to 3 PM. A patient arrived at the holding area at 7:45 AM, her IV was placed at 7:50 AM, she entered the operating room at 7:59 AM, the trachea was intubated at 8:12 AM, the operative site was prepared at 8:15 AM, and the incision was made at 8:23 AM. The patient left the operating room at 10:59 AM. From the perspective of operating room scheduling, the case started at 7:59 AM. The operating room time of the case was 3 hours.

For example, a surgeon is scheduled to perform a hepatic resection. However, soon after incision, the patient is found unexpectedly to have widespread metastases. Further surgery is cancelled. The patient exits from his operating room 2.5 hours earlier than planned. Including a planned 0.5-hour turnover, the second case of the day could start 3 hours earlier than planned. However, the second case of the day in that operating room will be performed by a different surgeon. He is unavailable, caring for patients in his outpatient office. The result is a delay of 3 hours. That delay would not contribute to future calculations of turnover times.

Operating room workload for a service is its total hours of cases including turnover times. This excludes the urgent cases if separate operating room time is allocated for urgent cases.

Underutilized operating room time = [Allocated operating room time] – [Operating room workload], or zero if this value is negative.[6] This means that underutilized operating room time equals the allocated operating room time minus the operating room workload, provided the allocated operating room time is larger than the operating room workload. Otherwise, the underutilized operating room time is 0 hour.

Adjusted utilization = 100% × (1 – [Underutilized operating room time] ÷ [Allocated operating room time]).[5]

For example, staffing is planned from 7 AM to 3 PM. An operating room's last case of the day ends at 1 PM. The operating room workload is 6 hours. There are 2 hours of underutilized operating room time. The adjusted utilization is 75%.[5]

Overutilized operating room time = [Operating room workload] – [Allocated operating room time], or zero if this value is negative.[6]

For example, an operating room is staffed from 7:30 AM to 5 PM. The last case of the day in the operating room ends at 7 PM. Then, there are 2 hours of overutilized operating room time.

Inefficiency of use of operating room time = [(Cost per hour of underutilized operating room time) × (Hours of underutilized operating room time)] + [(Cost per hour of overutilized operating room time) × (Hours of overutilized operating room time)].[6,7]

Operating room efficiency is the value that is maximized when the inefficiency of use of operating room time has been minimized.[6] "Efficiency" is characteristically thought of as the ratio of an output to the necessary input. When surgeons and patients are provided open access to operating room

time on any future workday, the output is a constant (see Tactical Versus Operational Decisions to Increase Productivity below). Maximizing "efficiency" then is achieved by minimizing the input. That occurs when service-specific staffing and case scheduling are so good that there are both 0 hour of underutilized operating room time and 0 hour of overutilized operating room time.

For example, why would a surgical department be allocated two operating rooms on Mondays? If the department's surgeons were allocated three operating rooms, then much of the operating room time would be underutilized. That would reduce operating room efficiency. If the department was allocated one operating room, then the surgeons would be working late to finish their cases, resulting in much overutilized operating room time. That would reduce operating room efficiency. The choice of two operating rooms provides the best balance.

In our experience, this example provides what most facilities consider the objective of operating room allocation—providing the right amount of operating room time to get the cases done (i.e., not too much or too little). That is the essence of operational operating room management decision making. That *must* be differentiated from the longer-term tactical stage of operating room allocation, wherein an increase or reduction in allocated operating room time is expected to result in a change in operating room workload.[8]

The example also shows why good operational decisions cannot be made based on operating room utilization. True, operating room allocation would not be three operating rooms based on either operating room efficiency or operating room utilization because there would be many hours of underutilized operating room time. However, the choice of one or two operating rooms would not be clear based on operating room utilization because the resulting hours of overutilized operating room time are ignored. In contrast, decision making based on operating room efficiency considers both the expected underutilized and overutilized operating room time.

For example, Dr. Abrams is an orthopedic surgeon in a solo practice. She is allocated operating room 1 on Mondays and Wednesdays for 10 hours, from 7 AM to 5 PM. Dr. Yue is another orthopedic surgeon in a solo practice. He is allocated operating room 1 on Tuesdays and Thursdays for 10 hours, also from 7 AM to 5 PM. Both Dr. Abrams and Yue consistently perform slightly less than 10 hours of cases in their allocated operating room time, virtually never more. Both perform spinal surgery cases. However, Dr. Abrams tends to perform one more case of the same type as Dr. Yue within the allocated operating room time because Dr. Abrams operates much more quickly than Dr. Yue. Operating room efficiency is identical and unaffected by how quickly Dr. Abrams operates (see continuation of the example at the end of this section).

Managerial Cost Accounting

Labor cost equals the sum of two products: staffed hours multiplied by the cost per hour of staffed hours and hours worked late multiplied by the cost per hour of hours worked late. More complicated managerial accounting models generally are not needed for purposes of operating room allocation and case scheduling. Labor cost can generally be estimated as the sum of the allocated operating room time multiplied by the cost per hour of staffed hours and the hours of overutilized operating room time multiplied by the cost per hour of overutilized operating room time.

Operating room productivity equals the operating room workload divided by the labor costs.

Anesthesia group productivity equals anesthesia workload divided by labor costs.

For example, the only anesthesia service that a group provides at an outpatient surgery facility is operating room anesthesia. Staffing is planned for five operating rooms from 7 AM to 3 PM. There is virtually never any overutilized operating room time. Then, each increase in operating room workload (i.e., the cases performed) results in an increase in operating room and anesthesia group productivity.

For example, an anesthesia group practices at a hospital both with substantial underutilized operating room time and overutilized operating room time. Recent increases in elective operating room workload have been in the early evenings, resulting in increased overutilized operating room time. Then, the increase in operating room workload could be reducing anesthesia group productivity. That would be happening if the cost per hour of overutilized operating room time is much higher than the cost per hour of regularly staffed hours.

Although it may seem good to make operational operating room management decisions based on increasing anesthesia group productivity, we recommend against the approach. Instead, make operational operating room management decisions to maximize operating room efficiency. Usually the decisions will be the same, but not always.

We recommend decision making based on operating room efficiency, for two reasons.[1,9] First, whereas decisions based on operating room efficiency are invariant to the perspective of the cost assessment, decisions based on labor cost are not. Based on whose labor cost should decisions be made? Although for the anesthesia group the ideal would be to make the decisions based on its labor costs, other options include the labor cost of the hospital or society. Second, labor costs vary depending on staff scheduling and staff assignment, whereas operating room efficiency does not. If labor costs were used, distributed decision making would no longer be consistent depending on the perspective of who makes the decision. For example, if one anesthesia provider works overtime to cover for another anesthesia provider who has called in sick, that would affect decisions based on labor costs but not based on operating room efficiency.

Revenue is the money received from third parties to provide care for a specific patient.

Variable costs are costs that increase proportionate to the volume of patients receiving care.[10]

For example, the amount of endotracheal tubes and medications used will vary with the number of patients who receive anesthesia care. Hence, disposable equipment and pharmacy costs are variable costs.

Fixed costs are those costs that are not related to the volume of patients receiving care.

For example, an anesthesia machine costs the same regardless of how often it is used. An anesthesia machine is a fixed cost.

For example, a new eight-operating room ambulatory surgery center has virtually no overutilized operating room time but much underutilized operating room time. On a short-term

basis, labor costs can be viewed as fixed. Even if operating room workload was increased, all the cases would still be completed within allocated operating room time. The number of anesthesia providers needed to staff the operating rooms would be unchanged. However, on a longer-term basis, labor costs can be reduced by closing an operating room.

Contribution margin equals revenue minus the variable costs for providing care to those patients.

Profit equals revenue minus the sum of fixed and variable costs. This is the same as contribution margin minus fixed costs.

For example, let us return to the orthopedic surgeons, Drs. Abrams and Yue, who were described previously. Dr. Abrams performs one extra spinal surgery case in the same number of hours of operating room time than does Dr. Yue. For the anesthesia group, Dr. Abrams is more profitable than is Dr. Yue, because the anesthesia group gets more revenue for the same fixed costs of staffing the operating room. For the hospital, Dr. Abrams is less profitable than Dr. Yue, because the revenue for the spine surgery cases is less than the variable costs, including the cost of the implanted hardware.[11]

OPERATING ROOM EFFICIENCY ON THE DAY OF SURGERY

Operating room efficiency is maximized by choosing staffing and scheduling cases to minimize the [(Cost per hour of underutilized operating room time) × (Hours of underutilized operating room time)] + [(Cost per hour of overutilized operating room time) × (Hours of overutilized operating room time)]. This relationship is simplified on the day of surgery.

At most surgical facilities, operating room nurses are full-time hourly or salaried employees. Thus, on the day of surgery, the increment in nursing labor cost from 1 hour of underutilized operating room time is negligible relative to the cost from 1 hour of overutilized operating room time. Finishing cases early, but still before the end of staffed hours, reduces labor costs negligibly versus the labor cost that would result from overutilized operating room time. The same applies to nurse anesthetists and/or anesthesiologists who are employees of the surgical facility or corresponding anesthesia group.

Few anesthesiologists and nurse anesthetists in private practice can earn enough money to cover the cost of their salary plus benefits unless they are scheduled to care for whatever patients may need urgent surgery along with patients having elective, scheduled surgery. Thus, the incremental revenue lost on the day of surgery by having 1 hour of underutilized operating room time is negligible relative to the indirect/intangible costs from working late unexpectedly (i.e., the opportunity cost is effectively zero).[12,13]

Consequently, on the day of surgery, the cost per hour of underutilized operating room time is negligible relative to the cost per hour of overutilized operating room time.[1,14] Thus, on the day of surgery, minimizing the inefficiency of use of operating room time (see Definitions above) requires only that management minimize the product of the cost per hour of overutilized operating room time and the hours of overutilized operating room time.

Usually, the cost per hour of overutilized operating room time can be considered constant. Consequently, on the day of surgery, the inefficiency of use of operating room time is minimized by minimizing hours of overutilized operating room time.[1,14] Case scheduling to maximize operating room efficiency minimizes hours of overutilized operating room time, as previously reported for surgical suites.[15] The following two scenarios illustrate the implications of the results.

For example, an anesthesiologist is assigned to an operating room staffed from 8 AM to 3 PM, but with 1 expected hour of overutilized operating room time. The anesthesiologist works quickly. She places every intravenous catheter and arterial cannula on the first attempt and performs a fiberoptic intubation in 10 minutes. Because of her rapid work, the cases finish at 3 PM, preventing 1 hour of overutilized operating room time. The anesthesiologist increased operating room efficiency.[14]

A different anesthesiologist is assigned to another operating room staffed from 8 AM to 4 PM, but with 7 hours of scheduled cases. The anesthesiologist works equally quickly, resulting in cases finishing at 2 PM instead of at 3 PM. Because overutilized operating room time was not reduced, the anesthesiologist did *not* increase operating room efficiency.[14]

These scenarios show that "working fast" is *not* synonymous with increasing operating room efficiency. The last scenario of the preceding section showed that working fast is not synonymous with maximizing profit either.

For example, a different anesthesiologist is supervising resident physicians in two operating rooms. Staffing is planned from 8 AM to 4:30 PM. The anesthesiologist needs to decide which of the two operating rooms to start first. One operating room is scheduled with two cases from 8 AM to 6:30 PM, the other with five cases from 8 AM to 3:30 PM. To maximize operating room efficiency, the anesthesiologist should first start the operating room expected to have 2 hours of overutilized operating room time.[14]

By following this simple principle, individual and collective decision making can be closely linked to enhancing operating room efficiency. Without understanding the principles of operating room efficiency, the anesthesiologist is likely to have made the opposite decision because there are more cases in the other operating room.

The same principles and use of scenarios can be applied to housekeepers, operating room nurses, managers, postanesthesia care unit nurses, etc.

For example, staffing is planned from 7 AM to 3:30 PM. Recently the hospital hired a new operating room nurse. On Monday, she assisted in operating room 12, resulting in cases finishing at 2 PM instead of 3 PM. On Tuesday, she assisted in operating room 14, resulting in cases finishing at 4:30 PM instead of 5:30 PM. She increased operating room efficiency more on Tuesday than Monday, because reducing 1 hour of overutilized operating room time increases operating room efficiency more than does reducing 1 hour of underutilized operating room time.

TACTICAL VERSUS OPERATIONAL DECISIONS TO INCREASE PRODUCTIVITY

Consider a common operating room management problem: staffing is planned from 7 AM to 3 PM. A surgeon has been allocated 8 hours of operating room time every Monday for years. The surgeon has always underestimated the operating room times of

his cases. The surgeon has never finished before 6 PM and usually ends between 7 and 8 PM.

The anesthesiologists and operating room nurses may complain about working late every Monday. They may lobby to have a committee meet to rectify the situation. Simultaneously, the administrators may discuss the surgeons' lack of respect for rules and hospital resources. Nevertheless, physicians who refer their patients to the surgeon reward him by continuing to send him work because their patients are pleased with his expeditious service.

The fundamental issue is the surgeon's frequent misrepresentation of the estimated operating room times of his cases, in order to get them onto the operating room schedule.[16] The merits of the tactical issue (i.e., whether this is overall good or bad practice) have little relevance to anesthesia productivity. The relevant operational decision is clear: on a short-term basis, managers should change staffing to match the reality of the existing workload. Doing so neither increases nor reduces operating room capacity or convenience for the surgeon and his or her patients. What it does is to reduce labor costs by reducing the hours worked late in lieu of staffed hours.

For example, when an anesthesiologist was hired, the job description said that work hours were 7 AM to 5 PM. Yet, every Monday for the past 5 years, the anesthesiologist has finished working between 7 and 8 PM. Staffing is planned to 8 PM because that is the reality of the existing operating room workload.

In the two preceding scenarios, the surgeon and patient are choosing the day of surgery. Cases are not being turned away, provided they can be done safely, even if they will likely be performed in overutilized operating room time.[17] Subject to that priority, operating room time can be allocated based on maximizing operating room efficiency. To describe operational reality, mathematics needs to be based on the surgeon and patient having open access to operating room time on the workday of their choosing.

For example, all operating rooms are allocated at a hospital for 8 hours. The adjusted utilizations range from 75–85% among the surgical services. Thus, there is essentially only underutilized operating room time. At this hospital, allocating operating room time based on operating room efficiency would give precisely the same result as allocating operating room time based on adjusted utilization. This is because virtually no operating room ever finishes late. A zero has been substituted for the hours of overutilized operating room time in the equation for the inefficiency of use of operating room time (see earlier, "Inefficiency of use of operating room time"). The surgeons can be considered to have open access to operating room time on the workday of their choosing, and they have chosen to perform cases only when they can be completed within allocated hours.

The preceding scenarios demonstrate that service-specific staffing can be considered for any facility when decisions are made based on operating room efficiency and on surgeon and patient open access to operating room time on any future workday. The next scenario shows that the assumption of fixed hours applies only to a minority of surgical suites.[7]

For example, an ambulatory surgical center has a policy that operating room time is allocated based on operating room utilization. Staffing is planned from 8 AM to 3:30 PM. This policy is enforced strictly. A surgeon asks to book a case to start at 1:30 PM, with an expected (realistic) operating room time for the case of 2.5 hours. He is told "No," that would be unacceptable, because the case will likely end at 4 PM.

The preceding scenario will seem unreal to most clinicians in the United States. That is the point. Only scheduling cases if they can reasonably be expected to finish by the end of allocated operating room time is not the reality of short-term operational decision making at many facilities. Although considering a facility to have fixed hours of operating room time is an accurate and practical model from a tactical perspective, it is not realistic for day-to-day decision making in a surgical suite.[1,17–19]

We return to the first scenario of this section, which describes persistent overutilized operating room time. Should the surgeon be encouraged to continue to schedule cases beyond the hours that have been allocated? That is a reasonable tactical question, which includes consideration of the financial impact of the surgeon's cases versus the long-term effects on hiring and retention of operating room nurses and anesthesia providers.[8] The tactical decision can, and probably should, be considered from multiple perspectives, including societal. However, the operational decision making focuses on the reality of the existing workload. Operational decisions, specifically service-specific staffing, are what most managers can control.

Not having fixed hours of operating room time is particularly common at hospitals at which surgeons mischaracterize cases as "urgent" to get them onto the operating room schedule.

For example, an academic department is allocated three operating rooms from 7 AM to 3 PM on all weekdays. No case is scheduled unless it will fit into the 8 hours based on historical operating room time data from the operating room information system. The service schedules 20% of its operating room hours as urgent cases. Many of these patients likely could have waited safely for several days for surgery. Thus, these were elective cases. The surgeons called the cases as "urgent" to achieve open access to operating room time. Operating room efficiency would have been greater had more operating room time been allocated originally so that the cases could be performed in allocated, rather than overutilized, operating room time.

Suppose that on a long-term (tactical) basis, the behavior of the academic surgeons was considered so bad that penalties are applied. Then, there would be very little overutilized operating room time. The methods described in this chapter would be valid and appropriate, but not necessarily a useful improvement. Consequently, there is reason to consider whether the behavior of the above surgeons is inherently bad.

From the societal, hospital, and surgeons' perspective, likely the behavior is good, or at least not bad enough to penalize the surgeons. They are serving as their patients' advocates, assuring timely surgery. Further, in some healthcare systems, including that in the United States, the surgeons are also increasing hospital and physician contribution margin.

Hospitals receiving fee-for-service reimbursement achieve an overall positive contribution margin for the elective cases of almost all surgeons,[8,18,20] because a large percentage of operating room costs are fixed. If professional revenues for the anesthesia providers and surgeons were also considered, then every surgeon would provide an overall positive contribution margin

for their elective cases. The implication, then, is that if a case can be performed safely, it is economically irrational not to perform the case.[8,18]

The rationale for providing surgeons with open access to operating room time, provided a case can be performed safely, makes particular sense for hospitals with intensive care units (ICUs) that often are full. For patients needing such care, the ICU is a frequent bottleneck that results in delays or cancellations of surgical cases. There are two ways to approach this problem, other than simply providing and staffing more ICU beds.

One strategy to reduce the risk of delays or cancellations is to adjust the days that services are scheduled to perform surgery.[21] Although such techniques can be implemented practically,[21] the incremental benefit to hospitals may be small. If most surgeons schedule patients for ICU admission on the same days of the week, usually the cause of case cancellations is visible to the surgeons. The surgeons generally suffer more financially from case cancellations and delays than do hospitals and anesthesiologists. In this situation, the hands-on facilitation of a local operating room manager or an expert in managing organizational conflict can help. Such interventions are valuable and important.[22] However, they are not commonly decisions made by anesthesia group managers, although they can facilitate such processes.

The second of the two strategies is to provide surgeons with flexibility in the days when they have operating room time. Cases should get onto the operating room schedule to assure that the expensive bottleneck (the ICU) is always full. For example, although 90% of patients may have post coronary artery bypass graft (CABG) lengths of stay < 48 hours, there can be marked variability in length of stay.[23] Consequently, it can be very difficult to predict when a relatively full ICU will have an open bed as a result of a patient transfer. When the bottleneck to doing surgery is downstream from operating rooms and the service time for that downstream process is highly variable, then flexibility in scheduling the operating room cases is needed to maximize throughput.

The same applies to expensive capital equipment, which like the ICUs is a fixed cost that is best kept fully used. Operating rooms of the future will include more imaging and robotics, resulting in even higher capital costs. The percentage of hospital costs for surgery that are attributed to labor likely will decrease as capital costs increase to support these and other expensive technologies. To maximize use of that equipment, surgeons should have open access to operating room time to do a case on whatever future workday they are available, provided the case can be performed safely using existing equipment.

The caveat of "provided the case can be performed safely" is of strikingly large importance. Safety includes access to limited ICU beds, hospital ward beds, postanesthesia care unit beds, fluoroscopy equipment, nonfatigued staff, implants, and so forth. What can be done safely limits how much work can be done in a surgical suite on any given day. Characteristically, tactical decision making limits what can be done safely. Then, operational decision making functions within these boundaries.

Based on these arguments, realistic operational decision making needs to function within a structure that allows the surgeon and patient to choose the day of surgery. The reason why this is so important is that surgeons are not the individuals primarily responsible for operating room efficiency through their filling of the operating room time allocated to them. Rather, the parties primarily responsible for operating room efficiency are the nursing and anesthesia group managers who choose the operating room allocations to match staffing to the surgeons' workloads.

For example, for 1 week each year, most of the thoracic surgeons are away at a conference. There is substantial underutilized operating room time, resulting in poor operating room efficiency. This is an example of poor operating room management. The managers should have increased operating room efficiency by adjusting staffing to match the surgeons' and patients' hours (e.g., by making that time available for the extra staff to use some of their accrued vacation).

ALLOCATING OPERATING ROOM TIME AND SCHEDULING CASES BASED ON OPERATING ROOM EFFICIENCY TO INCREASE PRODUCTIVITY

Allocating operating room time (i.e., planning service-specific staffing) and scheduling cases based on operating room efficiency can increase operating room and anesthesia group productivity by reducing labor costs.

Performing Calculations Using Complete Enumeration

In practice, operating room allocations that are calculated based on operating room efficiency are done by service and day of the week. That is because day of the week is the best predictor of a service's workload.[7,24] Calculating an operating room allocation means determining how many operating rooms should be staffed daily for each service and, for each of these operating rooms, how many hours of staffing should be planned (e.g., 8, 10, or 13 hours).[7,24] This can be done by complete enumeration. Specifically, all possible staffing solutions are considered, starting with 0 hour and progressively increasing staffed hours until additional increases in the staffed hours cause the efficiency of use of operating room time to decrease for that service.[24] If shifts of 8, 10, and 13 hours are considered, then the successive choices are 0, 8, 10, 13, 16, 18 hours, etc. Increasing the staffed hours causes the efficiency of use of operating room time to increase progressively to a maximum, after which it decreases.[7] The complete enumeration can be constructed such that every series of cases performed by the same surgeon on the same day would be performed in its original sequence. The only change is in the start times.

For example, a surgeon is allocated operating room time individually on Thursdays. The surgeon does 10 hours of cases every Thursday. A 0-hour allocation would have a lower operating room efficiency than an 8-hour allocation because of 10 versus 2 hours of overutilized operating room time each Thursday. An 8-hour allocation would have a lower operating room efficiency than a 10-hour allocation because of 2 versus 0 hour of overutilized operating room time each Thursday. Finally, a 13-hour allocation would have a lower operating room efficiency than a 10-hour allocation because of 3 versus 0 hour of underutilized operating room time each Thursday. Thus, the surgeon would be allocated 10 hours of operating room time.

There is a unique solution to the choice of the operating room allocation that will maximize operating

room efficiency if operating room allocations can be of any duration,[7] but not necessarily when fixed choices are considered. When two choices provide nearly the same inefficiency of use of operating room time, the operating room workload can be reviewed to consider which most closely matches how the surgeons in the service are using the operating room time.

For example, a gynecology group performs an average of 14 hours of cases each Monday, with a range of 13.0–14.5 hours. Forecasted operating room efficiency would be nearly identical whether 13 hours of operating room time were allocated in one operating room or 8 hours in each of two operating rooms. The gynecology group has had two operating rooms (i.e., reliable first case of the day start times) for the past 6 years. They have consistently scheduled cases into those operating rooms such that there is only underutilized operating room time, not overutilized operating room time. Two operating rooms would be the most reasonable choice. In this example, planning operating room allocation based on operating room efficiency versus adjusted utilization results in no effective improvement.

Maximizing operating room efficiency is the same as minimizing the sum of underutilized hours and overutilized hours multiplied by the relative cost of overutilized to underutilized operating room hours.[7] Thus, only the relative cost of overutilized to underutilized operating room hours needs to be known, not the costs per se.[7] A commonly used[24] value for this ratio of costs is 1.75. This includes the direct costs of overtime at "time and a half" (1.50) and an increment (0.25) for indirect (intangible) costs of employee dissatisfaction, resignation, and recruitment and training.[24] Because of the marked effect of limiting consideration to common staff schedules (e.g., 8 or 13 hours), the resulting inefficiency in use of operating room time is characteristically highly insensitive to local experts' uncertainty in the choice of the value of this parameter.[25]

For example, on three Fridays, a service performed 12, 7, and 15 hours of cases, including turnover times. There are 8-hour shifts, with overtime scheduled by rotation. The relative cost of overutilized to underutilized hours is considered 1.75. If the service were allocated 8 hours of operating room time each Friday, then the cost of the inefficiency of use of operating room time would be 20.25 hours (0 underutilized + 1 underutilized + 0 underutilized + 1.75 × [4 overutilized + 0 overutilized + 7 overutilized]). If the allocation were two 8-hour operating rooms each Wednesday, the cost would be 14 hours (4 underutilized + 9 underutilized + 1 underutilized). If the allocation were three 8-hour operating rooms each Friday, the cost would be 38 hours (12 underutilized + 17 underutilized + 9 underutilized). Therefore, the service should be allocated two 8-hour operating rooms to maximize operating room efficiency.

There is one answer to the question "How close are current operating room allocations to those that would maximize operating room efficiency?" In contrast, there is no one answer to the question "How close are current operating room allocations to those that are optimal based on operating room utilization?" because there is then the subsequent question of how to determine the optimal operating room utilization. The best operating room utilization varies among services because it is sensitive to many parameters, such as staffed hours, turnover times, day-to-day variability in operating room workload, statistical distribution of operating room times of cases, and so forth.[17,26] Years of data can be required to estimate these parameter values sufficiently accurately to use them to decide on the operating room utilization to use as the service's goal.[27] Allocating operating room time based on operating room efficiency simultaneously takes into account all of these issues. When a manager says "We allocate operating room time based on operating room efficiency," that is close to a sufficient statement to describe precisely what happens in practice because the choice of the relative cost of overutilized to underutilized operating room time is invariably close to 1.75 and insensitive to any differences. In contrast, when a manager says "We allocate operating room time based on operating room utilization," that alone says virtually nothing about what happens in practice at the surgical suite.

Calculated Operating Room Allocations Differ from Those in Current Practice

Managers' efforts to reduce labor costs must focus predominantly on operating room allocation and case scheduling, because almost all anesthesia providers' costs are labor costs. For 10 of 11 facilities studied, allocating operating room time based on operating room efficiency achieved significantly lower labor costs than the plans that were being used by the local managers.[24,28] For nine of the 11 facilities, the statistical method approach resulted in plans that reduced labor costs by at least 10%.[24,28] The percentage increases in operating room efficiency were, by definition, even more.

A common anecdote reveals how poorly many facilities plan service-specific staffing. Often operating room nurses and anesthesiologists report that every operating room finishes at least an hour or two late every day. To consider the irrationality of the situation, suppose that the relative cost of overutilized to underutilized operating room time were 2.0. Then, it is twice as expensive to finish late versus early. Thus, with appropriate operating room allocations, the odds for each service and operating room to finish early should be approximately two chances in three.

In practice, reductions in labor costs are generally not proportional to the number of operating rooms.[24,28] Surgical suites at which many hours of operating room time are allocated to services do not have the largest percentage improvements from applying the operations research to operating room management.

There are at least two possible explanations for this observation. First, the principal challenge faced by managers does not seem to be the number of operating rooms to be allocated to services but how to manage variability in operating room workload from week to week. The fact that the operating room allocation decision is stochastic seems to be the conceptual problem in the practicing managers' decisions. Second, at surgical suites where allocating operating room time practically involves choosing between just two or three options, performing a full analysis once or twice seems to be sufficient for managers to be comfortable that they can interpret existing internal operating room workload reports in the appropriate stochastic context. In other words, the analysis is providing education. In contrast, at surgical suites with large services and many options for appropriate operating room

allocations, performing a full analysis at frequent intervals may be useful.

For example, consider a service with operating room workload averaging 5 hours every Tuesday. Because there are no overutilized hours, allocation based on operating room efficiency is identical to allocation based on operating room utilization. Once the principle is understood by managers, analysis is unneeded in the future. In contrast, suppose that the same facility has three of its eight operating rooms as unblocked, open, first-come, first-served "other" time. The surgical suite staffs in 8-, 10-, and 13-hour shifts. Then, those three operating rooms could be allocated as 8/8/8, 8/8/10, 8/10/10, 10/10/10, 8/8/13, 8/13/13/, 13/13/13, 8/10/13, 10/10/13, and 10/13/13. Intuition will not help with this complex decision.

Urgent Cases

Some hospitals have one or more operating rooms allocated for urgent cases during the regular workday. Typically, the appropriate number of operating rooms is chosen for such urgent cases by considering them to be performed by a pseudoservice, the "urgent" service. Then, the methods above are applied. At facilities not planning an operating room for urgent cases, when calculating operating room allocations for elective cases, each urgent case should be attributed to its surgical service.

The relative cost for overutilized to underutilized operating room time may be appropriately higher for the urgent service than the other elective services, because the choice affects not just how often staff work late but also patient waiting time for urgent surgery. However, urgent cases often cannot start immediately because of a lack of availability of personnel or equipment, such that overutilized operating room time would occur regardless of calculations. In practice, the use of the same relative cost for overutilized to underutilized operating room time as above (e.g., a factor of 1.75) can provide answers that clinicians consider reasonable.

Amount of Data Required for Effective Calculations

To assess how much data are required to produce acceptable results, a long series of data from a surgical suite was divided into training and testing datasets, with different training periods.[9] The complete enumeration was applied to the training data, and the expected labor costs that would have occurred during the subsequent testing period were calculated. Each increase in the number of months of data up to 9 months resulted in a statistically significant reduction in expected labor costs. There were large incremental benefits in using at least 7 months of data. For the studied hospital, there was no advantage to using more than 1 year of data.

The minimum amount of data needed for calculating operating room allocations based on operating room efficiency can be particularly important to managers at facilities purchasing a new operating room information system, anesthesia information system, or anesthesia billing system. The minimum period of data indicates the time from installation of the system to when management changes based on resulting data can be implemented. Application of the statistical methods using as little as 30 workdays of system data provided better operating room allocations to reduce labor costs than operating room allocations established by the practicing managers with years of data.[9]

Sources of Data

Data for analysis can come from an operating room information system, an electronic anesthesia patient record information system, or anesthesia billing data.[29] Operating room information system data have the advantage of virtually always having necessary data fields completed. Anesthesia billing data have the advantage of accuracy, because billing errors can be costly or even lead to challenges of fraudulent behavior.

Facilities with operating room information systems that do not have data review at the time of data entry often have datasets that contain errors or omissions, including lack of knowledge of the actual operating rooms in which some cases were performed. This manifests as the false appearance of two cases overlapping in the same operating room at the same time. The typical fix is to change the recorded operating room of each case that overlaps to a unique unknown operating room. For example, suppose that one case is listed as being performed in operating room 1 from 9 AM to 10 AM and another in operating room 1 from 9:30 AM to 11 AM. Among all cases in the dataset, the latter case is the 129th for which the true operating room is unknown. The operating room assignment of the second case can be considered to be Unknown129. Making such a change affects calculated turnover times and thus may affect operating room allocations. Nonetheless, studies demonstrated that the impact of this adjustment on the labor costs that result from poor operating room allocations is of negligible importance, for three reasons.[30,31] First, operating room allocations are based on each service's total hours of cases, a large number, plus total hours of turnover times, a smaller number. Second, for cases in an operating room that have a preceding case and a following case, two turnover times are lost. Yet, the turnover time between the remaining cases is increased between the two cases surrounding the reassigned case to the default maximum turnover time.[30] Third, the effect of allocating operating room time only in fixed increments (e.g., 8 or 16 hours) is of larger importance.

Assessing Trends, Seasonal Variation, and Data Errors

Use of complete enumeration assumes that there are no systematic differences among weeks in the expected operating room workload (i.e., there are no trends or seasonal variation).[24] National survey data show that these assumptions will hold for most facilities.[32] Raw data were reanalyzed from the 1994 to 1996 National Survey of Ambulatory Surgery. As a positive control, to assure that seasonal variation could be detected if present, the average number of myringotomy tubes inserted each day in ambulatory surgery centers of the United States was examined. As expected, myringotomy tube insertions peaked each winter, corresponding to the peak incidence of middle ear infections. Specifically, the average number of tubes inserted each day varied systematically among months for all 26 of the overlapping 11-month periods in the 36 months of the survey. In contrast, the average number of ambulatory surgery cases performed with an anesthesia provider each day in the United States per 10,000 population was found not to vary systematically month to month on an 11-month basis.

Good routine practice is to test for statistically significant trends or sea-

sonality, to confirm that analysis is reasonable for each surgical suite. For example, the runs test can be applied to the total labor cost over each consecutive 4-week period.[24,33] Calculate the total labor cost for each 4-week period. Subtract the median from each value. Delete zero differences. Assign a "+" to positive differences and a "–" to negative differences. Finally, compare the number of runs of +'s and -'s to a critical value from appropriate statistical tables.

Virtually never is it necessary to incorporate methods appropriate for data with trends and seasonality into the analysis. When the runs test detects trends or seasonality, characteristically this reflects a problem with the data or special conditions that need to be modeled separately.

In addition to using the runs test, plot each service's operating room workload for the days of the week when the service is allocated operating room time. The graphs are helpful to detect unrecognized errors in the data. For example, plotting operating room workload for a service against time can show if a service had no cases listed for a day of the week for some part of the data period being used. This usually occurs when the data sent for analysis include one or more surgeons who recently left the facility.

Finally, look for the presence of many zero values in the histogram of operating room workload for each combination of the day of the week and the service allocated operating room time. This usually happens when the service's scheduling is characteristic of an individual surgeon rather than a group of surgeons. These "holes" often represent time when an individual surgeon is away (e.g., on vacation). These can be hard to identify in a graph of operating room workload versus time. Such services should have their allocations of operating room time combined with another service to achieve reliable staffing predictions.

Services with Low Operating Room Workloads

Provided cases are scheduled sequentially into operating rooms (below), then services with average operating room workloads that are consistently <8 hours have no overutilized hours. Allocating operating room time based on adjusted utilization does not differ from doing so based on operating room efficiency. Many facilities apply a minimum adjusted utilization for operating room allocations.

For example, a service's operating room workload averages 5 hours every Monday. The facility requires an adjusted utilization of at least 50% for operating room allocation. Thus, the service is allocated a single operating room for 8 hours. Its adjusted utilization is 62%. There are 3 underutilized hours and 0 overutilized hours. Because there are no overutilized hours, allocation based on operating room efficiency is identical to allocation based on operating room utilization.

Each service not receiving an operating room allocation on a given day can be combined into an "other" service (i.e., open, unblocked, first-scheduled, first-served time). At facilities without substantial cross-training of staff, there may be different "other" services for different nursing teams. The calculations of the preceding sections are repeated for the "other" service(s) on each workday.

Importantly, do not simply measure the average operating room workload of a service, observe that it is too low for an allocation of an 8-hour operating room for the day, and then automatically pool it into "other" service time. Apply the graphical methods of the preceding section to assure that the reason for a low operating room workload reflects an actual low workload, not a service that operates every other week on the studied day of the week. Likewise, assure that incomplete data or a trend in operating room workload is not being observed.

Using Qualitative Information to Improve Forecasts

Qualitative information not available from information system data should be used when finalizing operating room allocations.

For example, a surgeon operates at an outpatient surgery center on Fridays in her 8 hours of allocated operating room time. For years, she has consistently performed 7.0–7.5 hours of cases at the surgery center in that 8 hours of operating room time. The operating room allocations are being updated for the next quarter. Based on historical data, she would, of course, be allocated 8 hours of operating room time on Fridays. However, she is 8 months pregnant. She has requested 3 months of maternity leave. She should not be allocated operating room time during the next quarter because it would be underutilized, thereby reducing operating room efficiency. Even without personally allocated operating room time, the surgeon would continue to have open access to operating room time on any future workday, if she were to change her mind and work for a few days during her period of maternity leave. Note that if she were not provided open access to operating room time, then there would be an adversarial relationship between the facility not wanting to plan a "block" for her versus her desire to keep some block time to provide herself and her patients some flexibility.

Forecast Remaining Underutilized Operating Room Time

A concern at some facilities is that underutilized operating room time is needed for nonclinical but important activities. For example, equipment for the next day's cases may be set up by nurses whose operating rooms finish earlier than the end of their shift. The manager of such a facility may express concern that changing operating room allocations to increase operating room efficiency will impair processes that function well by taking advantage of existing underutilized operating room time.

Expected underutilized time can be estimated empirically after future operating room allocations have been determined. Applying the allocations, each historical day's resulting total underutilized hours are calculated. The statistical distribution of each day's total hours of underutilized operating room time can be described using histograms or percentiles.

Case Scheduling to Maximize Operating Room Efficiency

Allocating operating room time to increase operating room efficiency is of little value unless cases are also scheduled into the operating room time appropriately.

A series of thought experiments and computer simulations were performed to evaluate case scheduling based on maximizing operating room efficiency.[14] The performances of different case scheduling heuristics were compared. The analyses showed that managers can achieve efficient operating room scheduling while leaving case

scheduling decisions to the convenience of the surgeons and patients, provided three simple scheduling rules are followed. In other words, there were small differences in resulting operating room efficiency among several different scheduling heuristics, with these three exceptions.

The first of three scheduling rules is that a service should not schedule a case into another service's operating room time if the case can be completed within its own allocated operating room time.[14]

For example, two gynecologists are partners in a group that has been allocated 10 hours of operating room time on Tuesdays. One of the gynecologists has scheduled 6 hours of cases into the operating room time, leaving 4 hours of allocated but unscheduled operating room time. An orthopedic surgeon has scheduled 2 hours of cases into his personally allocated 8 hours of operating room time. Nine days before the day of surgery, the second gynecologist wants to schedule a new 2-hour case. The available start time would be after her partner who has already scheduled cases. The case would not be scheduled into the orthopedic surgeon's operating room time, even if the second gynecologist wants to start earlier. The reason is that the gynecology group has available operating room time for the case.

The reason for this result is that operating room allocations are calculated based on expected operating room workload on the day of surgery. Services fill their allocated operating room time at different rates.[34] Almost all facilities with allocated operating room time follow the preceding scheduling rule. Thus, the importance of this finding was not that it showed a new way to schedule cases but that it showed that most facilities make decisions based on operating room efficiency.[14]

The second of the three scheduling rules is that a case should not be scheduled into overutilized operating room time if it can start earlier in another of the service's operating rooms.[15] This applies to services allocated two or more operating rooms. Suppose that operating room workload is 23 hours. The hours of overutilized operating room time would be considered slightly less if two operating room were allocated for 13 hours (total 26 hours) versus three operating room for 8 hours (total 24 hours). This result may not apply unless the case scheduling results in similar packing of the cases into the allocated operating room time.[14,35] Simulations show this does occur generally.

For example, a service has been allocated operating room 1 and operating room 2 from 7 AM to 3 PM. One surgeon in the service has scheduled cases in operating room 1 to finish around 2 PM. Operating room 2 is empty. A second surgeon in the service wants an afternoon start. He asks to start an elective 3-hour case at 2:30 PM in operating room 1. Even though operating room workload would be the same, scheduling the case into operating room 1 would be expected to result in overutilized operating room time and thereby reduce operating room efficiency. His request should be rejected. The surgeon should either take the first case of the day, start in operating room 2, or choose a different workday.

The preceding scenario matches what is done at most surgical suites. Cases are generally not scheduled in overutilized operating room time when a service has another allocated operating room that is empty. Consequently, as the first rule above, this rule shows that scheduling cases based on maximizing operating room efficiency differs little from what is commonly done in practice.[14] Changes resulting from decision making based on operating room efficiency are generally not in case scheduling. Rather, they are in operating room allocations (as above) and in the third rule regarding how operating room time is released.

The third of the three scheduling rules is that if a service has already filled its allocated operating room time, then, to maximize operating room efficiency, its new case should be scheduled into another services' operating room time instead of into overutilized operating room time.[14,34]

For example, a service has filled its allocated operating room time but has another case to be scheduled. If the operating room time of another service were not released, the case would be performed in overutilized operating room time. Operating room efficiency is greater by performing that case in operating room time allocated to another service that otherwise would be underutilized on the day of surgery.

For example, a surgeon may be subverting the case scheduling system for the "other" first-scheduled, first-served operating room time. The surgeon may be creating fictitious patients to "hold" operating room time for his cases (e.g., at the desirable 8 AM start time). At a Surgical Services Committee meeting, a manager suggests that there be the policy that, when a case is cancelled, first access to cancelled operating room time goes to other surgeons with waiting cases, not the surgeon canceling the case. That recommendation is not sound. When a service has filled its allocated operating room time and has another case to schedule, operating room efficiency is enhanced by releasing the operating room time of the service expected to have the most underutilized operating room time. No cases should be waiting to be scheduled.

To evaluate which service should have its operating room time released, simulations were performed scheduling new hypothetical cases into actual operating room schedules. Services fill their allocated operating room time at different rates. Thus, theoretically, the service that should have its operating room time released for a new case should be the service that is predicted, at the time the new case is booked, to be the service that will have the most underutilized operating room time on the scheduled day of surgery. Yet, performance is only slightly better versus scheduling the case into the operating room time of the service with the largest difference between allocated and scheduled operating room time at the time when the new case is scheduled.[34] The latter is far easier to implement practically.

In contrast, releasing the operating room time of the service with the second most, instead of the service with the most, allocated but unscheduled operating room time has a large negative effect on operating room efficiency.[34] The reason is that usually a particular case can only be scheduled into a few services' operating room time without resulting in overutilized operating room time. The differences among those few services in their amount of expected open operating room time often are large. This occurs because day-to-day variability in the operating room workload of services on a day of the week generally exceeds variability due to the timing of how quickly different services filled their allocated operating room time.

The timing of when allocated operating room time should be released has

been studied.[36] Potentially, the scheduling office could wait to release the allocated operating room time until closer to the day of surgery, when data may be available on subsequently scheduled cases, in order to improve the quality of the decision. Simulation results were equivocal as to the benefit of such a decision. Under two conditions, postponing the decision of which service had its operating room time released for the new case until early the day before surgery had a negligible effect on resulting operating room efficiency versus releasing the allocated operating room time when the new case was scheduled.[36] This finding applies to an ambulatory surgery center with brief cases. At such facilities, typically there is only one good choice for the service to have its operating room time released.[34] Thus, there is no good reason to wait in making the decision. This finding often also applies to large surgical suites in which cases are scheduled as if there were many smaller suites. For example, at a 25-operating room surgical suite, one nursing and anesthesia team may staff the six operating rooms used for urology and general surgery. From the perspective of releasing operating room time for a new urology or general surgery case, only six operating rooms are available, not all 25.

For example, a hospital contains a team cross-trained in neurosurgery and otolaryngology. One week hence, on next Monday, neurosurgery has been allocated one 8-hour operating room. Otolaryngology has been allocated one 8-hour operating room also. The otolaryngologists have scheduled 9 hours of cases into their operating room. A third otolaryngologist wants to schedule another 2-hour case. The neurosurgeons have scheduled a case for 3 hours from 7 AM to 10 AM. The otolaryngologist with the new case can book the case because the surgeons have open access to operating room time on whatever workday they choose. Provided the otolaryngologist is available at 10:30 AM, then the neurosurgeons' operating room time would be released. There is no advantage to waiting to schedule the case. Yet, if the neurosurgeon with the 7 AM to 10 AM case was to schedule another case, ideally the otolaryngologist could be persuaded to start his case later in the day.

Despite this consideration of how best to release allocated operating room time, it is important to appreciate that results are highly sensitive to the operating room time being allocated appropriately based on operating room efficiency. Issues of when to release allocated operating room time pale in practical importance versus operating room allocation and staffing. Although operating room management problems are observed on the day of surgery, often the root cause and only practical way to fix the problem is to plan operating room allocations and staffing properly several weeks or months before the day of surgery.[37]

For example, operating room information systems data are used to calculate operating room allocations, which then are reviewed by an operating room committee. An ophthalmologist complains that his allocated operating room time on Wednesdays has been "released" for 2 of the past 3 weeks. Each time, the otolaryngology service has filled its allocated 8 hours of operating room time and so has booked cases into his operating room time. The ophthalmologist is upset that the schedulers are treating him unfairly by repeatedly releasing his allocated operating room time. Although he schedules many cases a couple of days before the day of surgery, his operating room workload is consistently at least 7 hours each Wednesday. The ophthalmologist's concerns are well founded; this should not be happening. However, the problem is not that the schedulers are releasing his operating room time. Rather, they are making the proper decision to maximize operating room efficiency. The problem is that the otolaryngology service should be allocated more than 8 hours of operating room time.

Finally, although this chapter has focused on decision making before the day of surgery, the same principles apply to decisions made on the day of surgery.[1] The principles described can also be used to decide how cases are moved on the day of surgery,[38] how staff are assigned on the day of surgery,[39] and how cases are sequenced in each operating room.[40,41]

IMPACT OF REDUCING TIMES ON PRODUCTIVITY

Impact of Reducing Surgical and Turnover Times

The impact of interventions on labor costs can be forecast using each facility's own data, along with corresponding confidence intervals.[12] For example, turnover times can be reduced between each case.[12] Surgical times can be reduced to national average values for each procedure.[13] For both interventions, first the labor cost is calculated assuming that operating room time is allocated and cases are scheduled based on operating room efficiency. Second, the intervention is performed, thereby reducing operating room workload by service. Third, using the revised workload values, operating room time is reallocated based on operating room efficiency and the new estimates for labor costs projected. Fourth, the differences are calculated. By analyzing the differences in 4-week epochs, to prevent effects of variation by day of the week, confidence intervals can be calculated for the differences.[12,13,24]

For example, consider a hospital that allocates operating room time to many small services, each having adjusted utilizations of <85% with 8-hour allocations.[13] Cases are being scheduled based on operating room efficiency (i.e., sequentially into operating rooms[14]). Reducing operating room times cannot result in reduced overutilized hours because there are none. Labor costs will not be reduced (i.e., they are fixed to achievable reductions in operating room times).

For example, a different hospital has few surgical services, most with more than one operating room, and many operating rooms with workloads exceeding 8 hours.[13] Conclusions are different than in the preceding example. Reducing operating room times can result in reductions in workload sufficient to reduce allocated operating room time (e.g., an operating room allocated for 10 hours would now be allocated for 8 hours). Thus, at this hospital, there would be financially important reductions in labor costs from reducing operating room times.

Equivalent analyses can be performed at teaching facilities to calculate[13] the impact of longer operating room times (due to factors such as teaching time and development of skills in trainees)[42,43] on labor costs.

These examples show that, generally, cost reduction from reducing operating room or turnover times can only be achieved provided operating room allocations are reduced. The initial impact is increased underutilized operating room time and reduced overuti-

lized operating room time. This initial step is evident to clinicians. The secondary step is revisions of operating room allocations based on the new values of decreased operating room workload. The latter step provides for the large reductions in labor cost. Whereas the former is often a palatable change, the latter can be less popular politically.

Usually reductions in labor costs from reducing turnover times tend to be small. At four academic tertiary hospitals studied, reductions in average turnover times of 3–9 minutes would result in 0.8–1.8% reductions in labor cost.[12] Reductions in average turnover times of 10–19 minutes would result in 2.5–4.0% reductions in labor costs.[12] These analyses can be fruitful in educating stakeholders that achievable reductions in the times to complete tasks often have less effect on operating room efficiency than does good management decision making.

Impact of Not Changing Operating Room Allocations

Some facilities do not make decisions systematically based on increasing operating room efficiency and are unlikely to change their practices because of organizational inertia. Then, the methodology above can be used to calculate the higher labor costs that the facility sustains from operating room time not being allocated and cases not being scheduled based on operating room efficiency.[9,24,28]

For example, anesthesia group expenses exceed revenue at a facility. The calculation is performed using labor costs of anesthesia providers. The estimate of the resulting additional labor costs is used by the head of the anesthesiology group when she negotiates an appropriate subsidy from the hospital.

Calculations of subsidies can also apply to negotiations with medical schools, ambulatory surgical facilities, or a multispecialty group. At two academic medical centers, estimated annual excess labor costs were $1.6 million and $1.0 million, respectively.[28]

Impact of Not Reducing the Number of Allocated Operating Rooms

Some organizations aim to adjust their operating room allocations to be as close as possible to those that are expected to maximize operating room efficiency while not reducing the number of allocated operating rooms. This approach does not result in maximal operating room efficiency. Instead, it reflects organizational pressure to open as many operating rooms as are available for first case of the day starts. The mathematics can be weighted to allocate more operating rooms by repeating the analyses using a higher relative cost of overutilized to underutilized hours. An increase in the relative cost gives an increase in how many operating rooms are allocated.[17] The smallest value is chosen for which the allocated number of staffed operating rooms matches the desired, usually current, number of operating rooms. This analysis is run separately for each day of the week.[17]

Increasing the number of allocated operating rooms results in a slightly smaller percentage increase in operating room labor cost than in staffing.[17] The reason is that opening more operating rooms than are needed to maximize operating room efficiency does not change operating room workload. Thus, the increase in allocated operating room hours increases underutilized operating room time and reduces overutilized operating room time. The cost per hour of overutilized operating room time exceeds that of underutilized operating room time. Consequently, the percentage reduction in operating room efficiency is less than the percentage increase in allocated operating room hours. The same argument applies to labor costs.

INDIVIDUAL PRODUCTIVITY

In the previous sections, the economic evaluations focused on overall operating room and anesthesia group productivity. In contrast, this section considers the issue of individual productivity, specifically individual anesthesiologists.

Individual versus Group Productivity

Group and individual productivity are distinctly different. For example, in baseball, there are a variety of measurements of individual productivity for each position: earned runs average, strikeouts and walks for pitchers; hits, batting average, and home runs for batters; and double plays, errors, and fielding percentage for fielders. In contrast, the measurement of group productivity is simply the final output: wins and losses. Similarly, for anesthesia care, individual measurements should focus on the individual's contribution, whereas group measurements should examine overall productivity or output.

One of the greatest errors in management is to take a group goal or benchmark and apply it to individuals.

For example, a group develops a benchmark for their group of X units per anesthesiologist. Then, it would be a mistake to assume that each anesthesiologist in the group should produce a minimum of X units. Each individual will fulfill different functions.

For example, consider the earlier example of two spine surgeons, Drs. Abrams and Yue. Dr. Abrams tends to perform one more case of the same type than does Dr. Yue within the same 10 hours of allocated operating room time because Dr. Abrams operates much more quickly than Dr. Yue. The anesthesiologist caring for Dr. Abrams' room will produce more billing units than Dr. Yue's anesthesiologist. If the group is using cases or total units billed as a group benchmark for work done but then *mistakenly* applies this benchmark to individuals, then the individual anesthesiologist caring for Dr. Yue's room will appear to be less productive. In reality, for the group to be successful, both operating rooms needed to be staffed. For an individual benchmark of work, the group may decide to use something different from billed units (e.g., time worked or shifts scheduled).

Defining Individual Productivity

Just as for operating room and anesthesia group productivity, the individual productivity of anesthesiologists is the dividend of workload divided by labor units. The individual workload can be defined in several ways. On the other hand, labor units usually are defined by the clinical full-time equivalent (FTE; percentage of time a full-time anesthesiologist works clinically). In groups that provide care to multiple hospitals with multiple staffing models (e.g., personally performed, medically directing < 1:2 residents, medically directing > 1:2 certified registered nurse anesthetists [CRNAs]), the labor unit may need to be converted to a dollar cost. However, for most groups, this is not necessary.

TABLE 97–1.

Confounding Factors or Anesthesia-Independent Factors

	Surgery	Anesthesia Time (h)	Turnover (min)	No. Cases Done	Base/Case (Total Billed)	TU/Case (Total Billed)	(Total tASA Billed)
Operating room 1	Lap chole (fast)	1	20	7	7 (49)	4 (28)	77
Operating room 2	Lap chole (slow)	2	20	4	7 (28)	8 (32)	60
Operating room 3	CABG	2.5	30	3	20 (60)	10 (30)	(90)
Operating room 4	Lap chole (prior commitment)	2	20	2	7 (14)	8 (16)	(30)
L&D	Labor epidural	6	n/a	3	5 (15)	4 (12)	(27)

Hypothetical surgical suite and labor and delivery (L&D). The anesthesiology group staffs the anesthetizing sites from 7:30 AM to 4:30 PM. Confounding factors affect billed units can be seen by comparing billed units for different operative rooms: surgical times (operating room 1 and 2), type of surgery (operating room 1,3), underutilized operating room time (operating room 2 and 4), and obstetric anesthesia (L&D). For operating room 4, the surgeon must leave at noon, so no cases are available to be done after this time. For labor epidural, only "face-to-face" time is billed, i.e., 1 hour for 6 hour epidural.

Base, base units; CABG, coronary artery bypass graft; lap chole, laparoscopic cholecystectomy; tASA, total American Society of Anesthesiologists; TU, time units.

Therefore, the productivity will be measured as the workload done per anesthesiologist or FTE.[44]

Defining the workload for anesthesia care is not the same as work done by other physicians. The most common unit used for work performed by nonanesthesiologists is the work relative value unit (work RVU) from the resource-based relative value system (RBRVS).[45] Anesthesia care in the United States is billed primarily using American Society of Anesthesiologists (ASA) units made up of basic, time and modifier units.

The ASA units provide a more accurate description of work done than simply "cases performed." The use of ASA units allows the recognition of both base (case complexity) and time units. Thus, total hip arthroplasty usually produces more total anesthesia billing units because hip arthroplasty is more complex from an anesthesia perspective (i.e., more base units) and usually is a considerably longer operation (i.e., more time units). Therefore, the ASA units can differ tremendously among cases.

Confounding Factors to Measuring Individual Productivity

Unlike many specialties, the amount of work done by an individual anesthesiologist often is impacted by factors outside the individual's discretion, which we term "confounding" factors. To illustrate the confounding factors of surgical time, type of surgery, underutilized operating room time, and obstetric anesthesia care, a hypothetical facility will be used as an example (Table 97–1). At the facility, the anesthesiology group must staff the four operating rooms as well as the labor and delivery suite. For this example, all operating rooms are allocated for 9 hours (7:30 AM to 4:30 PM). The resultant billed ASA units will be examined. For the initial example, we will assume that all the operating rooms are staffed by individual anesthesiologists. Provided there are no hours of overutilized operating room time, labor costs are the same.[44]

Surgical times. In operating room 1, there is a "fast" surgeon performing laparoscopic cholecystectomies with an average anesthesia time of 1 hour. Turnover time for this operating room is 20 minutes. Therefore, the surgeon is able to perform seven cases, with the last case ending at 4:30 PM. The base units per case are seven units, and the time units per case are four units (15-minute time units). The total base units, total time units (TU), and total ASA units (tASA) billed for operating room 1 are 49, 28, and 77 units, respectively (Table 97–1). In operating room 2, there is a "slow" surgeon also performing laparoscopic cholecystectomies, but with an average anesthesia time of 2 hours. Because of longer surgical times, only four cases are done, with the last case ending at 4:30 PM. The total base units, TU, and tASA for operating room 2 are 28, 32, and 60, respectively (Table 97–1). Because both operating room 1 and operating room 2 are in operation the same amount of time, the differences in base units, TU, and tASA units billed are *due to the differences in the surgical times*.

Type of surgery. In operating room 3, cardiac surgery is performed with the operating room finishing by 4:30 PM. The base units for the anesthesia for coronary artery bypass graft surgery (CABG) are 20 units/case, greater than those for laparoscopic cholecystectomy. The total base units, TU, and tASA for operating room 3 are 60, 30, and 90 respectively (Table 97–1). Because operating rooms 1 and room 3 were staffed for approximately the same amount of time, the differences in billed units between operating rooms 1 and 2 versus operating room 3 are *due to the differences in type of surgery performed*.

Underutilized operating room time. In operating rooms 1, 2, and 3, there was no underutilized operating room time. In contrast, operating room 4 has 4.5 hours of underutilized operating room time after its laparoscopic cholecystectomies (Table 97–1). The many possible reasons for this underutilized operating room include the following: poor operating room allocation, few patients scheduled for surgery that day, scheduled cases have been cancelled, or the surgeon has prior commitment (personal time, clinic patients scheduled, or surgery at another hospital). The total base units, TU, and tASA for

TABLE 97–2.

Concurrency and Individual Productivity Measurements

MD	Operating Room Site	Surgery	TU per Operating Room	tASA per Operating Room	Billed Units per FTE	
					TASA/FTE	TU/FTE
	Operating Room 1	Lap chole (fast)	28	77		
A	Operating Room 2	Lap chole (slow)	32	60	167	76
	Operating Room 4	Lap chole (prior commitment)	16	30		
B	Operating Room 3	CABG	30	90		
C	L&D	Labor epidural	12	27	27	12

Hypothetical surgical suite and labor and delivery (L&D) described in Table 97.1. In this example, a medical-direction model is shown. MD-A medically directs three anesthesia providers (certified registered nurse anesthetists, anesthesia assistants, or residents), while MD-B and MD-C still provide personally performed care. Therefore, concurrency or staffing ratios are not the same. MD-A is credited with the billed units, time and total ASA, for three rooms and hence has higher values of tASA/FTE and TU/FTE than MD-B or MD-C.
Base, base units; CABG, coronary artery bypass graft; FTE, full-time equivalent; lap chole, laparoscopic cholecystectomy; MD, anesthesiologist.

operating room 4 are 14, 16, and 30, respectively (Table 97–1). Therefore, the decreased billed units for operating room 4 compared to operating room 2 (same anesthesia times and type of surgery) are *due to the underutilized operating room time*.

Obstetric anesthesia. Similar to the operating room staffing commitment, the anesthesiology group has committed to covering the labor and delivery suite with one anesthesiologist. The billings for 7:30 AM to 4:30 PM are shown in Table 97–1. During the work hours examined, three labor epidurals were placed and managed. Each of these epidurals lasted 6 hours, but only four time units (1 hour) were billed. (Note: In Texas, the Medicaid billing rules allow billing only for "face-to-face" time.) The base units, time units, and total ASA billing units for obstetric care on this day would be 15, 12, and 27, respectively (Table 97–1). Although the obstetric anesthesiologist worked the same hours as the anesthesiologists in operating rooms 1, 2, and 3, the billed units are significantly different from those in the operating rooms. In fact, only operating room 4 is similar in units billed, and that operating room was active for only half the time! Therefore, the potential billed units in obstetric anesthesia care were significantly less than potential billed units for operating room anesthesia care for an equivalent time interval *due to obstetric care billing methodology*.

Together, these scenarios illustrate that management and rewards decisions for individual anesthesiologists may need to be based on factors other than the units billed.

Staffing Ratios or Concurrency in Medical Direction

In the example of confounding factors, we assumed that the care was provided by one anesthesiologist per operating room reflecting a physician-only anesthesiology group. Other possible staffing models include an "academic medical direction" model (each anesthesiologist concurrently medically directing one or two anesthesia providers, be they residents in training, CRNAs, or anesthesia assistants), "private-practice medical direction" model (each anesthesiologist medically directing 2–4 anesthesia providers who are not residents in training), or "medical supervision model" (medically supervising >4 nonresident anesthesia providers). In any of these models, the measurement of work done per anesthesiologist differs as well.

To illustrate this effect, the hypothetical case described in Table 97–1 is revised. In this new illustration (Table 97–2), we assume that the three operating rooms with laparoscopic cholecystectomies (operating rooms 1, 2, 4) are covered by one anesthesiologist (MD-A) working with three providers and that operating room 3 (CABG) and labor/delivery are still covered by individual anesthesiologists (MD-B, MD-C). MD-A bills for care done in three operating rooms and therefore receives more units than MD-B and MD-C. Thus, when concurrency differs among the anesthesiologists, those with greater concurrency will bill more units per anesthesiologist.[46,47]

However, both the labor costs and revenue may vary if the concurrency or types of providers differ. In Table 97–2, the staffing costs will be greater for operating rooms 1, 2, and 4 than for operating room 3 or the obstetric suite. Labor costs depend on the type of provider and the compensation levels of the local job market. Revenue differs for some payers (especially Medicare) with changes in concurrency and provider type. These factors are discussed in greater detail in Chapter 98.

Measuring Individual Productivity

The challenge for any group, academic or private practice, is that when instituting a system to pay for individual productivity, the group must understand what each measurement values and devalues. Furthermore, any new system should be considered a behavior modification system because that is essentially what it is—compensating each individual for specific work done. Therefore, each group must decide what behavior they need to change and choose measurements that will value the behavior the group wants done.[48]

Briefly, for each category of possible measurement (charges or ASA units, time units, or shift worked), there are distinct advantages and disadvantages. For either type of units (total ASA units or time units), differences in billed charges are influenced by factors outside the individual anesthesiologist's

discretion, mainly surgical times, type of surgery, underutilized schedule, and concurrency. Total ASA units billed or total charges both value billed charges, specialty care (type of surgery), and short operating room time cases while they devalue availability to work (but no cases performed due to underutilized time) or low-billed charges sites (e.g., remote sites, obstetrics, or in-house call). Time billed recognizes only "billable time," not the time actually worked. Therefore, time billed values longer operating room time cases and time with the patient but devalues unbilled time (e.g., turnover time, call, availability to work but no cases performed due to underutilized time) and specialty care (type of surgery). In either system using total ASA units or time units, activities that are not billed using ASA units are not easily included. These activities include critical care medicine, pain management services, and preoperative clinic. Shifts worked (paid either by the shift or by hourly wages for late calls) is independent of the factors noted. Shifts worked values availability but devalues the actual amount of work done per shift.

Each anesthesia group must define its issues and develop a plan that works for its members specifically.

For example, if the issue is that the late cases are not evenly distributed, a system of paying for late cases (can be any of the above measurements) can be developed. The group could choose from among several measurement systems. Work done during the day could be paid using a shift-based measurement while the late cases are paid by hourly wage. Alternatively, compensation could be based on time billed during the late cases.

For example, the behavior that another group may aim to change is the willingness to accept add-on cases during the day. In this situation, the group may decide to use a system of billed units (total ASA units or time units) that will devalue unbilled time and reward caring for patients.

For example, a group that now covers several hospitals has traditionally had an "equal-share" system. The perception is that work in Hospital B is not as demanding as in Hospital A. On the other hand, billed charges in Hospital B are equal to those in Hospital A, but Hospital B works less hours than Hospital A (the influence of surgical duration on billed units). The group may decide to resolve this by valuing a shift at Hospital A more than a shift at Hospital B or using a time-billed system. If the group chooses billed charges or total ASA units, then the group would not have succeeded in valuing the work at Hospital A more.

Because of the many confounding factors, including surgical times, types of surgery, operating room allocation, and case scheduling and concurrency differences, many anesthesia groups find it difficult to measure the work done by individuals. Most private-practice and academic groups measure work done by individuals by the shifts worked. That is, most groups do not use charges, total ASA units, or billed time as a measure of individual work.[49]

Most private-practice groups distribute income (and compensation) of partners based on the work done by each partner. Thus, the income distribution plan is really an individual productivity measurement system. In a survey of private-practice groups in 2003, the majority of groups distribute income equally among partners.[49] This type of system inherently means that each partner works the same number of shifts (regular hours, late shifts, call, and time off) and that the work done per shift is not under the individual anesthesiologist's discretion. Some other groups use a "point" system, where shifts are given a number value and partners acquire points by working shifts. Again, under this system, the work done per shift is not under the individual anesthesiologist's discretion. A few groups use billed charges, total ASA units, or billed time to determine revenue distribution. Larger groups with more than one hospital tend to have one of these latter systems.

For academic groups, incentive pay for clinical work can be viewed as a system to compensate based on individual clinical productivity. Most academic groups do not vary incentive pay by work done per shift.[49] When incentive payments are available, most are based on working shifts, be they during the day or on call. Again, larger groups with multiple sites tend to use billed charges, total ASA units, or billed time.[50,51]

CONCLUSION

Operating room allocation is a two-stage process.[8] During the initial tactical stage of allocating operating room time, considering operating room hours to be fixed is reasonable. For operational decision making on a shorter-term basis, such a conceptual model produces results markedly inconsistent with how surgical suites are and should be run. Consider the workload to be fixed on a short-term basis. Provide staff flexibly to match the existing workload, not vice versa. Do so by making operational decisions based on maximizing operating room efficiency, as this is an important step to maximizing anesthesia group productivity.

Individual productivity is influenced by surgical times, types of procedures, underutilized operating room time, and concurrency. Thus, most groups base compensation on the shifts that each individual is scheduled to work.

CHAPTER 98

Practice Management

Philip J. Mesisca, MBA, CMPE, and Susan Chapman Moss, MPH

Practice management details are often delegated to nonphysician administrative professionals and their support staff, but it is important that all physicians have a global comprehension of basic practice management topics. Practice management, in its simplest form, focuses on the nonclinical pieces of a medical practice. There are entire textbooks just on practice management, so this chapter provides a brief overview of practice management for an anesthesiology-trained physician. It broadly covers some global practice management areas that relate to all physicians such as the structure of groups, human resource management, and strategic planning. It also delves into setting up a pain practice, financial management topics, and managed care contracting. When appropriate it covers details and issues specific to anesthesia, such as billing and compliance, staffing models, and data analysis and reporting.

To many physicians, worrying about the business side of their practice is something that they may have no interest in or even something they are embarrassed about as that is not why they decided to become a doctor. If, however, more money goes out than comes in, no business or physician will be able to continue to do what matters most to them. So, however confusing or distasteful the practice management side of the business may be, it is a necessary one.

We hope this brief chapter complements the other chapters in this book and helps you become a physician who can face the challenges of the future of medicine by understanding basic business practice processes and relating them to the practice of anesthesiology.

GOVERNANCE AND ORGANIZATIONAL DYNAMICS OF A PRACTICE

What is the practice's mission? Are decisions made to influence the strategic direction of the practice? How does the practice facilitate decision making? How are conflicts resolved? What are the plans for the future? How is the practice going to get there? The answers to these questions help to determine a practice's governance and group dynamics.

Practice Models

Most anesthesiologists join either an academic or a private-practice organization. Academic medical groups have always had complex, multiple missions: teaching, advanced clinical practice, and research. Academic practices in general pay less; however, that does not necessarily mean that their clinical workload is less. Generally most academic anesthesiologists do have some percent of their time that is nonclinical, often devoted to research and/or academics. These nonclinical workdays, while often generating grant and contract salary support, rarely generate the revenues that the clinical work does, but they do bring their own sense of fulfillment, rewards, and prestige.

In a private practice, the core mission is the clinical responsibilities, and the pace often is faster. In a private-practice model, anesthesiologists are more likely to be assigned cases by themselves or to supervise multiple rooms with certified registered nurse anesthetists (CRNAs) compared to fewer rooms with residents that academic anesthesiologists would generally cover. Of course, exceptions to the norm do occur regularly.

Structure and Contractual Issues

Practice structure, at the highest level, considers and clarifies lines of authority (chain of command), decision-making process, communication flows and processes, as well as levels of authority that relate to how centralized or decentralized the practice prefers to function.

An example of a private-practice model might consist of a general partnership as the overriding entity. There may then be an executive committee

KEY POINTS

1. Practice structure considers and clarifies lines of authority, decision making, and communication flows and processes, as well as levels of authority that relate to how centralized or decentralized the practice prefers to function.
2. When considering staffing models for anesthesia care delivery, several issues must be contemplated, including the complexity of the case, experience of the provider, physical status of the patient, hospital regulations, surgeon expectations, and residency teaching rules.
3. Charges and payments for professional anesthesia services generally include base relative value units (accounting for anesthetic complexity), plus time units, plus additional unit modifiers multiplied by a dollar conversion factor.
4. Before you begin negotiations with third-party payers, be certain you have an accurate understanding of the value of your group to the hospital or institution that you contract with.
5. It is important that every service rendered is captured and whatever monies that contractually should be collected for those services are collected.
6. Monthly information that should be tracked for trend purposes includes total cases and units, cases and units per location, payer mix, charge lag, charges, contractual adjustments, cash collections, accounts receivable, net collection rate, days in accounts receivable, aged accounts receivable, total credit balances, and collection agency net collections.
7. From a billing compliance perspective, if it is not documented, then it did not happen. Compliance with various rules and regulations is both important and pertinent. Furthermore, the consequences of not knowing, or not following, these regulations can be substantial.

that might be considered the second level of decision making. This group may be empowered to make operational decisions and financial commitments to a maximum threshold established by the general partnership. Depending upon the size of the practice, there may be smaller groups or specific individuals who also have authority and operational decision making for smaller units or divisions.

There are other practice models, such as employment by a health system, the U.S. Military, Public Health Service, or Department of Veterans Affairs, where the anesthesiologist is fully employed to perform clinical duties and generally does not need to worry about the economics of billing or case volumes. Other anesthesiologists may work as locum tenens, essentially temporary contracted physicians who are hired by groups and hospitals to cover staffing shortfalls. For any of these arrangements, it is important that the structure of the practice is clear and understood in a written format. Much like documentation for billing compliance, if it is not written down, one could assume that it did not, or will not, happen. Buy-in formulas for new partners should be understood and clear. Understanding who can leave, or be asked to leave, why, and with how much notice is important to comprehend as well as the financial repercussions of such actions. Noncompete clauses, if included, should be clearly understood and explained. The process of assigning and requesting time off, call coverage, and overall assignments should be clear and in writing as well.

Compensation Arrangements

The total amounts of monies available for physician compensation are relatively easy to calculate. Revenue less all other expenses leaves an amount of money. That money can be paid fully to physicians as base salary and bonus, as base salary and incentive, or as base salary with some monies saved for the future. The size of the pie, so to speak, is influenced by numerous factors discussed throughout this chapter. How the pie is divided is the basis for understanding the compensation model for a practice.

The best compensation arrangement for a practice is the one that meets the needs of the group and allows the group to fulfill its mission while retaining and recruiting physicians, as needed.

In an academic practice, the compensation arrangement will often consider the teaching, administration, and research responsibilities, funding, and performance in addition to clinical responsibilities. In a private practice, the focus is on the clinical workload.

There are two main compensation formulas. At one end of the spectrum the group splits the bottom line. This equal share method takes into account that the anesthesiologist is assigned to cover a specified location (or locations) and does not control volume or the payer mix at those sites. Some consider this model fairer because it does not penalize an anesthesiologist who might work with a slower surgeon or at an inefficient location. At the other end of the compensation spectrum is more of an individual model of paying a physician for the amount of work he or she does. This allows the anesthesiologist to be paid based on the amount of work they do. Proponents of this model argue that this rewards the anesthesiologist who improves turnover times, takes extra calls, does a late-day elective case, or uses less vacation time.

Many anesthesia groups follow a hybrid of these two models to balance the needs and priorities of the members.

HOSPITAL RELATIONSHIPS

Negotiating Coverage and Stipends

The relationship between hospital administrators and anesthesia groups has evolved over the past decade as a result of increasing demand for anesthesia services, a national shortage of anesthesia providers, and growing financial pressures on both parties (e.g., third-party reimbursement trends, erosion of hospital operating margins, rising physician compensation levels). In many regions of the country, the balance of power has begun to shift toward anesthesia groups as a result of supply-and-demand issues, with hospital administrators struggling to stay ahead of or at least in step with these market forces.

Successful negotiations hinge on the clear articulation of needs by both parties and willingness to accept a reasonable, mutually beneficial offer. The hospital should set expectations related to daytime and call requirements, number of anesthetizing locations and services, growth and new programs, and administrative activities. In order to justify financial support, the anesthesia group may need to educate hospital administrators about the local and national physician compensation and recruitment market, efficiency concerns that impact anesthesia productivity (operating room utilization rates, turnover times), and the financial health of the practice (revenue cycle, practice overhead). Stipends typically include administrative activities (directorships, participation in hospital committees), call coverage (obstetrics, trauma), income guarantees, and recruitment costs for new anesthetizing locations. These costs may be justified based on full-time equivalent (FTE) calculations and market-rate compensation data. Academic groups may receive support for educational expenses, such as residency program director and coordinator and salary and benefits for residents and fellows.

Credentialing

In order to meet regulatory requirements and maintain clinical standards, physicians must obtain hospital appointments through a credentialing process involving verification of state medical licensure, state and federal Drug Enforcement Administration (DEA) numbers, employment and training history, and other key documentation.

PROVIDERS

Physician Anesthesiologist

An anesthesiologist has completed a 4-year college program, 4 years of medical school, and at least 4 more years of residency (internship year plus 3 years anesthesiology). The role of an anesthesiologist includes coverage in the operating room, the postanesthesia care unit, and the delivery room. Additionally, many anesthesiologists work as intensivists in critical care units or as pain management specialists, dealing with acute and chronic pain patients.[1]

Certified Registered Nurse Anesthetist

Education and experience required to become a CRNA include the following:

- Bachelor of Science in Nursing (BSN) or other appropriate baccalaureate degree.

- Current license as a registered nurse.
- At least 1 year of experience as a registered nurse in an acute care setting.
- Graduation with a master's degree from an accredited nurse anesthesia program. The programs range from 24–36 months, depending upon institutional requirements. All programs include clinical training in university-based or large community hospitals.
- Pass a national certification examination following graduation.[2]

Resident/Fellow

After completing a 4-year bachelor's degree, students then take 4 years of graduate education leading to a degree in medicine (MD) or osteopathy (DO). They spend 4 more years in an anesthesiology residency (there are approximately 160 anesthesiology medical residency programs in the United States). Some residents take 1 more year of study, called a *fellowship,* in a specific area of anesthesiology, such as critical care medicine, pain medicine, research, or education.[3]

Other Types of Providers

Anesthesiologist Assistant (AA): AAs are highly skilled allied health professionals who work under the direction of licensed anesthesiologists to develop and implement anesthesia care plans. All AAs possess a premedical background and a baccalaureate degree, and they complete a comprehensive didactic and clinical program at the graduate school level. AAs may be either licensed as AAs or practice under the license of an anesthesiologist under the principle of delegation. The exact details regarding delegation and licensing of AAs are different from state to state.[4]

Physician Assistant (PA): PAs are healthcare professionals licensed to practice medicine with physician supervision. PAs can conduct physical examinations, diagnose and treat illnesses, order and interpret tests, counsel on preventive healthcare, assist in surgery, and in virtually all states can write prescriptions. Graduation from an accredited PA program and passage of the national certifying examination are required for state licensure. The average PA program curriculum runs approximately 26 months. What a PA does varies with training, experience, and state law.[5]

Nurse Practitioner (NP): An NP is a registered nurse with advanced academic and clinical experience. NPs are educated through programs that grant either a certificate or a master's degree. The scope of an NP's practice varies depending upon each state's regulations.[6]

Anesthesia Technician/Technologist (AT): ATs support the work of anesthesia clinical providers and often assist with monitoring lines, patient transport, patient and room preparation, and stocking of equipment at the anesthetizing site.

HUMAN RESOURCE MANAGEMENT

Management of human resources is essential to practice management. The mix of physicians, nurses, trainees, billing personnel, and other support staff makes the management somewhat more complicated than in a typical nonmedical organization. As in any organization, each position is essential for the overall efficacy of the practice. If the physicians are working hard but the ATs are not properly completing their responsibilities, the overall efficiency of the operating room is somewhat compromised. Likewise, if physician productivity is outstanding but the billing personnel are not well trained on their functions, then there will be a disconnect in the overall billing process that will result in lost collections that impact the financial health of the practice and ultimately the ability of that practice to retain and recruit. To varying degrees, each group has an impact on the other. The best practices find ways to understand this impact and to ensure that all facets of human resources are considered.

Human resource management includes ensuring that your group abides by all employment regulations, ensures proper training of staff, conducts annual employee evaluations, and maintains employee job descriptions and a compensation and benefits program consistent with the mission of the group. It also includes planning for staffing needs, clinical and nonclinical, and having programs or strategic plans in place to ensure that the group's recruitment and retention efforts are successful.

Clinical Staff

The clinical staff consists of the anesthesiologists, residents, fellows, CRNAs, NPs, PAs, AAs, student registered nurse anesthetists (SRNAs), and medical assistants. Many of these positions have been described previously. Some of them, such as medical assistants, are primarily used in a pain management practice. Others, such as NPs and PAs, are sometimes employed as part of the critical care team and sometimes as part of the acute or chronic pain management team.

Nonclinical Support Staff

The majority of your nonclinical support staff will be related to your billing efforts, unless you decide to contract out your billing and collections. Given the nature and complexity of anesthesia professional billing, it is extremely important that you employ individuals who have experience with anesthesia billing as it is so different than billing for every other physician specialty. It is a good idea, especially for compliance purposes, to employ certified procedural coders (CPCs) to handle the professional fee billing coding. Having a CPC in your practice is an excellent way to ensure that you are coding properly and the small cost of employing a CPC is a worthwhile investment when you consider the cost of a potential audit finding in terms of paybacks and penalties.

Many practices employ an executive director who has various titles, such as administrator, chief operating officer, chief administrative officer, or director of finance and administration, to name a few. Depending upon the size and complexity of the group, this position usually is either directly responsible for, or oversees the personnel needed to perform these administrative functions. This includes accounting personnel to handle financial statements, analysis, investments, planning, purchasing, accounts payable, and payroll. Personnel also are needed to assist with clinical credentialing, recruitment, employee benefits, and other assorted duties. Sometimes the group contracts out for some or all of these services instead of hiring employees to fulfill these roles.

Recruitment and Retention

The role of human resource management can be considered from three levels. The first level includes the basic and legal parts of employing people in a practice. Finding, interviewing, and hiring are all part of the basic first steps.

The second level includes ensuring that your practice follows the laws and regulations that govern and protect people. This includes maintaining policies and procedures that properly interpret and integrate numerous, often difficult to understand, federal, state, and local laws in addition to healthcare regulatory agencies such as the Joint Commission on Accreditation of Health Care Organizations (JCAHO).

The third level is very important to the recruitment and retention success of a practice. Developing ways to train, measure, motivate, and reward all staff members at all levels is both difficult and important. Formal and informal performance reviews, employee surveys, ensuring fair market pay, respectful but warranted discipline and mentoring, and assessing and responding to the myriad of work and personal obligations that impact the staff cannot be overlooked for a practice to be successful.

STAFFING MODELS

When considering staffing models for anesthesia care delivery, several issues must be contemplated, such as the complexity of the case, experience of the provider, physical status of the patient, hospital regulations, surgeon expectations, and residency teaching rules.

Personally Performed

From a billing perspective, for a Medicare case, personally performed means the following:

- The physician personally performed the entire anesthesia service alone (full payment to physician); or,
- The physician is involved with one anesthesia case with a resident, and the physician is the teaching physician as defined by Medicare rules and regulations (full payment to physician); or,
- The physician is continuously involved in a single case involving a student nurse anesthetist (full payment to physician); or,
- The physician is continuously involved in one anesthesia case involving a CRNA (or AA); both the CRNA (or AA) and the physician may be paid pursuant to the medical direction payment policy (50% payment to physician and 50% payment to CRNA or CRNA's employer such as the hospital or physician group); or,
- The physician and the CRNA (or AA) are involved in one anesthesia case, and the services of each are found to be medically necessary. Upon review of documentation, if it is determined that both were necessary for the case, then full payment may be made for each of the two providers (full payment to physician and full payment to CRNA or CRNA's employer, i.e., the hospital or physician group).[7]

Care Team

If not performing a case independently, an anesthesiologist generally oversees CRNAs, SRNAs, AAs, interns, residents, or combinations of these individuals. In some care team models, Medicare would consider that medical direction has been met, and 50% payment made, if the physician medically directs qualified individuals in two, three, or four concurrent cases and the physician performs each of the following activities:

- Performs a preanesthetic examination and evaluation,
- Prescribes the anesthesia plan,
- Personally participates in the most demanding procedures in the anesthesia plan, including, if applicable, induction and emergence,
- Ensures that any procedure in the anesthesia plan that he or she does not perform are performed by a qualified anesthetist,
- Documents his or her presence during some portion of the anesthesia monitoring and monitors the course of anesthesia administration at frequent intervals,
- Remains physically present and available for immediate diagnosis and treatment of emergencies, and
- Provides indicated postanesthesia care.

These "seven steps," as they are known, must be met to bill Medicare for a medically directed service. Also, the total number of rooms that could be covered at any given time is limited to four. Exceptions to these medical direction rules allow a physician to perform other, specific services and not violate the medical direction rules described. The overall medical direction rules apply to cases involving student nurse anesthetists if the physician directs two concurrent cases, each of which involves a student nurse anesthetist or the physician directs one case involving a student nurse anesthetist and another involving a CRNA, AA, or resident.

If anesthesiologists are in a group practice, one physician member may provide the preanesthesia examination and evaluation while another fulfills the other criteria. Similarly, one physician member of the group may provide postanesthesia care while another member of the group furnishes the other component parts of the anesthesia service.

A physician who directs the administration of anesthesia to not more than four surgical patients cannot ordinarily be involved in furnishing additional services to other patients. However, addressing an emergency of short duration in the immediate area, administering an epidural or caudal anesthetic to ease labor pain, or periodic rather than continuous monitoring of an obstetrical patient does not substantially diminish the scope of control exercised by the physician in directing the administration of anesthesia to surgical patients. It does not constitute a separate service for the purpose of determining whether the medical direction criteria are met. Furthermore, while directing concurrent anesthesia procedures, a physician may receive patients entering the operating room suite for the next surgery, check or discharge patients in the recovery room, or handle scheduling matters without affecting fee schedule payment.[7]

IN- AND OUT-OF-OPERATING-ROOM COVERAGE

Healthcare advances have led to the significant growth of interventional/procedural medicine, and anesthesia providers are being asked to respond to this trend. Anesthesiologists have expanded their workplace beyond the confines of the operating rooms and are traversing the hospital campus to anesthetize patients undergoing a diverse mix of procedures in locations such as electrophysiology or cardiac catheterization laboratories, radiology suites, in vitro fertilization sites, and endoscopy rooms. In addition to off-

site procedural locations, anesthesia providers often cover diverse services, such as preoperative assessment clinics, recovery areas, obstetric services, inpatient pain consultative services, outpatient pain clinics, and critical care units. Each location requires a unique anesthesia staffing pattern influenced by volume, clinical complexity, geographic proximity to other anesthesia locations and providers (an important factor for emergency backup and coverage for personal breaks), efficiency demands (turnover times in the operating rooms, patient visits in preoperative or pain clinics), and service/availability demands (dedicated ICU or obstetrics staff). Meeting these multiple and often competing demands for clinical services can be challenging given current recruitment and retention factors. Coverage of multiple hospitals and Ambulatory Surgical Centers (ASCs) requires either dedicated staff for each location or staff that are highly flexible about assignments.

Financial performance associated with each location will be closely linked to efficiency, case volume, and payer mix and should be closely monitored by the group.

Staffing patterns vary widely by location, from 1:1 coverage of complex surgical cases to 1:4 coverage of routine surgical cases. Obstetrics, ICU, recovery, preoperative evaluation clinics, and pain staffing are based on volume and/or availability. Ambulatory surgical centers designed for high throughput require highly motivated staff and possibly additional staff to meet turnover demands.

PAIN MANAGEMENT PRACTICE

Office Setup

Setting up a pain management practice is complex and has little to do with setting up or running an anesthesia-based practice. Running an anesthesia practice is different than running other medical specialties, especially because an anesthesia practice does not have an outpatient office, it bills by time (unlike any other physician specialty), it does not have relative value units to measure clinical productivity (as do almost all other physician specialties), and it worries little about registering patients, implementing a telephone triage system, or patient satisfaction as it relates to parking or helpfulness of the front desk staff. When setting up a pain management practice, these items do matter.

Like many other physician specialties, a significant amount of planning and cost are needed to establish a pain management practice. Space rental or lease costs, equipment, furnishings, and supplies all contribute to the up-front costs that need to be incurred before the first chronic pain patient steps through the door.

Financial Arrangements

Unlike an anesthesia practice that covers poorly utilized operating rooms, the argument that "we don't control patient volume and should not be penalized for operating room downtime" does not apply to a pain management practice. Some groups consider their pain practice to be an integral part of the group and do not want to separate them financially for fear that it may fracture the team concept that most successful anesthesia practices use. Keeping them in the normal compensation structure keeps the group intact and, much like an obstetric anesthesiologist who may not have sufficient reimbursement to cover their expenses, a pain specialist should be treated the same, for good or for bad.

Others view pain differently in that anesthesiologists in a pain practice do control their volume and should be rewarded or penalized accordingly for their efforts. A pain specialist who accommodates that extra patient, has evening or Saturday hours, gives free talks to the local community, visits potential referring physicians, responds back to referring physicians, hires excellent support staff, and focuses on customer service should be encouraged and rewarded for his or her efforts. Likewise, a pain specialist who does not complete his or her referral letters or shows up late in the morning or refuses to see the add-on patient in the late afternoon should not be rewarded by partaking in the financial gains that the others have worked hard for.

FINANCIAL MANAGEMENT

Viewed from a national level, U.S. academic anesthesia departments and private practice anesthesia groups both face a myriad of financial challenges due to both revenue and expense concerns. Revenue constraints include contract rates and reimbursement policies dictated by Medicare and other payers, billing office performance, and hospital support for medical administration, CRNA expenses, and trauma or other call coverage. Expenses are heavily influenced by recruitment and retention needs because professional staff salaries and fringe benefits compose the majority of anesthesia practice expenses. Equipment and support staff expenses compose a relatively small portion of anesthesia budgets in comparison to other hospital-based specialties such as radiology.

Successful financial management requires a thorough understanding of financial statements, effective budgeting, strong financial oversight, and paying great attention to detail. In today's healthcare environment, thin operating margins require innovative approaches to important business problems. Often the best business solutions may be technology intensive (e.g., electronic charge capture and billing systems, electronic staff scheduling/deployment systems).

Understanding Financial Statements

Although a detailed understanding of financial statements may be daunting to clinicians, a basic understanding of them is necessary for effective practice management (Danzi and Boom have provided a brief summary for clinicians). All business managers use three basic financial statements to document and assess their practice's financial performance: the income statement (or profit-and-loss statement), the balance sheet, and the cash flow statement. The income statement is used to indicate profitability by detailing revenues and expenses. The balance sheet is used to describe the financial position at any given point in time by detailing practice assets, liabilities, and equity. The cash flow statement provides an explanation of uses of cash (i.e., cash from operations, investing, and financing activities). The income statement is most commonly used to monitor monthly financial health, whereas balance sheets and cash flow statements often are reviewed on a quarterly or annual basis. Most physician practices use cash basis[a] rather than accrual ac-

[a]Generally accepted accounting principles (GAAP).

counting principles because financial performance is heavily influenced by the revenue cycle while expenses typically remain stable.

Budgeting

A budget is a quantitative financial plan for a defined period of time that serves to articulate financial and operational goals, objectives, and strategic plans. A budget allows you to quantify and prioritize these goals, objectives, and plans and provides you with a way to measure financial and operational performance. Approaches to budgets include the historical (uses historical data updated with new facts, trends, and assumptions), zero-based/bottom-up (assumes all costs must be justified), and flexible budgeting methodologies (updated throughout the budget period according to major cost drivers such as volume). Capital budgets focus on projects or tangible assets (e.g., property, plant, or equipment items) that exceed a certain expense threshold. Important operating budget considerations include professional staff salaries and fringe benefits, payer reimbursement assumptions, malpractice costs, operational changes (such as additional anesthetizing locations), and investment income returns. Revenue budget assumptions should address volume growth of anesthetic procedures, contract rates for payment, payer mix, and collection rates, although expense budget assumptions should consider the impact of staffing needs (resignations and hiring), compensation and incentive plans, and inflationary costs. Operating room utilization and efficiency influence both staffing needs and revenue generation and, therefore, should be carefully reviewed as part of the budgetary process.

Revenues and Expenses

The three main sources of anesthesia practice revenues are patient services revenue, contract revenue, and nonoperating revenue (interest and investment income). For the purposes of this discussion, we exclude other income sources such as research grants, philanthropy, royalty income, and endowments.

Clinical volume and type of service, contract rates, payer mix, and billing performance are the main drivers of patient services revenue. Contract revenue may be derived from professional services agreements, hospital stipends, or other management service contracts. Major expense categories include physician and CRNA compensation and benefits, support staff expenses, malpractice fees, billing and overhead fees, depreciation, bad debt (mostly for uninsured or underinsured patients), and other operating expenses such as rent, utilities, and information technology. It is important to understand which expenses are fixed (costs that remain constant despite changes in case volume, e.g., anesthesia machines) rather than variable (costs that fluctuate with volume, e.g., anesthetic drugs), particularly if volume predictions are uncertain. For example, when hiring additional staff to cover a new anesthetizing location, the practice will incur a fixed and incremental compensation expense, but revenue will depend on the volume and efficiency of the newly added site unless otherwise negotiated in advance with the hospital.

Financial Analysis

Practice profitability requires an ongoing analysis of performance against expectations, goals, and targets. Essential financial analyses should include periodic budget analyses of the variance between actual and budgeted performance, service-specific margin analyses (percentage by which revenues exceed expenses; may be calculated on a direct, total, or contribution-basis), and benchmarking analyses (comparison to published compensation,[b] productivity, billing, and expenses[c] data).

Capital

Large capital (tangible asset) items, such as anesthesia machines, monitoring equipment, and electronic medical records, typically are purchased through the hospital and may require advanced planning via the capital budgeting process. Smaller items, such as computers for administrative use, may be purchased through practice funds.

BILLING AND PAYMENT FOR ANESTHESIA SERVICES

Professional Versus Technical Billing

The provision of anesthesia services is paid for by two separate reimbursement mechanisms: (1) a technical or facility fee and (2) a professional fee. Third-party payers compensate the hospital for the technical or nonprofessional costs of anesthesia services via the facility fee (e.g., anesthesia equipment, supplies, and technicians), although professional and practice expenses are reimbursed through professional fees. Facility fees or charges are derived from the duration and type of anesthetic services rendered and reimbursed via payer-specific contract rates (e.g., Diagnosis-Related Group (DRG) or case rate, percent of charges, fee for service).

Professional Billing for Anesthesia, Obstetric, Critical Care, and Pain Management Services

Medicare payments for most physician services are made on the basis of a standardized fee schedule (resource-based relative value scale [RBRVS]) that was implemented in 1992, which replaced the traditional customary and prevailing charge system. However, Medicare's method of calculating anesthesia professional reimbursement for anesthesia services differs from that used for other physician services in that the relative value units (RVUs) are based on a schedule developed and maintained by the American Society of Anesthesiologists (ASA). The anesthesia RVUs for any service are described as "base units" and correlate to work effort (i.e., estimated anesthetic intensity or complexity). In addition to base units, payment for anesthesia services reflect time units (often 15 minutes per unit), additional modifying units (e.g., physical status), on occasion, and an anesthesia-specific conversion factor (or per unit payment rate). Professional fee schedules for most other payers are reflective of Medicare's approach under the RBRVS system. Monitoring catheters and nerve blocks administered during time-based anesthesia services are billed separately.[d]

Concurrency modifiers are used to indicate the type of oversight rendered by the attending anesthesiologist in conjunction with a resident and/or CRNA. Personally performed (modifier AA) indicates that an attending anesthesiologist was present for the entire case, whereas medical direction (QK or QY) denotes concomitant in-

[b]The Association of American Medical Colleges (AAMC), Society of Academic Anesthesiology Chairs (SAAC)/Association of Anesthesiology Program Directors (AAPD), Medical Group Management Association (MGMA) academic and private practice compensation surveys.

[c]MGMA best performing practices.

[d]Assumes that these services were not the primary mode of anesthesia and were not included in the calculation of anesthesia time units unless clinically appropriate

volvement in one, two, three, or four anesthetics in conjunction with a resident or CRNA. The CRNA portion of a medically directed case is billed with a QX modifier. Medical supervision (AD) indicates physician involvement in more than four concurrent cases.

Billing for nonsurgical obstetric anesthesia (i.e., labor epidurals) typically follows one of four methods recommended by the ASA: (1) base units plus patient contact time plus one time unit per hour, (2) base units plus time units subject to a reasonable cap, (3) a flat fee, and (4) an incremental fee schedule.[e]

Critical care, acute pain, and chronic pain management services are billed as evaluation and management services and procedures and are reimbursed under the RBRVS system. Critical care services are billed based upon physician time expended (e.g., < 30 minutes, 30–74 minutes). Acute and chronic pain services are billed via a variety of Current Procedural Terminology (CPT) codes,[f] including inpatient consultations, subsequent hospital day care, new patient visits, followup visits, and interventional procedures.

Professional billing for consultation services rendered in a preoperative clinic requires detailed documentation of (1) a written request for consultation (documentation of medical necessity), (2) a thorough description of the patient's history and physical examination with evidence of medical decision making, and (3) a written response of findings and recommendations to the consultation requesting physician. Local payer reimbursement rules will influence the feasibility and profitability of billing for such services.

Documentation and Coding

Adequate medical record documentation is required to substantiate billing for all anesthesia services with specific criteria established by local payers based on current Medicare rules or the payer's specific policies. The coding of anesthesia services (assignment of appropriate nationally standardized codes indicating the type of procedure or service rendered) typically is performed by professional coders employed directly by the practice or by the billing office. Documentation and coding are essential for compliance purposes and for negotiating the claims denial and appeals process.

Charges versus Payments

A professional charge for a time-based anesthesia service is generated based on the total number of ASA units (base, time, and additional modifying units) and procedures where the unit and procedure charges are set by the physician practice. The payment or reimbursement usually is based on negotiated contract rates and varies by payer. The key differences between charges and payments are the result of contractual adjustments and write-offs. For example, for a practice with a $100 per ASA unit charge, a 7-hour triple coronary artery bypass would generate a charge of $4800 (for 20 time units plus 28 base units). Medicare reimbursement[g] for this case if personally performed, however, would total $895.68 based on the $18.66 conversion factor (Boston, 2005)[h] with a $3904.32 contractual adjustment.

Reimbursement for invasive monitors (arterial or pulmonary arterial catheters, etc.), regional anesthetic blocks, evaluation and management (E&M) services, and other procedures are based on a flat fee schedule negotiated with each payer rather than ASA units. Whereas charges are influenced by volume and service mix, payments are affected by payer mix, contract rates, and payer policies, and the speed of payment depends upon submission of "clean claims."

Billing Services

Anesthesia practices may choose to bill and collect for their own professional fees or outsource these activities to a billing company. Given the complexities of anesthesia billing, it is essential to employ a service with expertise in this area. Such expertise often is difficult to recruit and retain in-house for small- to mid-size anesthesia groups and may be outsourced to a billing company. The accuracy of claims is the responsibility of the physician group independent of billing service arrangements, so it is imperative that billing functions be monitored closely and include a robust compliance plan (see Billing Compliance below). Billing performance should be closely monitored by the practice/department to continually ensure accuracy, effectiveness, and efficiency (Table 98–1).

MANAGED CARE CONTRACTING

Negotiation Strategies

Most physicians believe that they deserve to be paid more money but the managed care company does not. This is obviously not true for every situation, but it is a good starting point for discussing managed care contracting or any third-party negotiation.

Before you begin negotiations, be sure you have an accurate understanding of the value of your group to the hospital or institutions that you contract with. That is important because if you cannot come to an agreement with the payer, your only option will be to not contract with them. If the hospital has a contract with that payer and many of the surgeons have a contract with that payer, you will be

TABLE 98–1.

Analysis of Billing Performance

1. Monthly review of key statistics (budgeted vs. actual, current vs. prior year)
   a. Volume, charges, and payments
   b. Payor mix
   c. Days in accounts receivable, aged accounts receivable
   d. Charge or front-end lag (number of days from date of anesthetic service to date of claim submission)
   e. Case reconciliation (verification that all cases performed resulted in sending out a claim to the correct payor)
2. Collection rate variance and volume/service mix variance by payor
3. Per unit reimbursement analysis (actual vs. contract rate)
4. Write-offs by type (free care, account settlement, bad debt, payor policy, filing limits, provider enrollment, missing referral/authorization, etc.)
5. Matched collection rates at 2-, 6-, and 9-month intervals (gross collection rate, net collection rate, adjudication rate)

[e]Reimbursement for surgical obstetric anesthesia is based on time and base units as described above.
[f]CPT Code Book.
[g]Sample calculation only not reflective of Medicare payment reduction for concurrency.
[h]2005 Medicare anesthesia conversion factor for metropolitan Boston.

under tremendous pressure to obtain a contract with that payer. If you do not, you must be in a position to present data that can explain why.

It is extremely important to educate the payer and the hospital about anesthesia salaries in the local market, what others pay, the national shortages, and other issues that are well known to you but may not be to the payer or the hospital. Make sure what you are asking for is reasonable, or your negotiation may break down early.

Understand each payer's fee schedule, not just their anesthesia per unit rate. Many practices are provided a fair anesthesia per unit rate; however, their fee schedule for procedures (e.g., pulmonary arterial catheter insertion) or for pain or critical care services may be very poor. Understand where your primary business volumes incur, and be sure you can prioritize what services are most important when negotiating your fee schedule.

Do not allow a payer to dictate policies and fee schedules; however, you also must be realistic regarding a fair-market payment scale in your local community. Like most negotiations, it is best if the final agreement is a win/win. An important but frequently overlooked contract issue is being sure that if the payer does not pay quickly or underpays, there should be clear language regarding the penalties and next steps to resolve the problem.

Medical Director Relationship

Try to deal directly with the key players at the carrier (e.g., medical director, director of physician reimbursement, etc.). Develop a relationship to educate the payers. This may not yield immediate financial windfalls, but it does help them to better understand your practice and foster possible improvements in the long term. However, do not forget that this negotiation is a business transaction, and whatever monies are paid to you or your practice are fewer monies that the carrier has to pay others.

DATA ANALYSIS AND REPORTING

There is a tendency for physicians and many administrators to want too much data that may not be pertinent to understanding their practice and practice operations. Focusing on the key issues leads to more effective analysis with fewer distractions.

Tracking What You Need to Know

Tracking what you need to know falls into three categories:

- Information needed to ensure that your billing process is collecting all the money that should be collected
- Information to be comfortable that your billing process is meeting all billing compliance rules and regulations
- Information that notes trends to which your practice may need to react or form a strategic plan

In general, you want to be sure that every service you rendered is captured, and whatever monies that contractually should be collected for those services are collected. You want to be sure that services are reconciled against case logs (e.g., operating room final schedules) so that you know what services were rendered and that you have a charge to submit for that service. You need to know what bills have been paid and whether or not they have been paid correctly. Of all the bills that are not yet fully paid, how old (aged) are they and what is being done to collect the remainder (payment plan has been set up, etc.)?

Following a statistically valid sample of random accounts through the revenue cycle process is a helpful method for fully understanding how the system is working and validate some of the monthly data. If you review randomly selected cases from the operating room schedules and track each through the billing cycle, you will have a very good sense of how your billing process is working. Sometimes reports of average data and group numbers do not always tell the entire story. This sampling process, although somewhat time consuming, is a great way to know what is truly happening and whether or not your monthly reports are accurate.

Billing Metrics and Trends

Trends are important for strategic purposes. Remember, 1 month does not a crisis make. Some of the monthly information that should be tracked for trend purposes includes the following:

- Total cases and total anesthesia units (is volume increasing or decreasing?)
- Cases and anesthesia units per location and per FTE physician
- Payer mix (especially if better payers are being replaced by poorer payers over time)
- Charge lag (how long it takes from when you render the service until the charge is entered into the billing system)
- Charges, contractual adjustments, and cash collections in total and by division/location/FTE (e.g., ambulatory surgery center, multiple hospitals, acute pain, chronic pain, critical care, etc.)
- Accounts receivable (is the total accounts open and still due to be paid growing or decreasing over time?)
- Net collection rate (collections divided by gross charges less contractual adjustments plus refunds). This should not be confused with gross collection rate, which is a more common measure that has less value, in our opinion. Essentially, the net collection rate is a measure of how much money is being collected as a percentage of what is collectable. For example, if your charge was $1500 and you have a contract that payer X agrees to pay you 60% of your charges, then your expected payment would be $900. If you are paid $850, then your net collection rate is 94%. Generally, depending upon factors such as self-pay or charity care, a net collection rate in the high 80s to mid 90s would be expected.
- Days in accounts receivable (how long it takes to collect the money due on your charges)
- Percent of accounts receivable older than 90 days from date of service (the older past due accounts age, the less likely that you will eventually collect them)
- Total credit balances (many times credit balances grow and mask other problems)
- Collection agency net collections (many practices worry about what a collection agency charges, yet what really matters is how much money they collect for you net of their fees). Some larger practices always have two collection agencies and split what is turned over to each evenly, then track the net results. When one agency outperforms the other over time, they may drop the

lower performer and contract with a new agency.

BILLING COMPLIANCE

Although it may seem at times that all the myriad of rules and regulations are in place just to make the practice of anesthesiology more difficult, there are reasons why compliance with various rules and regulations is both important and pertinent. The consequences of not knowing, or not following, these regulations can be substantial.

It must be noted that Medicare rules and regulations change occasionally, and sometimes they are interpreted differently by various carriers and agencies, so you should always check with your practice or hospital leadership and billing compliance experts as well as your local carrier to ensure that your understanding of billing practices rules and regulations are up to date and correctly interpreted for the state in which you are located.

Common Problems

What scenarios seem to present the most opportunities for anesthesia billing compliance problems?

- *Physicians not understanding the billing rules and regulations.* Anesthesia time starts when the anesthesia practitioner begins to prepare the patient for anesthesia services in the operating room or an equivalent area and ends when the anesthesia practitioner is no longer furnishing anesthesia services to the patient, that is, when the patient can be placed safely under postoperative care. It rarely correlates with the surgical start and stop times, nor does it necessarily correlate with the in- or out-of-operating-room times. Because the stop time often occurs after the patient leaves the operating room and the begin time often starts before the patient is brought into the operating room, the chance for overlap is obvious. Overlap is not a problem as long as it is properly documented and the impact on medical direction billing is understood and followed. The problem occurs when the billing does not accurately reflect the existence or extent of simultaneous care (i.e., "concurrency").
- *Medically directing more than four concurrent cases.* When the physician is responsible for more than four concurrent cases, he or she is no longer medically directing any of them. Exceeding four cases has significant negative ramifications on your overall reimbursement. The problem that many anesthesiologists do not understand is that even a 1-minute overlap invokes billing concurrency that may impact billing regulations and reimbursement amounts. Fig. 98–1 illustrates a typical workday and the consequences of 1 minute of overlap that affects reimbursement significantly. In this illustration, Case 1 in Room A started at 7:31 and finished at 11:32. Case 2 in Room B started at 7:52 and finished at 8:46. Case 3 in Room C started at 8:00 and finished at 14:12. Case 4 started in Room D at 7:15 and finished at 8:42. Case 5 started in Room B at 8:42 and finished at 13:14. During the 8:42 interval, the anesthesiologist actually was responsible for five cases. Even though it was only for that 1 minute, all five cases now are considered nonmedically directed.
- *Rounding.* It is statistically improbable that the majority of anesthesia cases will start and/or stop exactly at 5-minute intervals. It is a mistake, and wrong, to round your start and/or stop times, even if you are rounding to less time. Many physicians believe that because different clocks may not be synchronized, then they can just round because it really is only a matter of minutes. That rationalization may seem appropriate, but in reality billing compliance requires exact minutes to be reported, not more and not less. It may seem obvious why rounding up would be inappropriate, but why would rounding down? The situation described above is a good example to illustrate the reasoning for this seemingly innocent action. If the physician had rounded down, then Case 5 would have been noted as starting at 8:45 instead of 8:42. Case 4 would have been noted as ending at 8:40 instead of 8:42. The total minutes charged to each case actually would be less than the total minutes the physician was responsible for each case, so it would appear that, if anything, the physician would be shortchanging his or her reimbursement by several minutes. In reality, it would mean that instead of five cases being handled concurrently, the maximum concurrent cases now would appear to only be four, thus greatly improving reimbursement because all the cases now would be considered medically directed, resulting in much greater payment.
- *Not meeting the other noted necessary criteria for medical direction.* For example, relieving a CRNA in a room for a break while still being responsible for the other rooms. Taking over a case by yourself does not allow you to medically direct other concurrent cases. Likewise, not being present for induction, if appropriate, also would prevent that particular case from being considered medically directed.
- *Forgetting that if it is not documented, then it did not happen.*
- *Having a written policy in place, then not following it.* For example, your group has determined that to be considered immediately available, you cannot be further away from the operating room suite than this boundary or these locations. You put that policy in writing, have all physicians sign that they have re-

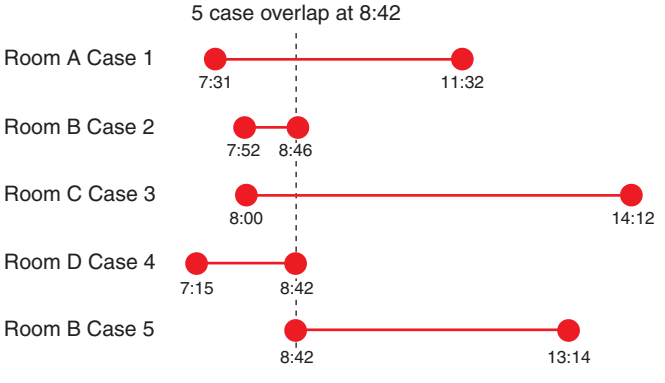

FIGURE 98–1. Example of an overlap of five concurrent cases.

ceived the policy and understand it, and then you place that policy in the file and never monitor or worry about it. If you have a policy, you had better make sure you can follow it, do follow it, and have a process in place to monitor compliance and take corrective action if individuals do not comply.

STRATEGIC PLANNING

Strategic planning is a process whereby an organization (e.g., anesthesia department or practice) defines its mission and objectives, analyzes internal and external factors (e.g., growth, new business, competition, reimbursement changes), defines priorities, and develops action plans. A practice can assess its position in the market and identify new business ideas via competitive analyses and review of market share data. This information is integral for business planning purposes, such as considering coverage of new out-of-operating-room sites and additional hospitals, participation in ambulatory surgical centers, or development of outpatient pain practices. The identification of strategic opportunities may occur through many avenues, ranging from proactive review of the marketplace and the strategy of competitors to the receipt of external requests for services by the practice or hospital. Consensus building and leadership involvement are key ingredients for success given the importance of building a vision, aligning the various constituencies (anesthesia, surgery, nursing, administrators, etc.), objectively reviewing data, and setting expectations.

The strategic planning process should result in a formal plan that includes a statement of goals and objectives, analytic tools such as financial statements and market research, an operational plan (evaluating personnel, space/facilities, workflow issues, and equipment needs), implementation plan, and assessment of any legal and regulatory impact. This plan should be used throughout the implementation phase as well as later to measure success against stated goals.

The principles outlined here will greatly facilitate the management of anesthesia practice, whether that be solo or group practice. Furthermore, they will help assure that the practice is being managed and compensated appropriately and that compliance with federal, state, and payer policies are being met. Collectively, these approaches will add to the satisfaction of anesthesia practice because they will reassure the practitioner that the billing and management aspects of the practice meet the same high standards as do the clinical aspects of the practice.

Nalbuphine	IV/IM	5–10 mg	10 mg/mL, 1 mL	Solution	0.90
Opioid Antagonists					
Alvimopan[d]	PO	6–12 mg	6 mg	Tablet	[d]
Methylnaltrexone[d]	PO	0.3–3 mg/kg	[d]	[d]	[d]
Methylnaltrexone[d]	IV/IM/SC	0.1–0.2 mg/kg	[d]	[d]	[d]
Naloxone	IV/IM	0.04–1 mg	0.4 mg/mL, 1 mL	Solution	1.00
Naltrexone	PO	50 mg	50 mg	Tablet	3.20
Nalmefene	IV	0.02–0.5 mg	100 μg/mL, 1 mL	Solution	3.30
			1 mg/mL, 2 mL	Solution	47.00
Opioid Adjuncts					
Carbamazepine	PO	200–400 mg	200 mg	Tablet	0.11
Gabapentin	PO	300–600 mg	300 mg	Capsule	1.00
Pregabalin	PO	50–100 mg	50 mg	Capsule	1.90

[a]Reflects the cost to a hospital that is part of a large buying group for the size and form listed.
[b]The required preservative-free preparation is generally not available in the United States.
[c]Not approved by the FDA for this indication in the United States.
[d]An investigational agent in the United States.
[e]Much higher doses are commonly used in opioid-tolerant patients.
COX, Cyclooxygenase; PR, per rectum; SC, subcutaneous.

TABLE A–2.

Sedative, Hypnotic, and General Anesthetic Agents

Drug	Route	Usual Dose	How Supplied	Form	Cost[a]
Barbiturates					
Methohexital	IV	1–2 mg/kg	500 mg	Powder	30.00
	PR	25 mg/kg			
Thiopental	IV	3–6 mg/kg	500 mg	Powder	4.40
Benzodiazepines					
Diazepam	IV	2–10 mg	5 mg/mL, 2 mL	Solution	1.90
	PO	5–10 mg	5 mg	Tablet	0.05
Lorazepam	IV/IM	1–5 mg	2 mg/mL, 1 mL	Solution	2.00
Midazolam	IV/IM	1–5 mg	1 mg/mL, 2 mL	Solution	0.50
	PO	0.5–0.75 mg/kg	5 mg/mL, 2 mL	Solution	3.00
Benzodiazepine Antagonist					
Flumazenil	IV	0.5–1 mg	0.1 mg/mL, 5 mL	Solution	38.00
Antihistamines					
Diphenhydramine	IV/IM	25 mg	50 mg/mL, 1 mL	Solution	0.90
Hydroxyzine	IM	25 mg	50 mg/mL, 1 mL	Solution	0.70
Promethazine	IV/IM	12.5 mg	25 mg/mL, 1 mL	Solution	0.60
Neuroleptics					
Chlorpromazine	IV/IM	25–100 mg	25 mg/mL, 1 mL	Solution	1.40
Droperidol	IV/IM	2.5–10 mg	2.5 mg/mL, 2 mL	Solution	1.25
Haloperidol	IV/IM	1–5 mg	5 mg/mL, 1 mL	Solution	5.40
Volatile Anesthetics					
Desflurane	Inhalation	MAC = 6.0%	240 mL	Liquid	108.00
Enflurane	Inhalation	MAC = 1.7%	250 mL	Liquid	91.00
Halothane	Inhalation	MAC = 0.75%	250 mL	Liquid	17.80
Isoflurane	Inhalation	MAC = 1.2%	250 mL	Liquid	28.00
Sevoflurane	Inhalation	MAC = 2.0%	250 mL	Liquid	201.00
Others					
Etomidate	IV	0.15–0.3 mg/kg	2 mg/mL, 10 mL	Solution	16.70
Ketamine	IV	0.2–2 mg/kg	10 mg/mL, 20 mL	Solution	13.00
	IV	0.2–2 mg/kg	50 mg/mL, 10 mL	Solution	5.60
	IM	2–5 mg/kg	100 mg/mL, 5 mL	Solution	7.10
Propofol	IV	0.5–2.5 mg/kg	10 mg/mL, 20 mL	Solution	2.80
		25–150 μg/kg/min	10 mg/mL, 50 mL	Solution	7.10
Dexmedetomidine	IV	0.2–0.7 μg/kg/h	100 μg/mL, 2 mL	Solution	52.00

[a]Reflects the cost to a hospital that is part of a large buying group for the size and form listed.
MAC, Minimal alveolar concentration; PR, per rectum.

TABLE A–3.

Muscle Relaxants and Reversal Agents

Drug	Route	Usual Dose	How Supplied	Form	Cost[a]
Depolarizing					
Succinylcholine	IV	1–2 mg/kg	20 mg/mL, 10 mL	Solution	2.10
	IM	4–6 mg/kg			
Nondepolarizing					
Atracurium	IV	0.4 mg/kg	10 mg/mL, 10 mL	Solution	11.00
Cisatracurium	IV	0.2 mg/kg	2 mg/mL, 10 mL	Solution	15.00
Mivacurium	IV	0.2 mg/kg	2 mg/mL, 10 mL	Solution	14.00
Pancuronium	IV	0.1 mg/kg	1 mg/mL, 10 mL	Solution	3.30
Rocuronium	IV	0.6 mg/kg	10 mg/mL, 10 mL	Solution	24.00
Vecuronium	IV	0.1 mg/kg	10 mg	Powder	5.60
Reversal Agents					
Edrophonium	IV	0.5–1 mg/kg	10 mg/mL, 10 mL	Solution	19.00
Neostigmine	IV	0.04–0.08 mg/kg	1 mg/mL, 10 mL	Solution	3.00
Pyridostigmine	IV	0.2–0.4 mg/kg	5 mg/mL, 2 mL	Solution	17.00

[a]Reflects the cost to a hospital that is part of a large buying group for the size and form listed.

TABLE A–4.

Local Anesthetics

Drug	Route	Maximum Dose	Contents	Size	Form	Cost[a]
Topical						
Benzocaine	Topical	2-second spray	20% benzocaine	60 mL	Liquid spray	23.50
Cetacaine	Topical	2-second spray	14% benzocaine 2% butamben 2% tetracaine	56 mL	Liquid spray	59.00
Cocaine	Topical	3 mg/kg	4%	10 mL	Solution	47.00
EMLA cream	Topical	20 g	2.5% lidocaine + 2.5% prilocaine	5 g	Cream	8.30
Lidocaine	Topical	5 mg/kg	4%	50 mL	Solution	6.90
			2%	100 mL	Viscous solution	16.00
			5%	35 g	Ointment	12.00
Spinal						
Bupivacaine	Intrathecal	[b]	0.75% bupivacaine + 8.25% glucose	2 mL	Solution	3.50
	Intrathecal	[b]	0.5% bupivacaine[d]	10 mL	Solution	2.00
Lidocaine	Intrathecal	[b]	1.5% lidocaine + 7.5% glucose	2 mL	Solution	9.00
Tetracaine	Intrathecal	[b]	1% tetracaine	2 mL	Solution	4.40
Tetracaine	Intrathecal	[b]	Tetracaine powder	20 mg	Powder	9.00
Epidural/Nerve Block/Local Infiltration[c]						
Bupivacaine	Injection	3 mg/kg	0.25–0.75% bupivacaine	10 mL	Solution	2.00
				30 mL	Solution	3.25
Chloroprocaine	Injection	12 mg/kg	2% chloroprocaine	30 mL	Solution	4.00
	Injection		3% chloroprocaine	30 mL	Solution	6.00
Lidocaine	Injection	7 mg/kg	0.5% lidocaine	50 mL	Solution	1.70
	Injection		1% lidocaine	2 mL	Solution	0.30
	Injection		1% lidocaine	20 mL	Solution	0.65
	Injection		2% lidocaine	20 mL	Solution	1.00
Mepivacaine	Injection	7 mg/kg	1% mepivacaine	30 mL	Solution	6.00
	Injection		1.5% mepivacaine	30 mL	Solution	8.00
	Injection		2% mepivacaine	20 mL	Solution	7.00
Ropivacaine	Injection	3 mg/kg	0.5% ropivacaine	30 mL	Solution	10.00
	Injection		1% ropivacaine	20 mL	Solution	11.00
IV Regional (Bier Block)						
Lidocaine	Injection	0.75 mL/kg	0.5% lidocaine	50 mL	Solution	1.70

[a]Reflects the cost to a hospital that is part of a large buying group for the size and form listed.
[b]Systemic toxicity unlikely to be achieved via the intrathecal route.
[c]This list does not include every concentration and package size available.
[d]Not approved by the FDA for this indication in the United States.

TABLE A–5.

Antiemetics

Drug	Route	Usual Dose	How Supplied	Form	Cost[a]
Dopamine Antagonists					
Droperidol	IV/IM	0.625–1.25 mg	2.5 mg/mL, 2 mL	Solution	1.25
Haloperidol	N/IM	1 mg	5 mg/mL, 1 mL	Solution	5.40
Prochlorperazine	IV/IM	10 mg	5 mg/mL, 2 mL	Solution	7.00
Serotonin Antagonists					
Dolasetron	IV	12.5 mg	20 mg/mL, 0.625 mL	Solution	14.00
Granisetron	IV	1 mg	1 mg/mL, 1 mL	Solution	146.00
Ondansetron	IV	4 mg	2 mg/mL, 2 mL	Solution	2.10
Antihistamines					
Diphenhydramine	IV/IM	25 mg	50 mg/mL, 1 mL	Solution	0.90
Hydroxyzine	IM	25 mg	50 mg/mL, 1 mL	Solution	0.70
Promethazine	IV/IM	12.5 mg	25 mg/mL, 1 mL	Solution	0.60
Neurokinin Antagonist					
Aprepitant	PO	40 mg	40 mg	Capsule	36.00
Glucocorticoids					
Dexamethasone	IV	4 mg	4 mg/mL, 5 mL	Solution	1.70
Antimuscarinic					
Scopolamine	Transdermal	14 μg/h	14 μg/h	Patch	4.50

[a]Reflects the cost to a hospital that is part of a large buying group for the size and form listed.

TABLE A–6.

Cardiovascular Drugs

Drug	Route	Usual Dose	How Supplied	Form	Cost[a]
Anticholinergic Agents					
Atropine	IV	0.01–0.02 mg/kg	0.4 mg/mL, 1 mL	Solution	0.60
			0.1 mg/mL, 10 mL	Solution	2.40
Glycopyrrolate	IV	0.005–0.01 mg/kg	0.2 mg/mL, 1 mL	Solution	0.70
Scopolamine	IV	0.2–0.8 mg	0.4 mg/mL, 1 mL	Solution	4.20
Antidysrhythmic Agents					
Adenosine	IV	6–12 mg	3 mg/mL, 2 mL	Solution	27.00
Amiodarone	IV	5–10 mg/kg	50 mg/mL, 3 mL	Solution	4.60
Digoxin	IV	0.125–0.5 mg	0.25 mg/mL, 2 mL	Solution	1.40
Isoproterenol	IV	0.5–4 μg	0.2 mg/mL, 5 mL	Solution	4.10
		0.1–1 μg/kg/min			
Lidocaine	IV	1–2 mg/kg	20 mg/mL, 5 mL	Solution	3.40
		1–4 mg/min			
Phenytoin	IV	5–15 mg/kg	50 mg/mL, 5 mL	Solution	1.50
Procainamide	IV	5–15 mg/kg	100 mg/mL, 10 mL	Solution	1.00
Inotropes					
Dobutamine	IV	2–20 μg/kg/min	12.5 mg/mL, 20 mL	Solution	3.20
Dopamine	IV	2–20 μg/kg/min	80 mg/mL, 5 mL	Solution	2.40
Inamrinone	IV	0.5–1.5 mg/kg	5 mg/mL, 20 mL	Solution	64.00
		5–10 μg/kg/min			
Milrinone	IV	50 μg/kg	1 mg/mL, 10 mL	Solution	11.00
		0.5 μg/kg/min			
Vasopressors					
Ephedrine	IV/IM	5–50 mg	50 mg/mL 1 mL	Solution	0.50
Epinephrine	IV	0.01–1 mg	1 mg/mL, 1 mL	Solution	0.50
			0.1 mg/mL, 10 mL	Solution	2.10
Norepinephrine	IV	1–20 μg/min	1 mg/mL, 4 mL	Solution	8.40
Phenylephrine	IV	40–80 μg	10 mg/mL, 1 mL	Solution	0.65
		10–80 μg/min			
Vasopressin	IV	0.01–0.04 U/min	20 U/mL, 1 mL	Solution	4.10
Antihypertensive Agents					
Enalaprilat	IV	1.25–2.5 mg	1.25 mg/mL, 2 mL	Solution	5.40
Hydralazine	IV	2–20 mg	20 mg/mL, 1 mL	Solution	11.30
Labetalol	IV	5–40 mg	5 mg/mL, 20 mL	Solution	3.60
Methyldopa	IV	250–500 mg	50 mg/mL, 5 mL	Solution	9.40
Phenoxybenzamine	PO	10–20 mg	10 mg	Tablet	4.80
Phentolamine	IV	1–5 mg	5 mg/mL, 20 mL	Powder	25.00
β-Blockers					
Esmolol	IV	10–40 mg	10 mg/mL, 10 mL	Solution	17.00
Metoprolol	IV	1–10 mg	1 mg/mL, 5 mL	Solution	2.50
Propranolol	IV	1–10 mg	1 mg/mL, 1 mL	Solution	7.70
Calcium Channel Blockers					
Diltiazem	IV	0.25–0.35 mg/kg	5 mg/mL, 10 mL	Solution	6.00
		5–15 mg/h			
Nicardipine	IV	5–15 mg/h	2.5 mg/mL, 10 mL	Solution	74.00
Nifedipine	SL	10 mg	10 mg	Capsule	0.30
Nimodipine	PO	60 mg	30 mg	Capsule	6.40
Verapamil	IV	2.5–5 mg	2.5 mg/mL, 4 mL	Solution	1.25
Vasodilators					
Alprostadil	IV	0.05–0.4 μg/kg/min	0.5 mg/mL, 1 mL	Solution	90.00
Fenoldopam	IV	0.1–1 μg/kg/min	10 mg/mL, 1 mL	Solution	200.00

(continued)

TABLE A–6.

Cardiovascular Drugs (Continued)

Drug	Route	Usual Dose	How Supplied	Form	Cost[a]
Nitroglycerin	IV	0.5–10 μg/kg/min	5 mg/mL, 10 mL	Solution	5.25
	SL	0.4 mg	0.4 mg	Tablet	0.06
	Topical	1 inch	2%, 30 g	Ointment	12.00
Nitroprusside	IV	0.5–10 μg/kg/min	50 mg	Powder	5.00
Diuretics					
Acetazolamide	IV	250 mg	500 mg	Powder	16.00
Bumetanide	IV	0.5–2 mg	0.25 mg/mL, 2 mL	Solution	1.25
Ethacrynic acid	IV	50–100 mg	50 mg	Powder	18.00
Furosemide	IV	5–40 mg	10 mg/mL, 2 mL	Solution	0.60
Mannitol	IV	0.25–1 g/kg	250 mg/mL, 50 mL	Solution	2.60
			200 mg/mL, 500 mL	Solution	14.00

[a]Reflects the cost to a hospital that is part of a large buying group for the size and form listed.
SL, Sublingual.

TABLE A–7.

Agents Affecting Blood Clotting

Drug	Route	Usual Dose	How Supplied	Form	Cost[a]
Anticoagulants Affecting Clotting Cascade					
Antithrombin III	IV	2000–5000 U	1000 U	Powder	1560.00
Argatroban	IV	2 μg/kg/min	100 mg/mL, 2.5 mL	Solution	741.00
Bivalirudin	IV	750 μg/kg 30 μg/kg/min	250 mg	Powder	386.00
Dalteparin	SC	2500–10,000 IU	12,500 IU/mL, 0.2 mL	Solution	135.00
			10,000 IU/mL, 1 mL	Solution	440.00
Drotrecogin	IV	24 μg/kg/h	5 mg/mL, 0.5 mL	Powder	205.00
Enoxaparin	SC	0.5–1.5 mg/kg	100 mg/mL, 0.4 mL	Solution	21.00
			100 mg/mL, 1 mL	Solution	54.00
Fondaparinux	SC	2.5–10 mg	5 mg/mL, 0.5 mL	Solution	31.00
			12.5 mg/mL, 0.8 mL	Solution	77.00
Heparin	IV	5000–25,000 U	1000 U/mL, 10 mL	Solution	3.40
	SC	5000 U	5000 U/mL, 1 mL	Solution	0.80
Lepirudin	IV	0.4 mg/kg 0.15 mg/kg/h	50 mg	Powder	130.00
Tinzaparin	SC	50–175 IU/kg	20,000 IU/mL, 2 mL	Solution	121.00
Anticoagulants Affecting Platelets					
Abciximab	IV	0.25 mg/kg 0.125 μg/kg/min	2 mg/mL, 5 mL	Solution	453.00
Aspirin	PO	81–325 mg	81 mg, 325 mg	Tablet	0.01
Cilostazol	PO	100 mg	100 mg	Tablet	1.80
Clopidogrel	PO	75 mg	75 mg	Tablet	3.40
Dipyridamole	PO	75 mg	75 mg	Tablet	0.90
Eptifibatide	IV	180 μg/kg	2 mg/mL, 10 mL	Solution	57.00
		1–2 μg/kg/min	2 mg/mL, 100 mL	Solution	494.00
Ticlopidine	PO	250 mg	250 mg	Tablet	2.00
Tirofiban	IV	0.4 μg/kg/min	250 μg/mL, 50 mL	Solution	372.00
		0.1 μg/kg/min	50 μg/mL, 250 mL	Solution	372.00
Fibrinolytic Activators					
Alteplase (tissue plasminogen activator)	IV	100 mg	100 mg	Powder	2600.00
Hemostatic Agents					
Aminocaproic acid	IV	4–5 g	250 mg/mL, 20 mL	Solution	2.10
Aprotinin	IV	280 mg	1.4 mg/mL, 200 mL	Solution	410.00
	IV	70 mg/h			
Desmopressin	IV	0.3 μg/kg	4 μg/mL, 1 mL	Solution	6.30
Eptacog alfa (factor VIIa)	IV	90 μg/kg	4800 μg	Powder	5400.00
Phytonadione (vitamin K)	IV	5–25 mg	10 mg/mL, 5 mL	Solution	19.00
Protamine	IV	25–250 mg	10 mg/mL, 5 mL	Solution	5.00
Tranexamic acid	IV	10–100 mg/kg	100 mg/mL, 10 mL	Solution	275.00

[a]Reflects the cost to a hospital that is part of a large buying group for the size and form listed.
SC, Subcutaneous.

TABLE A–8.

Anesthetic Adjuncts

Drug	Route	Usual Dose	How Supplied	Form	Cost[a]
Antacid and Aspiration Prophylaxis					
Cimetidine	PO	300 mg	300 mg	Tablet	0.13
	IV/IM	300 mg	150 mg/mL, 2 mL	Solution	1.10
Famotidine	PO	20 mg	20 mg	Tablet	0.15
	IV/IM	20 mg	10 mg/mL, 2 mL	Solution	0.80
Metoclopramide	PO	10 mg	10 mg	Tablet	0.20
	IV/IM	10 mg	5 mg/mL, 2 mL	Solution	0.65
Omeprazole	PO	20 mg	20 mg	Capsule	2.50
Ranitidine	PO	150 mg	150 mg	Tablet	1.10
	IV/IM	50 mg	25 mg/mL, 2 mL	Solution	3.00
Pantoprazole	PO	40 mg	40 mg	Capsule	2.90
	IV/IM	40 mg	40 mg	Powder	22.00
Sodium citrate solution/citric acid	PO	30 mL	30 mL	Solution	0.50
Sucralfate	PO	1 g	1 g	Tablet	0.30
Bronchodilators and Other Drugs for Asthma					
Albuterol	Inhalation	90 μg	200-dose	Inhaler	11.25
	Inhalation	2.5 mg	0.83 mg/mL, 3 mL	Nebulizer solution	0.35
Aminophylline	IV	5 mg/kg 0.5–1 mg/kg/h	25 mg/mL, 10 mL	Solution	0.60
Beclomethasone	Inhalation	40 μg	100-dose	Inhaler	43.00
Budesonide	Inhalation	200 μg	200-dose	Inhaler	119.00
Cromolyn	Inhalation	800 μg	200-dose	Inhaler	48.00
Flunisolide	Inhalation	250 μg	100-dose	Inhaler	59.00
Formoterol	Inhalation	12 μg	12 μg	Powder for inhalation	1.00
Ipratropium	Inhalation	17 μg	200-dose	Inhaler	50.00
Levalbuterol	Inhalation	45 μg	200-dose	Inhaler	34.00
Metaproterenol	Inhalation	650 μg	200-dose	Inhaler	26.00
Montelukast	PO	10 mg	10 mg	Tablet	2.40
Omalizumab	SC	150–300 mg	150 mg	Solution	426.00
Salmeterol	Inhalation	50 μg	50 μg	Powder for inhalation	1.25
Terbutaline	IV/SC	0.25 mg	1 mg/mL, 1 mL	Solution	17.00
Tiotropium	Inhalation	18 μg	18 μg	Powder for inhalation	2.90
Zafirlukast	PO	20 mg	20 mg	Tablet	1.00
Zileuton	PO	600 mg	600 mg	Caplet	0.70
Intravenous Dyes					
Fluorescein	IV	500 mg	100 mg/mL, 5 mL	Solution	3.50
Indigotindisulfonate	IV	40 mg	8 mg/mL, 5 mL	Solution	7.00
Methylene blue	IV	10 mg	10 mg/mL, 1 mL	Solution	3.60
Glucocorticoids					
Dexamethasone	IV	1–10 mg	4 mg/mL, 5 mL	Solution	1.00
Hydrocortisone	IV	100 mg	100 mg	Powder	1.60
Methylprednisolone	IV	40–1000 mg	40 mg	Powder	1.70
			1000 mg	Powder	15.00
Other Hormones					
Glucagon	IV	0.5–1 mg	1 mg	Powder	36.00
Insulin, human	IV/SC	1–20 U	100 U/mL, 10 mL	Solution	23.00
Levothyroxine	IV	50–150 μg	200 μg	Powder	5.40
Octreotide	IV/SC	50–150 μg	100 μg/mL, 1 mL	Solution	17.33
Oxytocin	IV	10 mU/min	10 U/mL, 1 mL	Solution	2.30

(continued)

TABLE A–8.

Anesthetic Adjuncts (Continued)

Drug	Route	Usual Dose	How Supplied	Form	Cost[a]
Secretin	IV	0.2–0.4 μg/kg	16 μg	Powder	293.00
Miscellaneous Agents					
Baclofen	Intrathecal	50 μg	50 μg/mL, 1 mL	Solution	63.00
Caffeine sodium benzoate	IV	250–500 mg	125 mg/mL, 2 mL	Solution	8.10
Carboprost tromethamine	IM	250 μg	250 μg/mL, 1 mL	Solution	45.00
Dantrolene	IV	1–10 mg/kg	20 mg	Powder	71.00
Doxapram	IV	0.5–1 mg/kg	20 mg/mL, 20 mL	Solution	74.00
Hydroxocobalamin	IM	1 mg	1 mg/mL, 10 mL	Solution	6.00
Methylergonovine	IM	0.2 mg	0.2 mg/mL, 1 mL	Solution	3.70
Physostigmine	IV	1 mg	1 mg/mL, 2 mL	Solution	3.70
Sodium nitrite	IV	300 mg	30 mg/mL, 10 mL	Solution	32.00
Sodium thiosulfate	IV	12.5 g	250 mg/mL, 50 mL	Solution	17.00

[a]Reflects the cost to a hospital that is part of a large buying group for the size and form listed.
SC, Subcutaneous.

TABLE A–9.

Intravenous Antibiotics

Drug	Route	Usual Dose	How Supplied	Form	Cost[a]
Acyclovir	IV	5–10 mg/kg	50 mg/mL, 20 mL	Solution	32.00
Amikacin	IV	7.5 mg/kg	250 mg/mL, 2 mL	Solution	5.90
Amphotericin B	IV	0.25–1 mg/kg	50 mg/mL, 20 mL	Powder	8.70
Ampicillin	IV	1–2 g	1 g	Powder	5.60
Ampicillin/sulbactam	IV	2 g/1 g	2 g/1 g	Powder	10.60
Azithromycin	IV	500 mg	500 mg	Powder	22.00
Aztreonam	IV	1–2 g	2 g	Powder	35.00
Caspofungin	IV	70 mg	70 mg	Powder	382.00
Cefazolin	IV	1 g	1 g	Powder	0.90
Cefepime	IV	1–2 g	1 g	Powder	13.00
Cefotaxime	IV	1–2 g	1 g	Powder	7.70
Cefoxitin	IV	1–2 g	1 g	Powder	8.50
Ceftazidime	IV	1–2 g	1 g	Powder	11.00
Ceftizoxime	IV	1–2 g	1 g	Powder	8.50
Ceftriaxone	IV	1–2 g	1 g	Powder	38.00
Cefuroxime	IV	0.75–1.5 g	1.5 g	Powder	10.00
Chloramphenicol	IV	12.5–25 mg/kg	1 g	Powder	17.00
Ciprofloxacin	IV	400 mg	10 mg/mL, 40 mL	Solution	22.00
Clindamycin	IV	600 mg	150 mg/mL, 4 mL	Solution	8.50
Dalfopristin/quinupristin	IV	7.5 mg/kg	420 mg/180 mg	Powder	92.00
Ertapenem	IV	1 g	1 g	Powder	38.00
Erythromycin	IV	1 g	1 g	Powder	5.80
Fluconazole	IV	400 mg	2 mg/mL, 200 mL	Solution	113.00
Ganciclovir	IV	5 mg/kg	500 mg	Powder	34.00
Gentamicin	IV	1–7 mg/kg	40 mg/mL, 2 mL	Solution	1.70
Imipenem	IV	0.5–1 g	500 mg	Powder	26.00
Levofloxacin	IV	0.5 g	5 mg/mL, 100 mL	Solution	33.00
Linezolid	IV	600 mg	2 mg/mL, 300 mL	Solution	62.00
Meropenem	IV	0.5–1 g	1 g	Powder	45.00
Metronidazole	IV	0.5–1 g	5 mg/mL, 100 mL	Solution	12.00
Nafcillin	IV	1 g	1 g	Powder	6.00
Oxacillin	IV	1 g	1 g	Powder	6.00
Penicillin G	IV	1,000,000 U	20,000 U/mL, 50 mL	Solution	9.50
Piperacillin/tazobactam	IV	3 g/0.375 g	3 g/0.375 g	Powder	13.00
Rifampin	IV	600 mg	600 mg	Powder	56.00
Ticarcillin	IV	3–4 g	20 g	Powder	62.00
Ticarcillin/clavulanic acid	IV	3 g/0.1 g	3 g/0.1 g	Powder	11.00
Tobramycin	IV	1–7 mg/kg	40 mg/mL, 2 mL	Solution	4.50
Trimetrexate	IV	1–1.5 mg/kg	25 mg	Powder	125.00
Vancomycin	IV	0.5–1 g	1 g	Powder	4.50
Voriconazole	IV	4–6 mg/kg	200 mg	Powder	83.00

[a]Reflects the cost to a hospital that is part of a large buying group for the size and form listed.

TABLE A–10.

Intravenous Fluid Solutions and Electrolytes

Solution	Contents	How Supplied	Cost[a]
Albumin	5% albumin	250 mL	44.00
	25% albumin	50 mL	44.00
Calcium chloride 10%	13.6 mEq calcium chloride	10 mL	0.60
Calcium gluconate	4.7 mEq calcium gluconate	10 mL	0.70
Dextran 1	15% dextran 1	20 mL	7.00
Dextran 40	10% dextran 40 in 0.9% sodium chloride	500 mL	20.00
Dextran 70	6% dextran 70 in 0.9% sodium chloride	500 mL	12.00
Dextrose (D5)	5% glucose (dextrose)	1000 mL	1.75
	10% glucose (dextrose)	1000 mL	1.75
Dextrose + 0.5 normal saline (D5/$^1/_2$NS)	5% glucose (dextrose) 66 mEq/L sodium chloride	1000 mL	1.75
Dextrose + normal saline (D5/NS)	5% glucose (dextrose) 132 mEq/L sodium chloride	1000 mL	1.75
Hetastarch	6% hetastarch 132 mEq/L sodium chloride	500 mL	21.00
Lactated Ringer solution	130 mEq/L sodium 109 mEq/L chloride 4 mEq/L potassium 3 mEq/L calcium 28 mEq/L lactate	1000 mL	1.10
Magnesium sulfate 50%	40 mEq magnesium sulfate	10 mL	0.70
Normal saline	132 mEq/L sodium chloride	1000 mL	1.10
Plasma-Lyte A[b]	140 mEq/L sodium 5 mEq/L potassium 3 mEq/L magnesium 98 mEq/L chloride 27 mEq/L acetate 23 mEq/L gluconate	1000 mL	19.00
Plasma-Lyte M[b]	5% glucose (dextrose) 40 mEq/L sodium 16 mEq/L potassium 5 mEq/L calcium 3 mEq/L magnesium 12 mEq/L acetate 12 mEq/L lactate	1000 mL	12.00
Plasma-Lyte R[b]	140 mEq/L sodium 10 mEq/L potassium 5 mEq/L calcium 3 mEq/L magnesium 47 mEq/L acetate 8 mEq/L lactate	1000 mL	12.00
Potassium chloride	2 mEq/mL	10 mL	0.90
Sodium bicarbonate 8.4%	1 mEq/mL sodium bicarbonate	50 mL	1.70
THAM	3.6% tromethamine	500 mL	148.00

[a]Reflects the cost to a hospital that is part of a large buying group for the size and form listed.
[b]This is one brand name. Similar solutions are available under other brand names, such as Isolyte and Normosol.
