SECTION C

ANESTHESIA DRUGS AND DRUG DELIVERY SYSTEMS

CHAPTER 36

Mechanisms of General Anesthetic Action

Max B. Kelz, MD, PhD,
Jay Yang, MD, PhD, and
Roderic G. Eckenhoff, MD

General anesthetics were formally introduced into medical practice more than 160 years ago and have been hailed as one of the most significant medical advances of all time. Yet there is still considerable mystery about how the drugs work and how to characterize the state that they produce. This should not be too surprising, because a description of the transition from consciousness to unconsciousness necessarily requires an understanding of the former, and the neurobiology of consciousness is still in its infancy. Nevertheless, considerable progress has been made toward the characterization of anesthesia and the potential mechanisms of the drugs that produce it. In this chapter, we summarize the current body of evidence for the mechanism(s) of general anesthesia, with emphasis on the inhaled anesthetics because they are used most commonly. Excellent and comprehensive reviews summarize current knowledge of the molecular, cellular, and in vivo pharmacology,[1,2] so we have selected only a few of the putative molecular targets to illustrate the principles and to support the notion that alteration of a neurophysiologic process, rather than the activity of an individual protein, is responsible for the state of general anesthesia.

GENERAL ANESTHESIA

Mechanistic searches are greatly aided by clear physiologic or behavioral end points. Those associated with anesthesia, however, often are ambiguous and arbitrary. Most people associate anesthesia with unconsciousness or "sleep," but the transition to this state often is not apparent to the observer, so the lack of physical movement in response to a noxious stimulus is the most common end point associated with the term *anesthesia.* This is essentially the same end point used in Boston more than 160 years ago. But it is immediately apparent that many pathways can lead to such an end point, most notably paralysis, which itself is at the end of many pathways. Nevertheless, the mobility end point is well entrenched and has been useful as a practical comparison of the potency of different drugs. After all, surgery is greatly facilitated by a motionless patient. Thus was born the concept of minimum alveolar concentration (MAC; see Chapter 37), a useful tool for practitioners. Investigators, on the other hand, were hampered by such a concept and only now are starting to break the state of anesthesia into its many components in an attempt to relate them to the underlying targets and pathways. For example, most acknowledge the presence of hypnosis, amnesia, excitement, weakness, and analgesia in the state of anesthesia. These are distinct from the many arbitrarily assigned "side" effects of the drugs, including alterations in vascular, cardiac, respiratory, metabolic, and renal function. Also produced are a series of "toxic" effects, which might be unique, or simply an enhancement of the primary or the side effects. This disassembly of effects is likely to facilitate the linkage with molecular targets and with their reassembly to the final in vivo state of

KEY POINTS

1. The mechanisms by which the inhaled general anesthetics work are not fully understood. No single molecular target has been proven to transduce anesthesia.
2. Correlation of the physicochemical character of anesthetics with their potency suggests target sites are dominantly hydrophobic, with a small degree of polarity and chirality. Internal protein cavities best fit this description.
3. Inhaled anesthetic binding site character is not highly specific, predicting more than a few anesthetic binding targets. The interaction at some of these targets may not contribute significantly to anesthetic action.
4. Use of the lipid membrane as a direct target for inhaled anesthetics has been dismissed prematurely. Some components of anesthetic action may occur via this interaction.
5. Many potential protein targets in the synapse have been identified, suggesting that inhaled anesthetic action results from disruption of the specific process of synaptic transmission rather than from a receptor-like interaction with a single molecular target.
6. Anesthetic effects on a process, such as synaptic transmission, may have a different system-level effect depending on placement in the neural circuitry. The circuits that regulate sleep and arousal are well positioned to mediate the hypnotic properties of anesthetics.

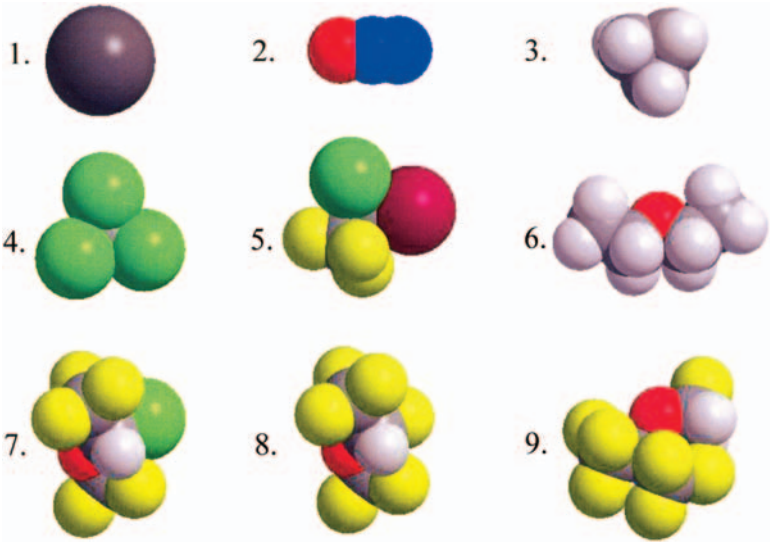

FIGURE 36–1. Space -filling representation of some inhaled general anesthetics. 1, xenon; 2, nitrous oxide; 3, cyclopropane; 4, chloroform; 5, halothane; 6, diethyl ether; 7, isoflurane; 8, desflurane; 9, sevoflurane. Atoms are color coded: light gray, carbon; white, hydrogen; blue, nitrogen; red, oxygen; green, chlorine; yellow, fluorine; magenta, bromine; dark gray, xenon.

anesthesia. At the very least, it facilitates the formation and testing of critical hypotheses. We return to these ideas toward the end of this chapter.

GENERAL ANESTHETICS

Mechanistic searches are aided by clear structural motifs among the drugs that produce the end point. This permits a search for the complementary motif on the target macromolecules. Here too, general anesthetics fall short of the mark. A **structurally diverse** range of molecules is capable of producing a state of anesthesia (Fig. 36–1). Nonetheless, certain physicochemical features appear to be important. For example, **hydrophobicity** correlates exceedingly well with anesthetic potency, with only a few exceptions (Fig. 36–2). Although impressive, this only suggests that the domain(s) producing the effects is hydrophobic, limiting the choices to most proteins and all lipid membranes. Other more subtle features of the drugs seem to be important. Most inhaled anesthetics have an asymmetric distribution of hydrogen atoms, giving the molecule enough of a dipole moment to interact favorably with more polar environments. The few **nonimmobilizer** drugs (Fig. 36–3), introduced to allow for selection of relevant targets,[3,4] lack this feature and therefore are extremely insoluble in water.[4] Although the mechanism of their failure to cause anesthesia is not clear, it likely is related to their low dipole and poor solubility in water and therefore, lower occupancy in targets. Also, there is a clear relationship between potency and the presence of halogens (and their size) on the anesthetic molecule. Given that the halogens are uncharged atoms, then polarizability must be important, another indication that the sites responsible for anesthesia are relatively polar. That the focus is beginning to narrow on protein as the target still cannot exclude lipid because the general head group region has both polar and hydrophobic character.

Related to hydrophobicity is the **cutoff effect** (Fig. 36–4). In a homologous series of compounds, for instance, *n*-alcohols, anesthetic potency increases progressively as the hydrocarbon chain lengthens, until a certain length is reached and then anesthetic potency is abruptly lost. This typically occurs at 10–14 carbons, depending on assay and end point, and has been used to implicate specific molecular targets.[5] Interpretation of this phenomenon has varied, but is conventionally viewed as indicating the geometric capacity of a binding site—a molecular ruler. Of course, this interpretation requires that the alcohol actually bind to the target in question, a requirement that is almost never tested. In the one case where it was, a cutoff effect was observed with no apparent loss in binding affinity,[6] suggesting that cutoff is due to mechanisms other than steric hindrance, perhaps (like the nonimmobilizers) to the extremely low solubility of the

FIGURE 36–2. Log/log plot of the oil/water partition coefficient against human minimum alveolar concentration (MAC) in atmospheres for 12 inhaled anesthetics. Note the tight correlation over almost five orders of magnitude, strongly suggesting that the anesthetic site(s).

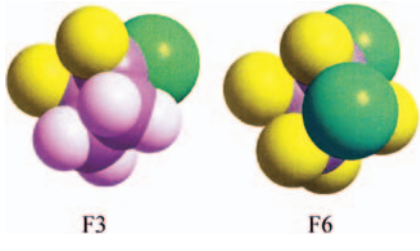

FIGURE 36–3. Two nonclinical molecules used for research purposes. The molecule on the left [chlorotrifluorocyclobutane (F_3)] has anesthetic properties similar to isoflurane, whereas the molecule on the right [dichlorohexafluorocyclobutane (F6)] is devoid of anesthetic activity, despite being very soluble in oil. Because F6 is much less soluble in water that F_3, this suggests the anesthetic site(s) on molecular targets transducing the minimum alveolar concentration (MAC) end point has some polar character in addition to being hydrophobic.

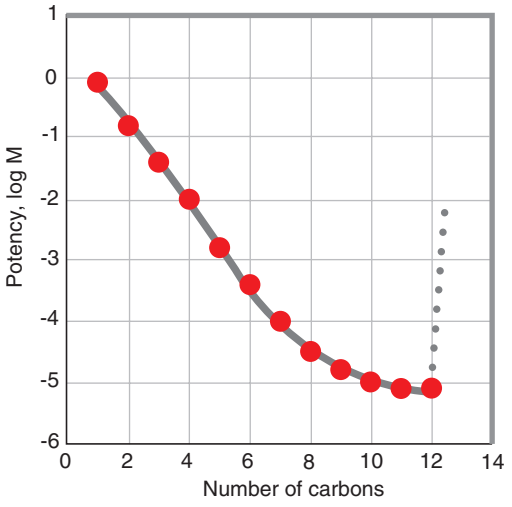

FIGURE 36–4. The cutoff effect. As one ascends a homologous series of compounds, such as the *n*-alkanols, anesthetic activity increases until about C12, where activity is abruptly lost with the addition of just one more carbon. The cutoff point is different for different chemical series, in different in vitro systems, and in different organisms. Long interpreted as reflecting the dimensions of the anesthetic site on an important molecular target, a form of molecular ruler, the progressive decline in water solubility of the long-chain molecules suggests that occupancy of sites may decline for reasons unrelated to site dimensions. This suggests that the mechanism for failure of long hydrocarbons and nonimmobilizer molecules to produce immobility is similar.

long compounds in water. The final blow to the cutoff effect being useful as a molecular ruler of important protein binding sites was the demonstration that polyhydric alcohols (essentially *n*-alcohol polymers) retained anesthetic activity at molecular sizes in large excess of the *n*-alkanol cutoff.[7]

The final drug feature that has been used to aid the search for targets is **enantioselectivity.** Many of the inhaled anesthetics have chiral carbons, indicating that mirror image molecules are possible (Fig. 36–5). Such pairs are identical from a physicochemical standpoint but have a different arrangement of atoms in space, which would be expected to interact with a unique spatial distribution of atoms in a protein binding site, for example, more specifically than in a more fluid-like assembly of lipid molecules. Small differences in the immobilizing potency of the isoflurane enantiomers were found,[8] and in at least one species for the halothane enantiomers.[9] Although this has the potential for selecting relevant targets, the small degree of enantioselectivity (~20%), combined with the fact that many proteins display enantioselectivity for inhaled anesthetics, renders the potential small. It is even possible that the few chiral molecules in phospholipid bilayers (i.e., cholesterol), or that very general and conserved chiral features of proteins (such as L-α-amino acids and uniquely handed helices), contribute to this small degree of selectivity.

Thus, in general, drug features have given us only general clues to the identity of important anesthetic targets and the underlying mechanisms of their dysfunction.

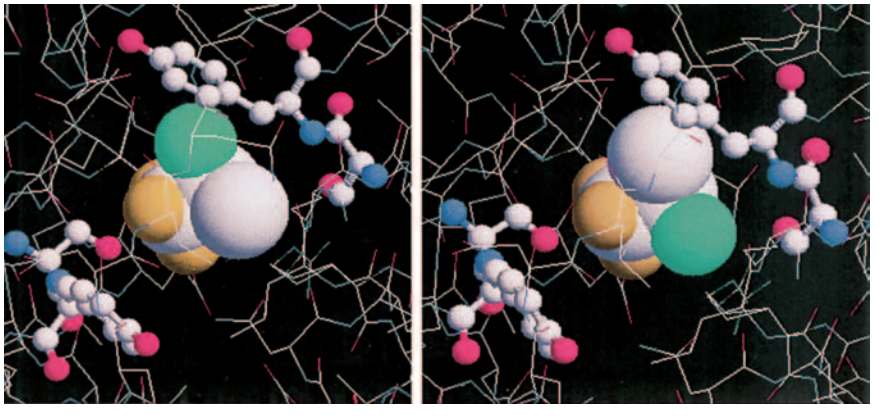

FIGURE 36–5. Stereoselective binding of halothane enantiomers. Binding of racemic halothane in hydrophobic cavity of apoferritin revealed a 2:1 preference for the *S*-enantiomer over the *R*-enantiomer. This provides credibility that the small degree of enantioselectivity observed in vivo is transduced through protein targets.

ANESTHETIC TARGETS

Lipid Bilayers

The dramatic correlation of hydrophobicity with anesthetic potency predated an understanding of protein interiors, so initial focus fell on the obvious oily candidate: the lipid bilayer (Fig. 36–6). The idea was that solubilization of the hydrophobic anesthetic into the thin lipid membrane altered a property sensed by the cell or by proteins wholly or partially embedded in the lipid. The crucial property was (and still is) unclear, so surrogate properties that could be easily measured, such as the gel–liquid phase transition, were studied extensively. Changes induced by the anesthetics in these properties could be demonstrated, but several features gradually emerged that diminished enthusiasm in the lipid membrane as an important transducer of anesthetic effects. First, measurable changes in phase transition at clinical concentrations of anesthetic were small, mimicked by only 1–2°C. Second, other compounds that dissolved well and produced similar effects in these bilayers (e.g., nonimmobilizers) did not produce anesthesia. Finally, the emergence of protein-centered theories shifted attention away from the lipid bilayer.

A shift in attention, however, does not suffice to eliminate the potential for an important contribution. New theories, coupled with improved understanding of the lipid bilayer and its interaction with anesthetics and membrane protein, call for a return to the lipid bilayer at some point to test whether anesthetic modulation contributes to in vivo anesthetic effects. For example, it is clear that phase transitions are not a relevant feature

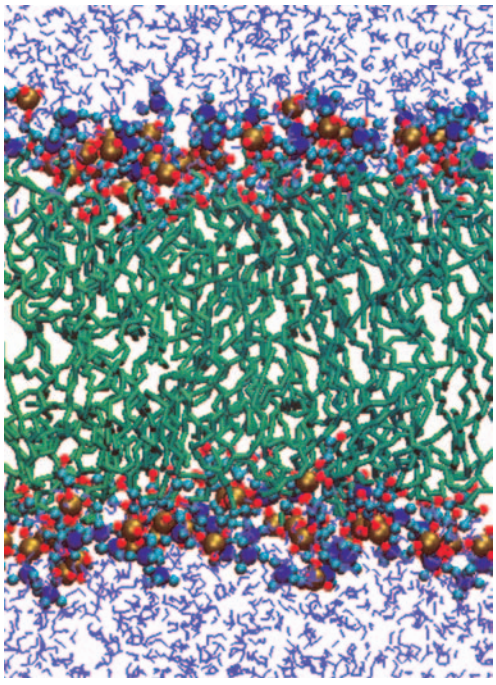

FIGURE 36–6. Snapshot of a lipid membrane in a molecular dynamics simulation. This gives an idea of the complexity and organization of this essential and widely distributed structure. Our poor understanding of its communication with proteins embedded in it, and of effects of solutes distributed in it, have conspired to make it difficult to eliminate the lipid bilayer as a viable potential target for transducing some anesthetic effects.

of biologic membranes, so conclusions based on their measurement must be viewed cautiously. It now is clear that anesthetics distribute in the lipid bilayer heterogeneously, less in the center (acyl trough) and more toward the outer edges. This asymmetric distribution can influence lipid properties not easily measured, such as lateral pressure (Fig. 36–7), but posited to have a potent effect on membrane protein conformational transitions.[10] Interestingly, even though nonimmobilizers partition well into the lipid bilayer, the distribution within the bilayer is very different than that of an anesthetic,[11] yet again opening the door for lipid theories. Furthermore, lipid microdomains exist (e.g., lipid rafts) that appear to organize specific proteins into functional groups may have a higher affinity for inhaled anesthetics (because of unique lipids or unique proteins), increasing the opportunity for anesthetic effects on signaling pathways.[12] Finally, in most assays of membrane protein activity (e.g., ion channels), protein is functionally inseparable from the lipid. For example, mutagenesis of membrane protein by itself cannot be directly used to implicate a protein target because the mutation also might influence the interaction with lipid. Thus, it is premature to rule out the biologic lipid membrane as an important direct target for the inhaled anesthetics.

Proteins

Proteinaceous components of the cell as targets for anesthetics were first proposed by Claude Bernard in 1875 but did not gain favor until the demonstration that the activity of lipid-free preparations of protein were reversibly influenced by anesthetics, and in a way that reproduced the correlation with hydrophobicity.[13] Because this paralleled the understanding that the interior of proteins are as hydrophobic as that of lipid membranes, this association should not have been surprising. When combined with enantioselectivity and an ability to measure and alter protein function, especially in ion channels, protein-centered theories rapidly became favored. Many protein targets have been proposed and studied, and we review some of them briefly. *However, at this time it is safe to conclude that not a single protein target, or even class or family of protein targets, has been proven to play the central role in inhaled anesthetic action.* This is not to say, however, that favored candidates have not emerged, especially for the injectable induction agents. We first review some essential basics of protein–ligand interactions as they relate to anesthetics and then present the evidence for specific targets.

Binding

The submolecular mechanism by which the anesthetic causes a change in protein function or activity must first involve a binding event—formation of drug–target complex. This often is the initial criterion for establishing the relevance of any proposed drug target but has not been used for inhaled anesthetics because the affinity for protein targets is low, and they appear to be fairly promiscuous, binding to many targets. Both nuclear magnetic resonance spectroscopy and photolabeling have sug-

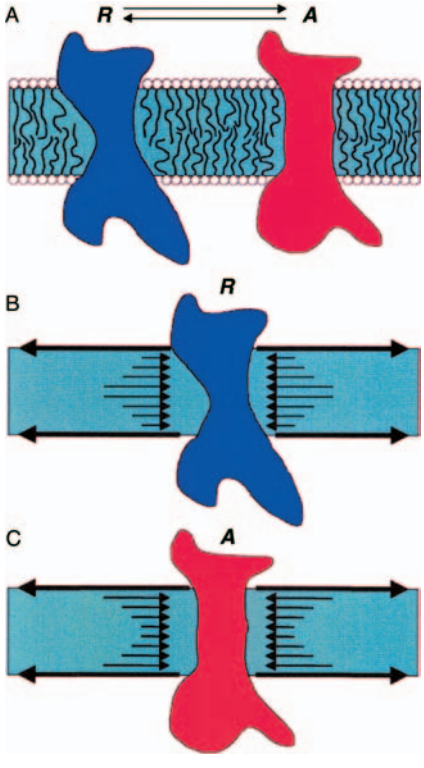

FIGURE 36–7. Lateral pressure hypothesis of membrane–protein communication. **A.** Membrane protein in two conformations: R for resting, and A for activated. The A conformer requires some expansion in the membrane center. **B.** Membrane lateral profile of vectors that favors the R state. **C.** Pressure profile that favors the A conformer. A solute that distributes unevenly across the membrane will, of necessity, alter this lateral pressure profile, resulting in a modulation of conformational state and therefore of activity. Molecular dynamics simulations predict that anesthetic molecules do distribute unevenly across the lipid bilayer. FIGURE 36–8. Top. Autoradiogram of rat brain sagittal section photoaffinity labeled with ^{14}C-halothane. The degree of halothane binding is indicated by the level of darkness; no other stain has been applied to this section. There appears to be no regional preference, and excess unlabeled halothane reduces incorporation by ~70% (image not shown), indicating that this distribution represents specific binding. **Bottom left.** ^{19}F-Nuclear magnetic resonance coronal section of in vivo rat brain after equilibration with sevoflurane. **Bottom right.** Orientation of the left panel. Both experiments demonstrate widespread anesthetic distribution in mammalian brain. (Fig. 36–8B used by permission.[105] Copyright 1995 Lippincott Williams & Wilkins.)

gested a large number of protein binding targets (27) and no particular regional preference in the brain (Fig. 36–8).[14] This renders untenable the conventional radioligand binding approach for discovering targets. Whether anesthetics also significantly alter the function of a large number of proteins is not clear, but even if only a minority of the binding target pool, the number of contributing targets is still large.

Nature of the Binding Site Until recently, the nature of anesthetic binding sites has been inferred from correlations with anesthetic structural or physicochemical features. For example, the Overton-Meyer relationship suggested that sites are in the hydrophobic interior of proteins, and the relationship of halogen size and asymmetric hydrogens with potency suggested that polar amino acids must contribute to these sites. High-resolution structures of a clinically used inhaled anesthetic complexed to a protein target have been revealed for two protein models: serum albumin[15] and apoferritin (Fig. 36–9).[16] Although unlikely to transduce important effects of anesthesia, the affinity of both proteins (see later) suggests substantial occupancy at clinical concentrations of anesthetic (~0.2 mmol/L), and thus the binding site architecture is likely to bear resemblance to those in targets underlying effects relevant to anesthesia. Both structures show occupancy of preexisting internal packing defects, also known as *cavities.* The apoferritin example goes further to suggest that a packing density of just over half full represents an optimal balance between enthalpic and entropic forces. Finally, both examples suggest that polar (but uncharged) amino acids contribute to the strength of binding. In the apoferritin cavity, two SYL (serine-tyrosine-leucine) triads interact with either halothane or isoflurane atoms to produce the highest affinity binding yet described for these compounds (Fig. 36–9). The stringency of these features is not yet clear, but preliminary estimates based on current entries in the Protein Data Bank *(http://www.rcsb.org/pdb)* suggest that <1% of the proteome (~3000 proteins) have comparable binding sites for volatile anesthetics.

Affinity and Stoichiometry

Affinity of a drug for a site, indicated by the association constant (K_a) or, more commonly, the dissociation constant ($K_d = 1/K_a$), is experimentally defined as the drug concentration at which half the sites are occupied. It is more properly called "apparent" affinity, because other aspects of the mixture can modify the true affinity of the ligand–site complex. Relevant to this is whether the binding event "causes" a conformational change (see later) in the protein to which it binds. If so, the apparent affinity will be lowered by the amount of free energy used to change the protein conformation (Fig. 36–10). Thus, a set of binding site features that produces a 10 μmol/L *absolute* K_d with an anesthetic perhaps will have an *apparent* K_d of 1 mmol/L, if approximately 2 kcal/mol of free energy is required to change the protein conformation.

The slope of the relationship between drug concentration and occu-

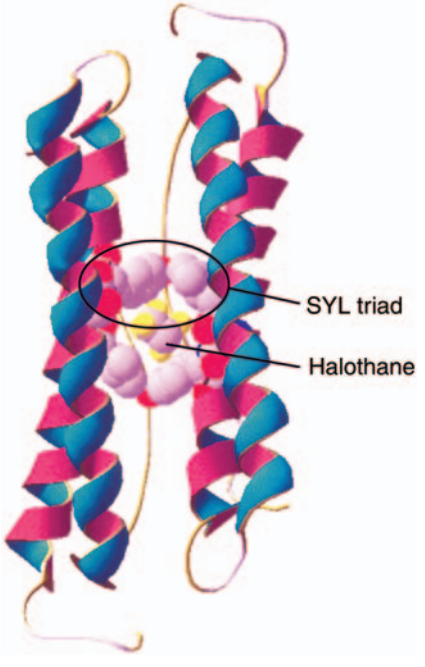

FIGURE 36–9. High-resolution structure of the high-affinity anesthetic binding site in an interface between two subunits of apoferritin. The halothane is shown in the middle, coordinated by two SYL triads (see text for details). Note that the parallel helical bundle motif of this binding domain is found in the transmembrane region of the ligand-gated ion channel subunits and in many receptors (see Figs. 36–14 and 36–15).

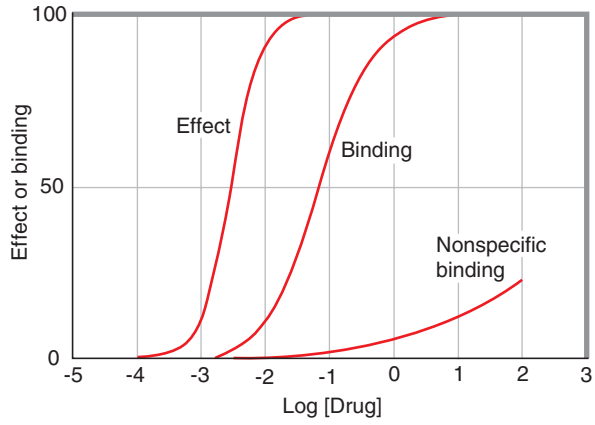

FIGURE 36–10. Sigmoid-shaped dose–response curve for a typical anesthetic-like drug. The effect curve often is most left shifted is the steepest. The binding effects that underlie the effect usually is shifted to the right, and may or may not have the same slope, depending on the number targets, the number of sites per target, and whether the sites interact (cooperativity). This indicates that molecular sites underlying a specific effect do not necessarily need to be fully occupied to reach full (saturation) effect. Nonspecific binding (that generally not associated with the primary effect) is most right shifted and may appear to be linear in many experiments.

pancy, the Hill slope, is an indication of both the number of sites on a target and whether they interact. For example, a single site should always have a Hill slope of 1, reflecting a relationship where the site goes from 0–100% occupancy over an approximately 100-fold change in drug concentration (Fig. 36–10). Multiple sites on a single target also can demonstrate a Hill slope of 1, or they can "cooperate," increasing the slope. In other words, if occupancy of the first site enhances occupancy of the second (as in oxygen binding by hemoglobin), the slope will rise, although rarely over 2 or 3. Although difficult to measure as indicated, anesthetic K_d values in model proteins typically are approximately 1 mmol/L, and Hill slopes are generally 1 or slightly greater, even though more than one binding site has been found in most proteins studied. Serum albumin has at least six sites,[15] apoferritin 12,[16] and the intact nicotinic acetylcholine receptor (nAChR)15–20.[17–19] As might be deduced from the preceding paragraph, occupancy of multiple sites is a potentially powerful method of donating free energy to the protein in order to alter its conformation. Occupancy of only one additional binding site in a protein produces as much free energy as an approximately 10-fold increase in affinity.

An issue frequently causing confusion has been what affinity an important anesthetic target should display for anesthetics. Prevailing logic has suggested that, for a target to be relevant to a particular end point, for example, immobility, the dissociation constant for the anesthetic–target complex should approximate that achieved at MAC. However, this logic holds only if one assumes that this target is alone capable of producing the end point, an assumption that rarely is valid. Furthermore, even if the target is wholly responsible for the end point, it is difficult to know the expected K_d because drug efficacy at this target is not known. It is rare for the relationship between receptor occupancy and median effective concentration (EC_{50}) to be linear; thus, predicting that more than some degree of occupancy should be anticipated at clinical concentrations is difficult. As our discussion on Hill slopes indicates, this limits the expected K_d to an approximately 100-fold range.

Coupling Mechanism

As discussed earlier, the anesthetic can only alter the protein's activity through a contribution of binding energy—through either the affinity or the stoichiometry of the complex. This binding energy alters protein activity through at least three potential, and partially overlapping, mechanisms. The first mechanism, **competition**, occurs when the drug–protein complex is strong enough to compete with the binding of an endogenous ligand, therefore inhibiting the associated effect (Fig. 36–11). This was the mechanism initially proposed for anesthetic inhibition of firefly luciferase.[13] The two forms of competition are isosteric and allosteric. In isosteric competition, the drug occupies the same binding site as the endogenous ligand, physically preventing binding. An anesthetic example is halothane occupancy of the retinal cavity in the G-protein coupled receptor (GPCR) rhodopsin.[20] In allosteric competition, the drug binds elsewhere in the protein, altering the structure sufficiently to disfavor ligand binding in its otherwise unoccupied site. Clear examples of this have not emerged, but there are examples of a closely related form of allosterism, **cooperativity**. In this case, allosteric binding of anesthetic *favors* a conformation that binds the endogenous ligand more tightly. In firefly luciferase, for example, the binding of adenosine triphosphate (ATP) and anesthetic is cooperative.[21] Cooperative effects of agonist and anesthetic in some receptors may also be due to binding cooperativity.[19,22]

The second general category of drug–effect coupling is **ensemble modulation** (Fig. 36–12). Functional proteins exist in an ensemble of conformations, each of which is associated with some aspect of activity. Resting, active, desensitized, etc., all describe states of activity with a specific underlying protein conformation. Some conformers may possess binding sites for anesthetics that are more attractive than others and therefore are populated to a greater extent when the anesthetic is present. The anesthetic changes protein activity by selecting the most favorable conformer for binding and increasing its prevalence. One can immediately see the overlap with allosterism. Like allosterism, ensemble modulation can explain either an enhancement or an inhibition in protein activity, depending on which conformer has the most attractive anesthetic binding sites.

The final general mechanism for coupling binding to a change in protein function is **oligomerization modulation** (Fig. 36–13). Much protein activity and signaling is controlled by interactions with other proteins. In general, these interactions are highly specific but relatively weak so that they can be readily reversed. The protein–protein interface may include features attractive to an anesthetic, such as cavities. If these features are optimal when the proteins are linked, then the anesthetic will enhance the interaction or oligomerization; if they are optimal when separated, anesthetics will disfavor oligomerization. Examples of the former appear to be the sarcoplasmic reticular calcium adenosine triphosphatase (AT-

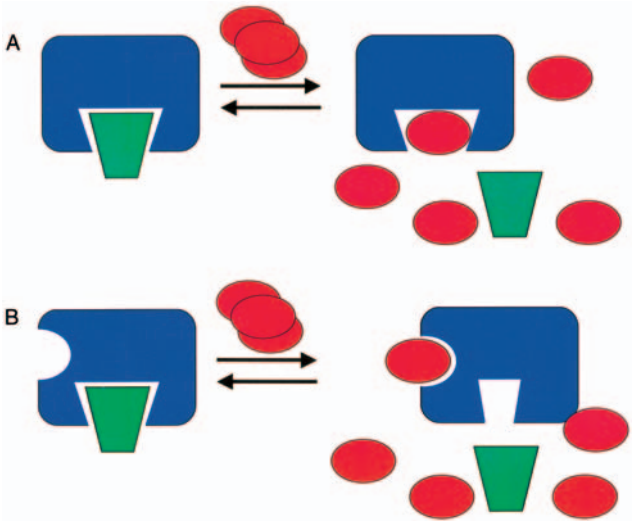

FIGURE 36–11. A. Example of isosteric competition, where the anesthetic (*red oval*) achieves a high enough concentration to actually replace the endogenous ligand (*green trapezoid*) in its site of action. **B.** Example of allosteric competition, where the anesthetic binds preferentially to a conformer that disfavors binding of the endogenous ligand, but at a distant site.

Pase)[23] and of the latter the PSD-95 PDZ domain proteins (see later).[24] The synaptic vesicle machinery is highly dependent on these oligomerization events, and components that might be modulated by anesthetics in this way have been identified.[25] It should be apparent that this mechanism has important implications as to the number of potential effects these drugs might have. Whereas the set of all proteins expressed—the proteome—is very large (~300,000 proteins), the number of protein–protein interactions, the so-called *interactome,* is much larger. Thus, anesthetic effects at the interactome level, produced by effects at the interface, could dwarf those at the individual protein level.

An important caveat in this discussion is that all binding interactions do not necessarily result in an important change in protein activity. It is possible that an anesthetic binding site is precisely preserved across the entire conformation or oligomerization ensemble, in which case anesthetic binding will not alter the distribution of conformers and therefore will have no effect on activity. How commonly this form of "unproductive" binding occurs is not clear.

Summary

Any or all of these general coupling mechanisms may be involved in anesthetic-induced protein dysfunction. The distinction often is difficult but is important if we are to intelligently modify the drugs to favor or disfavor specific interactions.

Potential Protein Targets

As suggested earlier, the anesthetic sensitivity of a number of protein systems has been studied over the past few decades, and, remarkably, many are altered within only a 10-fold range of clinical concentrations. We briefly review some of these systems and the evidence for inclusion. This discussion is not intended to be a comprehensive list of those proteins studied; many have come and gone. Rather, we focus on some of the more recent and compelling candidates, especially those with associated in vivo evidence for a contribution.

Soluble

As pointed out earlier, proteins have domains as hydrophobic as those of the lipid bilayer, and it now is clear that anesthetics bind to and influence the activity of many soluble proteins. Much of the published work involved model systems, such as firefly luciferase, serum albumin, and apoferritin, which are un-

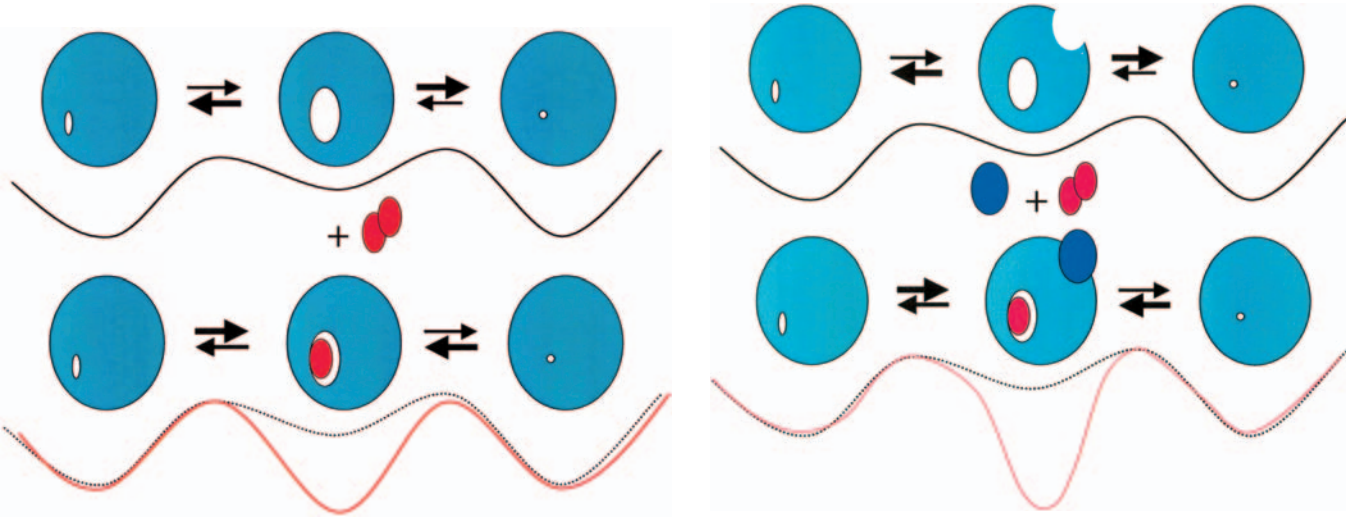

FIGURE 36–12. Simple ensemble of protein conformers, with the relative free energy shown beneath. **A.** Anesthetic favors the conformer with the most attractive cavities, lowering its free energy (*red line*) and increasing its concentration. **B.** Same cartoon demonstrating cooperativity, but in this case the anesthetic-preferred conformer also preferentially binds an endogenous ligand. Thus, free energy is lowered even further in the presence of both ligands, more dramatically enhancing the population and therefore activity associate with this conformer. (Fig. 36–12A used by permission.[104] Copyright 2001 American Society for Pharmacology and Experimental Therapeutics.)

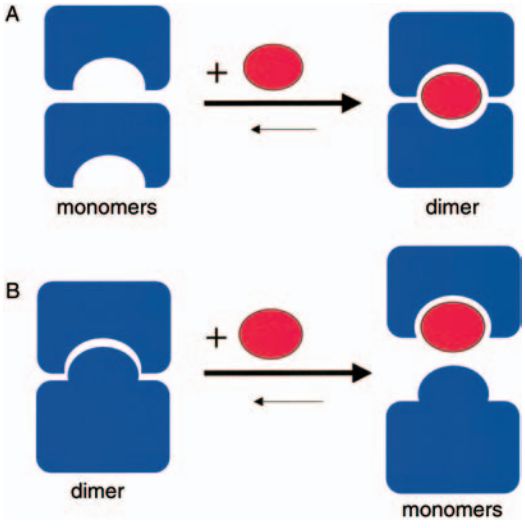

FIGURE 36–13. Example of oligomerization modulation. **A.** Anesthetic binding site is created by dimerization of a monomer that otherwise has no binding site. Thus, the anesthetic will be observed to increase the population of dimer. **B.** On the other hand, occupancy of an anesthetic site in the monomer disfavors binding of the second protein because of a steric clash. In this case, the anesthetic will be observed to decrease the population of dimer. Although both mechanisms may occur in vivo, the situation shown in A probably is more likely.

likely to contribute directly to anesthesia. However, plausible candidates, centrally located in signal transduction cascades or cellular machinery, have emerged. For example, protein kinase C (PKC) transduces receptor activation to phosphorylation of key membrane proteins, such as certain ion channels and other receptors, and has been shown to bind general anesthetics.[26] Alteration of its activity by anesthetics would be expected to have generalized and widespread cellular effects that might contribute to anesthesia, although controversy exists as to both the expected and observed directions of effect (reviewed by Rebecchi and Pentyala[27] and Gomez et al.[28]). Initially thought to be inhibited by general anesthetics, later studies performed under physiologic conditions showed PKC to be activated. This one system demonstrates the complexity of sorting out anesthetic targets and effects. The observed effects in this relatively simple physiologic assay can result from anesthetic effects on membrane lipid, stimuli–kinase coupling, kinase–target coupling, or the phosphorylated target itself. Anesthetics might interact with any component. Studies in intact, genetically altered animals are in progress but to date have not provided unambiguous answers. Further studies on PKC isoform distribution and activity are required to sort out the influence of anesthetics and potential contribution to the anesthetic state.

Another attractive anesthetic target would be any of the components of the cellular cytoskeleton, motility apparatus, and vesicle transport systems. These systems subserve a variety of basic cellular functions, the alteration of which would manifest as a decrease in cellular activity or communication. For example, tubulin forms microtubules, which are crucial elements of cellular scaffolding and motility. Assembly of the monomer into the large tubular oligomer apparently is altered by anesthetics, albeit at high concentration.[29] Entire mechanisms for general anesthesia based on microtubular dynamics and organization have been proposed,[30] and some experimental support has been reported.[31] Oligomerization of actin, a protein acting with myosin and other proteins to subserve cellular motion, is inhibited by anesthetics and is another relatively unexplored potential general mechanism of anesthesia.[32]

Anesthetics also affect the synaptic vesicle machinery. A decrease in synaptic transmission is generally agreed to accompany general anesthesia; therefore, inhibition of synaptic vesicle transport, fusion, and release is a plausible general mechanism of central nervous system (CNS) dysfunction. Evidence comes from several disparate sources. In a genetic screen of the nematode *Caenorhabditis elegans,* mutations in the vesicle fusion soluble N-ethylmaleimide sensitive attachment factor (SNARE) proteins were found to produce resistance to some anesthetic end points.[25] Furthermore, one component, syntaxin, and various SNARE assemblies have been shown to bind isoflurane using nuclear magnetic resonance approaches.[33] Transcript profiling[34] in mammals has shown an upregulation of synaptotagmin, another vesicle release protein. The latter does not necessarily implicate synaptotagmin as a direct anesthetic target, but it lends credence to the idea that synaptic vesicle release is inhibited during general anesthesia. Other synaptic targets implicated are the PDZ domain proteins. These domains are responsible for fusion events (oligomerization) between proteins and are intimately involved in synaptic vesicle trafficking. Work has shown that anesthetics disrupt the oligomerization, and the probable binding site responsible has been identified in a truncated version of PSD-95.[24]

Membrane

Ion Channels A variety of proteins embedded in, and dependent on, the lipid bilayer for their activity are altered by general anesthetics in in vitro assays. Most studied are the ion channels, due in large part to the availability of electrophysiologic approaches for measurement of function. Of the ion channels, most emphasis has been placed on the ligand-gated cys-loop receptor–channel complex, the prototype of which is the nAChR. These proteins are transmembrane heterooligomers of five subunits arranged around a central ion channel. A variety of anesthetics inhibit this excitatory channel, perhaps by promoting the desensitized state via cooperative binding with acetylcholine; the probable basis for the muscle relaxation associated with many general anesthetics. Volatile anesthetics bind this receptor specifically, and a site underlying cooperative binding behavior has been tentatively identified.[17,19] The nAChRs are also found in the brain, adding credibility to the possibility that alterations in their activity contribute to anesthesia. In vivo support of an important role for these receptors is still lacking.

γ-Aminobutyric acid (GABA)ergic neurotransmission was identified 20 years ago as a plausible substrate for anesthetic effects,[35] so recent emphasis has been placed on the inhibitory GABA type A ($GABA_A$) and glycine receptor–ion channel complex as potential contributors to at least the sed-

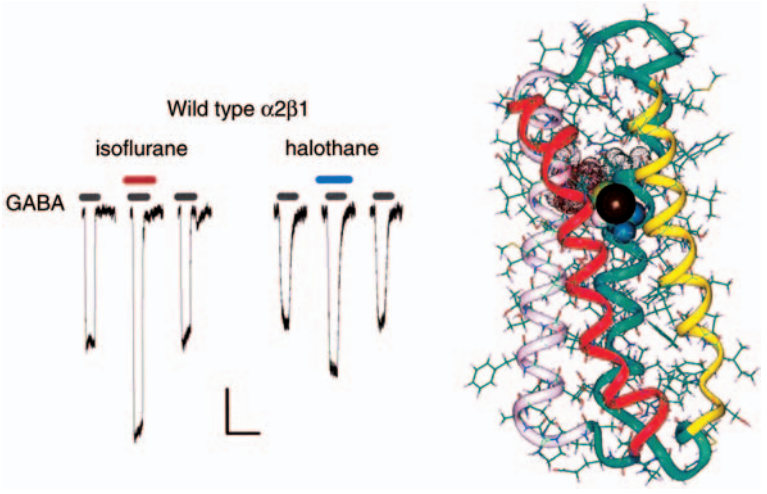

FIGURE 36–14. Enhancement of activity of γ-aminobutyric acid type A ($GABA_A$) chloride conductance by isoflurane and halothane. In both cases, the effect of an endogenous ligand, GABA, is significantly enhanced by the presence of the anesthetic. The probable basis for this is shown in Fig. 36–12B, and the region of the protein thought to transduce this effect is shown on the right by the hypothetical placement of an anesthetic in the interhelical space. Note the similarity of this hypothetical structural motif and binding site to the crystal structure shown in Fig. 36–9. (Fig. 36–14 used by permission.[106] Copyright 2001 by the Society for Neuroscience.)

ative or amnestic component of general anesthesia. Like the nAChR, many general anesthetics (most volatile ones and alcohols) probably bind cooperatively with agonist (either GABA or glycine). However, because these receptors undergo desensitization more slowly that the nAChR, the final effect is enhanced agonist-stimulated currents instead of inhibition (Fig. 36–14). These ion channels are inhibitory (produce hyperpolarization), so enhancement of their activity is expected to inhibit synaptic transmission. The difficulty of isolating or expressing sufficient $GABA_A$ receptor of any subunit composition for biochemical studies so far has precluded the demonstration of specific volatile anesthetic binding.

Most studies to date have focused on the action of volatile anesthetics on $GABA_A$ receptors mediating rapid synaptic transmission. However, volatile anesthetics also act on $GABA_A$ channels mediating tonic inhibition. Tonic $GABA_A$ channels are found in many areas of the nervous system, including the hippocampus and the spinal cord interneurons. Although the precise receptor subunits composing the tonic $GABA_A$ channels remain unknown, the α_5- and δ-subunits likely are involved because tonic currents inhibited by bicuculline are not seen in null-mutant mice devoid of these subunits. These $GABA_A$ channels are more sensitive to agonist than the rapid type, requiring only low micromolar concentrations of GABA for opening, concentrations found in even extrasynaptic regions of a nerve cell. Similarly, tonic $GABA_A$ channels are more sensitive to volatile anesthetics than those mediating rapid synaptic transmission.[36] Because of this sensitivity and expression in the hippocampus, it is reasonable to hypothesize that these channels mediate the amnestic component of volatile anesthetic action. A thorough characterization of the volatile anesthetic effects on the various tonic $GABA_A$ null mutant mice has not been reported.

In an attempt to both find sites of action as well as to implicate anesthetic targets, site-directed mutagenesis has been coupled with electrophysiology. For example, an asparagine to methionine mutation at position 265 in the $GABA_A$ β_3 subunit largely eliminated enflurane enhancement of GABA action in vitro, but the knock-in mouse, in which the wild-type β_3-subunit was replaced by the point mutant, had minimally altered righting reflex sensitivity or MAC.[37,38] Greater success was obtained with the injectable general anesthetics (induction agents) in this same model. For example, like enflurane, etomidate and propofol failed to enhance GABA-evoked currents in vitro, but in this case, the whole animal sensitivity to both injectable drugs was significantly diminished. The technology of mutant receptor knock-in is far superior to an overall elimination of the receptor produced by the knock-out technology because the normal cellular process that regulates expression of the wild-type receptor is preserved. Based on structure–activity studies demonstrating the role of both α- and β-$GABA_A$ subunits[39] as well as other ligand-gated channels in determining volatile anesthetic responsiveness in in vitro expressed receptors, a multiple knock-in mutant mouse in which many sites are simultaneously altered is more likely to exhibit relative resistance to the volatile anesthetics.

Another hypothesis is that the two-pore domain family of background K (KCNK) channels is involved in volatile anesthetic action. This gene family encodes for K^+-selective ion channels with a common structural feature of two protein domains putatively lining the ion channel and four transmembrane domains. Two two-pore domain proteins are thought to assemble as a dimer, creating a complete protein complex with a functional K^+-permeable ion channel normally open at all physiologic membrane potentials, thus contributing to the background leak K channel critical in determining the resting membrane potential and regulating neuronal excitability.[40] Opening of channels encoded by two members of the KCNK family, TREK-1 and TREK-2, and more recently a third member, TRESK, are enhanced by volatile anesthetics, thereby hyperpolarizing the cell membrane. However, the enhancement is not seen in all the family because the channel activity of a closely related member, TRAAK, is not affected. As in the case for $GABA_A$ receptors, the hypothesis that the anesthetic-responsive KCNK channels play a role in the general anesthetic action at the whole animal level was examined and confirmed in TREK-1 knock-out mice. For example, mice without the TREK-1 gene were approximately 20% less sensitive to halothane, sevoflurane, desflurane, and chloroform (but not pentobarbital) as defined by the loss of righting reflex (LORR) and withdraw to tail clamp. Interestingly, an invertebrate analogue of this channel[41] was discovered a decade earlier in the pond snail,[42] pointing out the importance of information derived regardless of the model organism used.

Calcium channels have been studied for years because of the central role of calcium in intracellular signaling. Because of its importance, intracellular calcium is tightly controlled via many systems, including voltage- and ligand-gated channels, exchangers, ATPases, and soluble binding proteins. Many of these systems have been shown to be influenced by anesthetics, although in general the magnitude of effect is modest at clinical concentrations.[43] Nevertheless, small effects on calcium signaling may have large intracellular consequences[44] (see later discussion on relevance), so a summary here is justified. The effects of volatile anesthetics on even one subset of calcium channels, the voltage-gated calcium channels (CaVs), are variable, probably reflecting the molecular heterogeneity of the CaVs. Of the functionally characterized CaV, the N- and P-type channels, which are putative presynaptic channels regulating neurotransmitter release, were inhibited by inhaled anesthetics.[45,46] The best evidence supporting a possible role of inhibition of N-type CaV in the pharmacology of inhaled anesthetics comes from the observation that N-type CaV knock-out mice exhibited increased sensitivity to halothane,[47] although as noted elsewhere in this chapter, this is an extremely common observation regardless of the target manipulated. The T-type CaV channels, although not involved in synaptic neurotransmitter release, play an important role in generating spontaneous oscillatory bursting of groups of neurons in the thalamus thought to be involved in regulating the state of arousal and sleep. The T-type channels are significantly blocked by clinically relevant concentrations of the inhaled anesthetics.[48] The molecular mechanism of how these drugs inhibit the CaV channels is not known but appears to involve acceleration of channel inactivation and slowing of the recovery from this nonconducting state.[49] There is no evidence of anesthetic binding to these targets, so whether this electrophysiologic effect is mediated via anesthetic interactions with lipid or protein is uncertain.

Voltage-gated sodium channels (NaVs) play a key role in regulating neuronal excitability and therefore are a plausible target for the inhaled volatile anesthetics. However, NaVs were largely dismissed as a relevant target because initial studies indicated that high concentrations were required for inhibition in squid axons (reviewed by Elliott et al.[50]). However, later studies of mammalian brain NaVs indicated that these channels are significantly inhibited by lower, more clinically relevant concentrations of volatile anesthetics.[51] In fact, these anesthetics displace specific ligand binding to $GABA_A$ receptors and the NaVs with approximately equal potency,[52] and rank-order effects appears to qualify the presynaptic NaV as a feasible target for contributing to general anesthesia (Box 36–1).

BOX 36–1.

Isoform and State Dependence of Anesthetic Action

It now is clear that voltage-gated sodium channels (NaVs) constitute a family of closely related proteins with distinct physiologic and pharmacologic properties, although which isoforms are present in the presynaptic terminal remains unknown. Systematic comparison of the sensitivity of different NaV isoforms to isoflurane confirmed the differential sensitivity of the different isoforms to this volatile anesthetic.[53] Of curiosity is the observation that volatile anesthetics had no effect on the NaV1.8 tetrodotoxin-resistant isoform predominantly expressed in the primary afferent neurons thought to play a critical role in pain signaling, which could explain why volatile anesthetics exhibit no analgesic property. An additional confounder that may explain some of the inconsistencies reported in the literature is the fact that halothane inhibition of NaV was dependent on coexpression of protein kinase C.[41] Therefore, both the state of the NaV itself (resting vs inactivated) and the presence or absence of other modulatory proteins most likely influence the effect of volatile anesthetics on NaVs.

Receptors The dominant receptor type in the brain is the GPCR. This enormous family includes most of the neurotransmitter and sensory receptors, whether small molecule, peptide, or lipid. These receptors are monomeric and have seven transmembrane domains arranged like an envelope around a central cleft, or cavity. On the cytoplasmic face, GPCRs couple to the heterotrimeric (three different subunits) G-protein messenger systems. The native ligand binding site tends to be at various depths in the interhelical cavity, and although some features are conserved, the site can accommodate a wide variety of ligand structure and chemistry (Fig. 36–15). Ligands range from small molecules (volatile odorants, catecholamines) to small peptides (endogenous opioids). That anesthetics act on these receptors is suggested by the anesthetic-sparing effect of agonists for the dopamine and α_2-adrenergic receptors, in addition to alterations of activity of the eicosanoid receptors.[54] Finally, volatile anesthetics have been shown to bind the conserved agonist site in many of these receptors (Fig. 36–15),[20] producing either inhibition or excitation.[55] Effects downstream of these receptors (e.g., on the G-protein transduction pathway) are also possible. Evidence is ample for anesthetic effects on G-protein mediated signaling[27,54] and the importance to function in vivo. For example, *C. elegans* with diminished Go activity (a negative modulator of synaptic activity) was 2-fold resistant to isoflurane.[56] These effects probably are related to effects on the receptor, or the receptor–G interface, as evidence for

FIGURE 36–15. Structure of the prototypical G-protein coupled receptor (mammalian rhodopsin, PDB No. 1F88) showing the anesthetic binding site (*blue object*) located through photolabeling experiments. Occupancy of this interhelical hydrophobic site competes with native ligand (retinal), a mechanism shown in Fig. 36–10A. The general motif of an interhelical site in a parallel bundle (see Figs. 36–9 and 36–14) is retained. (Used by permission.[20] Copyright 2002 American Society for Pharmacology and Experimental Therapeutics.)

direct binding to any G-protein subunit or the heterotrimeric complex has not yet emerged.[27] This work is highly intricate because of the multiple complexes and states and at this time is unresolved.

Mitochondria Mitochondria have long been suspected as contributing to anesthetic action because of their obvious role in cellular energy production. However, the anesthetic concentrations required for inhibition of ATP production and the apparently slow kinetics for ATP depletion seemed to obviate their role. Recent evidence has renewed interest in the mitochondrion. First, signaling and feedback between mitochondria and cellular consumers of ATP is considerably more precise and rapid than originally thought, effectively eliminating the kinetic argument against their contribution to the anesthetic state. Second, mitochondrial genes have been implicated in unbiased genetic screens in simple organisms (see later). For example, mutations in a mitochondrial complex I subunit gene dramatically increased sensitivity to halothane, enflurane, and isoflurane. As expected, mitochondria isolated from this mutant had a reduced rate of oxidative phosphorylation in the presence of halothane.[57] Furthermore, several subunits of the oxidative phosphorylation complexes, including complex I, were found to bind halothane specifically.[58] Perhaps most importantly, children with biopsy-proven complex I disease were found to be extraordinarily sensitive to the anesthetic sevoflurane,[59] rendering this anesthetic target the only to date that has supportive evidence from the gene, the binding interaction, to the human. The underlying mechanism for how the altered mitochondrial function affects anesthetic sensitivity is unclear, but given the recent evidence that mitochondria modulates synaptic transmission through the regulation of presynaptic Ca^{2+} dynamics,[60] it is possible that the gas-1 mutation affects synaptic transmission. Another potential mitochondrial target is the VDAC-1, an anion channel also related to mitochondrial steroid synthesis and synaptic activity and implicated through halothane and neurosteroid binding assays.[58,61]

Summary

A wide variety of molecular candidates have been examined, and although several are compelling, proof for involvement in the in vivo anesthesia end point is still lacking. But how does one determine the relevance of a molecular interaction to the in vivo effect, especially when it is as complex as consciousness?

MOLECULES TO BEHAVIOR

How to Determine Relevance of In Vitro Assays

The plethora of potential targets, the imprecise definitions of anesthesia, the variable end points, and the low-affinity drugs have conspired to make it difficult to judge the contribution of molecular targets to drug behavior, an already difficult task. As a start, two broad concepts of anesthetic action have been proposed; one favors a single molecular target site (the "unitary" hypothesis), whereas the other proposes that anesthesia results from the combination of actions at many molecular targets (distributed hypothesis). Lipid theories are an example of unitary theories, as are those that focused on the $GABA_A$ receptor. Distributed action hypotheses will require careful dissection of more molecular targets. Historically, the hunt for the volatile anesthetic targets has taken two general approaches: the study of effects on a well-defined and functionally or physically isolated target (bottom-up approach), and those that start with the anesthetic effect on an organism with the goal of defining the target responsible for the observed effect using either genetic or pharmacologic probes (top-down approach). Although both approaches have merits and limitations, it is the complex, dynamic coupling between "top" and "bottom" that has so far made clear conclusions difficult. Next, we discuss how information derived from one approach might contribute to testable hypotheses in the other, and how, when taken together, support for a neurophysiologic *process* (the "middle") rather than an individual protein or behavior, emerges as a likely anesthetic target. It is important to realize that disruption of a process might have multiple contributing, and perhaps synergistic, molecular events.

"Bottom-Up" Approach

This approach has dominated much of the literature on the mechanism of general anesthetic action. Examples are studies of the biochemistry of anesthetic action on a specific signaling cascade, such as activation of a G-protein coupled pathway, studies on the structural nature of anesthetic binding sites in synthetic proteins, and electrophysiology of heterologously expressed ion channels. An important weakness of this approach is that it requires the identification of a system for study based on the inherently biased criterion, plausibility.

Plausibility has driven studies on the effects of anesthetics on the electrophysiology of ion channels expressed in heterologous systems such as the *Xenopus* oocyte. Such electropharmacologic studies have demonstrated effects (enhancement or inhibition) of anesthetics on essentially all the ion channels examined, albeit some requiring higher concentrations of anesthetics than others. Herein lies the principal weakness of the bottom-up approach. How do we determine whether a given effect on a given target contributes to a particular behavioral end point? Discrepancy between the anesthetic concentration required for the effect on a given target protein and the clinical MAC (either positive or negative) has led to a call for dismissal of some putative targets as biologically irrelevant.[62] As we discussed for the relationship between K_d and EC_{50}, the relationship between EC_{50} and MAC is not likely to be linear. The nervous system is complex, and inclusion of even one simple nonlinear process, such as generation of an action potential in a synaptic transmission (a threshold effect), can easily shift an apparently irrelevant in vitro concentration–response relationship to one that is quantitatively consistent with clinical MAC (Fig. 36–16).[44] Even at the *single* synapse level, spatial and temporal integration of postsynaptic currents contributing to the generation of action potentials will interpose further nonlinear processes between a drug action at a receptor and an observable output. A simple cascading of multiple processes, each well described by a conventional continuous concentration–response curve (i.e., Hill equation), will further shift the composite concentration–response curve to the left with an increase in the Hill slope.[63,64] Thus, a quantitative discrepancy in the experimentally and clinically observed concentration–response relationship cannot discredit the biologic relevance of a putative anesthetic target.

Given the apparent difficulty of linking molecular events and behavior, other

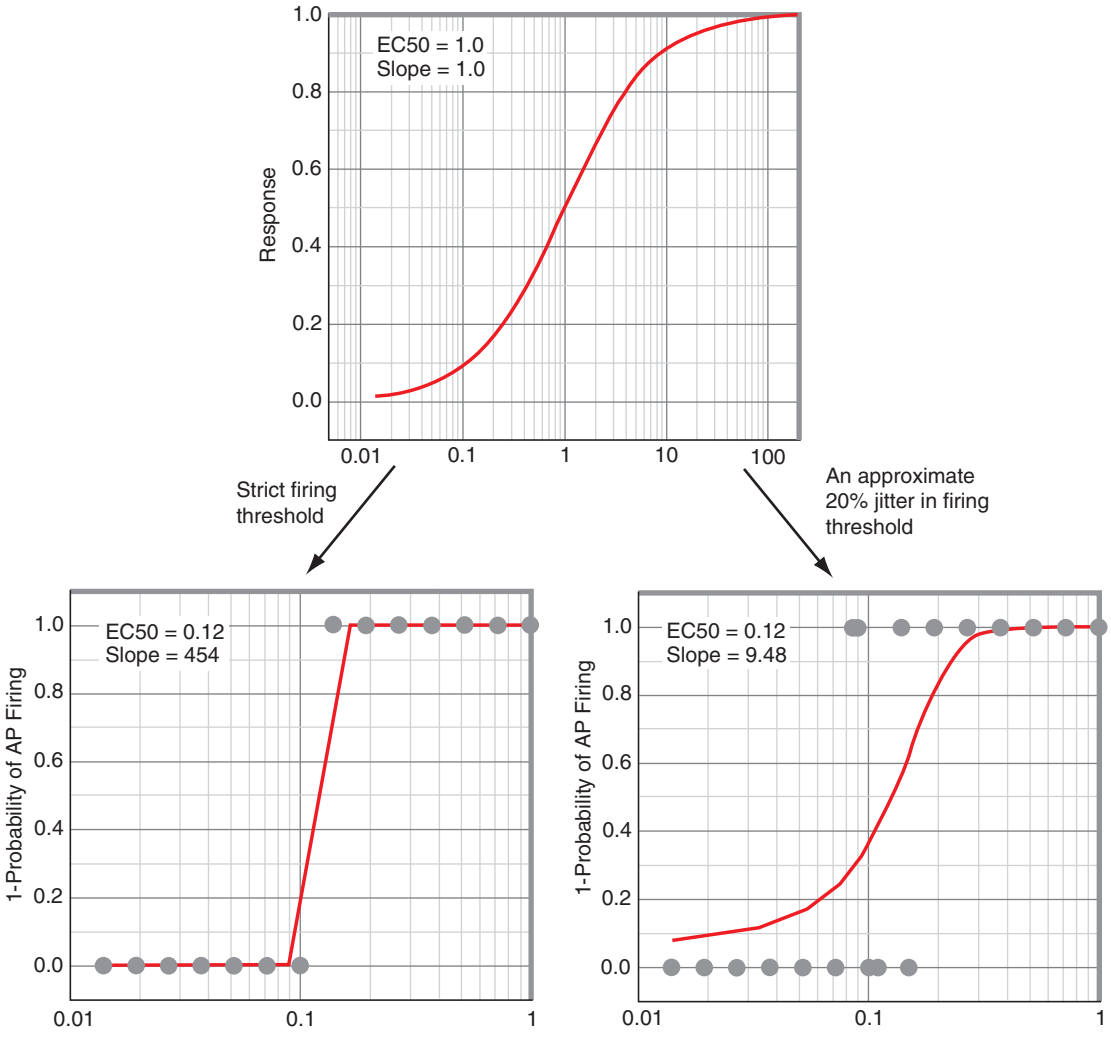

FIGURE 36–16. Effects of a single nonlinear threshold process on a continuous concentration–response relationship describing a volatile anesthetic (VA) action. **Top.** Simulated continuous concentration–response relationship of a VA action on a response described by Response = [VA]/([VA] + 1), yielding EC_{50} = 1.0 and slope = 1.0. Suppose the response represents enhancement of γ-aminobutyric acid (GABA)ergic inhibitory post-synaptic current (IPSC) decay rate and that initiation of an action potential is inhibited by a 10% increase in the IPSC duration. If the threshold for action potential (AP) firing is set at exactly 10% with no variability, we obtain an effective concentration response described by a logistic equation with EC_{50} = 0.1 and slope = 454. **Bottom left.** If we incorporate an approximate 20% jitter in the AP firing so that on occasion IPSC prolongation slightly › 10% fails to inhibit and likewise a VA-induced event slightly ‹ 10% inhibits AP firing, we obtain the relationship on the right, described by EC_{50} = 0.1 and slope = 9.48. **Bottom right.** Further cascading of more threshold events in between the continuous concentration–response, such as those obtained in in vitro studies, and the final anesthetic end point, such as immobility to noxious stimulus surely to be present in even the simplest neural pathway, will result in a large transformation of the overall concentration–response relationship, giving little credence to using the sensitivity or the slope of a concentration–response relationship to include or exclude a putative VA target.

"litmus test" criteria have emerged. For a target to be seriously considered as a candidate, most agree that the anesthetic must actually occupy a binding site in or on the target (see earlier). Thus, it is remarkable how many candidates are being favored in the complete absence of binding data. Other criteria used to establish relevance are Overton-Meyer behavior (correlation of potency with lipid solubility), enantioselectivity, sensitivity (correlation of in vitro EC_{50} with MAC), lack of response to nonimmobilizer compounds, hydrostatic pressure reversal, cutoff, and plausibility. For example, if differences in potency exist in the intact organism for the enantiomers of a given anesthetic, then the targets responsible for this anesthetic effect also should exhibit this difference in potency in vitro. If the organism fails to lose consciousness with a particular compound (e.g., F6 or F8), then any related molecular target also should remain unaffected.[65] However, this litmus test logic assumes that a single target can produce anesthesia, and now that several molecular targets have emerged that satisfy many of these criteria, such criteria should be viewed with considerable skepticism.

A final means of establishing linkage of the molecular event with the behavior involves use of specific pharmacologic probes. For example, concentration–effect experiments with anesthetics can be performed in the presence of other sedative drugs, and then the interaction can be characterized as synergistic, additive, or antagonistic through isobolographic analysis. If the second drug is known to be highly specific for a given molecular target, then some insight might be gained into the targets used by anesthetic. Although this approach has identified many potential targets for the inhaled anesthetics, its use has been somewhat reduced by the fact that the second drug rarely produces the same

end point as that of the anesthetics. For example, the opioids and the benzodiazepines, unless given in very high doses, do not produce the MAC end point, whereas this is the standard end point for the volatile anesthetics. Yet in both cases, the second drug decreases the volatile anesthetic MAC by 10–50%. Agonism at the GPCR α_2-adrenergic receptors reduces anesthetic requirements by as much as 90%,[66] although whether synergistic or additive cannot be clear because these agents cannot independently reach this end point. Finally, this pharmacologic approach is further confounded by the fact that the effects are global, and it now is recognized that the same targets may have important influences only regionally (see later).

Summary Bottom-up studies allow for well-controlled experiments with well-defined end points (e.g., examination of the extent of anesthetic potentiation of $GABA_A$ receptors) and for straightforward subsequent genetic manipulation of the target protein through conventional site-directed mutagenesis of the complementary DNA encoding the protein of interest expressed in vitro. However these approaches are primarily useful for generating *testable hypotheses,* where the biologic relevance of the putative target can be proposed and then examined in a more intact system, such as with targeted pharmacologic or knock-out, knock-in, or knock-down genetic approaches.

"Top-Down" Approach

An alternative approach to determining the sites and mechanisms of drug action is a "top-down approach" where the starting point is an individual or a population of intact organisms. Populations typically harbor random mutations in their genome, and thus individuals with high or low sensitivity to volatile anesthetics can be identified through standard potency experiments and the potential molecular basis hypothesized based on the discovered genetic differences. For example, strain differences in mice have been demonstrated[67] but are small (< 50%), and the underlying genetics appear to be complex. This approach is limited, however, because it requires that considerable variability exist within the population of organisms in order to clearly select for the differences. The Hill slopes of 20 in the human population suggest that sufficient variability in the response does not exist in order for this to be a productive approach, unless enormous numbers of individuals can be tested.

Although difficult in human studies, such numbers can be easily studied in simple organisms, such as the fruit fly *Drosophila melanogaster* or the worm *C. elegans*. These systems give the added advantage of relatively easy identification of the genetic defect from the selected population, an approach called "forward genetic" screening. The primary advantage of such a system lies in the possibility of revealing a direct correlation between a genetic target and a complex behavior involving no a priori assumptions or biases. Furthermore, the natural prevalence of mutations often can be considerably enhanced by chemicals or ultraviolet light in these simple systems, greatly increasing the odds of finding interesting alterations. On the other hand, the fundamental limitation of simple model systems lies in the definition of the anesthetic state or the behavioral end point used and its relevance to the state of general anesthesia in higher organisms. For example, the yeast *Saccharomyces cerevisia* is an enormously useful eukaryote for genetic studies, but how can one possibly define anesthesia in the absence of behavior? Is anesthetic-induced immobility in a nematode analogous to anesthesia? Should similar end points be chosen across species, *immobility* for example, independent of the anesthetic concentration dependence, or should arbitrary end points be chosen that happen to have similar concentration–response relationships across species? Will determining the genetic basis for anesthetic-induced growth inhibition in the yeast, or escape behavior in the fly, tell us anything about how anesthetics work in a human? Although such questions are legitimate and vexing, conservation of biologic processes throughout phylogeny has been proven time after time, and a fundamental biologic mechanism operating in simple organisms is likely to have a homologous mechanism in the more complex organisms. Research using the forward genetic approach to seek the volatile anesthetic site of action in simple organisms has yielded several exciting potential targets.

Similar to humans, nematodes have different behaviors that demonstrate different sensitivity to anesthetics. For example, complex behaviors such as mating, chemotaxis, and coordinated movement are inhibited at halothane concentrations similar to human MAC values,[25] whereas immobility occurs only at concentrations approximately eight times higher (Fig. 36–17).[68] The top-down screening of a de novo mutagenized population using immobility as the end point has identified genes encoding the worm homologues of two mammalian proteins as the genetic basis for increased sensitivity to anesthetics (resistant organisms for the immobility end point have not been discovered): a subunit of mitochondrial complex I protein (see earlier) and stomatin, a transmembrane protein enriched in the lipid raft microdomains. Interestingly, these studies have clearly documented that these mutations do not affect sensitivity to all volatile anesthetics, the first solid evidence against a unitary hypothesis of volatile anesthetic action. A very powerful tool in these simple creatures is that suppressors (i.e., strains with additional mutations that negate the phenotype of the original mutation) can be sought. Identification and function of the suppressor then can be reconciled with that of the original mutation to provide validation and further understanding of the underlying pathways and mechanisms. For example, a suppressor of the worm mitochondrial complex I mutation was found that increased the capacity for oxidative phosphorylation in isolated mitochondria and partially restored-wild type anesthetic sensitivity in the intact worm.[69] This strengthens the association between anesthetic sensitivity and mitochondrial function.

A similar screening of *C. elegans* mutants using the loss of more complex behaviors, such as coordinated movement, as the behavioral end point identified the syntaxin-1A gene, mentioned earlier,[25] as being associated with anesthetic resistance (up to 6-fold). Further work, including binding studies and suppressors, has provided evidence for the involvement of syntaxin-1A in anesthetic action and has led to the attractive and intuitive hypothesis that anesthetics interfere with the release of neurotransmitters at the presynaptic terminal, producing a general reduction in synaptic transmission (see later).[70] Again, these simple creatures have provided compelling hypotheses for testing in higher organisms.

Moving up the complexity and evolutionary scale, studies in *D. melanogaster* have documented that specific ion channels can contribute to volatile anesthetic sensitivity (Fig. 36–18). For example, forward genetic screening has succeeded in isolating a putative

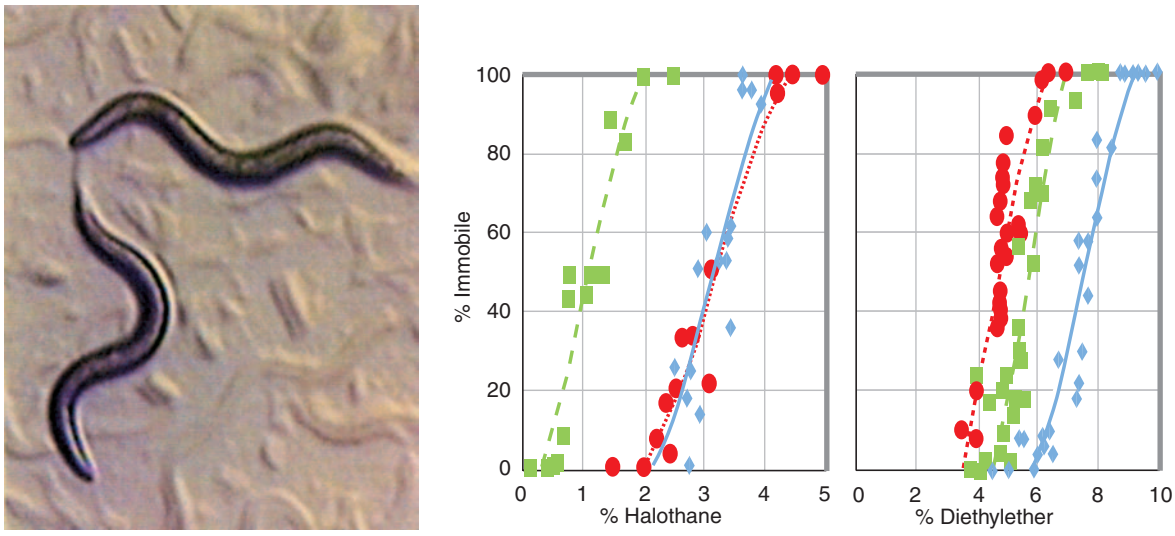

FIGURE 36–17. "Worm" model. *Caenorhabditis elegans* is only 1 mm long, but the short generation time, the ease of manipulation, the fully understood genome, and the presence of complex behaviors have made it a popular model for anesthetic studies. **Right.** Anesthetic dose–response curves for the wild-type and for more sensitive mutants (shifted to the left). (Graphs used by permission.[107] Copyright 1990 National Academy of Sciences.)

ion channel resembling the voltage-gated sodium and calcium channels as important for anesthetic-induced immobility.[71] As in the worm, the different ion channels show variable sensitivity to different volatile anesthetics, suggesting that multiple neurophysiologic mechanisms mediate the action of different anesthetics even in simple organisms.

A final related approach that avoids investigator bias is assaying for the genes or proteins whose expression is altered during or after exposure to volatile anesthetics. This approach carries the tenuous assumption that the organism will choose to alter the expression of those targets directly affected by the anesthetic in an attempt at homeostasis. In some published studies, the expression of many genes or proteins is altered.[72,73] However, using a more (perhaps overly) rigorous statistical approach, a study found only a modest transcriptional response after considerable exposure to either halothane or isoflurane in both animals and cells.[34] It is still too early to summarize this approach because the methodology, analysis, and interpretation are evolving.

Taken together with the evidence presented, observations from both bottom-up and top-down studies clearly suggest that a search for a small number of targets for volatile anesthetic action in a complex organism is overly simplistic and unlikely to yield a satisfactory or interpretable answer. However, future studies using novel methods for confirming a critical role of a given genetic defect in determining the inhaled anesthetic sensitivity may yet prove that our arguments against the unitary hypothesis are erroneous.

Integration of Molecular Responses

If anesthesia is an integrated response to a large number of molecular events, then validation at the molecular level, or in translational attempts of single candidates, will be difficult. For example, the most popular means of testing hypotheses from both bottom-up and top-down approaches is to produce genetically altered animals (usually mice). As mentioned for $GABA_A$ receptors, this form of validation suffers from at least two weaknesses. First, in a knock-out (null mutant) animal, developmental compensation may occur in multiple associated pathways, possibly providing new mechanisms for anesthetic-induced perturbations. However, this does argue against highly specific "unitary" targets because the likelihood that such adaptation in other components of the pathway will produce similarly unique and functionally active binding sites seems rather small. The second weakness, for both knock-out and knock-in strategies, is that the physiologic alteration may be of sufficient magnitude to render end point evaluation difficult (e.g., seizures, lethality). Consistent with these concerns, this means of testing individual targets has generally yielded ambiguous results.

A large number of targets does not rule out a unitary mechanism of action, however. Such a mechanism might be found at a higher level of resolution, such as at the level of a neurophysiologic process. Candidates at this level are numerous but could include transcription or translation, mitochondrial activity, membrane resting potential, action potential conduction, and synaptic transmission. Each process has multiple and overlapping molecular contributors.

Decades of study have implicated the *synapse* as a key neurophysiologic substrate affected by volatile anesthetics.[74] This idea initially was based on the simple observation that axonal conduction of action potentials was more resistant to volatile anesthetics than synaptic transmission. Insight gained from the large number of bottom-up and top-

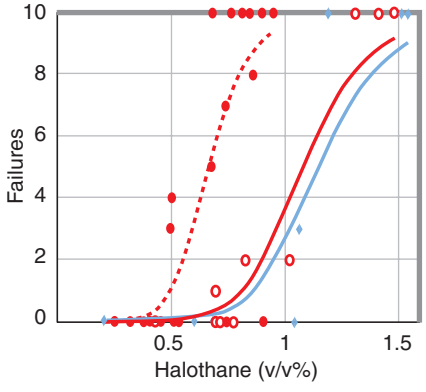

FIGURE 36–18. "Fly" model. *Drosophila melanogaster* is a similarly popular organism for anesthetic studies for the same reasons as is the worm but is a somewhat more complex organism. EC_{50} concentrations in this assay are more analogous to those required for immobility in mammals and shown are hypersensitive mutants. FIGURE 36–19. Some potential targets of inhaled anesthetics in the synapse. Synaptic transmission is a likely neurophysiologic process targeted by the inhaled anesthetics. On the presynaptic side, interference with calcium channels or mobilization of intracellular calcium[109] will reduce neurotransmitter release and perhaps cause synaptic failure. Interference with vesicle trafficking and fusion proteins[110] would clearly add to this effect. Heterotrimeric G-protein and G-protein coupled receptors (GPCRs) also are likely to affect anesthetic sensitivity, as already demonstrated in *Caenorhabditis elegans* and other systems. Thus, the seemingly unrelated putative protein targets of volatile anesthetics already revealed by both the bottom-up and top-down studies may play a key role in the presynaptic events of transmission. So too are the dynamics of transmitter concentrations in the synaptic cleft. The activity of all the major neurotransmitter transporters is altered by volatile anesthetics, either raising or lowering synaptic cleft concentrations. This is important because of the apparent cooperativity with anesthetics in some postsynaptic receptors [ligand-gated channels (LGIC)] or the competition with others (some GPCRs). Finally, the effects on many postsynaptic receptors already alluded to are thought to contribute to anesthetic action. Likewise, increased "shunting" of the postsynaptic charge due to enhancement of the KCNK leakage channels or tonic γ-aminobutyric acid type A ($GABA_A$) channels will limit depolarization of the postsynaptic membrane and likely preclude the generation of postsynaptic action potentials. Anesthetic action on other lipophilic proteins, such as stomatin and others residing in lipid rafts enriched in signaling proteins, could disrupt the signaling initiated by neurotransmitter activation of the myriad of metabotropic receptors regulating synaptic transmission. Presynaptic: GPCR (*blue*), G-protein coupled receptor with associated heterotrimeric G-protein (αβγ); VGIC (*green and purple*), voltage-gated ion channels, either calcium (Ca) or potassium (K); LGIC (*orange*), tonic ligand-gated ion channels; NT (*dark blue*), neurotransmitter transporters; SNARE (*orange*), synaptic vesicle transport and fusion proteins; V (*light green*), synaptic vesicles; ER, endoplasmic reticulum, containing ryanodine receptors (*magenta*) and inositol-trisphosphate channels (*yellow*); M, mitochondria, containing ATP-gated potassium channels (*green*), the respiratory complexes (RC, *orange*), and the voltage-dependent anion channel (VDAC, *dark blue*) with its associated peripheral benzodiazepine receptor (PB, *yellow*). Postsynaptic: LGIC (*red*), ligand-gated ion channels such as $GABA_A$, AMPA/KA, nicotinic cholinergic, $5HT_3$; GPCRs, neurotransmitter G-protein coupled receptors; PKC, protein kinase C; KCNK, tandem pore potassium channels (TREK, TASK, etc.); SC, sodium channels; LGIC (*orange*), tonic ligand-gated channels.

down studies of volatile anesthetics has supported and refined the notion that synaptic transmission is the most likely neurophysiologic *process* targeted by these drugs (Fig. 36–17).

Synaptic transmission, although the most fundamental unit of intercellular information transfer in the nervous system, is a highly complex process in itself (Fig. 36–19). When an action potential arrives at the presynaptic terminal, an increase in presynaptic Ca^{2+} concentration via voltage-gated calcium channels and release from intracellular stores activates the synaptic vesicle release machinery orchestrated by, and consisting of, a myriad of proteins. After release into the synaptic cleft, the concentration of transmitter available to the postsynaptic receptor is influenced by neurotransmitter uptake pumps and degradative enzymes for some synapses. On activation of the postsynaptic receptor (G-protein coupled or ligand-gated channel) and the consequent influx of ions and activation of cellular signaling molecules, the change in charge distribution may produce depolarization of the postsynaptic membrane and formation of an action potential if the threshold is exceeded. Thus, it should be clear that anesthetics can and do have an effect at each of the many points in the process.

Given a focus on synaptic transmission as a key *process* targeted by volatile anesthetics, some predictions can be made on the anesthetic phenotype of some mice not yet examined. For example, the null-mutant mice for the various calcium channels or release mechanisms that regulate presynaptic

BOX 36–2.

Further Definition of Targets within the Process

Despite the logical appeal of a forward genetic approach to identifying volatile anesthetic sites of action, a well-defined population of mouse mutants amenable to this approach is not presently available, relegating the genetic approach to volatile anesthetic site-of-action research to a painstaking testing of a specific mouse mutant. However, a true forward genetic screening to allow identification of volatile anesthetic sensitive-gene products in mice may be possible in the near future. A concerted effort using state-of-art techniques, including gene targeting, gene trapping, and RNA interference to produce mouse mutants on a large scale with the ultimate goal of creating knock-outs covering a substantial portion of the entire genome, is under way.[76,77] Of course we must be cognizant of the usual caveats of the inherent strain differences in anesthetic sensitivity[67] and genetic compensation in the traditional global knock. A combination of gene trapping and site-specific DNA inversion methods[78] may allow large-scale production of conditional knock-out mice in animals from a uniform background that could overcome these limitations. The technical ingenuity of all these approaches is that the genetic basis for any observed phenotype can be traced back with relative ease because the site of gene disruption is traceable, much like in the fruit fly and the worm model systems. Such projects envision a systematic hierarchical phenotyping of every mutant, starting with a low-cost tier I screen (home-cage observation, physical examination, blood hematologic and chemistry profiles, and skeletal radiographs), followed by a more specialized tier II screening with all results publicly available. In order for the general anesthesia research community to take advantage of these upcoming international scientific resources, an inexpensive large-scale screening of volatile anesthetic sensitivity in mice must be developed. Integration of results garnered from the bottom-up approach and the top-down approach, particularly in mice, while cognizant of a "neurophysiologic process" as the true target for the complex action of volatile anesthetic, is likely to provide a clearer picture of how these clinically essential drugs produce clinical general anesthesia.

calcium dynamics, all with impaired synaptic transmission, should demonstrate increased sensitivity to volatile anesthetics. In contrast, mouse mutants with enhanced synaptic transmission, which may result from mutations increasing neurotransmitter concentration in the synapse, should exhibit decreased sensitivity to anesthetics. If we assume that the state of clinical general anesthesia is a manifestation of all the downstream consequences of the failure of synaptic transmission, there will be many more, yet unidentified target proteins and processes contributing to this complex drug action. However, interpretation of the anesthetic phenotype of any gene-targeted mice must take into consideration the likely redundancy built into any complex system and the possibility of compensatory changes in the conventional null-mutant mice.

A model where a process is altered by widely distributed and perhaps small input effects also predicts difficulty in altering the output with isolated input manipulations. Analogy may be found on the Internet, where many coordinated small and essentially undetectable influences on router function (colluding routers) can have a considerably larger effect on Internet "function" than a few large and easily detected router "meltdowns."[75] A small-effects-at-multiple-targets model leads to predictions that so far have been largely verified. For example, altered plausible molecular targets with clear alteration of anesthetic effects in isolation, when introduced in a system or process context, produce little, if any effect, on anesthetic sensitivity. Although in biologic systems this is complicated by the principle of homeostasis and compensation, this observation appears to be consistent. In no case has a mutation of an individual target, or highly specific drug, altered anesthetic potency by > 20–50%. Furthermore, the facts that antagonists have not emerged, that there is little biologic variability, and that there is no adaptation, even when the drugs are given continuously for weeks, all argue for a highly distributed, redundant molecular effect. Redundancy is often used in systems design to produce reliability, a feature synonymous with low variation. Reliability of anesthetic action is a clinical feature we cannot afford to ignore, but its foundation in a distributed mechanism is a scientific feature that will be difficult to sort out.

Neuroanatomic Substrates

A process may be widely distributed within the nervous system (e.g., synaptic transmission), but the influence of its dysfunction could be sensed and exhibited regionally. Although there is no evidence for regional binding of anesthetic (Fig. 36–8), binding targets may be positioned within networks and pathways that rely on their neurotransmitter types and regional interactions for higher functions, such as behavior. Thus, GABAergic enhancement in the spinal cord or the cerebellum may have very different functional effects than enhancement in the hippocampus. The different functional components of general anesthesia likely arise from such regionality (Box 36–2).

Thus, volatile anesthetics produce a composite state that can be subdivided into functional components, which include amnesia, unconsciousness, analgesia, muscle atonia, and autonomic nervous system modulation. Each may represent specific interactions of general anesthetics upon discrete neuronal loci. Just as the search for molecular targets of anesthetic action have revealed multiple sites of modulation, so too has the hunt for cellular sites of anesthetic action. In this section, we focus upon different features of the anesthetic state that arise from anesthetic actions in various parts of the CNS.

Anesthetics and Immobility

The MAC end point (see Chapter 37) is defined as the minimum alveolar concentration of an agent that is required to suppress movement in response to a defined noxious stimulus. It should not be surprising, then, that anesthetics appear to exert their immobilizing effects most sensitively through interactions within the spinal cord. For example, transection of the brain at the level of the inferior colliculus does not alter MAC of inhaled anesthetics in mammals.[79] Although such lesions ablate ascending and descending forebrain and midbrain communications with the spinal cord, they do not impair spontaneous ventilatory efforts because brainstem respiratory groups are left intact. This works sug-

gests that MAC is primarily determined by a direct action of anesthetics upon the CNS at a level caudal to the brainstem—the spinal cord. Further work in multiple species supports this hypothesis. Surgical isolation of brain and spinal cord blood flow in goats (which lack significant cerebral perfusion from vertebral arteries) allowed independent determination of MAC. Delivery to the brain required a > 2-fold higher concentration than did whole animal MAC, suggesting that immobility is produced via direct interactions within the spinal cord.[80,81] In vitro evidence of anesthetic effects upon spinal cord has also been obtained. All volatile anesthetics tested to date appear to suppress the excitability of spinal motor neurons; however, even within the spinal cord different anesthetics exert their effects at multiple sites. For example, halothane reduces noxious-evoked movement via depression of dorsal horn neurons, whereas isoflurane appears to have smaller effects upon these sensory neurons yet produces an identical inhibition of movement by exerting a relatively greater suppression of anterior horn motor neurons or interneurons.[82]

Anesthetics and Hypnosis

Although the neural substrate responsible for generating consciousness remains unknown, much has been learned about the systems responsible for its nightly loss and subsequent return during the normal process of sleep. The physiologic changes associated with unconsciousness induced by both anesthesia and sleep are strikingly similar. They include decreased minute ventilation, blood pressure, heart rate, core body temperature, motor tone, and, most importantly, responsiveness to external stimuli. Positron emission tomography, used to study cerebral blood flow during both sleep and anesthesia, has confirmed that similar alterations in regional cerebral blood flow, metabolism, and regional neuronal activity occur during both sleep and general anesthesia.[83] These similarities and others (documented in the following) have led to the speculation that sleep and general anesthesia share an underlying neural substrate. Consistent with this hypothesis is the observation that an individual's underlying state of arousal alters anesthetic sensitivity. In rodents, loss of consciousness typically is assessed by the LORR behavioral assay, in which animals turned from supine to prone are unable to right themselves. Using this end point, Einon et al.[84] noted that the hypnotic duration of pentobarbital was prolonged when the drug was administered to rats during their sleeping hours compared with their normally wakeful hours. Sleep deprivation acts synergistically with anesthetics, reducing the dose of anesthetic required for hypnosis and allowing recovery from sleep deprivation.[85]

Further linkage between sleep and anesthesia derives from pharmacologic studies. Endogenous somnogens such as adenosine, which can induce sleep, also potentiate the hypnotic effects of inhaled and intravenous anesthetics and delay emergence from anesthesia.[86] Moreover, anesthetic exposure appears to affect levels of endogenous somnogens, such as prostaglandin D_2.[87]

Despite these overlapping features, it is clear that sleep and general anesthesia have important differences. The most notable is that sleep is readily reversed through external stimuli, whereas anesthesia is reversed only upon discontinuation of the anesthetic drugs. Another primary difference is that anesthetics appear to inhibit systems required for rapid eye movement (REM) sleep as well as cortical arousal.[88] Hence, general anesthesia has been likened to a form of non-rapid eye movement (non-REM) sleep from which one cannot be easily aroused.[83]

The similarities between non-REM sleep and general anesthesia extend to various measures of the electroencephalogram (EEG). For example, both power spectrum analysis and the bispectral index[89] show a high degree of similarity between non-REM sleep and general anesthesia. EEG entropy, a measure of the disorder inherent in the EEG, declines during deep non-REM sleep and during general anesthesia.[90,91] In both instances, as non-REM sleep or anesthetic depth increase, the EEG becomes more ordered, further reducing EEG entropy.

Neural Circuitry of Arousal

Similarities between general anesthesia and non-REM sleep have led to the speculation that the two states share a common underlying neural network. The degree of arousal is determined by the coordinated activity of several nuclei within the brain. One such region, the ventral lateral preoptic (VLPO) nucleus located in the anterior hypothalamus, was found to contain the only group of cells specifically active during non-REM sleep.[92] Subsequent studies in rodents using in vivo electrophysiologic recordings together with polysomnography have proved that VLPO neurons are sleep active, firing rapidly during sleep while being inhibited during wakefulness. VLPO neurons send projections to the orexinergic and all of the monoaminergic wake-active centers in the brain[93] (Fig. 36–18) and express the inhibitory neurotransmitters GABA and galanin. Hence, through GABA-mediated signaling, VLPO neurons inhibit wake-active centers responsible for regulating vigilance and cortical arousal and thereby favor sleep.

The major arousal centers, located in the hypothalamus and brainstem, consist of the orexinergic neurons (Ox) concentrated around the perifornical and lateral hypothalamus as well as the histaminergic cells in the tuberomammillary nucleus (TMN), the noradrenergic cells in the locus caeruleus (LC), the serotonergic cells in the dorsal raphe nucleus (DR), and the cholinergic mesopontine neurons in the lateral dorsal tegmentum (LDT) and pedunculopontine tegmentum (PPT). As a group, the TMN, LC, and DR (monoaminergic neurons) as well as the orexinergic neurons are maximally active during wakefulness, decrease their firing rate during non-REM sleep, and are virtually silent during REM sleep. These neuronal groups send diffuse projections that innervate the entire neuraxis. The cholinergic brainstem arousal system also displays state-dependent activity. However, unlike the orexinergic and monoaminergic groups, the brainstem cholinergic neurons show highest activity during both wakefulness and REM sleep and virtual quiescence during non-REM sleep.[93]

Anesthetic Effects on Arousal Centers

As is the case for natural sleep, early pharmacologic, lesion, and more recent gene knock-out studies indicate that the hypnotic component of general anesthesia is modestly affected by modulation of any of the monoaminergic, orexinergic, or cholinergic wake-active systems. Thus, at the systems level, general anesthetics produce unconsciousness in part by inhibiting arousal. Disruption of cholinergic neurotransmission, in particular, appears to participate in the hypnosis associated with halothane, isoflurane, sevoflurane, propofol, opioids, and ketamine. Consistent with this is the observation that physostigmine, an acetylcholinesterase

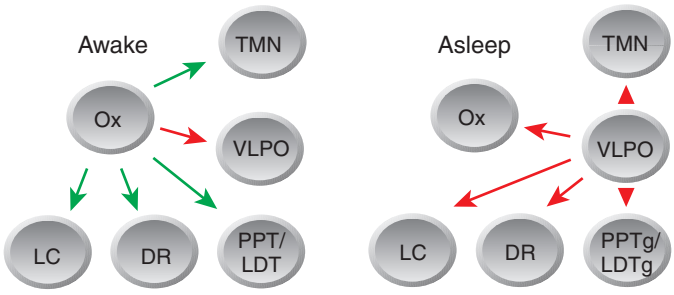

FIGURE 36–20. Endogenous arousal neural circuitry. Mutual antagonism between VLPO and hypothalamic orexinergic neurons influences state of arousal along with contributions from other members of the reticular activating system: TMN, LC, DR, PPT, and LDT. During non-rapid eye movement (NREM) sleep, VLPO activity predominates, inhibiting firing of TMN, LC, DR, PPTg, LDTg, and Ox neurons. Conversely, during wakefulness, orexinergic neuronal activity inhibits VLPO and excites other members of the reticular activating system. Excitatory connections are shown in green. Inhibitory connections shown in red. DR, dorsal raphe; LC, locus caeruleus; Ox, orexin neurons; PPTg/LDTg, pedunculopontine and lateral dorsal tegmentum, respectively; TMN, tuberomammillary nucleus; VLPO, ventrolateral preoptic nucleus.

inhibitor that crosses the blood–brain barrier, partially antagonizes sevoflurane or propofol hypnosis[94] In addition to interacting with other wake- and sleep-active groups, cholinergic brainstem nuclei such as the LDT and PPT project to the thalamus and cortex. When these brainstem centers are activated, desynchrony of the EEG typical of wakefulness or REM sleep occurs (reviewed by Jones[95]). Conversely, when cholinergic output of the LDT and PPT is inhibited, as occurs with general anesthesia (see discussion of anesthetic effects on nAChRs), EEG activity in the cortex assumes a striking similarity to that seen during non-REM sleep.

Similar to the cholinergic centers, monoaminergic centers are most active during wakefulness. The noradrenergic LC has long been known as a region of brain associated with vigilance. Independent excitation of the LC enhances an individualís state of arousal, whereas reduction of theLC firing rate decreases alertness.[96] Inhibition of the LC appears to be a primary mechanism of action through which the α_2-adrenergic agonist dexmedetomidine exerts its strong hypnotic effect.[97] Inhibition of the LC further destabilizes wakefulness by releasing inhibition of the sleep center VLPO. Classic pharmacologic studies over the past 5 decades have demonstrated that increasing central adrenergic output from the LC is associated with an increased anesthetic requirement, a fact known to any anesthesiologist caring for a patient who recently ingested cocaine, amphetamines, or similar psychostimulants. Conversely, decreasing catecholaminergic output reduces MAC, as evidenced by reserpine or α-methyldopa depletion experiments and by isolated destruction of the LC.

Modulation of serotonergic output from the DR also affects anesthetic sensitivity. As with the LC, lesion and pharmacologic inhibition of serotonergic signaling reduces MAC. Blockade of 5-hydroxytryptamine 2A (5-HT_{2A}) receptors with the two different antagonists has been shown to reduce the MAC of isoflurane and halothane. When combined with in vitro data demonstrating that inhaled anesthetics such as isoflurane inhibit signal transduction mediated through G-protein coupled 5-HT_{2A} receptors, these data suggest that 5-HT_{2A} receptors are in the neural circuitry influencing MAC.[98]

Like other aminergic nuclei, the histaminergic neurons of the TMN are part of a phylogenetically ancient arousal system, conserved across vertebrates. The TMN is reciprocally connected to, and tonically inhibited by, other neurons of the VLPO. In brain slice studies, norepinephrine inhibits GABAergic activity in the TMN and thus releases inhibition. Serotonin and orexin depolarize the TMN through activation of an electrogenic sodium/calcium (Na/Ca) exchanger, suggesting that the TMN is excited by increased activity of the other wake-active arousal centers. Moreover, activity of TMN neurons has been linked to hibernation as well as to the hypnotic component of general anesthetic action.[99,100] As discussed earlier, one molecular mechanism shared by many (but not all) anesthetics is their ability to potentiate inhibitory GABAergic signaling. Nelson et al.[100] establish the TMN as an important neuronal site mediating the sedation of propofol, pentobarbital, and the classic $GABA_A$ agonist muscimol because the anesthetic facilitation of $GABA_A$ receptor signaling inhibits the tonic TMN inhibition of VLPO activity.

Orexinergic neurons release the neuropeptides orexin-A and orexin-B (also called hypocretin), thereby coordinating and stabilizing the activity of the entire reticular activating system during wakefulness. Orexinergic neurons are ideally positioned to be the master regulator of arousal. They send dense excitatory projections to all other monoaminergic as well as cholinergic arousal nuclei.[101] Thus, increased firing of orexinergic neurons stimulates activity of the other arousal nuclei and inhibits VLPO neurons, thereby driving the system toward wakefulness (Fig. 36–20). Mutual antagonism between VLPO and orexinergic neurons creates a bistable switch[93] that drives an organism either toward wakefulness (low VLPO activity in conjunction with increased orexinergic activity) or toward sleep (high VLPO activity in conjunction with decreased orexinergic activity).

Orexin receptors are GPCRs that, because of the binding and functional results discussed earlier, are reasonable direct anesthetic targets. Moreover, several reports suggest that modulation of orexinergic neurotransmission alters anesthetic responsiveness. Using the LORR behavioral assay as an end point, intrathecal administration of an orexin-A agonist and antagonist were shown to reduce and prolong, respectively, the duration of barbiturate induced hypnosis.[102] Direct evidence for orexin modulation of anesthetic hypnosis was also obtained when intracerebroventricular administration of orexin-A produced cortical arousal, opposing the depressive effects of 1.0 and 1.5 MAC of isoflurane.[103] But, as with other catecholaminergic systems, a direct effect of anesthetics upon orexin-mediated signal transduction remains unproven. However, the fact that pharmacologic and genetic interference with orexin signaling reduces wakefulness, motor tone, cardiovascular, respiratory, and thermoregulatory parameters, coupled with the demonstration that anesthetics bind specifically to sensory GPCRs, suggests that direct interactions between anesthetics and orexinergic neurons contribute to the clinical state of anesthesia.

Anesthetics and Other End Points

Although the majority of research on the mechanisms of anesthetic action

has been focused at the molecular level, the interpretation of these findings in the context of the whole animal requires knowledge of the neuronal networks upon which anesthetics exert their site-specific effects to produce different behavioral end points. Toward that end, elegant and sophisticated studies are clarifying and standardizing end points for quantitative application and qualitative association with the networks. Using these approaches, future studies promise to unravel the neuroanatomic loci that mediate many anesthetic actions, both desired and undesired.

SUMMARY

Despite their importance and widespread application in medicine, the general inhalational anesthetics still defy a comprehensive description of their action. A rational explanation for this state of affairs is that inhalational anesthesia relies on a multitude of targets, a proposal well aligned with the results of binding, in vitro functional studies, and behavioral phenomenology. Nevertheless, substantial progress at the molecular level has allowed a pool of protein candidates to be proposed and a detailed understanding of the submolecular mechanisms of anesthetic action. Progress has been made in the linkage of specific end points to underlying targets and neuronal circuitry.

However, little progress has been made toward developing novel inhaled molecules with a more favorable therapeutic ratio. A reason for this lack of progress may be a fundamental dissociation between the pharmacology and the application. To date, the development of anesthetic molecules has been guided by more practical goals: fast kinetics to facilitate rapid induction, emergence, and patient throughput; enhanced stability to reduce metabolic degradation and its associated toxicity and to prolong shelf-life; and operating room safety (i.e., absence of flammability or toxicity from inhalation of trace amounts in the ambient air). These goals may have had the unintended consequence of actually reducing specificity for molecular targets and may not have achieved a lower toxic potential. It is clear that greater molecular complexity will be necessary to enhance specificity, but this may come at the price of slower kinetics, lower and less predictable efficacy, and a less "complete" anesthetic. Such an outcome predicts that combination drug therapy will assume a greater role in anesthetic care in the future.

CHAPTER 37

Pharmacology of Inhalational Anesthetics

Stuart A. Forman, MD, PhD, and George A. Mashour, MD, PhD

Experimentation with inhalation of gases and vapors for the purpose of obtunding the distress associated with surgery began in the 19th century. The administration of inhaled anesthetics spread rapidly following the successful public demonstration of ether anesthesia by William T. G. Morton on October 16, 1846 at Massachusetts General Hospital.

Inhaled agents were the sole means of reliably inducing general anesthesia until the development of intravenous delivery techniques and drugs. Inhalants continue to be used in a large fraction of general anesthetics because of their ease of use and predictable effects. The inhalational route of administration is always available, and the same route is used for drug removal. Thus, inhaled anesthetics require no metabolic clearance (indeed, metabolism is associated with toxicity). Modern equipment for administration of inhaled anesthetics is simple and robust, providing an elegant method for inducing, maintaining, and reversing general anesthesia. Furthermore, monitoring anesthetic concentrations in end-tidal expired gases (see Chapters 27 and 31) provides an estimate of drug concentrations in the circulating blood and central nervous system (CNS). This ability to assess drug concentrations in the body reduces pharmacokinetic uncertainty when determining how much inhaled vapor to administer.

ANESTHETIC DOSE–RESPONSE CONCEPTS

Varying the amount of delivered anesthetic will alter the physiologic functions of the patient. An understanding

KEY POINTS

1. Inhaled anesthetics are delivered and eliminated via pulmonary ventilation. The most useful definition of "dose" for these drugs is the partial pressure in alveolar gases, which is readily monitored in end-tidal expired gases.
2. Some early inhaled anesthetic alkanes and ethers were flammable. Halogenation reduces flammability. Fluorination tends to decrease metabolic breakdown.
3. All halogenated anesthetics break down, releasing carbon monoxide and heat when they contact *desiccated* alkaline chemicals, such as those in common carbon dioxide (CO_2) adsorbents. Potential harm to patients from this breakdown can be prevented by proper use and maintenance of anesthesia equipment and by use of less alkaline CO_2 adsorbents.
4. Biophysical properties of inhaled anesthetics, including blood/gas partition coefficients and tissue–blood partition coefficients, determine the speed of drug uptake, distribution among tissue groups, and elimination.
5. Low blood solubility of inhaled anesthetics is associated with rapid uptake and elimination via the lungs.
6. The rate at which the alveolar anesthetic concentration (FA or P_{alv}) approaches the inspired (circuit) concentration (FI or P_{circ}) depends on minute alveolar ventilation (increased ventilation accelerates FA/FI), cardiac output (increased output slows FA/FI rise), and the blood/gas partition coefficient of the anesthetic (high solubility slows FA/FI rise).
7. The concentration (partial pressure) of anesthetic in highly perfused tissues (brain, spinal cord, heart, liver, kidney) equilibrates rapidly with that in alveoli.
8. Nitrous oxide diffuses into air-filled spaces in the body, causing expansion and/or increased pressure. This action may impair regional or total body blood flow.
9. General anesthesia is a state that includes hypnosis (loss of awareness), amnesia (loss of memory), and immobility (lack of motor responses to pain). These primary effects of anesthetics are mediated in the central nervous system.
10. Minimum alveolar concentration (MAC) is the alveolar concentration of anesthetic that blocks movement in half of subjects in response to a surgical incision. MAC is influenced by age, pharmacologic and physiologic factors (e.g., temperature), and genetic factors.
11. MAC–awake is the alveolar concentration of anesthetic causing loss of response to verbal commands in half of subjects.
12. Amnesia can be produced by anesthetic concentrations lower than MAC–awake.
13. Awareness and explicit recall of intraoperative events is due to inadequate delivery of anesthetics for the patient's needs. Awareness during anesthesia occurs in about one in 1000 to 2000 patients and may cause psychological disturbances leading to posttraumatic stress disorder.
14. Anesthetists should know the risk factors associated with awareness and strategies for preventing it. Ideally, all patients should be interviewed postoperatively to elicit reports of awareness during general anesthesia.
15. All potent volatile anesthetics in current use decrease mean arterial pressure in a dose-dependent manner.
16. Severe cardiovascular and respiratory depression can occur even at low volatile anesthetic concentrations in elderly, hypovolemic, or critically ill patients and at only 2–3 × MAC in healthy patients. Prevention of severe depression requires vigilant monitoring and anticipation of anesthetic requirements.
17. Nitrous oxide augments sympathetic activity and tends to oppose the hypotensive action of coadministered volatile agents.
18. Volatile anesthetics may increase heart rate, both by a baroreceptor reflex in response to decreased arterial pressure and by a direct vagolytic effect on the heart.
19. Volatile anesthetics tend to increase respiratory rate, decrease tidal volume, and blunt ventilatory responses to hypercapnia and hypoxia.

Continued

Key Points—continued

20. Desflurane is very pungent, and its use can be associated with airway irritability, bronchoconstriction, and laryngospasm during induction. Sevoflurane causes the least amount of subjective airway irritation.
21. Volatile anesthetics vasodilate cerebral vessels, increasing blood flow while reducing cerebral metabolic oxygen consumption. Cerebral vascular responses to altered pCO_2 are maintained in the presence of volatile anesthetics. Nitrous oxide increases cerebral metabolism.
22. Volatile anesthetics reduce both hepatic and renal blood flow, whereas nitrous oxide does not.
23. Halothane undergoes the most hepatic metabolism of the inhaled agents. Enflurane, isoflurane, and sevoflurane also are metabolized in the liver, whereas desflurane and nitrous are minimally metabolized.
24. Oxidative metabolism of halothane and other volatile agents can induce a severe immune-mediated hepatitis.
25. All potent volatile agents may trigger malignant hyperthermia in susceptible individuals.

of inhaled anesthetic pharmacology must begin with clear definitions of both the drug amount (dosage) and important effects (response).

The "dose" of an inhaled anesthetic can be a confusing concept. The dosage of inhaled anesthetic documented in an anesthetic record is most often the *delivered gaseous concentration* (in percent of total gas) in the vaporizer outflow (i.e., fresh gas). Dosage also may be defined as the *inspired concentration* of inhaled anesthetic in the breathing circuit or, analogous to injected drugs, as the *amount absorbed* by the body via the lungs. These definitions are of limited use because several factors, including ambient atmospheric pressure, fresh gas flow (FGF) rate, minute ventilation, and rate of uptake into the blood via the lungs, determine how these various "doses" affect patients. The most useful and practical definition of dosage for inhaled anesthetic drugs is the partial pressure in alveolar gas. The partial pressure of an inhaled drug is directly proportional to its fractional concentration in a gas mixture and is measured on an absolute scale of pressure (see Chemical and Physical Properties of Inhaled Anesthetics below).

The common effects induced by all general anesthetics are hypnosis (loss of perceptive awareness), amnesia (anterograde loss of memory), and ablation of movement in response to pain (inhibition of nociceptive reflexes).[1] These therapeutic actions, which define the state of general anesthesia, all are mediated by the CNS (brain and spinal cord). Some anesthetics can provide additional therapeutic actions, such as analgesia, attenuation of autonomic reflexes, and protection of the heart and brain from ischemia and reperfusion. In addition, nontherapeutic effects of anesthetics (side effects) must be considered, because these often influence the choice of anesthetic drug and dosage depending on the specific clinical setting.

PURPOSE AND SCOPE OF THIS CHAPTER

This chapter describes the chemical and biophysical properties of commonly used inhaled anesthetics and relates these properties to the clinical pharmacology. Various properties of inhaled drugs influence their chemical stability, rate of pulmonary uptake/elimination, and metabolism (pharmacokinetics), as well as clinically important differences among their therapeutic actions and toxicities (pharmacodynamics). Understanding these pharmacologic relationships is crucial for the safe and effective delivery of inhaled anesthetics.

Chemical and Physical Properties of Inhaled Anesthetics

The structures of various inhaled anesthetics, in three chemical categories, are depicted in Fig. 37–1. The chemical and physical properties of the gaseous and volatile anesthetics currently available for clinical use (nitrous oxide [N_2O], isoflurane, enflurane, halothane, desflurane, and sevoflurane) are summarized for comparison in Table 37–1.

Nitrous Oxide

N_2O was one of three inhaled anesthetics, along with diethyl ether and chloroform, that was used in the 19th century. In the early 20th century, more inhaled anesthetics were identified, including ethylene, ethyl chloride, and cyclopropane. Of these, only N_2O remains in use. All the others are combustible, a characteristic that can lead to infrequent catastrophic outcomes for both patients and caregivers.[2]

N_2O is a simple linear inorganic compound that is in the gas phase at normal ambient temperature and pressure and is chemically stable. N_2O has no odor or taste. The boiling point of N_2O is –88.5°C. At room temperature, N_2O condenses into a liquid at 745 psi (50 atm), making the storage and transport of large quantities in pressurized cylinders economical. A room-temperature cylinder will display a pressure near 745 psi as long as liquid N_2O remains. The pressure will fall only when the tank is completely depleted of liquid and is nearly empty. Pressure within the cylinder may drop during rapid delivery of N_2O as vaporization absorbs heat, cooling the tank and its contents. The weight of the tank, not the pressure, is the only reliable guide to assessing how much N_2O remains. N_2O can support combustion, so inhalation of N_2O during surgery with electrocautery or lasers does not prevent the ignition of flammable materials.

N_2O has a low potency as an anesthetic. It must be delivered at nearly 0.7 atm (530 mm Hg) to ablate awareness in half of patients and at over 1 atm in most patients to prevent movement during an incision. Therefore, N_2O is frequently used in combination with other inhaled or intravenous anesthetic agents.

Halothane

In the mid-20th century, efforts to develop safer inhaled anesthetics focused on reducing flammability by halogenation (adding bromine, chlorine, and fluorine) of alkanes and ethers.[3] Halothane is a halogenated alkane ($CF_3CHBrCl$) and became clinically available in 1956. It has a pleasant, nonpungent odor, and it is tolerated well during inhalation. Halothane is a liquid at normal temperature and pressure, and its high vapor pressure (243 mm Hg at 20°C) is many-fold higher than that needed to induce anesthesia. Clinically used concentrations of halothane are not flammable, but higher concentrations (in anesthesia machines) can ignite. Halothane is slightly unstable, decomposing in the presence of light and oxygen. To prevent photo-oxidative breakdown, hal-

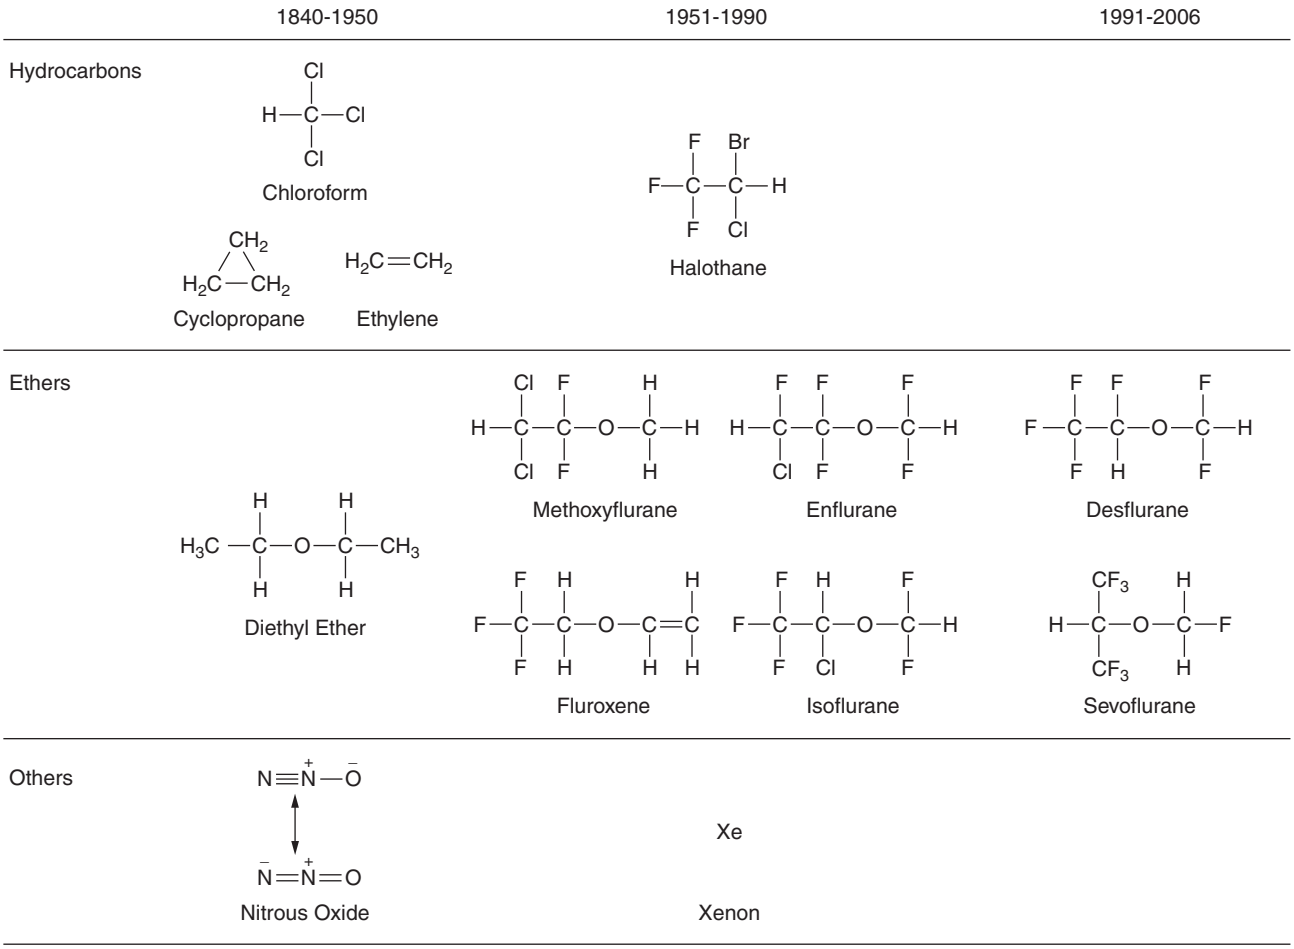

FIGURE 37–1. Structures of inhaled anesthetics. Three different classes of inhaled anesthetics were identified in the 19th century.

othane is stored in dark glass bottles containing 0.01% thymol. Newer halogenated volatile anesthetics do not require such chemical stabilizers.

Enflurane and Isoflurane

Enflurane and its isomer isoflurane were introduced into clinical practice in the 1970s. They are halogenated ethers that undergo much less metabolism and have faster onset/offset in comparison to halothane.

Enflurane is a halogenated ether ($CHFClCF_2OCHF_2$) and is more pungent than halothane, but it is reasonably well tolerated for inhalation induction. It is a clear liquid with a vapor pressure of 172 mm Hg at 20°C.

Isoflurane is a halogenated ether and an isomer of enflurane ($CF_3CHClO CHF_2$). It is a clear liquid with a vapor pressure of 238 mm Hg at 20°C. It is pungent and frequently stimulates coughing during inhalation induction.

Desflurane and Sevoflurane

Desflurane and sevoflurane, introduced in the 1990s, both are less potent and less blood soluble than other halogenated anesthetics. Low blood solubility provides rapid pulmonary uptake and elimination, which are highly desirable in clinical settings where rapid emergence from anesthesia is valued.

Desflurane is a highly fluorinated ether ($CF_3CHFOCHF_2$) that is extremely resistant to biodegradation. Desflurane has a high vapor pressure of 664 mm Hg at 20°C and boils at 22.8°C (73°F). To prevent boiling, desflurane is stored in special bottles with valves that open only when fitted into

TABLE 37–1.

Physicochemical Properties of Inhaled Anesthetics

Property	N_2O	Isoflurane	Enflurane	Halothane	Desflurane	Sevoflurane
Molecular weight	44	184.5	184.5	197.4	168	200.1
Boiling point (°C/°F)	−88.5/−127.3	48.5/119.3	56.5/133.7	50.2/122.4	22.8/74.3	58.6/137.5
Density (g/mL)	1.84×10^{-3} (gas)	1.5	1.52	1.86	1.45	1.50
Vapor pressure at 20°C (mm Hg)	43,879 (gas)	238	175	243	664	157
Oil/gas partition coefficient at 37°C	1.3	90.8	96.5	197	19	47–54

the filling port of a vaporizer. The unique desflurane vaporizer heats the anesthetic to 39°C to control its vapor pressure and delivery rate.[4] Desflurane vapor is extremely pungent, and coughing and autonomic stimulation are frequently produced during inhalation induction.

Sevoflurane is a highly fluorinated ether [$(CF_3)_2CHOCH_2F$]. It is a clear liquid with a vapor pressure of 157 mm Hg at 20°C. Sevoflurane has a pleasant odor and low pungency, making it well tolerated for inhalation induction of anesthesia.

BIOPHYSICAL PROPERTIES OF INHALED ANESTHETICS

The concepts of partial pressure and partition coefficients are central to understanding how gases distribute among various compartments in the body.

Partial Pressure

Partial pressure is the pressure exerted by one component of a gas mixture, where the sum of all the partial pressures equals the total pressure. For example, air contains approximately 79% nitrogen (fraction of N_2 = FN_2 = 0.79) and 21% oxygen (FO_2 = 0.21), so at 1 standard atmosphere barometric pressure (P_{Bar} = 1 atm = 760 mm Hg), the partial pressure of N_2 (PN_2) = 0.79 atm = 600 mm Hg and PO_2 = 0.21 atm = 160 mm Hg. Near sea level, where atmospheric pressure is approximately 760 mm Hg, the fractional concentration of a gas differs insignificantly from its partial pressure (in atm), and the two terms can be used synonymously. At high altitudes, where ambient pressure is lower, air contains the same fractional concentrations of nitrogen and oxygen, whereas their partial pressures are reduced relative to those at sea level. For example, in Denver (P_{Bar} = 630 mm Hg), PN_2 = 500 mm Hg and PO_2 = 130 mm Hg. Similarly, gaseous anesthetics such as N_2O, when used at high altitudes, will exert a lower partial pressure (and have a subsequently reduced anesthetic effect) relative to the same fractional concentration at sea level.

Vapor Pressure

Volatile anesthetic vapor pressure is the gaseous partial pressure at the liquid–gas interface, such as that in a vaporizer. Vapor pressure remains independent of total ambient pressure and is solely a property of the anesthetic agent and its temperature. Thus, in relation to carrier gases, the fractional concentration of a saturated volatile anesthetic in a vaporizer will be higher at high altitude (Fig. 37–2). When working at ambient pressures that differ significantly from sea level, anesthetists must adjust the delivered oxygen concentrations and vaporizer settings appropriately.

Partial pressure is the driving force for the diffusion of gases across permeable barriers into other gases, liquids, or tissues. At equilibrium, the partial pressure of any gas is equal in all intercommunicating compartments within a closed system. In the operating room, intercommunicating compartments include the anesthesia machine, the breathing circuit, and the patient's body, which is further compartmentalized. The partial pressure of an inhaled anesthetic is directly proportional to its concentration in liquid (i.e., blood) or tissue phases (e.g., brain), where concentration usually is defined as the weight, volume, or moles of drug per volume of liquid or tissue. Importantly, different liquids (e.g., blood or cerebrospinal fluid) and tissues may contain remarkably different drug concentrations at the same partial pressure, depending on the solubility of the gas in each liquid or tissue. The concentrations in two different compartments define a partition coefficient.

Partition Coefficients

A *partition coefficient* is defined as the ratio of concentrations of a drug in one compartment (gas, blood, or tissue) versus another intercommunicating compartment at equilibrium (i.e., equal partial pressure in both compartments). Therefore, partition coefficients have no units. Another useful concept is that the partition coefficient represents the number of volumes of the reference phase (e.g., gas) that contains the same amount of anesthetic as the second phase (e.g., blood), which we call the *effective volume* (or relative volume) of the second phase (Fig. 37–3 and Table 37–2). The effective volume concept is similar to the distribution volume of injected drugs when calculating metabolic or renal clearance and helps illustrate why drug equilibration in different tissues takes vastly different amounts of time. Both blood/gas partitioning and tissue/blood partitioning (Table 37–2) determine the distribution of inhaled anesthetics within the body.

Blood/Gas Partitioning

The *blood solubility* of inhaled anesthetics is another term for the blood/gas partition coefficient ($\lambda_{b/g}$). At equilibrium, the concentration (i.e., volume drug per volume = v/v) of most inhaled anesthetics is higher in blood than in surrounding gases. That is, $\lambda_{b/g} > 1.0$ (Table 37–2). Two notable exceptions are N_2O and desflurane, which have the lowest blood solubilities of the commonly used inhaled anesthetics. Blood/gas partitioning varies depending on temperature, hematocrit, and the lipid content of blood. The solubility of most gases, including inhaled anesthetics, increases as the temperature of a liquid, such as blood, decreases.[5] Blood cells and plasma contain protein and lipids, which provide a higher capacity for anesthetics. Thus, hemodilution (decreased cell mass) reduces, whereas hypertriglyceridemia increases, the blood solubility of inhaled anesthetics. Elevated levels of blood lipids after a fatty meal increase anesthetic solubility relative to that after fasting.[6]

Tissue/Blood Partitioning

In general, the solubility of inhaled anesthetics in tissues depends on the fraction of tissue that is lipid,[7] because most anesthetics are highly lipophilic. Thus, the more potent volatile anesthetics, which also are the most oil soluble (based on the Meyer-Overton correlation), tend to partition avidly into fatty tissues (Table 37–2).

PHARMACOKINETICS: INHALED ANESTHETIC UPTAKE AND DISTRIBUTION

Multicompartmental Kinetic Model

The inflows to and the outflows between the anesthesia machine circuit and the patient's lungs, blood and tissues can be depicted as a cyclical multicompartmental system wherein the anesthetic partial pressure in one compartment is the upstream partial pressure driving anesthetic into downstream compartment(s) (Fig. 37–4). These compartments have different phases: gas in the anesthetic circuitry

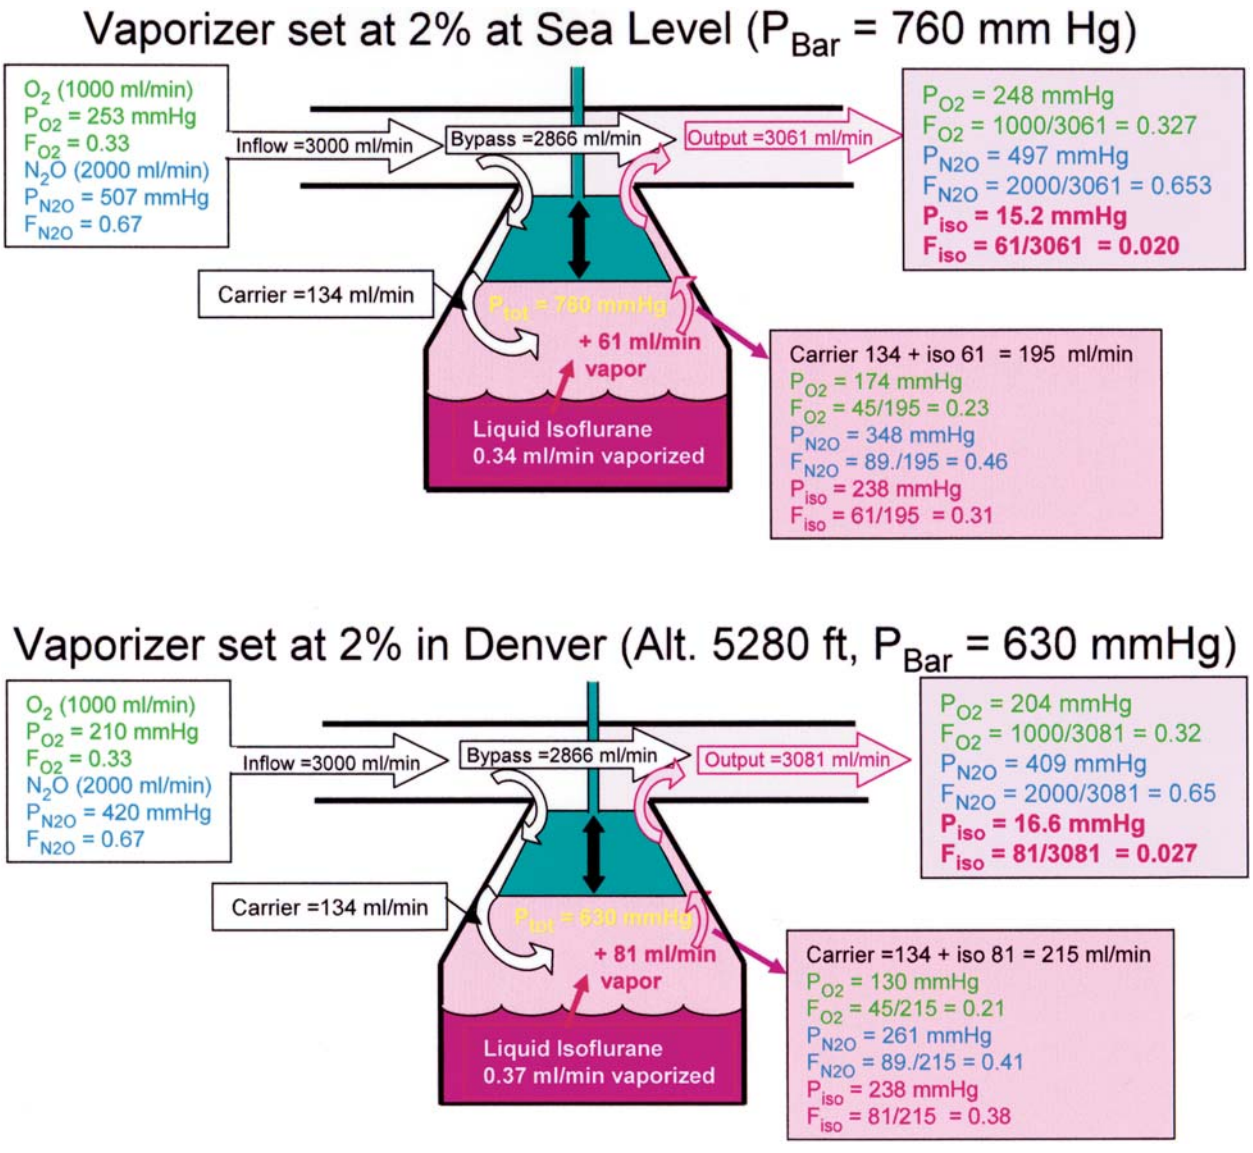

FIGURE 37–2. Vapor pressure, partial pressure, and concentration of inhaled anesthetics. Impact of atmospheric pressure on vaporizer output. Top. Variable bypass vaporizers are calibrated at 20°C and 1 atm (standard temperature and pressure). The partial pressure of isoflurane in the vaporization chamber is its vapor pressure, 238 mm Hg. Isoflurane vapor adds to the carrier gases (O_2 and N_2O), and the sum of the partial pressures equals atmospheric pressure (≈760 mm Hg at sea level) at all points in the flow path. With fresh gas flow = 3 L/min and the vaporizer set at 2.0%, the carrier flow through the vaporization chamber is 134 mL. Approximately 61 mL/min of isoflurane vapor (0.34 mL/min liquid) is added to the carrier gases so that the output of the vaporizer after dilution is 3061 mL/min at 2.0% isoflurane (P_{iso} = 15.2 mm Hg). Bottom. With the same flow and vaporizer settings in Denver (elevation 5280 ft ambient, pressure 630 mm Hg), isoflurane composes a larger portion of the carrier gas mixture, and, after dilution, the output of the vaporizer is 3081 mL/min at approximately 2.6% isoflurane. Thus, in Denver the *delivered concentration* of isoflurane is 30% higher than that at sea level. However, the delivered *partial pressure* of isoflurane in Denver is 16.7 mm Hg, only 10% higher than at sea level. Similarly, liquid isoflurane is vaporized at 0.37 mL/min in Denver, approximately 10% more than at sea level. Because its partial pressure directly determines the uptake and effect of isoflurane on patients, only minor changes in vaporizer settings are required at high altitudes. Partial pressures of N_2O and O_2 carrier gases in Denver will be approximately 17% lower than at sea level. Thus, at similar carrier gas flows, nitrous oxide will have a significantly reduced anesthetic action in Denver *versus* sea level. Moreover, the inspired O_2 concentration in Denver should be increased to reduce the risk of hypoxia, so increasing the N_2O concentration may not be possible.

and airspace of the lung, liquid in blood, and mixed liquid/solid in organs.[8] The model depicted in Fig. 37–4 is complex and requires computer assistance to calculate how the anesthetic partial pressure in various compartments changes over time (for details, see Fig. 37–4 legend). However, it is relatively easy to understand how an anesthetic moves between one upstream compartment and one downstream compartment (a two-compartment system).

Transfer of anesthetic gas from one compartment to another (e.g., from a vaporizer to the breathing circuit) is proportional to both the bulk carrier flow (FGF in this example) and the partial pressure difference ($P_{delivered} - P_{circ}$). As more anesthetic gas is transferred, the partial pressure difference between the compartments becomes smaller, and the transfer rate slows. The time it takes a given compart-

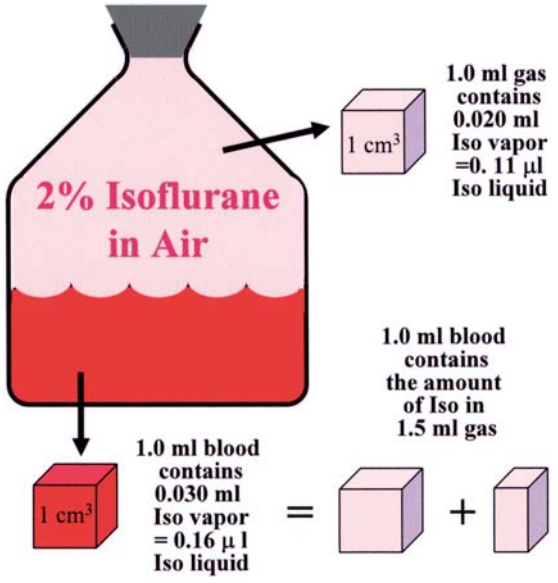

FIGURE 37–3. Blood/gas partitioning of isoflurane. After equilibrating a sealed container containing blood and isoflurane in air, a sample of blood will contain 1.5 times the amount of isoflurane as an equal volume of air.

ment to equilibrate with upstream anesthetic partial pressure is determined by its volume (or effective volume) and the bulk flow carrying anesthetic to that compartment.

Equilibration between two compartments is quantitatively described by an exponential equation (Equation 37–1), which is characterized by the time constant τ. After each time constant, the difference between upstream and downstream concentrations is reduced by approximately 63%. A general equation describing this relationship is as follows:

$$P_{downstream} = P_{upstream} \times (1 - e^{-t/\tau}) \quad (37–1)$$

where t = elapsed time measured from when the anesthetic is turned on during induction. The time constant is directly proportional to the downstream compartment volume (V): if the volume of the receiving compartment doubles, τ doubles and it takes twice as long for equilibration to occur. The time constant τ is inversely proportional to carrier flow (F): if the delivery flow doubles, τ halves and equilibration occurs twice as fast.

$$\tau(min) = \frac{V\ (L)}{F\ (L/min)} \quad (37–2)$$

After five time constants have elapsed, the difference between upstream and downstream compartments diminishes to approximately 1%. At equilibrium, the compartments

[c]Time constants (τ) are for equilibration between the blood and the specified tissue, calculated using Equation 37–2 and V_{eff}.
[d]Minimum alveolar concentration (MAC) is the anesthetic concentration inhibiting motor responses to skin incision in half of subjects.
[e]Minimum alveolar concentration-awake (MAC-Awake) is the anesthetic concentration that inhibits appropriate motor responses to spoken commands in half of subjects.

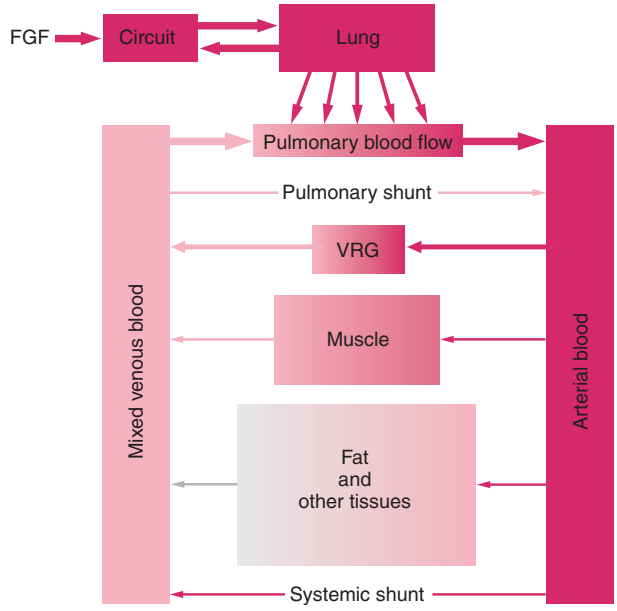

FIGURE 37–4. Model for uptake and distribution of inhaled anesthetics. Scheme depicts the flow of anesthetic gas from vaporizer to the breathing circuit, its transfer into blood via the lungs, and distribution to various tissues. The size of tissue compartments are drawn in general proportion to their effective volumes ($V_{eff} = V_{anatomic} \times \lambda_{tissue/blood}$), and arrows of different width indicate relative blood flows. A variety of mathematical models have been devised to quantitatively illustrate anesthetic flow and distribution, and most are elaborations on the model introduced in 1963 by Mapleson.[212] The model shown here is not intended to replicate reality, although it approximates it and serves as a simple way of illustrating how the various input parameters (fresh gas flow [FGF], type of agent, vaporizer setting, minute ventilation, and cardiac output) affect the rate of gas uptake. The following differential equations were used to generate the uptake and clearance data displayed in figures throughout this chapter ($\dot{V}$ = minute ventilation, $\dot{Q}$ = cardiac output, and $\dot{q}$ = tissue perfusion). The anesthetic partial pressure in the breathing circuit:

$$dP_{circ}/dt = FGF/V_{circ} \times (P_{delivered} - P_{circ}) - \dot{V}/V_{circ} \times (P_{circ} - P_{alv}). \quad (37\text{–}3)$$

The anesthetic partial pressure in alveolar gas

$$dP_{alv}/dt = \dot{V}/V_{lung} \times (P_{circ} - P_{alv}) - (\dot{Q} \times \lambda_{b/g})/V_{lung} \times (P_{alv} - P_{mv}). \quad (37\text{–}4)$$

Uptake into a specific tissue (i):

$$dP_i/dt = \dot{q}_i/(\dot{V}_i \times \lambda_{i/b}) \times (P_{alv} - P_i). \quad (37\text{–}5)$$

The anesthetic partial pressure in mixed venous blood:

$$P_{mv} = \frac{\sum_{i=1}^{n} P_i \times q_i}{\dot{Q}}. \quad (37\text{–}6)$$

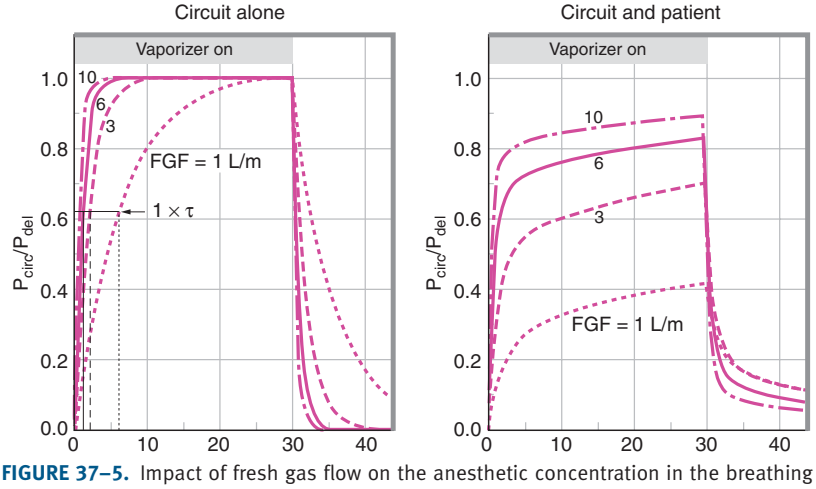

FIGURE 37–5. Impact of fresh gas flow on the anesthetic concentration in the breathing circuit. **Left.** Rise of anesthetic partial pressure follows a single exponential when there is only a single downstream compartment (the circuit). Anesthetic clearance from the circuit follows the same time course as its rise, depending on fresh gas flow. **Right.** Rise of the inspired anesthetic (isoflurane in this example) partial pressure is slowed by uptake into the patient.

have the same partial pressure of anesthetic, and no net anesthetic transfer between compartments occurs, even though carrier flow continues.

Equilibration time is independent of the source partial pressure if this pressure is small (see Concentration Effect and Second Gas Effect below). However, the time to reach a target partial pressure in the downstream compartment (i.e., to reach a specific depth of anesthesia) will be shorter if the upstream partial pressure is higher. A common practice is to deliver potent volatile anesthetics at two to three times the target partial pressure (*overpressure*) in order to reduce the induction time. Once the desired depth of anesthesia has been achieved, the vaporizer is set to a lower concentration to prevent the toxic effects of overdosage.

Inspired Partial Pressure of Anesthetic Gas

The example cited can be used to illustrate how long it takes to "prime" a breathing circuit with anesthetic, as is done before a single-breath induction. The upstream source is the output from a vaporizer ($P_{delivered}$), the drug carrier is FGF, and the breathing circuit volume is V_{circ}. The delivery of anesthetic is determined by the product of FGF and $P_{delivered}$. The time needed to equilibrate the circuit with the delivered gas is determined by the ratio of V_{circ} to FGF. High FGFs and low circuit volume, such as that in an open-circuit delivery system, enable rapid control of the anesthetic concentration in the circuit that is inhaled by the patient (Fig. 37–5).

The most common breathing circuit configuration is a circle system that allows rebreathing of exhaled anesthetic gases while scavenging carbon dioxide (CO_2). These circuits have total gas volumes of 6–8 L. If V_{circ} = 6 L and FGF = 6 L/min, then τ = 1 minute, and it will take approximately 5 minutes for the anesthetic concentration in the circuit to closely approach the concentration delivered by the vaporizer. However at FGF = 1 L/min, τ = 6 minutes, and it will take up to 30 minutes to fully equilibrate the circuit (Fig. 37–5, left).

To illustrate the impact of additional compartments in our model, consider what happens if a patient is breathing circuit gases when the vaporizer is turned on. In this case, uptake of

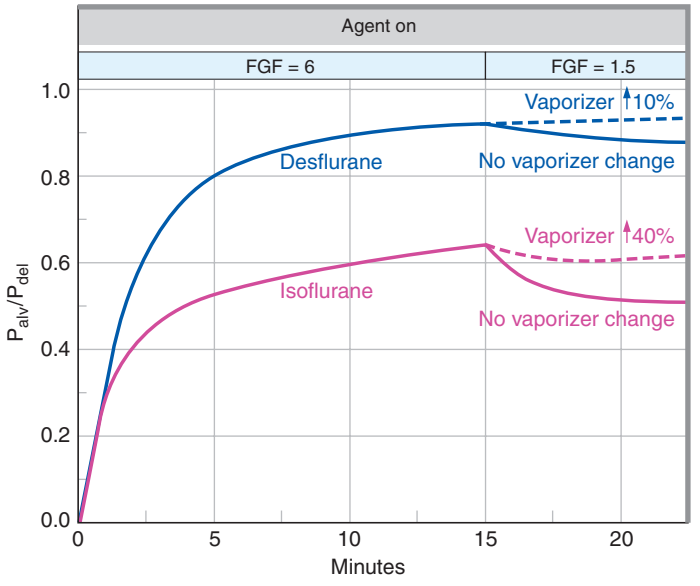

FIGURE 37–6. Lowering fresh gas flows after induction. After the initial rapid uptake of anesthetic, fresh gas flow can be dropped, reducing both drug delivery and waste. The drop in anesthetic concentration that results is larger for highly soluble agents.

anesthetic into the patient's body reduces the rate of rise of the partial pressure of anesthetic in the circuit (Fig. 37–5, right). These examples illustrate why a high FGF is most useful when rapid changes in inspired anesthetic concentration are needed, such as during induction and emergence. After the induction period, the rate of uptake of anesthetic into the patient slows, and, if a rebreathing circuit is used, FGF can be reduced, usually in the range from 1–3 L/min. After FGF is reduced, modestly increasing the delivered anesthetic concentration will help maintain drug delivery to match the uptake of anesthetic into the body (Fig. 37–6). Reducing FGF has economic, environmental, and medical benefits. Lower quantities of inhaled gases are used, resulting in reduced cost and less environmental pollution with waste gases. The patient's airway humidity is maintained, improving the clearance of bronchopulmonary secretions.

The extreme of low FGF is "closed-circuit" anesthesia, wherein almost all inhaled gases are rebreathed and fresh gas is delivered with only sufficient oxygen to replace that metabolized by the patient (≈0.25 L/min for a typical normothermic 70-kg adult), and anesthetic vapor is added to match uptake and maintain the level of anesthesia. The practice of closed-circuit anesthesia should be based on detailed knowledge of anesthetic gas uptake into patients (for a more thorough description, see Baum[9]).

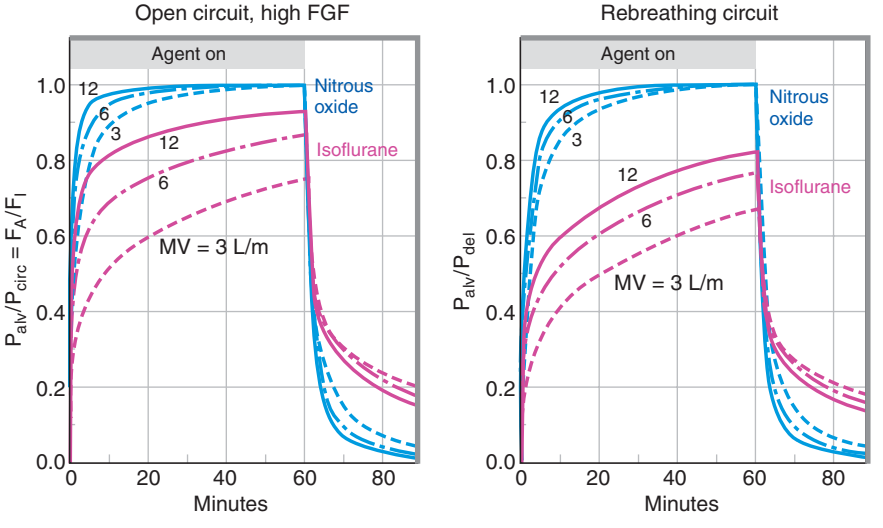

FIGURE 37–7. Impact of minute ventilation on the alveolar anesthetic concentration. **Left.** Rise of P_{alv} is shown in the traditional manner, normalized to inspired concentration (P_{circ}), which is constant only with very high fresh gas flows and no rebreathing. Increased minute ventilation accelerates the rise of P_{alv} and also increases clearance after delivery stops. **Right.** P_{alv} is shown normalized to the constant delivered anesthetic concentration. This illustration better reflects the rise of P_{alv} during a typical induction, where rebreathing occurs (fresh gas flow = 6 L/min).

Alveolar Partial Pressure of Anesthetic Gas

The alveolar anesthetic partial pressure (P_{alv}) is important because it is the upstream source or driving pressure that rapidly equilibrates with the blood, brain, and other highly perfused tissues (see Distribution of Inhaled Anesthetics in Body Tissues) and because its level can be monitored in end-tidal expired gases.

Transfer of Anesthetic from the Breathing Circuit to Alveoli

The transfer of inhaled anesthetic from the breathing circuit into the lungs depends on the minute alveolar ventilation rate and the difference between the partial pressures in the circuit (P_{circ}) and the lung (P_{alv}). Thus, hyperventilation enables the rapid adjustment of P_{alv}, which provides the upstream driving pressure for transfer of anesthetic to and from other body tissues. The impact of varying minute alveolar ventilation is illustrated in Fig. 37–7.

It is traditional to illustrate uptake with P_{alv} normalized to P_{circ} (inspired), which represents the case of high-flow, open-circuit anesthesia, wherein $P_{circ} \approx P_{delivered}$. However, with a rebreathing circuit, as we have described, $P_{circ}/P_{delivered}$ is not constant (Fig 37–5). In this instance, a clearer illustration of how P_{alv} varies over time is obtained by normalizing to $P_{delivered}$, which is held constant in our uptake model calculations. The difference between open-circuit and rebreathing models is illustrated in Fig. 37–7. Comparing the two panels, it is apparent that P_{alv} increases more slowly with moderate FGF and a rebreathing circuit, whereas the impact of changing minute ventilation is similar in both cases. For simplicity, we have adopted the traditional open-circuit model to illustrate the impact of other physiologic variables

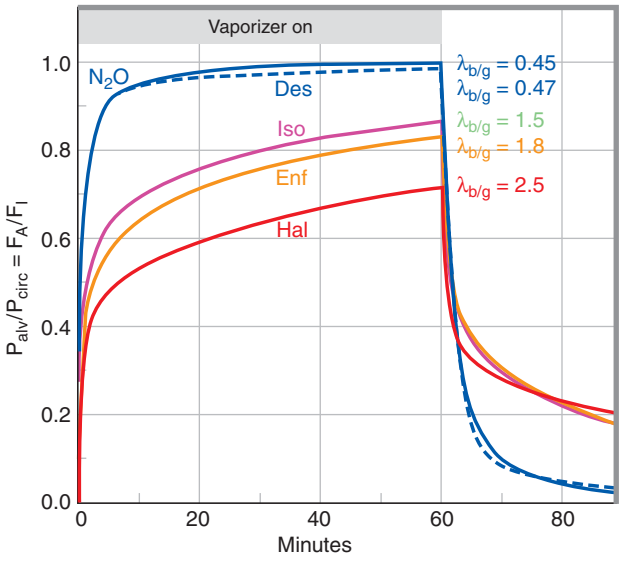

FIGURE 37–8. Impact of blood solubility on the alveolar anesthetic concentration. During induction, high blood solubility (high $\lambda_{b/g}$) results in a slow rise of P_{alv}, because a large fraction of alveolar anesthetic is taken up into blood. Conversely, low blood solubility results in rapid equilibration between alveolar and inspired anesthetic concentrations. The impact of $\lambda_{b/g}$ on anesthetic clearance mirrors that on uptake.

on anesthetic uptake (for washout in these figures, we have normalized to either $P_{delivered}$ or P_{circ} just before the agent is turned off).

Anesthetic Uptake into Pulmonary Blood

Pulmonary blood rapidly takes up alveolar anesthetic gases. The uptake into blood depends on blood solubility (the blood/gas partition coefficient $\lambda_{b/g}$), the rate of pulmonary blood flow (usually near the cardiac output), and the difference between the anesthetic partial pressure in the lung and that of mixed venous blood entering the lung. The more blood-soluble anesthetics produce a slower rise of P_{alv} relative to the inspired concentration (P_{circ}) because more vapor needs to be transferred into blood before the blood compartment is "filled" (Fig. 37–8).

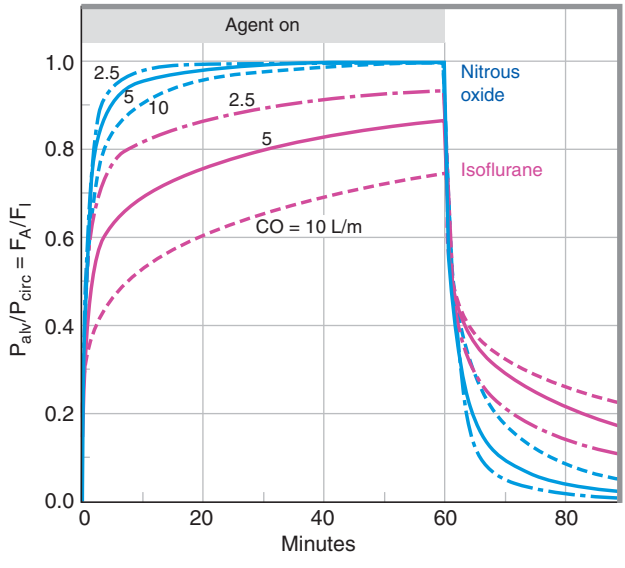

FIGURE 37–9. Impact of cardiac output on the alveolar anesthetic concentration. During induction, increased cardiac output (pulmonary blood flow) results in a slower rise of P_{alv}, because uptake from the alveoli into pulmonary blood is accelerated. The dependence of the P_{alv} rate of rise on cardiac output is greatest for highly soluble anesthetics and minimal for insoluble drugs such as nitrous oxide. The impact of cardiac output on anesthetic clearance is similar to that on uptake.

Stated another way, the effective blood volume is larger for the more soluble anesthetics (Table 37–2).

Increased cardiac output (pulmonary blood flow) slows the rise in P_{alv} by more rapidly removing the anesthetic agent from alveolar gases, whereas decreasing cardiac output accelerates the rise in P_{alv}. This effect is most significant for the highly blood-soluble anesthetics, for which the rate of rise of P_{alv} is reduced more by vapor uptake into blood. Changes in cardiac output cause smaller changes in the rate of rise of P_{alv} for the blood-insoluble anesthetics such as N_2O and desflurane (Fig. 37–9).

The role of cardiac output in inhaled anesthetic uptake (and therefore inhalation induction) can seem counterintuitive. Increased cardiac output results in more rapid delivery of anesthetic to the major sites of action in the nervous system, suggesting that anesthesia induction is faster, not slower. The key to untangling this conundrum is to understand that during induction, P_{alv} is the driving force for drug entry into the blood and nervous system. Because P_{alv} rises more slowly when cardiac output increases, partial pressure in the brain and spinal cord also will rise more slowly. What happens to the "extra" anesthetic that is taken up via the lung at an elevated cardiac output? The brain and other highly perfused tissues (see Distribution of Inhaled Anesthetics in Body Tissue) equilibrate rapidly with P_{alv}. However, muscle and fat tissue, which typically take hours to equilibrate with P_{alv}, are absorbing most of the additional anesthetic agent.

In summary, the rate of equilibration between the alveolar partial pressure (P_{alv}) and the inspired anesthetic partial pressure (P_{circ}) is dependent on three factors. (1) *Minute alveolar ventilation:* As minute alveolar ventilation increases, the lung more rapidly equilibrates with the circuit. (2) *Cardiac output:* As cardiac output increases, uptake from the pulmonary airspace into the blood and tissues slows the rate at which P_{alv} rises. (3) *Blood/gas partitioning:* High $\lambda_{b/g}$ increases uptake into blood, removing a higher fraction of anesthetic from the pulmonary airspace and slowing the rate at which P_{alv} rises.

Distribution of Inhaled Anesthetics in Body Tissues

Mixed venous blood entering the pulmonary capillary bed rapidly equilibrates with the alveolar partial pressure of an

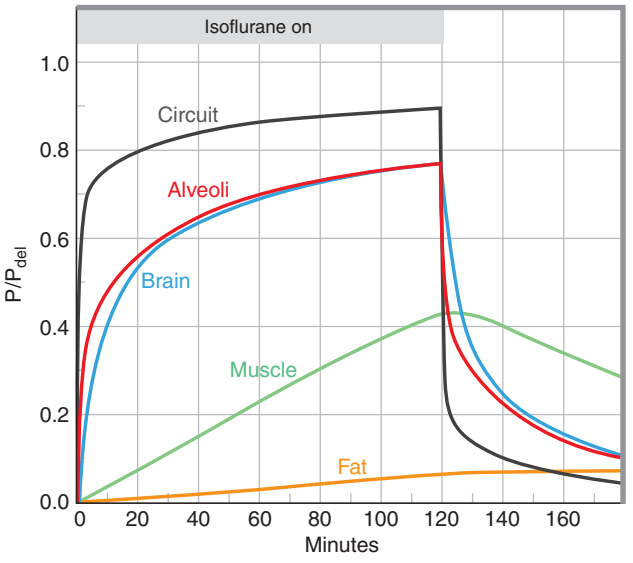

FIGURE 37–10. Uptake of anesthetics into different tissues. The partial pressure of isoflurane in different tissue beds is depicted during induction with fresh gas flow = 6 L/min, $\dot{V}$ = 5 L/min, and $\dot{Q}$ = 5 L/min. Note that the isoflurane partial pressure in highly perfused tissues (brain) closely matches that in alveoli, except when P_{alv} is changing very rapidly. Also note that the partial pressure of anesthetic in fat continues to rise after discontinuing isoflurane delivery, as long as $P_{alv} > P_{fat}$.

inhaled anesthetic (P_{alv}) so that blood exiting from the pulmonary vein has a partial pressure close to P_{alv}. Anesthetic then is distributed to various tissues via systemic arterial blood. Delivery of anesthetic to each tissue is determined by its blood flow rate, its anatomic volume, and its tissue/blood partition coefficient (Table 37–2). The effective volume (V_{eff}) for uptake of anesthetic in a given tissue is the product of its anatomic volume and $\lambda_{tissue/blood}$. The time it takes for anesthetic partial pressure in a given tissue to equilibrate with P_{alv} is decreased when tissue perfusion is high and increased when V_{eff} is large.

Highly perfused tissues include the brain, spinal cord, kidney, liver, and heart, which compose less than 10% of an adult body's mass while receiving approximately 70% of the normal cardiac output. Highly perfused tissues equilibrate within a few minutes with the arterial (alveolar) anesthetic partial pressure (Fig. 37–10 and Table 37–2). As a result, the alveolar partial pressure of anesthetic, which can be measured in end-tidal gases, usually is close to the brain and spinal cord partial pressures (unless the anesthetic concentration in alveolar gas is changing rapidly).

Muscle represents a large anatomic volume (average 35–40% of body mass) and the muscle/blood partition coefficient for all inhaled agents ranges from 1.2–3.1. Because muscle normally receives only approximately 10% of cardiac output at rest, the anesthetic partial pressure in muscle rises slowly, and equilibration with P_{alv} takes hours for most anesthetics used clinically (Table 37–2).

Fat receives approximately 13% of cardiac output and represents approximately 25% of body mass in the average adult, with considerable variation. In addition, the potent volatile agents partition highly into fat ($\lambda_{fat/blood}$ range 27–51) so that the effective volume for uptake of volatiles into fat is extremely large (Table 37–2). For the volatile anesthetics, uptake into fat is so slow that equilibration of the partial pressure with P_{alv} never occurs under normal clinical conditions. The only commonly used inhaled anesthetic with a low fat solubility is N_2O ($\lambda_{fat/blood}$ = 2.3), for which the equilibration time constant is approximately 2 hours.

The *vessel-poor group of tissues* include skin, ligaments, tendons, cartilage, and cortical bone. These tissues represent approximately 14% of the average adult's body mass and receive less than 2% of cardiac output. As a result, their contribution to anesthetic uptake is negligible.

Other Factors Affecting Uptake and Distribution of Inhaled Anesthetics

Intrapulmonary right-to-left shunts (perfused but nonventilated lung regions) do not participate in anesthetic uptake. They slow the rate of uptake into blood and make P_{alv} rise more quickly, especially for the more blood-soluble anesthetics. At the same time, pulmonary shunting results in an arterial admixture of mixed venous blood with blood from gas-exchanging lung regions. As the fraction of pulmonary blood flow passing through right-to-left shunts rises, $P_{art,}$ the direct upstream anesthetic pressure source for the nervous system, drops relative to P_{alv}. For the highly soluble anesthetics, the increased P_{alv} somewhat compensates for admixing, and P_{art} rises only slightly slower than normal (Fig. 37–11). With insoluble agents, the impact of shunt on uptake from lung (P_{alv}) is smaller and there is less compensation for admixing.

Anatomic and physiologic dead space (ventilated but nonperfused lung regions) effectively reduces alveolar ventilation relative to minute ventilation. Therefore, the impact of increasing dead space on anesthetic uptake is equivalent to reducing minute ventilation of lung regions without dead space. An increased dead space reduces agent delivery to alveoli and results in a slower rate of P_{alv} rise.

Systemic arteriovenous (left-to-right) shunting causes the anesthetic partial pressure in mixed venous blood to increase rapidly, slowing the uptake of anesthetic agent from alveolar gas. Therefore, alveolar anesthetic partial pressure rises more rapidly, compensating for the reduced uptake rate. Overall, the impact of arteriovenous shunting is to modestly increase the rate of rise in P_{alv} and the highly perfused tissues.

Systemic right-to-left shunting, like that in the lung, causes downstream arterial admixing. Thus, intracardiac shunts, such as patent foramen ovale or patent ductus arteriosus, result in regional P_{art} lower than P_{alv}. Patent ductus arteriosus shunting may result in different anesthetic partial pressures delivered to the brain and spinal cord. The overall effect of shunting can be difficult to predict because total cardiac output may also increase to compensate for the shunt.

Anesthetic-induced changes in cardiac and respiratory function affect the rate of anesthesia induction with volatile anesthetics. When spontaneous ventilation is maintained, the uptake of inhaled drug is reduced as anesthetic is absorbed and minute ventilation

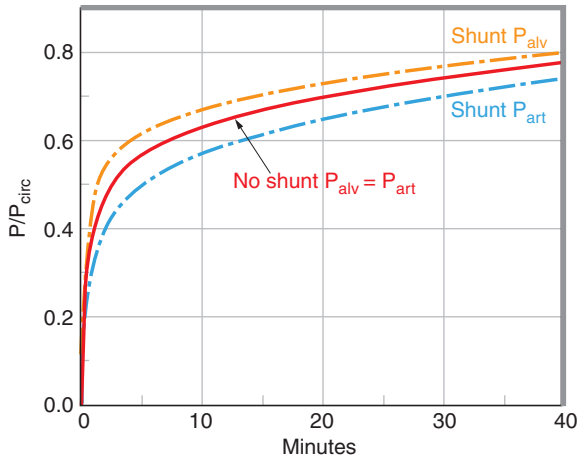

FIGURE 37–11. Impact of pulmonary right-to-left shunting on alveolar and arterial anesthetic concentrations. The impact of a 30% left-to-right shunt was calculated using a modified model from Figure 37–4. Pulmonary right-to-left shunting reduces alveolar uptake, increasing P_{alv}, and mixing of shunted blood results in a lower P_{art}. However, the increased P_{alv} compensates for admixing so that, compared with the zero shunt model, P_{art} is only approximately 10% reduced by the 30% shunt.

falls. Anesthetic depression of cardiac output is another dynamic factor that alters both uptake and distribution of anesthetic (see Anesthetic Uptake into Pulmonary Blood and Fig. 37–9).

Concentration Effect and Second Gas Effect

N_2O represents a special case in clinical anesthesia, because it is often the major constituent of the inhaled gas mixture. As a result, uptake of N_2O from the alveolar space into blood produces significant shifts of alveolar gas volume.[10] As alveolar gas volume diminishes, the concentration of N_2O is maintained (the *concentration effect*), and the concentrations of other gases increase (the *second gas effect*). Consider a single breath of a gas mixture of 70% N_2O, 29% O_2, and 1% isoflurane (Iso) near the start of an anesthetic when mixed venous blood does not contain N_2O (Fig. 37–12). When half of the alveolar N_2O is taken up into blood, the remaining alveolar gas volume will be 65% of the original volume with relative concentrations of 35 N_2O:29 O_2:1 Iso = 54% N_2O:45% O_2:1.5% Iso. Because of the reduction in alveolar gas volume, the alveolar N_2O concentration (and partial pressure) is more than half its original concentration (if 100% N_2O were inhaled, uptake would not reduce the alveolar concentration at all). Therefore, the concentration effect maintains the pressure gradient for uptake and increases the rate of rise of P_{alv} for N_2O toward the inspired concentration. The second gas effect is illustrated in Fig. 37–12. With N_2O uptake, the alveolar concentrations of both oxygen and isoflurane will become higher than the inspired concentration, accelerating their uptake into blood.[11]

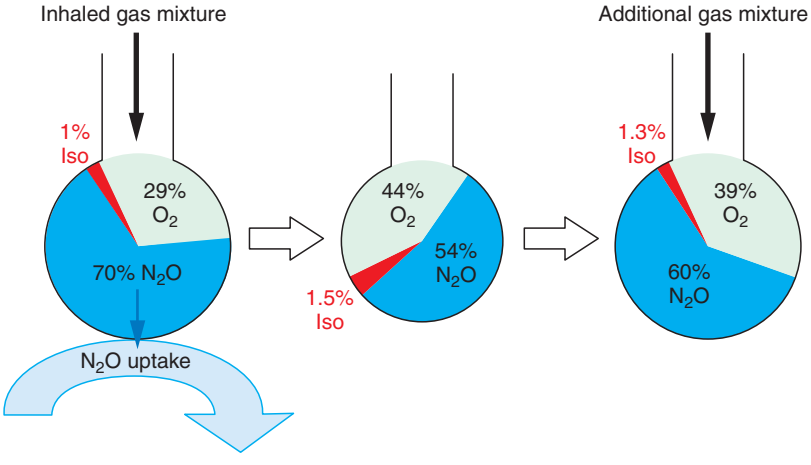

FIGURE 37–12. Concentration and second gas effects. When nitrous oxide is inspired at high concentrations, transfer from the lung into pulmonary blood causes the volume of alveolar gas to drop, drawing in more of the gas mixture and concentrating the remaining gases. This *concentration effect* on nitrous oxide itself results in a sustained alveolar driving pressure and more rapid uptake. The alveolar concentration of other gases, such as isoflurane and oxygen, become higher than the inspired concentrations, which increases their uptake as well—the *second gas effect*.

Nitrous Uptake into Airspaces in the Body

Inhalation of N_2O at high concentrations leads to important effects on airspaces within the body. Airspaces usually contain mostly nitrogen (79% of air), which has a low solubility in blood ($\lambda_{b/g}$ = 0.015), such that bulk transfer of trapped nitrogen gas cannot occur on the time scale of most anesthetics. N_2O ($\lambda_{b/g}$ = 0.45) is delivered to airspaces 30 times faster than nitrogen leaves. As N_2O diffuses into the preexisting airspace, the volume and/or pressure in the airspace increases. In most cases, both airspace volume and pressure will rise, but examples where one or the other effect dominates are useful for illustration.

A compliant airspace, such as a small air embolus or pneumothorax, can increase its volume with minimal pressure change. It will continue to expand until the partial pressure of N_2O within the airspace equals that in surrounding blood. Theoretically, at 50% inspired N_2O, the preexisting volume of the gas bubble would double (half of its gas volume would then consist of N_2O). Similarly, 67% N_2O could lead to a tripling of volume, and 75% N_2O could quadruple the volume (Fig. 37–13). Small venous air emboli then may become easier to detect with Doppler and echocardiographic monitors but may create more physiologic problems by obstructing blood vessels.[12,13] A small pneumothorax could expand to compress mediastinal structures and impair oxygenation or create hemodynamic compromise. The rate of airspace expansion depends on the volume, geometry, and compliance of the airspace as well as the blood flow delivering N_2O to it. Small venous air emboli may expand within seconds,

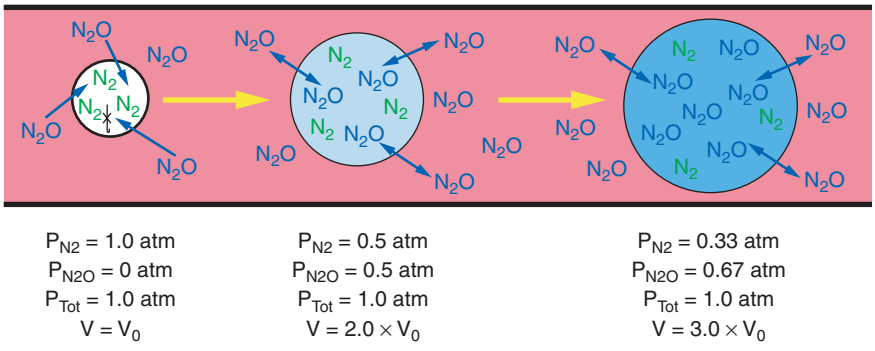

FIGURE 37–13. Expansion of venous air emboli by nitrous oxide. Nitrous oxide enters air pockets far faster than nitrogen leaves (because of low blood nitrogen-carrying capacity), causing airspace expansion. Expansion continues until the partial pressure of N_2O inside the air bubble matches that in surrounding blood. Thus, at 50% N_2O (PN_2O = 0.5 atm), air emboli can double in volume, and at 67% N_2O (PN_2O = 0.67 atm), they can triple in volume. Expansion of small venous air emboli can lead to occlusion of pulmonary capillaries, compromising both blood flow and gas exchange.

and a pneumothorax can expand toward equilibrium in less than 1 hour, whereas airspaces in bowel take may considerably longer to expand.

N_2O diffusion into noncompliant airspaces can create clinical problems. In a noncompliant space, volume does not change, so pressure increases as N_2O enters. For example, following intravitreal injection of sulfur hexafluoride (SF_6) or perfluoropropane (C_3F_8) gases, N_2O administration can result in rapid increases of intraocular pressure, compromising retinal blood flow.[14,15] Intracranial air bubbles (after craniectomy or pneumoencephalography) and the inner ear also represent airspaces in noncompliant body compartments.

Other commonly used inhaled anesthetics also diffuse into airspaces, but their low concentrations in clinical settings result in negligible impact upon airspace volume and pressure. Xenon is an experimental anesthetic inhaled at high concentrations (60–70%) and, like N_2O, is associated with airspace expansion.[16]

Elimination of Inhaled Anesthetics via Ventilation

Removal of inhaled anesthetics via the lungs is essentially the reverse of uptake, and many of the factors that affect induction also affect elimination rates. High FGF promotes faster washout of anesthetic from the circuit, enhancing the gradient for removal from the lung (Fig. 37–5). High minute ventilation clears alveolar anesthetic, reducing P_{alv} and providing a gradient for movement of anesthetic from the blood to the alveoli (Fig. 37–7). Highly blood soluble anesthetics are retained longer than insoluble drugs because the effective volume of blood is higher as $\lambda_{b/g}$ increases (Fig. 37–8). Similarly, increasing the cardiac output retards recovery. Increased delivery of anesthetic from tissues to the lung tends to maintain P_{alv}, which reduces the gradient for removal from the blood (Fig. 37–9).

Some aspects of anesthetic elimination do not mirror the uptake during anesthetic induction. The use of overpressure to accelerate anesthetic induction has no parallel during recovery, because the delivered concentration or partial pressure of anesthetic agent cannot fall below zero. Also, prior to induction the inhaled anesthetic partial pressure in all tissues is zero, whereas different tissues will typically have reached different partial pressures when anesthetic delivery is discontinued. In particular, the partial pressures in muscle and fat may be far lower than P_{alv} after a brief anesthetic. Because anesthetic will continue to be transferred into tissue as long as $P_{alv} > P_{tissue}$, these compartments may continue to absorb drug even after delivery ceases. This effect is illustrated in Fig. 37–10, where fat continues to take up isoflurane from blood long after delivery is discontinued, until $P_{alv} < P_{fat}$. This uptake helps reduce the anesthetic partial pressure within the highly perfused tissues and can reduce recovery time.

The longer anesthesia is maintained, the more drug is absorbed into muscle and fat, which are characterized by a slow uptake and release of agent. Thus, clearance of inhaled anesthetics is context sensitive: the longer the anesthetic, the slower the clearance. If fat and muscle reach high partial pressures (after many hours for most potent agents), recovery from anesthesia may be significantly delayed. Therefore, obese patients and those with a higher than normal muscle mass are at risk for slowed emergence after long exposures to soluble anesthetics.

PHARMACODYNAMICS OF INHALED ANESTHETICS

Therapeutic Effects and Anesthetic Depth

Although general anesthesia results in a multitude of physiologic alterations, there is no consensus among clinicians and researchers as to which actions are essential to the state of general anesthesia.[17] Our view is that the common desired outcomes of general anesthesia include hypnosis (loss of awareness), amnesia (loss of memory), and immobility (suppression of movement in response to pain). Some have argued that analgesia is also an essential component.[18] Pain is unquestionably a critical consideration in perioperative care, but the potent sedative/hypnotic effects of most general anesthetics confound the assessment of pain. Hypnosis and amnesia are produced via drug effects on neural networks within the brain, whereas immobility is primarily mediated by the spinal cord. In short, the major therapeutic actions of volatile anesthetics take place in the CNS. Beneficial and toxic effects of inhaled anesthetics on other physiologic systems (e.g., cardiovascular function, respiration) thus can be regarded as secondary. In this section, we discuss various measurements of anesthetic effects in the nervous system, as well as their limitations.

Because general anesthesia is defined as the loss of normal responses to environmental stimuli, anesthetic depth is most rigorously defined by stimulus–response testing using stimuli that range from benign (e.g., spoken commands) to noxious (e.g., laryngoscopy or surgical incision).[19] In addition, certain consistent pharmacologic effects of anesthetics that are stimulus independent are useful signs of anesthetic depth. Traditionally, both

TABLE 37–3.

Classic Stages and Planes of Inhalational Anesthesia

Stage 1 is defined as the time between normal waking state and the loss of consciousness *(hypnosis)* due to an anesthetic agent. There is also mild *analgesia* in Stage 1 anesthesia.

Stage 2 is associated with loss of awareness and recall *(amnesia)*. Stage 2 is associated with the undesired effects of cardiovascular instability excitation, dysconjugate ocular movements, and emesis.

Stage 3 is defined as surgical anesthesia, a state where *movement in response to pain in suppressed*. Various planes of anesthesia were described by Guedel, based on additional physiologic signs:

- *Plane 1* is associated with deep respiration, coordinated thoracic and diaphragmatic muscular activity, and papillary constriction.
- *Plane 2* is associated with diminished respiration, as well as fixed midline and dilated pupils.
- *Plane 3* is associated with continued diaphragmatic movement, diminished thoracic movement, and further papillary dilation.
- *Plane 4* is associated with thoracic immobility and diminished diaphragmatic movement.

Stage 4 is associated with cessation of spontaneous respiration and medullary cardiac reflexes and may lead to death.

desired and undesired clinical effects have been associated with the various stages and planes of anesthesia introduced by Snow[20] and modified by Guedel.[21] These descriptions (Table 37–3) were developed during the era of ether and chloroform anesthesia and therefore are not fully applicable to modern practice.

Minimum Alveolar Concentration, Minimum Alveolar Concentration–Awake, and Minimum Alveolar Concentration for Blockade of Autonomic Responses

Minimum Alveolar Concentration

In 1965, Eger introduced the concept of minimum alveolar concentration (MAC) as a stimulus–response measure of anesthetic potency.[22,23] *MAC is the alveolar concentration of inhaled anesthetic that prevents movement in half of subjects in response to a surgical incision.* Thus, MAC is the equivalent of a median effective dose (ED_{50}) for inhibition of movement in response to a specific noxious stimulus. If different noxious stimuli (e.g., varying point pressures or electric shocks) are used, the concentration of inhaled anesthetic required to suppress movement increases with stimulus intensity. Thus, MAC is most useful for comparing potency among different inhaled agents under the same conditions, with potency being inversely related to MAC. During measurement of MAC, equilibrium between the alveolar compartment and the nervous system must first be established. Other drugs that modulate pain sensation (e.g., opioids) or movement (muscle relaxants) cannot be present. MAC as originally defined depends on atmospheric pressure, but when agent concentration is expressed as a partial pressure, MAC becomes independent of ambient pressure. The MAC values of common inhaled agents in oxygen (Table 37–2) show that N_2O is least potent, followed by desflurane, sevoflurane, enflurane, isoflurane, and halothane. By definition, an exclusively inhalational anesthetic to a level of 1 × MAC is inadequate to prevent movement in half of patients. The ED_{95}, which is approximately 1.3 × MAC, may be a more clinically useful value. The ED_{95} corresponds to 0.9% for halothane, 1.68% for isoflurane, and 1.88% for enflurane.

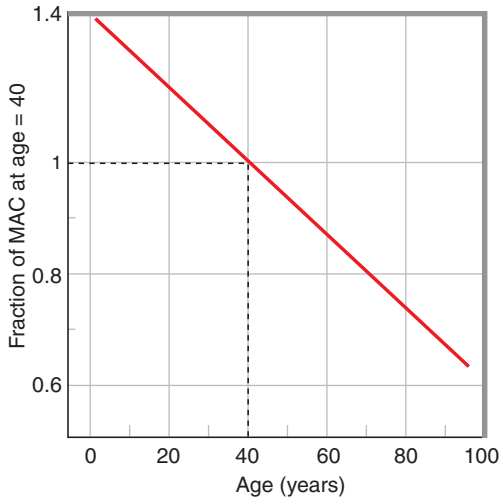

FIGURE 37–14. Minimum alveolar concentration (MAC) varies with age. MAC is maximal in the first year of life and drops with age. The figure shows the relationship on a semilogarithmic scale. The equation of the line is $MAC/MAC_{40} = 1.32 \times 10^{-0.00303Age}$, or a 6.7% drop in MAC per decade (Eger[24]).

Physiologic, genetic, and pharmacologic conditions may alter MAC. *MAC decreases with age* (Fig. 37–14). MAC was first measured in patient populations with an average age of approximately 40 years. Further studies showed that MAC is highest within the first year of life (age 6–12 months) and decreases with advancing age[24,25]

Physiologic factors such as temperature influence MAC. For each 1°C decrease in core temperature, anesthetic requirements decrease by 5%. Other physiologic extremes that affect CNS function (hypoxia, hypercapnia, acidosis, hypotension) also decrease MAC.

Whether MAC is affected by gender is controversial. Elderly Japanese women require 26% less xenon than do elderly Japanese men. In young men and women, however, MAC for desflurane does not significantly differ.[26] MAC is reduced in the parturient.[27] Increases in either progesterone or endogenous opiates (endorphins) during pregnancy have been proposed to account for increased anesthetic sensitivity, but these theories have not been substantiated by experiments.

Pharmacogenomic factors play a role in determining MAC. Mice of varying genomic backgrounds are differentially susceptible to volatile anesthetics such as halothane, isoflurane, and sevoflurane.[28] In humans, natural redheads have a significantly higher desflurane MAC than do other patients (Fig. 37–15).[29] Ninety percent of the

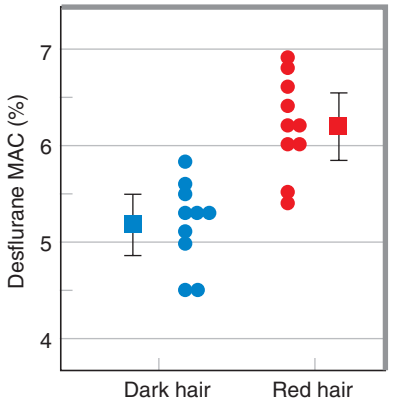

FIGURE 37–15. Minimum alveolar concentration (MAC) values are increased in natural redheads. On average, redheads require about 20% higher alveolar concentrations of desflurane to prevent movement. Anesthetic requirements for individuals are represented by circles; means are represented by squares; bars indicate 95% confidence intervals. (From Liem et al.[29] with permission.)

redheads tested had mutations reducing expression of the melanocortin-1 receptor gene. Genetically altered (knock-out) mice lacking the melanocortin-1 receptor gene also display a modest increase in MAC for desflurane, isoflurane, sevoflurane, and halothane.[30]

Pharmacologic factors alter MAC. The addition of 70% N_2O reduces the anesthetic requirements of other inhaled agents by 55–70% (Table 37–2). MAC is an additive phenomenon when two or more inhaled agents are combined.[31] Adjunct opiate or benzodiazepine administration reduces MAC. Acute alcohol intoxication reduces MAC, whereas chronic intake of alcohol or sedatives can increase resistance to anesthetics, a phenomenon known as *cross-tolerance.*[32]

MAC reflects the effects of inhaled anesthetics in the spinal cord. In animal models, MAC has been shown to be primarily dependent on anesthetic effects on the spinal cord and not on the brain.[33,34] Anesthetic-induced immobility is likely due to suppression of spinal motor neuron function, observed as a diminished Hoffmann reflex (H-reflex) and F-wave amplitudes.[35,36] Suppression of movement and H-reflex amplitude by sevoflurane follow similar dose–response relationships in humans.[37]

Minimum Alveolar Concentration–Awake

Minimum alveolar concentration–awake (MAC–awake) is the concentration of inhaled anesthetic that inhibits appropriate responses to spoken commands in half of patients.[24] MAC–awake has been measured both during induction of anesthesia (loss of response) and during emergence from anesthesia (recovery of response). The ratio of MAC–awake to MAC is not uniform for all inhaled agents. It is fairly constant for the halogenated volatiles (≈0.35 × MAC) and significantly higher for N_2O,[38] which likely reflects differing mechanisms of action (see Chapter 36).

Functional recovery from anesthesia is determined by MAC–awake for the specific agent as well as by its elimination kinetics. Therefore, the time needed to wake up after an anesthetic, especially a long one, depends on what concentration of anesthetic was inhaled relative to its MAC–awake. If the inhaled concentration was 2 × MAC–awake, then only a 50% reduction in P_{alv} will be needed before the patient awakens, which usually is rapidly achieved for most agents. If higher concentrations were inhaled, then recovery may be more than proportionately slowed because the slower phases of agent elimination will have a more dominant effect (see Elimination of Inhaled Anesthetics via Ventilation above).

Like MAC, MAC–awake is reduced in the elderly, by hypothermia, and by the presence of other drugs with hypnotic activity (ethanol, benzodiazepines, anticonvulsants, antidepressants).[24] MAC–awake also is reduced by neuraxial blockade (spinal or epidural), despite intact cranial nerve function.[39–42] This effect is believed to be due to diminished ascending signals from the spinal cord, which stimulate cortical arousal via the brainstem. MAC–awake is decreased by high doses of opiates, but this effect is smaller than the reduction of MAC.[43]

MAC–awake (hypnosis) is associated with volatile anesthetic effects on the cerebral cortex, γ-range (40-Hz) signals from different cortical regions become desynchronized during the transition from conscious to unconscious states.[44] Synchrony among widespread cortical networks is believed to be associated with higher cognitive function, and its interruption may account for loss of consciousness.[45] Loss of "functional connectivity" among different cortical networks during anesthesia has been demonstrated by functional brain imaging studies.[46,47]

Low concentrations of inhaled anesthetics block memory more than awareness.[38] When inhaling agents at MAC–awake, only a small fraction of "aware" experimental subjects (those responding to spoken commands) can recall events.[48] Amnesia is likely due to effects on the limbic network, including the amygdala and hippocampus. Lesions in the basolateral amygdala produce resistance to the amnestic effects of sevoflurane in animals.[49] Volatile anesthetics both attenuate hippocampal activity and inhibit long-term potentiation of hippocampal synapses that is associated with memory formation.[50,51]

Minimum Alveolar Concentration for Blockade of Autonomic Responses

Minimum alveolar concentration for blockade of autonomic responses (MAC–BAR) is the alveolar anesthetic concentration that suppresses cardiovascular responses to surgical incision in half of patients.[52] MAC–BAR typically is greater than MAC. For example, MAC–BAR for desflurane is 1.66 × MAC.[52] Like MAC and MAC–awake, MAC–BAR is reduced by opiates.[19]

Limitations on Traditional Anesthetic Depth Measurements

Stimulus–response testing usually is impractical in clinical settings. Neuromuscular blocking drugs ablate motor responses to both painful (MAC) and benign (MAC–awake) stimuli. Techniques for maintaining a motor response capability are laborious. As a result, autonomic signs such as blood pressure, heart rate, diaphoresis, tearing, and pupillary responses often are the only accessible data for assessing depth of anesthesia. These signs are valuable but unreliable guides to anesthetic depth. They also are confounded by drugs and diseases that impair cardiac and/or autonomic nervous system functions.

Numerous factors affect anesthetic sensitivity (including unknown genetic factors), resulting in widely varying individual anesthetic requirements. Too little anesthetic puts patients at risk for intraoperative awareness (see Intraoperative Awareness and Recall). Conversely, deep anesthesia (>1.5 × MAC) for all patients is neither feasible nor advisable. Deep inhalational general anesthesia in patients with cardiac disease, hypovolemia, and critical illnesses predictably causes profound hypotension and organ hypoperfusion. Healthy patients may tolerate deep anesthesia, but this practice results in slow emergence

and a high incidence of side effects. Research also suggests that excessively deep general anesthesia may accelerate the pathogenesis of neurodegenerative diseases such as Alzheimer's dementia[53] and may be associated with increased late mortality.[54] The delivery of sufficient but not excessive anesthesia together with optimal surgical conditions represents a central challenge facing the anesthetist.

Electroencephalographic Measurement of Anesthetic Depth

Given that the modern practice of general anesthesia frequently includes neuromuscular blockade to provide immobility, narcotics to provide analgesia, and other drugs to control autonomic activity, the essential therapeutic effects of general anesthetics are hypnosis and amnesia (ablation of awareness and memory). These effects, which are mediated in the brain, are the most difficult to assess clinically. Monitors that analyze electrical signals from the brain can provide anesthetists with more data to individualize the titration of general anesthetics to achieve these end points.

A number of techniques based on electroencephalography (EEG) have been developed and used. Fourier transformation of raw EEG data enables the derivation of median power and spectral edge frequencies.[55] Other EEG analyses assess bispectral phase relationships, burst suppression, and entropy. The bispectral index (BIS; Aspect Medical Systems, Natick, MA) is a proprietary algorithm based on burst suppression, near burst suppression, α-band power, and phase relationships between δ and θ waves.[56] The patient state index (PSI; Physiometrix, Inc., North Billerica, MA) is based on EEG component relationships between the frontal and occipital regions.[57] Entropy monitors (e.g., S/5, Instrumentarium Corp. [Datex-Ohmeda], Helsinki, Finland) analyze entropy (randomness in frequency and phase relationships) using both EEG and frontal electromyography.[58] Some of these monitors are available for intraoperative use for assessing hypnosis and detecting undesired consciousness. The concentration-dependent effects of volatile anesthetics correlate with EEG indexes such as BIS and spectral entropy (Fig. 37–16).[59] Auditory evoked potentials (a stimulus–response method) also have been used to assess anesthetic-induced unconsciousness and can be used in conjunction with other EEG parameters.[60,61] Nonetheless, all of these monitors have important limitations. Further research in identifying neural and EEG correlates of consciousness may improve their utility to assess the depth of anesthesia.

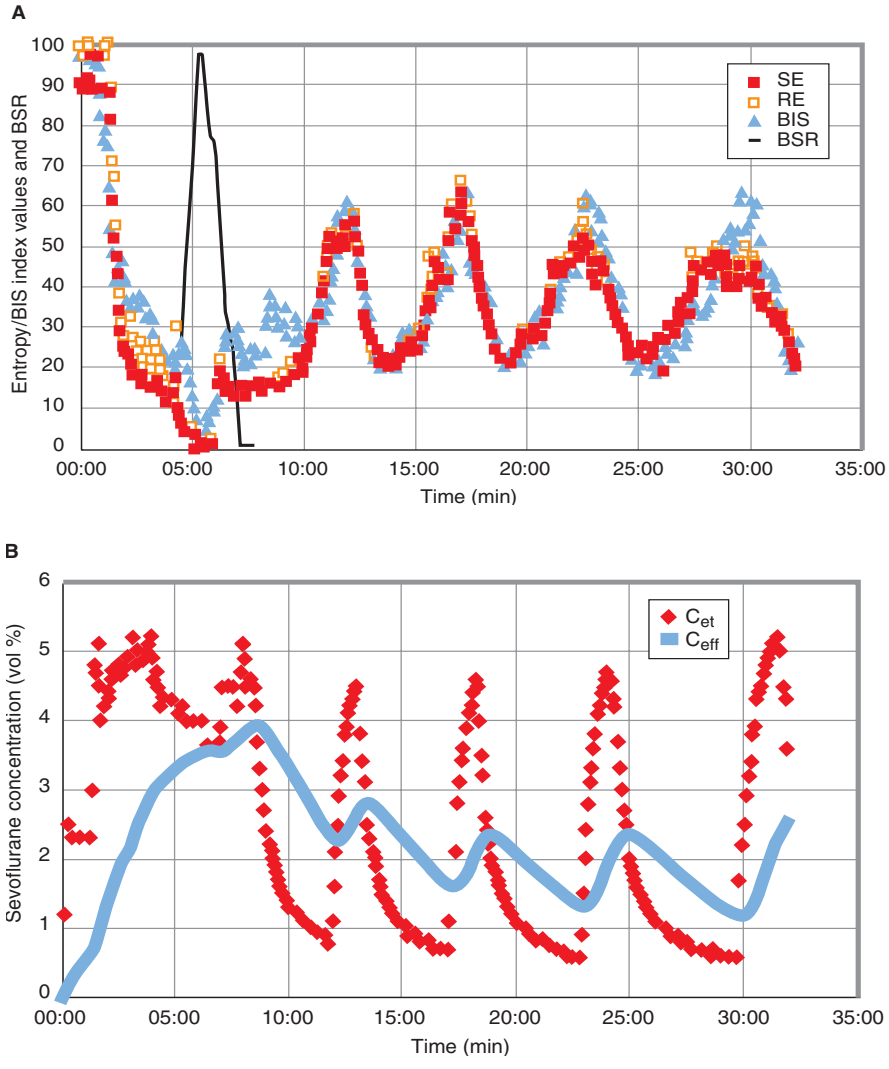

FIGURE 37–16. Correlation between processed electroencephalographic (EEG) parameters and volatile anesthetic concentration. **A.** Time course of state entropy (SE), response entropy (RE), bispectral index (BIS), and burst suppression ratio (BSR) of a single patient. Each symbol represents an EEG parameter of a 5-second epoch. **B.** End-tidal sevoflurane concentration (Cet) and calculated effect site concentration (Ceff) during the same time course in the same patient. INTRAOPERATIVE AWARENESS AND RECALL

The variability in patient sensitivities to general anesthetics and the uncertainty in clinical assessment of anesthetic depth inevitably result in some patients receiving either supratherapeutic or subtherapeutic doses of anesthetic agents. Inadequate anesthesia can result in awareness and explicit recall of intraoperative events, a problem that is a subject of clinical, public, and scientific attention.[62]

Incidence of Awareness with Recall during General Anesthesia

Large studies in both Sweden[63] and the United States[64] have used multiple postoperative interviews (Table 37–4) to elicit reports of intraoperative awareness. In a total of 31,360 combined patients, 40 cases of "definite" and "probable" awareness with recall were identified, an incidence of 0.13%. Assuming 30 million general anesthetics are administered, the number of patients experiencing

TABLE 37–4.

Modified Brice Interview

1. What is the last thing you remember before anesthesia?
2. What is the first thing you recall after waking up?
3. Do you recall anything in between?
4. Did you have any dreams during surgery?
5. What was the worst thing about your surgery and anesthesia?

Data from Brice DD, Hetherington RR, Utting JE. A simple study of awareness and dreaming during anaesthesia. Br J Anaesth 1970;42:535-42.

awareness with recall is approximately 40,000 per year in the United States.

Patient Reports and Posttraumatic Stress Disorder after Intraoperative Awareness

Spontaneous reports by patients of intraoperative awareness are rare, emphasizing the need to ask about these events using a structured interview.[65] Patients report a variety of intraoperative experiences following general anesthesia. A high proportion of these experiences are vague and dreamlike, whereas others are explicit recollections of intraoperative events. Explicit recollections may include hearing conversations among operating room personnel, pain associated with intubation or surgery, and extreme anxiety, particularly in paralyzed patients. These experiences can lead to postoperative psychological problems, the most severe being posttraumatic stress disorder (PTSD). PTSD is characterized by recurrent episodes of anxiety, irritability, anger, and vigilance, often associated with flashbacks or nightmares, avoidance of cues related to the trauma, and sleep disturbances.[66] The incidence of PTSD following intraoperative awareness is not known, but it is likely dependent on the length of the awareness episode and on the presence of pain, anxiety, and preexisting psychological problems. In a small study of 16 postawareness patients, more than 50% developed symptoms of PTSD requiring psychotherapy.[67]

Risk Factors for Awareness During General Anesthesia

The factors that contribute to intraoperative awareness include the use of muscle relaxants, patient resistance to anesthetics, surgical situations where "light" anesthesia typically is used, and errors by the anesthesia care team (Fig. 37–17).[68] Awareness with recall has been reported in patients who were anesthetized without muscle relaxants, but these cases are rarer than in patients in whom muscle relaxants were given.[69] Furthermore, severe psychological problems seem to develop primarily in patients who experience "awake paralysis" with anxiety and pain.[70] Patients receiving chronic therapy with sedatives, opiates, and some anticonvulsants can develop tolerance (resistance) to anesthetic drugs and require higher than normal anesthetic doses. Pharmacogenomic factors are likely to play a role, and patients with either a personal or a family history of awareness during general anesthesia may be at increased risk. Surgical procedures associated with high incidences of intraoperative awareness include major trauma, thoracoabdominal, and cardiac surgery. In these settings, hemodynamic instability often precludes the use of sufficient anesthetic agent concentrations to block awareness, resulting in reported incidences of awareness ranging from 1–40%.[71,72] Caesarean section under general anesthesia, where a "light" anesthetic is provided to reduce depression

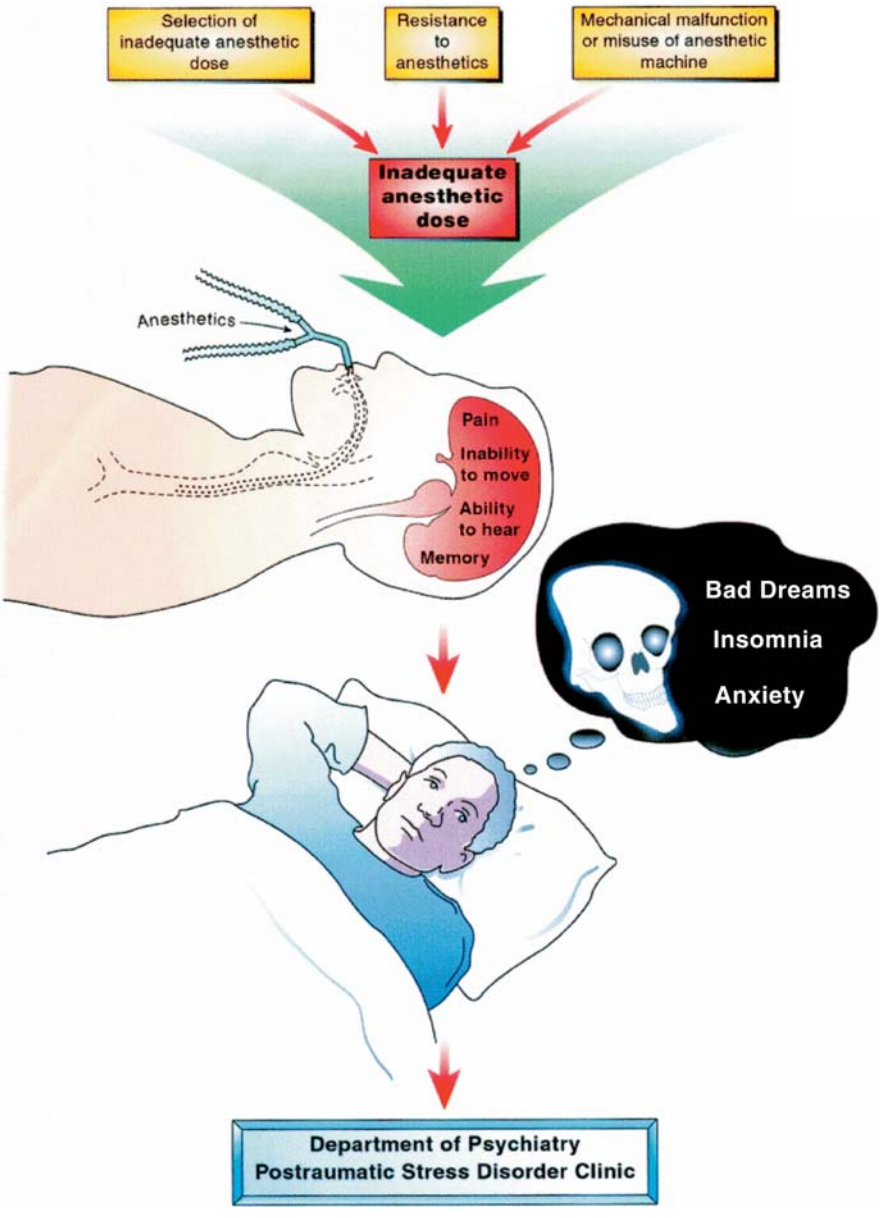

FIGURE 37–17. Causes and consequences of awareness during anesthesia. (From Ghoneim[68] with permission.)

of the newborn, also is associated with a high incidence of awareness (0.4%).[73] Inadequate dosing, misuse of equipment, and distraction of the care team can lead to patient awareness. Many cases of awareness appear to occur during prolonged attempts at airway intubation, when the hypnotic effect of intravenous induction agents wears off before muscle relaxants. Other reports have described awareness when vaporizers were empty or when drug pumps were not delivering proper doses of hypnotic agents. Reviews of awareness during general anesthesia incidents report that most cases were preventable.[74]

EEG Monitoring for Intraoperative Awareness

To date, use of one EEG-based monitoring technique (BIS) has been evaluated for its ability to reduce the incidence of awareness. In a follow-up to Sandin et al.,[63] Ekman et al.[75] interviewed 4945 patients who received BIS-guided general anesthesia with intubation and/or muscle relaxants. Two cases of awareness (0.04%) were found, an incidence 80% below that of the historical control group. Myles et al.[76] conducted a prospective, randomized, double-blinded, multicenter trial of 2463 patients at high risk for awareness with recall, who were assigned to either a standard care or a BIS-guided anesthesia group. Postoperative interviews identified two patients (0.16%) who experienced awareness with recall in the BIS-guided group and 11 (0.9%) in the high-risk control group. Of note, use of the BIS monitor in this study did not reduce the total number of reports of intraoperative experiences in the subjects tested (including reports judged as "possible awareness" or "no awareness") but only those with "confirmed" awareness with recall.

A number of confounding factors can affect the BIS, resulting in the possibility of reassuring monitor values with concomitant awareness. These factors include electrical artifact from electrocautery devices, physiologic alterations such as hypoglycemia, low-voltage EEG due to genetic variation or drugs, and neurologic abnormalities such as Alzheimer's dementia.[77] A common confounding factor that can alter BIS and spectral entropy values is electromyographic (muscle) activity and its reduction with neuromuscular blockade.[78,79] Furthermore, as with any monitor, appropriate interpretation and response are required for efficacy. In an incidence study by Sebel et al.,[64] approximately 40% of patients underwent BIS monitoring, yet this subset of patients did not have a reduced incidence of awareness reports.

Prevention and Management of Intraoperative Awareness

Preventing intraoperative awareness with recall begins with recognizing and addressing known risk factors. Caregivers must be familiar with their equipment, and they must maintain and use it properly. Amnestics, such as benzodiazepines, can reduce the incidence of awareness with recall and should be considered as premedication for most patients and in intraoperative circumstances where "light" anesthesia is unavoidable. Muscle relaxants should be used judiciously to provide adequate relaxation for surgery and avoided whenever possible. N_2O relaxant anesthesia should be supplemented with adequate (1.5–2 × MAC–awake) volatile anesthetics or intravenous hypnotic agents. When intubation is delayed or multiple attempts are required, consider supplementing the induction bolus with additional inhaled or intravenous agents. *All patients should be routinely informed of the risk of awareness during general anesthesia.* High-risk patients should be monitored using an EEG-based monitor when feasible. EEG monitoring, if used, should be performed according to manufacturer's guidelines, and monitor values suggesting inadequate anesthesia should result in increased dosage of hypnotic agents, unless other circumstances make this inadvisable.

Ideally, all patients should be interviewed in the postoperative period and asked specific questions (Table 37–4) to elicit reports of intraoperative awareness. When awareness is detected, the case should be treated like any complication that results in harm or potential harm to patients. A thorough debriefing of the patient is warranted, and the details of the patient's experiences should be reported in the medical record. Other members of the operative team should be informed, and patient recollections should be corroborated as thoroughly as possible. The incident should be reported to the departmental Quality Assurance Committee and possibly the hospital legal counsel. A patient reporting awareness during anesthesia should be reassured that his/her experience is valid, and an explanation of why and how the intraoperative awareness occurred should be offered. Expressions of sympathy and regret for the patient's suffering can help maintain a therapeutic relationship, and the patient should be offered professional psychological evaluation and therapy if he/she experiences uncomfortable emotional reactions to the experience. Maintaining contact with the patient with daily visits to his/her hospital room or phone calls can reduce malpractice risk.

SYSTEMIC ACTIONS OF INHALED ANESTHETICS

In this section, we summarize both the therapeutic and toxic secondary effects of inhaled anesthetics on important physiologic systems.

Central Nervous System

Cerebrovascular and Metabolic Effects

The effects of anesthetics on cerebral metabolism and vascular tone are summarized in Table 37–5. Normal cerebral blood flow (CBF) is tightly autoregulated and coupled to cerebral metabolic demands. Volatile anesthetics interrupt this autoregulation by acting as direct vasodilators of the cerebral vasculature.[80] Volatile anesthetics dose dependently increase middle cerebral artery blood flow velocity, with sevoflurane causing less vasodilatation than isoflurane or sevoflurane.[81,82] Both K^+ channels[83] and neuronal nitric oxide synthase[84] have been linked to these direct actions of anesthetics.

Volatile anesthetics also decrease the cerebral metabolic rate (CMR) of oxygen consumption.[17,80] Cerebral metabolism is decreased by halothane, isoflurane, sevoflurane, and desflurane.[85] The extent to which flow and metabolism are altered depends on the choice of agent. For example, halothane may increase CBF by almost 200%, but reduce CMR by only 10%.[86] In contrast, isoflurane increases CBF by approximately 20% but reduces CMR by 45%.[87,88] Volatile agents also partially uncouple flow–metabolism relationships and CO_2 reactivity.[89,90] These agents have not been shown to increase intracranial pressure in normocapnic adults undergoing supratentorial brain tumor resection without a

preoperative midline shift.[91] In children, isoflurane, sevoflurane, and desflurane all have been shown to increase intracranial pressure.[92] N_2O is distinguished from the potent volatile anesthetics in that it increases CBF and CMR and may increase intracranial pressure.[93,94] This is partly attributable to its sympathomimetic effects.[95]

EEG Effects

Volatile anesthetics alter the cortical EEG, decreasing high-frequency (γ-band) activity and increasing slower frequencies. Quantitative EEG analysis demonstrates that power shifts anteriorly.[44] In comparison, N_2O has little effect or increases the frequency of the cortical EEG.[96–98] Indeed, EEG-based monitors do not reliably detect the hypnotic effects of N_2O alone or in combination with other anesthetics.[99,100] Deep volatile anesthesia (1.5–2 × MAC) leads to burst suppression or isoelectric EEG patterns. Although all volatile anesthetics have been used to suppress seizures, both enflurane and sevoflurane have been reported to augment epileptic brain activity and may induce EEG patterns associated with epilepsy in normal patients.[101–103] Enflurane and sevoflurane may be useful during cortical mapping for ablation of seizure foci but should otherwise be avoided in patients with seizure disorders.

The effects of anesthetics that are thought to produce the state of general anesthesia are discussed in this chapter and in more detail in Chapter 36. The long-term effects of anesthetics on cognitive function are reviewed in Chapter 87.

Cardiovascular System

The effects of volatile anesthetics on the cardiovascular system are of paramount clinical importance intraoperatively, particularly in patients at risk for end-organ ischemia. They are summarized in Table 37–6.

Mean Arterial Pressure

Volatile anesthetics decrease mean arterial pressure (MAP) in a dose-dependent manner by direct vascular and autonomic nervous effects.[85] Volatile anesthetics reduce MAP by decreasing systemic vascular resistance, increasing vascular compliance (the change in circulatory volume with changes in pressure), and inhibiting myocardial contractility. Halothane depresses myocardial contractility more than other volatile anesthetics. Isoflurane and desflurane decrease systemic vascular resistance, although halothane, isoflurane, and sevoflurane increase arterial compliance (Table 37–7).[104] Desflurane has been found to stimulate sympathetic nervous system activity (especially with rapid increases in vapor concentration), which may account for its minor effect on vascular compliance.[105] N_2O raises sympathetic activity and systolic blood pressure[106] and thus counters the vasodilatory and hypotensive effects of coadministered volatile agents.[107]

Heart Rate

Volatile anesthetics increase heart rate, both by a baroreceptor reflex in response to decreased arterial pressure and by a direct vagolytic effect on the heart. In dogs, desflurane increases heart rate the most, followed by sevoflurane, isoflurane, and halothane.[108] Rapid increases in the alveolar concentration of desflurane are associated with increased heart rate and blood pressure (Fig. 37–18),[109,110] which are attributed to stimulation of sympathetic activity.[105] The minimal effect of halothane on heart rate is associated with its block of the baroreceptor reflex.[111] N_2O is associated with only modest transient increases in heart rate,[112] which reflect its sympathetic effects and preservation of MAP.

Myocardial Contractility

Volatile anesthetics cause myocardial depression, in part by inhibiting calcium ion influx in cardiac muscle.[113] Halothane causes marked dose-dependent inhibition of myocardial contractility and reduces cardiac output.[114,115] Isoflurane, sevoflurane, and desflurane have lesser effects on myocardial contractility. In dogs, all these anes-

thetics depress myocardial contractility, delay cardiac chamber relaxation, reduce chamber stiffness, and impair left atrial–left ventricular coupling.[116,117] N_2O administration also decreases intracellular calcium levels and depresses myocardial contractility.[118,119] Thus, although N_2O minimally affects blood pressure and heart rate, it has negative inotropic effects similar to those of potent volatile agents.

Cardiac Rhythm and Conduction

Volatile anesthetics affect the function of cardiac ion channels, increasing the risk of arrhythmias.[120] Halothane sensitizes the heart to the arrhythmogenic effects of epinephrine,[121] although isoflurane, desflurane, and sevoflurane do not.[122,123] Halothane, isoflurane, desflurane, and sevoflurane all prolong the QT interval.[124125] In dental outpatients, halothane produced more ventricular arrhythmias than did isoflurane.[126,127] In pediatric dental outpatients receiving halothane anesthesia, 48% had ventricular dysrhythmias compared to 8–16% of those inhaling sevoflurane.[128] Furthermore, sevoflurane-induced arrhythmias were primarily single supraventricular ectopic beats, although ventricular tachycardia was observed in 12% of patients receiving halothane. N_2O may induce atrioventricular junctional rhythms[129] and can lower the threshold for epinephrine-induced arrhythmias in conjunction with halothane.[130]

Coronary Artery Perfusion

Isoflurane is a coronary vasodilator and thus can potentially create "coronary steal," a diversion of blood flow away from fixed stenotic lesions.[131] The clinical significance of this phenomenon appears to be mostly theoretical. Isoflurane has been found to be safe in patients with coronary artery disease as long as adequate perfusion is maintained. Isoflurane also provides beneficial effects via ischemic preconditioning.[132] Desflurane and sevoflurane do not cause coronary steal.[133,134]

Respiratory System

Ventilation

Volatile anesthetics depress respiration through both central medullary and peripheral muscular effects. In general, inhaled anesthetics decrease tidal volume and increase respiratory rate. Halothane, isoflurane, desflurane,

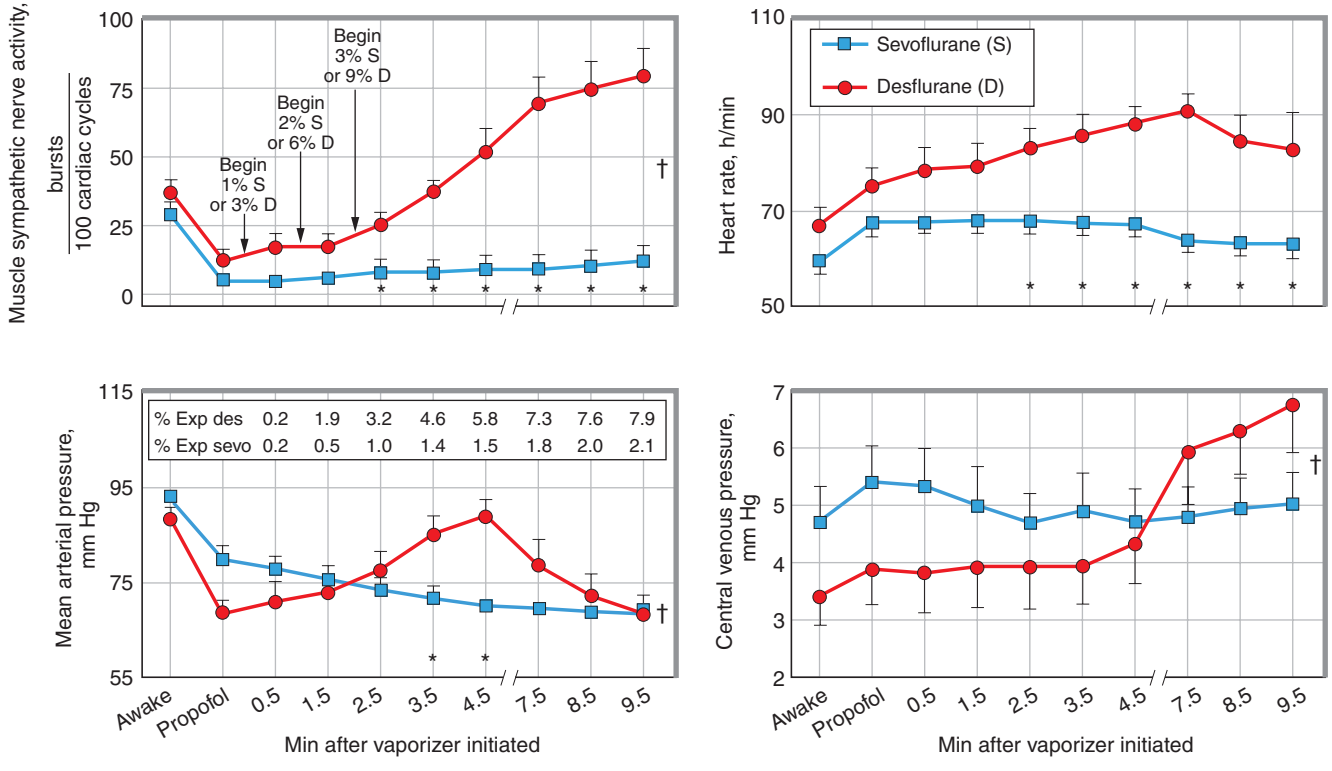

FIGURE 37–18. Effects of desflurane and sevoflurane on basic cardiovascular parameters in human subjects. Consecutive measurements of neurocirculatory variables (mean ± SEM) during induction of anesthesia with propofol and subsequent mask administration of sevoflurane or desflurane for a 10-minute period. The subsequent administration of sevoflurane did not alter heart rate or sympathetic nerve activity but led to a progressive decline in mean arterial pressure. In contrast, desflurane resulted in significant increases in neurocirculatory variables that persisted throughout the 10-minute mask administration period. (From Ebert et al.[110] with permission.)

and sevoflurane dose dependently reduce tidal volume. The concomitant increase in respiratory rate is more pronounced with halothane, desflurane, and sevoflurane than with isoflurane.[133,135–137] Compensatory tachypnea maintains minute ventilation with desflurane up to alveolar concentrations of 1.6 × MAC. Nonetheless, alveolar ventilation is reduced by all volatile anesthetics, resulting in an increased $Paco_2$. N_2O also causes tachypnea and decreased tidal volume, but alone it causes minimal changes in $Paco_2$. N_2O depression of ventilation is additive when given in combination with other inhalational agents.[138]

Factors that contribute to hypoxia and hypercarbia during inhalational anesthesia include hypoventilation, atelectasis, airway closure, decreased functional residual capacity, and ventilation–perfusion ($\dot{V}/\dot{Q}$) mismatch.[139] Volatile anesthetics blunt hypoxic and hypercarbic respiratory drive, increasing the risk of severe hypoxia and hypercarbia in spontaneously breathing patients.[140–142] Depression of hypoxic and hypercarbic ventilatory drives occurs even at subanesthetic doses. N_2O blunts the respiratory drive to hypoxia and hypoventilation, but its clinical effects are minimal because of its low potency.[143] After terminating delivery, rapid elimination of N_2O from blood dilutes alveolar gases and, if supplemental oxygen is not supplied, can lead to *diffusion hypoxia*.[144,145]

Hypoxic Pulmonary Vasoconstriction

Hypoxic pulmonary vasoconstriction (HPV) is a pulmonary vascular mechanism that diverts blood flow away from poorly ventilated areas of the lung, minimizing $\dot{V}/\dot{Q}$ mismatch. The mechanisms underlying HPV are not fully understood, but cyclooxygenase, calcium channels, and potassium channels appear to be involved.[146] N_2O has been shown *in vivo* to inhibit HPV.[147] In isolated lung models, halothane, isoflurane, sevoflurane, desflurane, and N_2O all dose dependently inhibit HPV.[148–150] In many animal studies, however, clinical concentrations of halothane, isoflurane, sevoflurane, and desflurane have not been found to inhibit HPV.[151–154] In a few studies of chronically instrumented dogs, isoflurane was found to attenuate HPV.[155] The conflicting data regarding isoflurane effects on HPV may be due to different flow conditions in the pulmonary vasculature during different experiments.

Bronchial Tone

Most volatile anesthetics, including halothane, enflurane, isoflurane, and sevoflurane, are bronchodilators that decrease respiratory resistance and increase dynamic compliance (Table 37–8).[156] At equi-MAC concentrations, respiratory resistance is reduced by sevoflurane > halothane > isoflurane.[157] In contrast to the other volatile anesthetics, desflurane is associated with either no bronchodilatory effects or with bronchoconstrictor effects at higher concentrations.[158] Inhalational induction with desflurane is associated with coughing and increased risk of laryngospasm, which likely is due to its pungency. Sevoflurane causes the least amount of subjective airway irritation and is well tolerated during inhalational induction.[159] N_2O has no effect on respiratory resistance.[157]

Hepatic and Renal Systems

Liver

Volatile anesthetics reduce overall hepatic perfusion by altering portal venous and/or hepatic arterial inflows. Most agents decrease portal venous flow. Isoflurane has the least overall effect on hepatic perfusion because of compensatory increases in hepatic artery flow.[160] In contrast, halothane causes hepatic artery vasoconstriction and decreases overall hepatic blood flow,[161] hepatic oxygen delivery, and hepatic vein blood oxygen saturation.[162] N_2O causes minimal circulatory effects on the liver.

Transient modest increases in liver enzymes are not uncommon following exposure to volatile anesthetics (halothane, desflurane, sevoflurane, and isoflurane). This effect is independent of surgical intervention and almost always is clinically insignificant.[163,164] The increase in liver enzyme levels after halothane administration may be due to anaerobic reductive metabolism that generates free radicals.[165] More severe hepatic injury (halothane hepatitis) is described in the section on Breakdown of Inhaled Anesthetics and Toxicity of Byproducts.

Kidney

Volatile anesthetic agents cause dose-dependent decreases in renal blood flow, glomerular filtration rate, and urine output, which can be minimized with preoperative hydration.[166–168] Autoregulation of renal blood flow is preserved during halothane anesthesia.[167] Decreases in renal blood flow during inhalational anesthesia reflect a reduction in effective circulating volume secondary to increased vascular capacitance. Anesthetics do not directly stimulate antidiuretic hormone (ADH) release, but diminished urine production due to ADH is associated with surgical stress.[169] N_2O causes minimal effects on renal blood flow and function. Nephrotoxicity can be associated with breakdown of volatile anesthetics (see Breakdown of Inhaled Anesthetics and Toxicity of Byproducts below).

Airway resistance	↔	↑	↓	↓	↓

Other Systemic and Adverse Effects

Muscular System

Volatile anesthetics potentiate neuromuscular blockade via direct effects on the neuromuscular junction.[170] The muscle relaxant effect of volatile agents is stronger than that of intravenous anesthetics; N_2O has no relaxant action. In animal models of isolated diaphragmatic muscle, enflurane and sevoflurane enhance fatigability at high concentrations.[171,172] This may be mediated in part by cyclic adenosine monophosphate, as administration of the phosphodiesterase inhibitor olprinone attenuates the effects of volatile anesthetics on diaphragmatic muscular fatigue.

Malignant Hyperthermia

Malignant hyperthermia is a life-threatening clinical myopathy triggered by all potent volatile anesthetics and/or succinylcholine. It is a pharmacogenetic disorder associated with autosomal dominant transmission of genes encoding mutant forms of the skeletal muscle calcium release channel (ryanodine receptor protein or RyR1).[173] Upon exposure to the triggering drugs, patients with malignant hyperthermia develop an exaggerated increase of intracellular calcium resulting in sustained skeletal muscular contracture, which is not affected by neuromuscular blocking agents. Sustained contracture produces a hypermetabolic state, leading to increased CO_2 production and eventually hyperthermia. This condition is fatal unless treated aggressively and rapidly with intravenous dantrolene.

Methionine Synthase Inhibition by N_2O

N_2O irreversibly oxidizes the cobalt atom of vitamin B_{12}, which inhibits the cobalamin-dependent enzyme methionine synthase. This pathway is essential for homocysteine breakdown, nerve myelination, methyl substitutions of neurotransmitters, and DNA synthesis. Most patients are unaffected by temporary inactivation of vitamin B_{12} after N_2O. Nonetheless, this reaction can result in pathology in patients with poor nutrition, preexisting vitamin B_{12} deficiency, or other metabolic diseases that converge on the same metabolic pathways. N_2O exposure has led to "anesthesia paresthetica," which is characterized by paresthesias, ataxias, and poor manual dexterity.[174] In one infant with a preexisting deficiency of 5,10-methylenetetrahydrofolate reductase, another enzyme in the methionine synthetic pathway, it was thought that superimposed exposure to N_2O resulted in neuronal damage, status epilepticus, and death.[175]

Endocrine Function

Halothane and enflurane impair glucose tolerance in animal models by reducing both insulin secretion and receptor sensitivity. Isoflurane has been shown to increase endogenous glucose production and decrease glucose utilization.[85,176] The selection of anesthetic may also play a role in modulating stress responses to surgery. In a study of 20 women requiring laparoscopic surgery for ovarian cystectomy, sevoflurane was associated with less increase of cortisol and adrenocorticotropic hormone levels compared to isoflurane.[177]

Immune Function

Potent inhalational anesthetics can alter immune cell functions in various ways, which in turn may affect recovery from surgery or tumor viability. Halothane depresses the neutrophil oxidative response to inflammatory mediators of infection, whereas desflurane, sevoflurane, and isoflurane have smaller effects.[178] Sevoflurane impairs transcription factors in human lymphocytes, which may reduce the inflammatory response.[179] Volatile anesthetics can induce apoptosis in human T-cells in vitro[180] and may affect cytokine function.[181]

Ischemic Preconditioning

Volatile anesthetics induce cellular responses that protect against ischemia and biochemical stress mediators. For example, sevoflurane decreases markers of myocardial and renal damage after coronary artery bypass grafting.[182] Animal models of renal ischemic injury demonstrate differential preconditioning, with desflurane demonstrating less protective effects against tubular necrosis than sevoflurane, isoflurane, or halothane.[183] Volatile anesthetics can protect against neural ischemia in animal models, through pathways involving both nitric oxide metabolism[184] and potassium channels.[185]

Genotoxicity and Teratogenicity

Halogenated hydrocarbons and ethers can cause DNA damage. Halothane and isoflurane produce genotoxicity in proliferating blood lymphocytes in vitro, whereas sevoflurane does not appear to be cytotoxic in an animal model.[186] The potential for anesthetic-induced teratogenicity has been studied. Prolonged N_2O exposure is teratogenic in a number of embryonic animal models.[187] N_2O inhibition of B_{12}-dependent DNA synthesis is the likely cause. Because of potential genetic damage after chronic exposure to inhaled anesthetics, it is currently recommended that operating room air contain less than 25 parts per million (ppm) of N_2O and less than 2 ppm of halogenated anesthetics. Under these conditions, there is little evidence of significant risk from workplace exposure to inhaled anesthetics.[188] Furthermore, approximately 75,000 pregnant women undergo nonobstetric surgery each year. Although there was once controversy over the effects of surgery and anesthesia in this population, volatile anesthesia appears to be safe for both the parturient and the fetus.[189]

BREAKDOWN OF INHALED ANESTHETICS AND TOXICITY OF BYPRODUCTS

Inhaled anesthetics represent a class of drugs that are eliminated largely via nonmetabolic pathways—for the most part, they leave the body as they entered, unaltered and via ventilatory gas exchange. Undesirable effects directly associated with anesthetics are summarized above (see Systemic Actions of Inhaled Anesthetics), whereas others are caused indirectly by chemical decomposition of inhaled anesthetics into toxic byproducts. The breakdown of volatile anesthetics into potentially harmful chemicals can occur in the presence of CO_2 adsorbents or via enzymatic biotransformation in the body. In general, greater breakdown of inhaled anesthetics leads to greater toxicity.

Nonmetabolic Decomposition of Inhaled Anesthetics

Whereas inhaled anesthetics are chemically stable under normal storage conditions (including within vaporizers), decomposition can occur under certain environmental conditions.

Sevoflurane Breakdown and Compound A

When sevoflurane contacts CO_2 adsorbents containing a strong base (Bara-

lyme and soda lime), chemical decomposition occurs, releasing volatile breakdown products.[190] The major degradation product, compound A [fluoromethyl-2–2-difluoro-1-(trifluoromethyl) vinyl ether], was shown to cause renal injury and death in rats when inhaled at high levels.[191] Renal injury is both dose and time dependent, with a threshold for detectable injury in laboratory animals of 150–300 ppm hours. Nonetheless, in human volunteer and clinical studies, blood urea nitrogen and creatinine levels remain unchanged after exposures that sometimes exceed 300 ppm hours. It is thought that humans sustain less renal injury than rats after compound A exposure because of lower levels of renal cysteine conjugated β-lyase enzyme activity.[192,193] Special laboratory markers for subtle renal tubular damage in humans are elevated after 300 ppm hours of compound A exposure, and levels normalize within a few days.[194] In clinical settings, the inhaled concentration of compound A is proportional to the sevoflurane concentration and inversely related to FGFs. Low gas flows allow compound A to accumulate in the breathing circuit, unlike high gas flows which wash out compound A with waste gases. At FGF ≥ 2 L/min, concentrations of compound A are low enough that the conservative exposure threshold of 150 ppm hours is unlikely to be reached. Sevoflurane package labeling guidelines should be heeded. There is little evidence that sevoflurane is harmful to patients with preexisting renal disease, but other anesthetic agents are more prudent choices.

Volatile Anesthetic Breakdown and Desiccated CO_2 Adsorbents

All the halogenated volatile anesthetics degrade in the presence of dry alkaline CO_2 adsorbents in rebreathing circuits (only sevoflurane breaks down in the presence of moist adsorbent). Decomposition in the presence of dry CO_2 adsorbents releases carbon monoxide (CO), formaldehyde, methanol, and heat. These exothermic reactions have resulted in the ignition of breathing circuit components[195] and in acute respiratory distress syndrome in patients.[196] They also can lead to significant carboxyhemoglobin levels in patients.[197] These problems are preventable and arise only when the CO_2 adsorbent is desiccated (e.g., if flushed overnight with high-flow oxygen) and depend on the type and quantity of strong base in the adsorbent [in descending order of reactivity: KOH > NaOH >> $Ba(OH)_2$]. Sevoflurane releases more heat than does desflurane or isoflurane,[198] whereas CO production is highest with desflurane > enflurane > isoflurane > sevoflurane > halothane.[199,200]

Photochemical Breakdown of Anesthetic Waste Gases

Waste gases scavenged from anesthesia machines enter the atmosphere, where they are exposed to solar radiation and other gases.[201,202] Ultraviolet light catalyzes the reaction between N_2O and O_2, producing the free radical nitric oxide, which in turn destroys atmospheric ozone. Waste N_2O from medical uses is less than 2% of the total added to the atmosphere (the majority results from agriculture and combustion of fossil fuels). All halogenated volatile gases break down when exposed to ultraviolet light to form halogen free radicals, which can deplete atmospheric ozone. Volatile anesthetic waste gases represent only a small portion of total atmospheric chlorofluorocarbons.

Biotransformation of Inhaled Anesthetics

Hepatic Drug Metabolism

In the liver, enzymes can transform volatile anesthetics by oxidation, reduction, and conjugation. These reactions convert hydrophobic substrates into more hydrophilic metabolites that are excreted via the kidneys. Of these, the most important pathways for volatile anesthetics are oxidative, and the enzymes responsible are various members of the large cytochrome P450 (CYP) family. Neonates lack some enzymes that are present in older humans, and diverse other factors, such as genetic variation, can alter individual metabolic activities. Intrinsic liver disease or hepatic congestion due to heart failure may result in diminished enzymatic capacity, and intrahepatic blood flow shunting may reduce the efficiency with which drugs are enzymatically cleared. CYP enzyme activities may be inhibited by drugs such as cimetidine and amiodarone, or they may be enhanced by prolonged exposure to "inducers" such as phenobarbital, phenytoin, and a wide range of other compounds, including inhaled anesthetics.

Halothane Hepatitis

Among the currently available agents, halothane undergoes the most hepatic metabolism (20–25%) and is associated most frequently with significant toxicity. Usually, less than 1% of halothane metabolism is reductive. Oxidative metabolism of halothane by CYP enzymes generates trifluoracetic acid, bromide, and an intermediate metabolite, trifluoroacetyl chloride, which can covalently modify proteins. Acetylation primarily occurs within the liver, and these modified proteins can act as neoantigens that stimulate the immune system to attack hepatocytes, resulting in fulminant hepatic necrosis. "Halothane hepatitis" occurs in 1:6000 to 1:35,000 adults following halothane anesthesia and is fatal in 50–75% of these cases.[203] Genetic factors likely are involved, and females are affected about twice as frequently as males. Many cases of hepatic necrosis occur following multiple exposures to halothane, consistent with an amplified secondary immune response. Halothane hepatitis has been reported in pediatric patients, but its incidence in children is 10–20 times lower than in adults.

Other inhaled anesthetics are metabolized by CYP enzymes to reactive acetyl intermediates that can modify hepatic proteins. Rare cases of fulminant hepatic injury following enflurane, isoflurane, and desflurane have been reported, and the incidence for each compound is related to the relative degree of metabolism (2.5%, 0.2%, and 0.02%, respectively).[204]

Fluoride Nephrotoxicity

Metabolism of some inhaled anesthetics releases inorganic fluoride ions (F^-), which can cause polyuric renal failure and increased mortality. Clinical findings include hypernatremia, hyperosmolarity, and increased blood urea nitrogen and creatinine. This problem is primarily associated with methoxyflurane, a very blood- and tissue-soluble anesthetic that is no longer used. Metabolic release of fluoride is clearly linked to methoxyflurane nephrotoxicity by dose-relationships and experiments in animals. Renal injury after methoxyflurane is rare at fluoride blood levels below 50 μmol/L, whereas moderate injury is seen at 50–80 μmol/L

and severe injury at higher levels. In rats, clinical and pathologic changes similar to those seen in human fluoride nephrotoxicity can be produced by intravenous administration of fluoride at similar levels.

Other fluorinated anesthetics, particularly enflurane and sevoflurane, release readily detectable amounts of fluoride when metabolized in the liver. However, nephrotoxicity is rarely associated with these drugs. Serum fluoride levels during and after enflurane anesthesia usually are below 50 μmol/L, whereas levels during and after sevoflurane anesthesia often peak above 50 μmol/L. However, sevoflurane is much less soluble in blood and tissue than is methoxyflurane. Sevoflurane is eliminated rapidly at the end of anesthesia, which halts fluoride production. In contrast, methoxyflurane is retained in tissues, and fluoride concentrations continue to rise after delivery is halted, reaching peak levels 2–3 days after anesthesia (for review, see Anders[205]). Methoxyflurane, more than sevoflurane, is decomposed to fluoride within the kidney, so intrarenal fluoride levels are higher than those detected in blood samples.[206]

TABLE 37–9.

Advantages and Disadvantages of Inhaled Anesthetics

Anesthetic	Advantages	Disadvantages
Nitrous oxide	No odor, taste, pungency Rapid uptake and elimination Analgesic effect Minimal cardiovascular depression Minimal biotransformation	Airspace expansion ↑ Nausea/vomiting Inhibits methionine synthase Environmental pollutant Supports combustion
Halothane	Inexpensive Nonpungent	Myocardial depression Arrhythmias Halothane hepatitis risk Very slow uptake and elimination
Enflurane	Good muscle relaxation Stable heart rate	Pungent Slow uptake and elimination Epileptogenic
Isoflurane	Good muscle relaxation Maintains cardiac output Low biotransformation Inexpensive	Pungent Slow uptake and elimination
Desflurane	Rapid uptake and elimination Very low biotransformation	Airway irritant Sympathetic stimulant Requires electric vaporizer Breakdown to carbon monoxide in circuit Expensive
Sevoflurane	Rapid uptake and elimination Nonpungent	Breakdown to compound A in circuit Potentially nephrotoxic Expensive
Xenon	No odor, taste, pungency Very rapid uptake and elimination Analgesic effect Minimal cardiovascular depression No toxic metabolites Environmentally safe Inhibits combustion	Limited worldwide supply Expensive Airspace expansion

INERT GASES: FUTURE ANESTHETICS?

Although the safety and speed of inhaled anesthetics have improved greatly since the 19th century, all of the currently used agents are far from ideal because of their toxic effects on various physiologic systems (Table 37–9). The inert gas xenon was shown to produce anesthesia in 1951, and further study has revealed a pharmacokinetic and pharmacodynamic profile that approaches the ideal for an inhalational anesthetic.[207,208] Xenon is an odorless, tasteless, nonflammable, nonexplosive gas. Like other noble gases (helium, neon, argon, krypton, and radon), it is entirely chemically inert, undergoes no metabolic transformation, and has no direct negative environmental effects. Xenon does not cause airway irritation, and its blood/gas partition coefficient is 0.14, which makes inhalation induction significantly faster than with N_2O or desflurane. Xenon, like N_2O, produces minimal cardiovascular or respiratory depression. It produces no direct systemic organ toxicity, and there is evidence that xenon has neuroprotective effects,[209] including attenuation of cognitive dysfunction after cardiopulmonary bypass in an animal model.[210] Because MAC for xenon is approximately 0.7 atm, its use as a sole anesthetic agent is possible. One of its few negative physiologic effects is, like N_2O, airspace expansion. Xenon has analgesic effects, which likely are due to inhibition of *N*-methyl-D-aspartate (NMDA)-sensitive glutamate receptors. Unlike ketamine, an intravenous anesthetic that also acts on NMDA receptors, xenon is not associated with emergence delirium.

The main barrier to routine use of xenon is its limited worldwide supply and the prohibitive cost of isolating and concentrating it. Xenon cannot be synthesized, so these factors are unlikely to change unless new sources are discovered. Energy expended in collecting xenon creates secondary negative environmental impacts. Methods for conserving (closed-circuit delivery) and reclaiming xenon from waste gases may make xenon more economically viable in the future.

CHAPTER 38

Anesthesia Delivery System

James B. Eisenkraft, MD

The anesthesia delivery system is the anesthesiologist's constant companion in the operating or procedure room. Whether a patient is to receive general anesthesia, regional anesthesia, or monitored anesthesia care, the delivery system must be checked and ready for immediate use. An understanding of the structure and function of the anesthesia delivery system is essential to the safe practice of anesthesia.

The anesthesia delivery system has evolved considerably over the past several years. The current voluntary consensus standard describing the features of a contemporary machine is that published by the American Society for Testing and Materials (ASTM) and designated F1850–00. This document, published in March 2000, is entitled *Standard specification for particular requirements for anesthesia workstations and their components*.[1] The term *anesthesia workstation* is defined as a system for the administration of anesthesia to patients. It consists of the anesthesia gas supply device, anesthesia ventilator, monitoring devices, and protection device(s). This standard supersedes the F1161–88 anesthesia machine standard published in 1989 by ASTM.[2]

The above standards represent a consensus adopted voluntarily by the machine manufacturers. Certain accrediting and licensing bodies, however, may choose to adopt such standards in whole or in part and make them requirements for machines used in that locality. The reader is referred to the source documents for more details.

The recent evolution of the anesthesia workstation and advances in technology have led to many changes in design. While all of the basic operations remain the same, the functions of many of the traditional components are now performed by more technologically advanced components. In many new models, the familiar rotameter tubes are replaced by virtual

KEY POINTS

1. A basic understanding of the anesthesia delivery system and its components is important to the provision of safe patient care.
2. The current voluntary consensus standard describing the features of a contemporary anesthesia workstation is the American Society for Testing and Materials (ASTM) F1850–00, published in 2000.
3. A full oxygen tank (E cylinder) has a pressure of approximately 1900 psig (pounds per square inch gauge) and evolves 660 L of gaseous O_2 at atmospheric pressure (14.7 psia [pounds per square inch absolute], 760 mm Hg).
4. By applying Boyle's law, the pressure gauge can indicate fullness of the O_2 tank.
5. Tank O_2 supply is regulated to enter the anesthesia machine at 40–45 psig. Pipeline O_2 is regulated to 50–55 psig.
6. The pin-index and diameter-index safety systems ensure that the correct medical gas enters the correct part of the machine.
7. The "fail-safe" valve (pressure sensor shut-off valve, O_2 failure protection device) only ensures that if the O_2 supply pressure is adequate, nitrous oxide (N_2O) and other gases may flow to their flow-control valves. This valve does not ensure O_2 flow.
8. N_2O can exist as a liquid at room temperature.
9. N_2O E cylinders have a pressure of 750 psig (the saturated vapor pressure of N_2O at 20°C) as long as some liquid N_2O remains.
10. Only one flow-control knob should exist for each gas emerging at the common gas outlet.
11. The O_2 flowmeter should be located downstream of all other gas flowmeters, that is, it should be the one closest to the common gas outlet.
12. The O_2 and N_2O flow controls are interlinked so that a gas mixture containing 25% or greater of O_2 is created at the flowmeters when N_2O and O_2 are in use. Use of a third or fourth gas may "defeat" this feature.
13. An O_2 analyzer in the patient circuit is essential to detect a hypoxic mixture. It should be automatically enabled and the low O_2 alarm set whenever the machine is capable of delivering an anesthetic gas mixture.
14. Anesthesia vaporizers create a saturated vapor concentration of the anesthetic and then dilute it to clinically useful concentrations.
15. The ideal vaporizer construction material has high specific heat and thermal conductivity.
16. Contemporary vaporizers for halothane, isoflurane, enflurane, and sevoflurane are variable-bypass, concentration-calibrated, and temperature-compensated vaporizers.
17. The volume of gas leaving a vaporizer is greater than that entering it because of the addition of anesthetic vapor.
18. The output of a variable-bypass, concentration-calibrated, agent-specific vaporizer is determined by the splitting ratio created by the dial setting. This determines what flow bypasses the vaporizing chamber (bypass flow) and what flow enters the vaporizing chamber to evolve the agent at its saturated vapor concentration.
19. Vaporizers are agent-specific. Erroneous filling should be avoided, and the use of agent-specific filling devices is encouraged.
20. Desflurane has a vapor pressure of 669 mm Hg at 20°C and boils at 22.8°C. It cannot be used in traditional designs of variable-bypass vaporizers. Desflurane is administered using the Tec 6 or D-Vapor vaporizer, in which the agent is heated to 39°C to form vapor under pressure at 1500 mm Hg and this vapor is added to the fresh gas stream. The ADU Aladin vaporizer is a hybrid variable-bypass and measured-flow design that can be used for all 5 inhaled anesthetics.
21. The anesthesia machine should be checked each day before anesthetizing the first patient and whenever any change has been made to the system. A shortened checkout should precede each administration of anesthesia. The checkout procedure should follow the directions given in the machine's operation and maintenance manual.

Continued

Key Points—continued

22. Presently, a positive-pressure check for leaks is recommended for traditional Dräger Narkomed machines and a negative-pressure check for Datex-Ohmeda machines. The FDA 1993 preuse checkout recommends the negative pressure leak check for traditional machines.

23. Use of free-standing vaporizers downstream from the common gas outlet can be hazardous and should be avoided.

24. Anesthesia circuits are classified as rebreathing (no CO_2 absorption) or nonrebreathing (including a CO_2 absorber; e.g., circle system).

25. In all circuits, the higher the fresh gas flow, the closer inspired gas composition approaches that of fresh gas.

26. Anesthesia ventilators are traditionally pneumatic and of "bag-in-a-bottle" or "double-circuit" design. The bellows is the interface between the patient circuit and the driving gas circuit.

27. Datex-Ohmeda ventilators are driven by 100% O_2, whereas the Dräger AV-E is driven by an air/O_2 mixture in the bellows housing.

28. In traditional ventilators a standing bellows design is preferred as it makes a leak in the breathing system more obvious. The bellows descend on inspiration and ascend on expiration. This design requires that the ventilator relief valve incorporate a positive end-expiratory pressure (PEEP) mechanism.

29. Having set the ventilator rate (f) and tidal volume (V_T) controls, one must appreciate that patient V_T is determined also by fresh gas flow (FGF), inspiratory-to-expiratory (I:E) ratio, circuit compliance, and peak inspiratory pressure:

$$\text{Patient } V_T = \left[\text{Bellows } V_T + \text{FGF} \times \frac{I}{I+E} \times \frac{1}{f}\right] - (\text{circuit compliance} \times \text{peak inspiratory pressure})$$

30. New designs of ventilator use computerized compensation (ADU, Aisys, Smart Vent) or fresh gas decoupling (Apollo, Fabius GS, Narkomed 6400, Anestar) to ensure that V_T is delivered as set on the ventilator.

31. Free-standing PEEP valves may be hazardous if added to the circuit incorrectly. PEEP valves are safer when designed as an integral part of the circuit. Addition of PEEP to a circle may decrease the V_T; the decrease depends on the position of the PEEP valve in the circle. The ideal position is as close to the ventilator pressure relief valve as possible.

32. Waste anesthesia gases should be scavenged.

33. National Institute for Occupational Safety and Health (NIOSH) recommends that exposure of operating room workers to halogenated agents should be kept below 2 ppm. N_2O levels should be controlled so that no worker is exposed at time-weighted average concentrations greater than 25 ppm. The latter guide should result in levels of approximately 0.5 ppm of the halogenated agents.

34. The ASTM F1850–00 standard calls for an integrated and prioritized alarm system, breathing pressure monitoring, and exhaled volume or ventilatory CO_2 monitoring.

35. In the event of a severe machine or gas delivery system malfunction, an alternative means for ventilating the patient's lungs with O_2 (or room air) should be immediately available. Thus a self-inflating bag whose function has been checked should be available in each anesthetizing location.

36. Use error is the most common cause of adverse outcomes in relation to anesthesia gas delivery equipment.

37. User education must be emphasized and there must be a thorough in-service whenever there is a new user or new equipment is introduced.

flowmeters displayed on a computer screen. The gas flow-control needle valves may be replaced by electronically controlled gas-mixing devices. Because space does not permit a detailed description of each model of workstation, the basic components and functions of a traditional anesthesia workstation are described. The reader should then be able to appreciate some of the changes that have been made in the most recent models.

Figure 38–1 depicts the components of a contemporary basic anesthesia delivery system. These include the anesthesia machine itself, which receives the gases oxygen (O_2), nitrous oxide (N_2O), and perhaps a third and fourth gas (e.g., air, heliox) delivered under pressure. A controlled gas mixture in terms of concentration of O_2 and other gas(es), as well as total gas flow rates, is created using the gas flow controls and delivered to a concentration-calibrated vaporizer, where a measured amount of a potent inhaled anesthetic agent may be added. The resulting fresh gas mixture of known composition and metered production rate leaves the anesthesia machine at the common gas outlet and flows continuously to the patient circuit. The patient circuit represents a mini environment that allows respiratory exchange and control of anesthetic and respiratory (i.e., PO_2 and PCO_2) gas tensions in the patient's alveoli, blood, and tissues (e.g., brain). An anesthesia ventilator bellows (or in some recent Dräger models, a piston) may be connected to the breathing circuit, by means of which the patient's lungs can be mechanically ventilated. Excess gases are vented from the anesthesia circuit via either the adjustable pressure-limiting (APL or "pop-off" valve) or the ventilator pressure relief valve. The vented gases enter the waste gas scavenging system and are removed from the operating room, usually through the hospital suction.

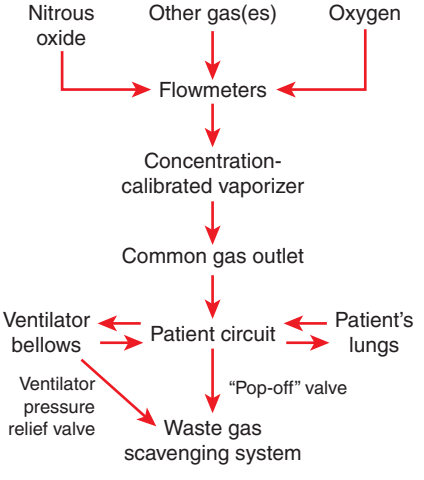

FIGURE 38–1. Schematic of generic anesthesia gas delivery system.

Presently, in the United States, the two largest manufacturers of anesthesia delivery systems (machines, ventilators, vaporizers, scavenging systems) are Dräger (Telford, PA) and Datex-Ohmeda (Madison, WI). Other manufacturers include Datascope, Blease, and Penlon. This chapter reviews the features of a basic anesthesia gas delivery system, referring to the product from a specific manufacturer where appropriate. The approach used is to trace the flow of gases, from their pressurized storage sources, and vapors through the various components of the delivery system, and to understand the function of each component. In this way the reader can more readily appreciate the rationale for the various checkout procedures and have a framework from which to diagnose problems that may arise during use of the equipment. A systematic approach to problems with the delivery system is presented elsewhere.[3] The most comprehensive source of reference for any individual model of workstation is the workstation manufacturer's operator's and maintenance manuals, and the reader is strongly encouraged to review the manual(s) relevant to the reader's equipment. Additionally, an alternative means for delivering O_2 or room air to the patient should be kept immediately available in the event of a severe workstation malfunction. Thus a self-inflating (e.g., Ambu) resuscitation bag, previously tested for correct function and, ideally, a full tank of O_2 should be immediately available in each anesthetizing location.

BASIC ANESTHESIA MACHINE

Figure 38–2 depicts the flow arrangements of a basic two-gas anesthesia

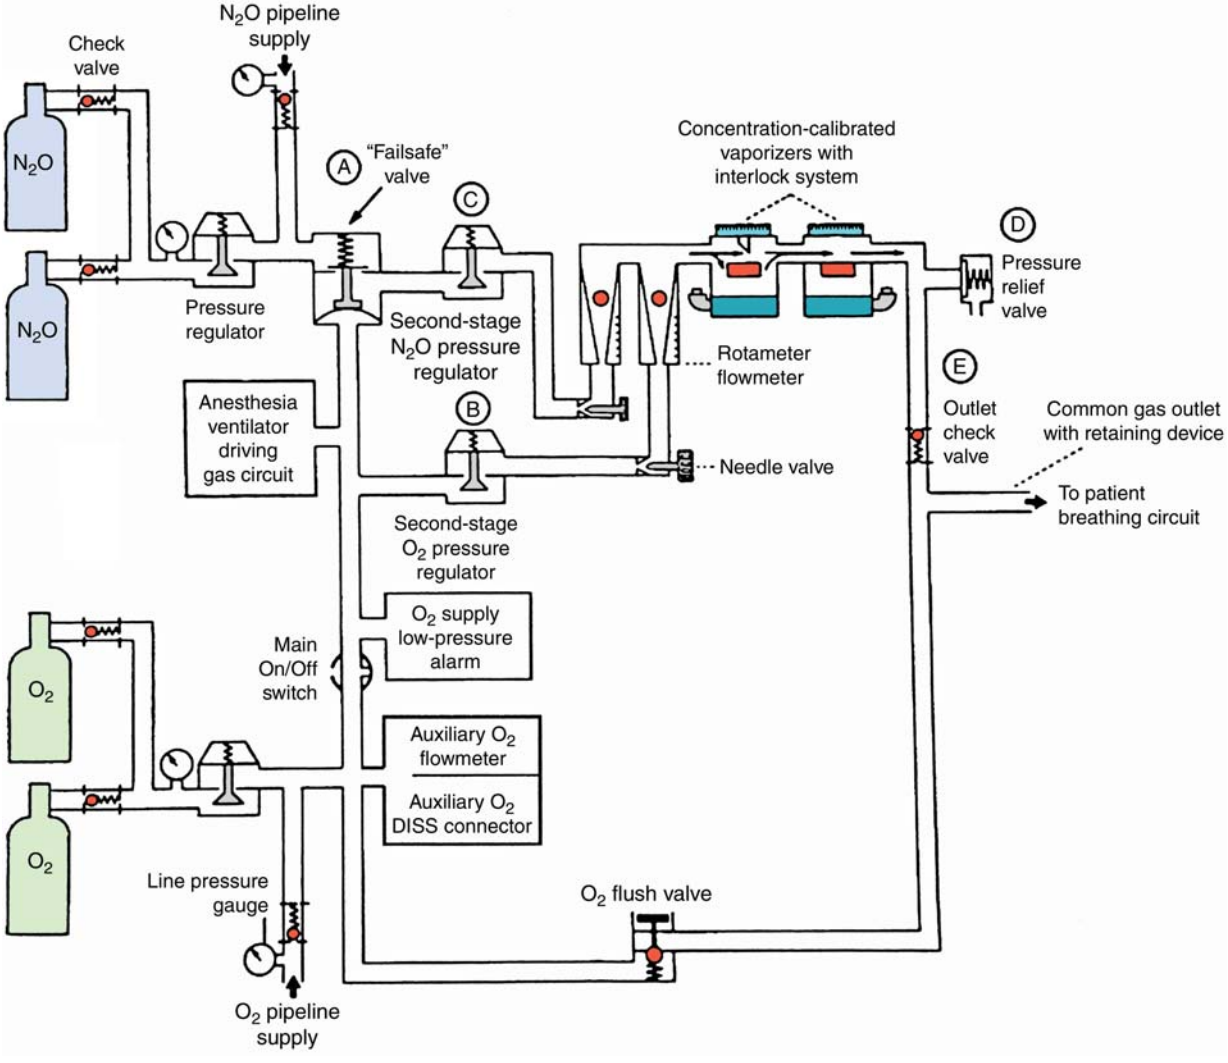

FIGURE 38–2. Schematic of flow arrangements of contemporary anesthesia machine. "Fail-safe" valve *A* in Datex-Ohmeda machines is termed a *pressure sensor shutoff valve*. In Dräger machines, it is the *oxygen-failure protection device* (OFPD). Second-stage O_2 pressure regulator *B* is used in Datex-Ohmeda (but not Dräger Narkomed) machines. Second-stage N_2O pressure regulator *C* is used in Datex-Ohmeda Modulus and Excel machines with the Link-25 Proportion Limiting Control System; this is not used in Dräger Narkomed machines. Pressure relief valve *D* is used in Datex-Ohmeda Modulus machines; it is not used in Dräger machines. Outlet check valve *E* is used in Datex-Ohmeda machines except Modulus II Plus and Modulus CD models; it is not used in Dräger machines. Datex-Ohmeda Excel machines have a pressure relief valve located downstream from the outlet check valve, between this valve and the machine common gas outlet.

machine. The machine receives each of the two basic gases, O_2 and N_2O, from two supply sources: a tank or cylinder source and a pipeline source.

Oxygen

Oxygen has a molecular weight of 32 and a boiling point of –183°C at a pressure of 760 mm Hg (14.7 pounds per square inch absolute pressure [psia]). (Absolute pressure is designated psia and gauge pressure is designated psig [pounds per square inch gauge pressure]. Gauges record pressure above or below existing atmospheric pressure. Thus 1 atmosphere [atm] pressure = 760 mm Hg = 14.7 psia = 0 psig.) Boiling point (the temperature at which O_2 changes from the liquid to the gas phase) is related to ambient pressure such that as pressure increases, so does the boiling point of O_2. However, a certain critical temperature is reached above which, no matter how much pressure is applied, the liquid O_2 boils to a gas. The critical temperature for O_2 is –118°C, and the critical pressure that must be applied at this temperature to keep O_2 liquid is 737 psia. Because room temperature is normally around 20°C and thus well above the critical temperature, O_2 can exist only as a gas at room temperature. This has certain implications for understanding the contents of an O_2 tank.

Oxygen tanks serve as the primary source of O_2 if there is no pipeline in the anesthetizing location, and as a backup supply in case of pipeline failure. Machines are usually equipped with one or two E cylinders, that hang on specific O_2 hanger yokes. The medical gas pin-index safety system ensures that the correct medical gas tank is hung in the correct yoke. The system consists of two pins that are fixed in the yoke, and which fit into two corresponding holes in the tank valve. The two pins are in a unique configuration for O_2 and should never be removed from the hanger yoke. Specific pin configurations exist for each of the medical gases supplied in small cylinders in order to prevent erroneous misconnections of gas supplies. A tank should never be force-fitted to a hanger yoke.

Oxygen tanks are filled at the factory to a pressure of approximately 1900 psig (add 14.7 to convert to psia) at room temperature. Once filled, they contain a fixed number of gas molecules (fixed mass of gas) that obey Boyle's law (i.e., pressure × volume = constant), provided that temperature does not change. A full E cylinder of O_2 at a pressure of 1900 psig will evolve 660 L of gaseous O_2 at 1 atm pressure (14.7 psia, or 760 mm Hg). The internal volume (V1) of an E cylinder is therefore approximately 5 L because, by Boyle's law, P1 × V1 = P2 × V2. Thus 1900 × V1 = 14.7 × 660. If the O_2 tank pressure is 1000 psig, the tank is 1000/1900, or 52% full, and will generate only 660 × 52%, or 340 L of gaseous O_2 at atmospheric pressure. If such a tank were being used at an O_2 flow rate of 6 L/min, it would empty in just under 1 hour (340/6 = 57 minutes). It is important to understand these principles when O_2 cylinders are in use to supply the machine or during patient transport. If the anesthesia machine is equipped with two E cylinders of O_2, only one should be open and in use at any one time so that both tanks are not emptied simultaneously.

There is a check valve in the hanger yoke for each O_2 (and other medical gas) cylinder to prevent leakage of gas out through the hanger yoke if no cylinder is hanging in place and the machine is being supplied by the pipeline or from a second O_2 tank (Fig. 38–2). If two O_2 tanks are hanging, the check valve in the yoke prevents transfilling of gas from one tank to the other. However, these check valves may leak, so if a hanger yoke does not have a tank hanging in it, a yoke plug should be inserted to prevent leakage of gas in the event of an incompetent check valve. These solid plastic block yoke plugs are usually attached to the back of the machine by a chain to prevent their loss. In the Dräger Apollo workstation, the tank pressures are measured using electronic pressure transducers and the values displayed on a screen.[4]

In many medical facilities the O_2 pipeline is supplied from a bulk liquid O_2 source. This may be more economical for the institution, depending on rate and volume of O_2 used.

Liquid O_2 is stored at temperatures of around –160°C under pressure in a storage vessel that resembles a large vacuum (Dewar) flask. When gaseous O_2 is drawn from the top of the storage vessel, liquid O_2 boils to replace it. The boiling (change of phase) helps to keep the remaining liquid O_2 cold. Because the O_2 gas evolved is very cold, it is first passed through a heating coil and then through a pressure regulator that maintains the hospital pipeline pressure at 50–55 psig. Alarms and safety devices, including relief valves and shut-off valves, ensure the safe functioning of the bulk O_2 storage and pipeline systems. Pipeline systems, although usually reliable, may fail. A recent report describes failure between the bulk liquid oxygen storage vessel and the pipeline, which resulted in the release of 8000 gallons of liquid O_2 into the atmosphere.[5] Consequently, ensuring that a backup (tank) supply is available is an important part of the preuse checkout.

Pipeline O_2 is available in the operating rooms usually via gas-specific and manufacturer-specific "quick connectors" or via oxygen-specific diameter-indexed safety system outlets. The operating room wall pipeline "quick-connectors" are both noninterchangeable among medical gases (so that an O_2 hose quick-connector cannot be connected to a N_2O wall outlet) and are also manufacturer specific (e.g., Schraeder, Datex-Ohmeda, Chemetron). At the machine end of the hose that conducts O_2 from the wall outlet to the machine is a connector that is gas specific by a national standard. The diameter-index safety system specifies that at the machine end the medical gas connectors be of different diameter. The diameter- and pin-index safety systems are designed to ensure that the correct medical gas enters the correct part of the anesthesia machine.[6]

For simplicity, the anesthesia machine is described as consisting of two basic systems, a high-pressure system for each gas, and a common low-pressure system for the gas mixture. Those parts upstream of the gas flow-control (traditionally needle) valves contain gas at relatively high pressures and are considered to be the high-pressure system. Those parts downstream of the flow-control valves (Fig. 38–2) contain gas at low pressure (measured in cm H_2O rather than psig) and constitute the low-pressure system. The low-pressure system extends from the flow-control valves to the machine common gas outlet. Although O_2 from the pipeline supply enters the machine O_2 high-pressure system at a pressure of approximately 50 psig, O_2 from a full tank enters the yoke at pressures of approximately 1900 psig. The O_2 tank source is therefore regu-

lated (O_2 passes through a regulator valve) and enters the machine high-pressure system at a nominal pressure of 45 psig (Fig. 38–2).

A pressure regulator is a device that reduces a variable high input pressure (in this case, ~1900 psig from the O_2 tank) to a constant low-output pressure (in this case, 45 psig) for the gas whose pressure is being regulated. Because the tank supply serves as a backup in case the pipeline fails, once the tank pressures have been checked during the preuse checkout, the tank supply should be turned off if gas from the pipeline source is being used. If the O_2 tank(s) remains turned on while the machine is being supplied from the pipeline, O_2 is drawn preferentially from the pipeline supply (50–55 psig) because the regulator that controls flow from the O_2 tanks only permits flow into the machine high-pressure system for O_2 when the pressure in the machine high-pressure system falls below about 45 psig (Fig. 38–2). However, the pipeline pressure at times may fluctuate to below 45 psig, in which case O_2 would be drawn from an open tank. Thus, if the machine is being supplied from the O_2 pipeline, the O_2 tanks on the machine should be turned off to prevent the tank O_2 supply being used and the backup tank supply being unintentionally depleted.

As long as pipeline supply pressure (50–55 psig) exceeds the pressure downstream of the first-stage O_2 (tank supply) regulator, the O_2 tank source will not supply the machine. If one wants to use the tank O_2 to supply the machine, the O_2 pipeline connector should first be disconnected from the wall. Thus, if one should ever suspect that a hypoxic gas (i.e., a gas other than O_2) is being delivered through the O_2 pipeline system at 50–55 psig (e.g., because of pipeline crossover or misfilling of the bulk O_2 supply tank), the machine's O_2 pipeline connection must be disconnected from the wall outlet so as to permit the tank O_2 supply to flow into the high-pressure system.

Having entered the machine high-pressure system for O_2 at a pressure of 45–55 psig (from tank or pipeline), O_2 may flow or pressurize in 7 directions (Fig. 38–2):

1. It provides the power source for a pneumatically driven anesthesia ventilator. Most anesthesia ventilators (e.g., those on Datex-Ohmeda Modulus, Aestiva, Excel ADU, and Aisys machines; Dräger Narkomed 2, Narkomed 3, and Narkomed 4, Narkomed GS, Narkomed Mobile) use compressed oxygen as the driving gas. The driving gas is used to compress ("drive" or squeeze the ventilator bellows during the inspiratory phase of positive pressure ventilation. It is important to realize this because if the machine, and therefore ventilator, are being supplied from the tank rather than the pipeline, the tank will be depleted much more rapidly. In general, the volume of oxygen needed to drive the ventilator is at least the minute ventilation (MV) set to be delivered (e.g., V_T 500 mL, respiratory rate [RR] 10 breaths/min, gives MV of 5 L). Thus, if the pipeline oxygen supply fails during use of the ventilator and one switches to the tank supply, one should consider ways to limit the rate of use of the tank oxygen by ventilating the lungs using the reservoir bag, having the patient breathe spontaneously if possible, and using the lowest flow of oxygen necessary at the oxygen flowmeter.
2. It supplies the auxiliary oxygen flowmeter that is present on most contemporary machines. This is the separate flowmeter that is commonly used to supply a nasal cannula.
3. It supplies oxygen to an auxiliary oxygen diameter-index safety system fitting. This may be used to power a Sanders injector design of jet ventilator, or a venturi design vacuum–suction system.
4. If the oxygen flush control (valve) is opened by pressing the oxygen flush control button, oxygen flows directly (bypassing the flowmeters) to the common gas outlet of the machine at a rate of 35–75 L/min and potentially at a pressure of 50 psig. Consequently, the flush must not be activated if a patient is connected to the breathing system and there is no means for pressure relief. For example, activation of the flush during the inspiratory phase of ventilation, during which gas can enter the breathing system but cannot leave, has the potential to cause positive pressure barotrauma.
5. It pressurizes an oxygen supply pressure failure alarm system such that if oxygen pressure in the high pressure system falls (usually to below 30 psig) an audible alarm sounds. On modern machines, a pressure-operated electrical switch ensures a continuous audible (and visual) alarm when the oxygen supply pressure falls below 30 psig. This will alert to a possible problem with the machine's oxygen supply pressure, such as pipeline failure or if the tank in use is nearing empty.
6. It pressurizes and opens the "fail-safe" valve (Fig. 38–2 item A). This is a pressure-sensitive valve that can decrease or totally interrupt the supply of nitrous oxide and other gases (e.g., heliox, and in some machines air) to their flow-control systems if the pressure of gas in the oxygen high pressure system falls below a threshold level.

   In the Datex-Ohmeda machines this valve is called the pressure sensor shut-off valve (PSSV). These valves interrupt the gas supplies to the nitrous oxide and other gas flowmeters when the oxygen pressure falls below a nominal 26 psig. In the Datex-Ohmeda machines, these valves are either fully open or fully closed.

   In the Dräger Narkomed 2, Narkomed 3, and Narkomed 4 machines, the "fail-safe" valve is called the oxygen-failure protection device (OFPD) and there is one interfacing the high-pressure system for oxygen with the high-pressure systems for each of the other gases supplied to the machine (e.g., nitrous oxide). Unlike the Datex-Ohmeda PSSV "fail-safe" valves, the OFPDs gradually reduce the supply pressure to the nitrous oxide and other gas flowmeters as the oxygen supply pressure decreases. The supply of other gases to their respective flowmeters is completely interrupted when the oxygen supply pressure falls below 12 ± 4 psig. In this way, a hypoxic mixture arising from oxygen supply problems to the flowmeters should be prevented. Thus in Dräger Narkomed, Datex-Ohmeda, and other brands of machines, when the oxygen supply pressure is low, only 100% oxygen is delivered.
7. It passes to the oxygen flow-control valve. In traditional machines this is the needle valve that is connected to the oxygen flow-control knob used to set the oxygen flow at the oxygen flowmeter.

In Datex-Ohmeda machines (e.g., Modulus II, Modulus II Plus, Modulus CD, and Excel models), to reach the oxygen flow-control valve, oxygen in the high-pressure system must first pass through a second-stage regulator valve where the pressure is downregulated to about 16 psig. This second-stage regulator (Fig. 38–2 item B) ensures that the oxygen flowmeter is supplied at a constant pressure of 16 psig. Thus even if the oxygen supply pressure to the machine falls to below 45–50 psig, as long as it exceeds 16 psig, the oxygen flow set at the flowmeter will be maintained. Without this second-stage regulator, if the oxygen supply pressure to the machine were to fall, the oxygen flow would decrease at the flowmeter and, if nitrous oxide were being used also, a hypoxic gas mixture might result at the level of the flowmeters. In summary, in Datex-Ohmeda machines, if the oxygen supply pressure falls below 30 psig, the low-pressure supply alarm sounds (see #5 above); below 20 psig the "fail-safe" valve will interrupt the flow of other gases to their flowmeters so that only oxygen can be delivered, and the oxygen flow set on the oxygen flowmeter will not decrease until the oxygen supply pressure falls below 16 psig.

Dräger Narkomed 2, Narkomed 3, and Narkomed 4 machines do not use a second stage oxygen pressure regulator (in Fig. 38–2 item B is absent) to supply the oxygen flowmeter at constant pressure. Instead they use OFPDs (see #6 above) to continually interface the pressure of oxygen in the high-pressure system with the pressure of nitrous oxide just upstream of the nitrous oxide flowmeter. A decrease in the oxygen supply pressure causes a proportionate decrease in the pressure of nitrous oxide supplied to its flowmeter. Thus as oxygen supply pressure decreases, the flow of oxygen and that of all other supplied gases will decrease in *proportion* so as to avoid creation of hypoxic gas mixture.

Nitrous Oxide

Like O_2, N_2O may be supplied to the machine from the pipeline system at a pressure of approximately 50 psig or from a backup E cylinder supply on the machine. N_2O has a molecular weight of 44 and a boiling point of –88°C at 760 mm Hg (14.7 psia) pressure.[7] Because it has a critical temperature of 36.5°C (critical pressure: 1054 psig), N_2O can exist as a liquid at room temperature (20°C). E cylinders of N_2O are factory-filled to 90–95% capacity with liquid N_2O. Above the liquid in the tank is N_2O vapor. Because the liquid agent is in equilibrium with its vapor or gas phase, the pressure exerted by the gaseous N_2O is its saturated vapor pressure (SVP) at the ambient temperature. At 20°C the SVP of N_2O is 750 psig.[7]

A full E tank of N_2O generates approximately 1600 L of gas at 1 atm pressure at sea level (14.7 psia). As long as some liquid N_2O is present in the tank and the ambient temperature remains at 20°C, the pressure in the N_2O tank will remain at 750 psig, which is the SVP of N_2O at 20°C.

Unlike with O_2, the content of a N_2O tank cannot be determined by reference to the N_2O tank pressure gauge. However, the content can be determined by weighing the tank and subtracting the weight of the empty tank (tare weight) to determine the weight of the remaining N_2O. By Avogadro's volume, one gram molecular weight (i.e., 44 g) of N_2O will occupy 22.4 L at standard temperature and pressure (STP: 760 mm Hg; 273.15°K or 0°C). Once all the liquid N_2O has been used and the tank contains only gas, Boyle's law may be applied. In this situation, where the tank pressure is 750 psig (from gas only) and the internal volume of the E cylinder is approximately 5 L (see Oxygen above), the volume of N_2O that will evolve at a pressure of 760 mm Hg (14.7 psia) can be calculated. Thus $P1 \times V1 = P2 \times V2$; $750 \times 5 = 14.7 \times V2$, or $V2 = 255$ L. At this point the N_2O tank is 255/1600, or 16%, full. At 20°C room temperature, an E tank of N_2O with a pressure of 400 psig would deliver ($400/750 \times 255$ L), or 136 L of N_2O gas.

Nitrous oxide from the tank supply enters the N_2O hanger yoke at pressures of up to 750 psig (at 20°C) and then passes through a regulator that reduces this pressure to 40–45 psig (Fig. 38–2). The pin-index safety system is designed to ensure that only a N_2O tank may hang in a N_2O hanger yoke. As with O_2, a check valve in each yoke prevents the back leakage of N_2O if no tank is hanging in the yoke.

The N_2O pipeline is supplied from a bulk storage container of liquid N_2O or from banks of large N_2O tanks, usually H cylinders. (Each H cylinder of N_2O evolves 16,000 L of gas at atmospheric pressure.) The pressure in the N_2O pipeline is regulated to approximately 50 psig to supply the outlets in the operating room. Having entered the anesthesia machine high-pressure system for N_2O, N_2O must flow past the fail-safe valve to reach the N_2O flow-control (traditionally a needle) valve and flowmeter (traditionally a rotameter) (Fig. 38–2).

In Datex-Ohmeda anesthesia machines that have the Link-25 Proportion Limiting Control System (see next section), a second-stage N_2O regulator further reduces gas pressure so that N_2O is supplied to its flow-control (needle) valve at a nominal pressure of 26 psig (Fig. 38–2). The actual downstream pressure of this regulator is adjusted at the factory or by a field service representative to ensure correct functioning of the Link-25 Proportion Limiting Control System.

Gas Flow Control Systems (Knobs, Needle Valves, Rotameters, Etc.)

The anesthesia machine is used to adjust the proportions of oxygen and nitrous oxide, as well as total gas flows delivered to the patient. For each gas (oxygen, nitrous oxide, etc.) this is achieved in a traditional machine (Fig. 38–3) by means of a control valve and a gas-flow measuring system.

The flow control knob is connected to a needle valve whereby gas flow is set and adjusted. Turning the knob counterclockwise opens the valve wider, permitting a greater flow of gas. The flow-control knob for oxygen is larger than those for the other gases, and it is fluted rather than knurled so that it is "touch-coded." Thus, the oxygen knob feels different than the knobs for the other gases.

Traditionally, gas flows on the conventional anesthesia machine are measured using the rotameter flowmeter (Fig. 38–3). There may be one rotameter, or two rotameters in tandem for each gas. If two are present for each gas, the first permits accurate measurement of low flows (usually up to 1 L/min) and the second of flows of 1–12 L/min. In North America, the oxygen rotameter(s) is(are) positioned on the right

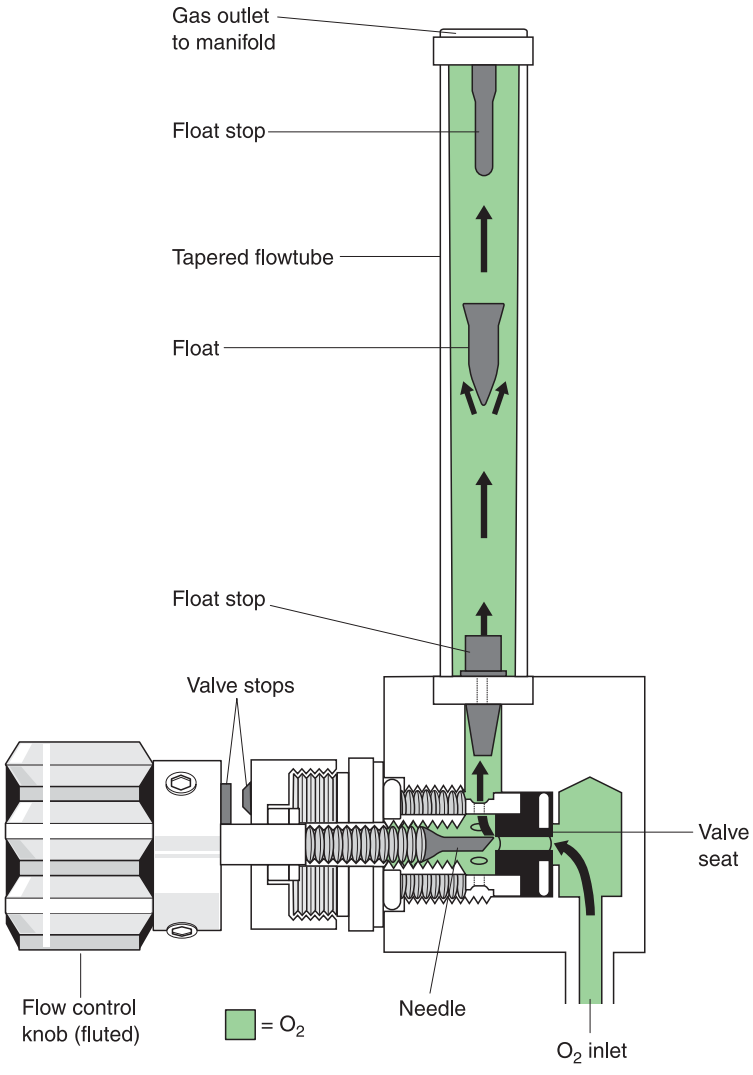

FIGURE 38–3. O_2 flowmeter and flow-control valve.

side of the rotameter bank. The rotameter is a constant pressure, variable orifice flowmeter, based on the Thorpe tube principle. Each rotameter consists of a vertical tapered glass tube that is of small diameter at the bottom and wider at the top, and contains a ball, float, or bobbin. The cross-sectional area between the outside of the float and the inside of the tapered glass tube represents the variable orifice. A certain pressure difference across the bobbin is required to "float" the bobbin in the upwardly flowing gas stream. As the orifice widens, increasing flows are required to create the same pressure difference across the bobbin, which floats at a higher level in the tapered glass tube. At low gas flow rates, flow is essentially laminar and Poiseuille's law applies:

$$\text{Flow} = \frac{\pi \times P \times r^4}{8 \times \eta \times L}$$

where P is the pressure drop across the bobbin, r is the radius of the tube, η is the viscosity of the gas, and L is the length of the bobbin or float.

When the orificial area (r^2) is larger and flows are greater, flow becomes turbulent, in which case:

Flow is proportional to the $\sqrt{P}$, r^2, length^{-1}, and density$^{-0.5}$.

Rotameter flowmeters are precision instruments. Flow tubes are manufactured for specific gases, calibrated with a unique float, and for use within a certain range of temperatures and pressures. Flowmeters are *not* interchangeable among gases and if a gas were passed through a rotameter for which it was not calibrated, the flows shown would likely be incorrect. Theoretical exceptions to this would be that at *low (laminar) flows*, the flow rates of gases with *similar viscosities* would be read identically (e.g., oxygen and helium have viscosities of 202 and 194 micropoise, respectively) and at *high flows* gases of *similar densities* (e.g., nitrous oxide and carbon dioxide, which both have a molecular weight of 44 atomic mass units) would be read identically. Again, it is emphasized that flow meters are not interchangeable among medical gases and are now manufactured such that they cannot be interchanged.

Virtual Flow Meters

As mentioned in the opening paragraphs of this chapter, some of the traditional mechanical components are being replaced by more sophisticated devices. For example, in some models of contemporary anesthesia workstation (Datex-Ohmeda S5/ADU; Dräger Fabius GS,), gas flows are still controlled by mechanical needle valves but flows are measured using electronic flow sensors based on the principle of the pneumotachograph. Essentially, the pressure difference is measured across a laminar flow resistor through which the gas flows. Reference to the Poiseuille formula (see Gas Flow Control Systems [Knobs, Needle Valves, Rotameters, Etc.] above) shows that if r, η, and L are constant, P can be used to measure flow. Flows are therefore measured using a differential pressure transducer, and displayed on a screen in the form of a virtual graduated flow meter, together with a digital display. In the Datex-Ohmeda S5/ADU and the Dräger Apollo workstations, the virtual flow displays are color coded (e.g., green column for O_2, yellow for air), whereas in the basic Dräger Fabius GS, all the flows are displayed as vertical yellow bars.

Advantages of electronic flow sensors are that they are less expensive than rotameters and the data can be used elsewhere in the workstation to record gas and agent consumption or to adjust ventilator bellows tidal volume (as in the Datex-Ohmeda ADU workstation).

An obvious concern with any electronically based system is what would happen if electrical power were totally lost. Also, many anesthesiologists are not completely comfortable unless they can see physical evidence of gas

flowing. For these reasons, the workstation manufacturers offer (e.g., as an option on the Datex-Ohmeda S5/ADU) a rotameter that is placed at the common gas outlet (CGO) of the machine and that displays the approximate total flow of gas leaving the CGO.

Some anesthesia workstations offer, as an option, an oxygen flow that cannot be discontinued completely because either a "stop" is provided on the oxygen flow-control valve to ensure a minimum oxygen flow of 200–300 mL/min past the needle valve (Datex-Ohmeda machines), or a gas flow resistor is provided (Dräger Narkomed 2, Narkomed 3, and Narkomed 4 machines) that permits a similar flow of 200–300 mL/min to bypass a completely closed oxygen flow-control needle valve. In the Dräger Narkomed machines, the minimum oxygen flow feature functions only in the "O_2/N_2O" mode but not in the "ALL GASES" mode.

Oxygen Ratio Monitoring and Proportioning Systems

A major consideration in the design of contemporary anesthesia machines is prevention of delivery of a hypoxic gas mixture. The fail-safe system described previously only serves to interrupt (Datex-Ohmeda pressure sensor shut-off valve) or proportionately reduce and ultimately interrupt (Dräger OFPD) the supplies of N_2O and (in some models) other gases (e.g., air, He) to their flowmeters if the O_2 supply pressure to the machine is reduced. It does not prevent the delivery of a hypoxic mixture to the common gas outlet, making the term *fail-safe* somewhat of a misnomer.

In traditional contemporary machines, N_2O and O_2 flow controls are physically interlinked either mechanically (Datex-Ohmeda) or mechanically and pneumatically (Dräger), so that a fresh gas mixture containing at least 25% O_2 is delivered at the flowmeters when only N_2O and O_2 are being used.[8,9]

Datex-Ohmeda anesthesia machines use the Link-25 Proportion Limiting Control System to ensure an adequate percentage of O_2 in the gas mixture created.[8,10] In this system, a gear with 14 teeth is integral with the N_2O flow-control spindle, whereas a gear with 29 teeth is allowed to rotate ("float") on a threaded O_2 flow-control valve spindle (Fig. 38–4). The two gears are connected together by a precision stainless steel link chain. For every 2.07 revolutions of the N_2O flow-control spindle, an O_2 flow control, set to the lowest O_2 flow, rotates once because of the 14:29 ratio of gear teeth. Because the gear on the O_2 flow-control spindle is thread-mounted so that it can rotate on the control valve spindle like a nut on a bolt (rather than being integral with the spindle), O_2 flow can be increased independently of N_2O. However, regardless of the O_2 flow set, if the flow of N_2O is increased sufficiently, the gear on the O_2 spindle will engage with the O_2 flow-control knob, causing it to rotate and thereby causing O_2 flow to increase. If N_2O flow is now reduced, the O_2 flow remains high unless it is deliberately decreased by the user. The 75% N_2O:25% O_2 proportioning is completed because the N_2O flow-control valve is supplied from a second-stage gas regulator, that reduces N_2O pressure to a nominal 26 psig (adjusted as previously described) before it reaches the flow-control valve, whereas the O_2 flow-control valve is supplied at a pressure of 14 psig from a second-stage O_2 regulator (Figs. 38–2 and 38–4). The Link-25 Proportion Limiting Control System permits the N_2O and O_2 flow-control valves to be set independently of one another, but whenever a N_2O concentration of more than 75% would be accidentally set, the O_2 flow is automatically increased to maintain at least 25% O_2 in the resulting mixture. This system thus increases the minimum flow of O_2 according to the N_2O flow set. The Link-25 Proportion Limiting Control System interconnects only the N_2O and O_2 flow-control valves. If the anesthesia machine has flow controls for other gases (e.g., He, air) (Fig. 38–4), a gas mixture containing less than 25% O_2 could potentially be set at the flowmeters.

In Dräger Narkomed 2, Narkomed 3, and Narkomed 4 machines the oxygen ratio monitor controller (ORMC) (Fig. 38–5) serves to limit the N_2O flow according to the O_2 flow and create a mixture of at least 25% O_2 at the flow-

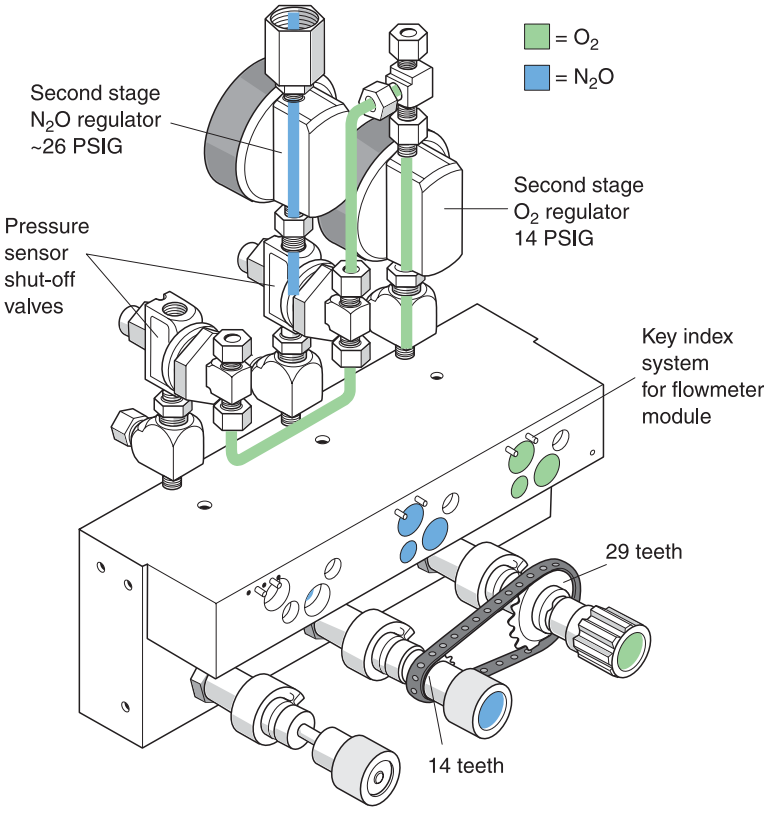

FIGURE 38–4. Datex-Ohmeda Link-25 Proportion Limiting Control System, which ensures at least 25% O_2 concentration at the level of the flowmeters when O_2 and N_2O are being used. When supply pressure to the second-stage O_2 regulator falls below a nominal 26 psig, the pressure sensor shut-off valves ("fail-safe" valves) cause the supply of N_2O and other gases to be shut off.

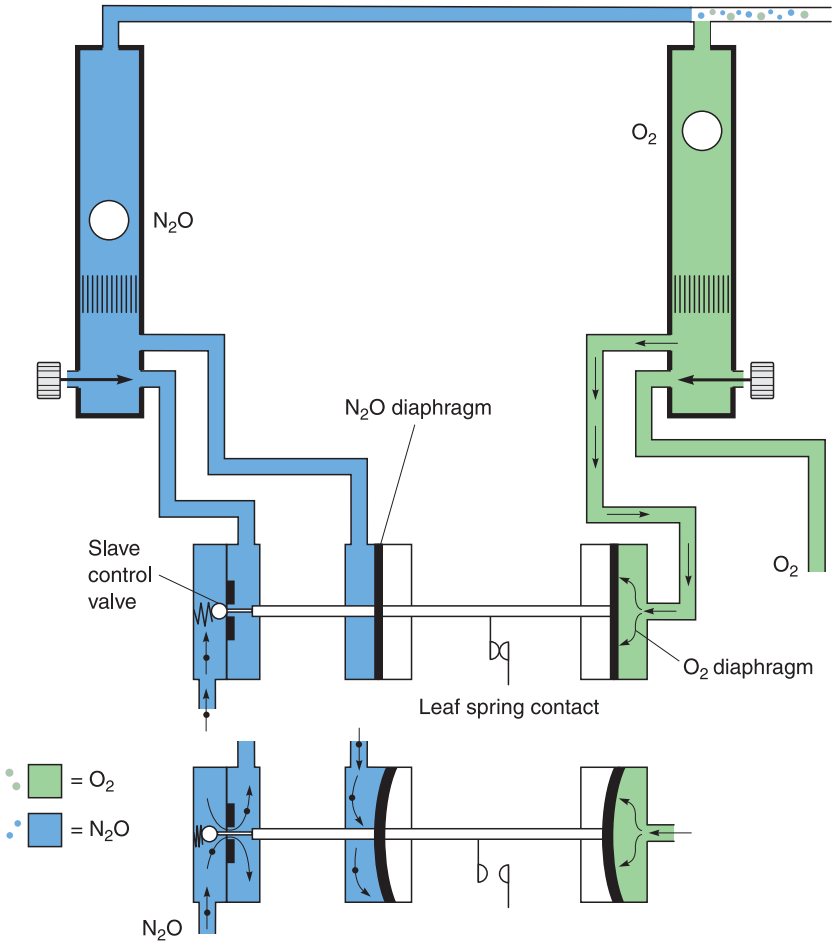

FIGURE 38–5. Dräger oxygen ratio monitor controller (ORMC). See text for details of operation.

meter level when these two gases are being used.[9] At O_2 flow rates of less than 1 L/min, even higher concentrations of O_2 are delivered. In addition, an alarm is activated when the ORMC is functioning to prevent a hypoxic mixture when the Narkomed machine is used in the "O_2/N_2O" mode, but not in the "all gases" mode (i.e., when air, helium, etc., might be switched into the system).

The ORMC works as follows: As O_2 flows past its flow-control needle valve and up the rotameter tube, it encounters a resistor that creates a back pressure that is applied to the O_2 diaphragm (Fig. 38–5). As N_2O flows past its flow-control valve and up the rotameter tube, it also encounters a resistor that causes a back pressure on the N_2O diaphragm. The two diaphragms are linked by a connecting shaft, the ultimate position of which depends on the relative back pressures and, therefore, flows of N_2O and O_2. The left-hand end of the connecting shaft controls the orifice of a slave valve, which, in turn, controls the supply pressure of N_2O to its flow-control valve. When the O_2 flow is high, the shaft moves to the left and opens the slave control valve (Fig. 38–5, lower). Conversely, if the N_2O flow is increased excessively, the shaft moves to the right, closing the slave valve orifice and decreasing the supply pressure of N_2O to, and thereby flow of N_2O from, its flow-control valve. When the ORMC is acting to prevent a hypoxic mixture, the leaf spring contacts (Fig. 38–5) are closed, annunciating an alarm. This alarm is disabled if the machine is in the "all gases" mode.[9]

The Dräger ORMC differs from the Datex-Ohmeda Link-25 Proportion Limiting Control System in several ways. First, the ORMC does not require second-stage O_2 and N_2O regulators. Second, the ORMC serves to limit the N_2O flow according to the O_2 flow, whereas the Link-25 Proportion Limiting Control System increases the O_2 flow as the N_2O flow is increased. As with the Link-25 Proportion Limiting Control System, the ORMC functions only with N_2O and O_2 and there is no interlinking of O_2 with other gases (e.g., air, He) that might also be deliverable by the machine. Thus when a third or fourth gas is in use, the proportioning systems afford no protection against a hypoxic mixture. Prevention of delivery of a hypoxic gas mixture when a third or fourth gas is supplied to the machine may be achieved by supplying that gas in a tank premixed with O_2 (e.g., heliox, a gas mixture of 75% He and 25% O_2).

Although elegant in design, both the ORMC and the Link-25 Proportion Limiting Control Systems are subject to mechanical and pneumatic failure and should be tested according to the manufacturer's instructions during the preuse machine checkout.[9,11] Furthermore, if the systems are functioning correctly, they only ensure adequacy of greater than 25% O_2 at the flowmeter level. An O_2 leak downstream from the flow-control valves (i.e., from the low-pressure system of the machine) could result in a hypoxic mixture flowing from the common gas outlet. Consequently, an oxygen analyzer in the patient circuit is essential if a hypoxic mixture is to be detected. The controlled flows of O_2, N_2O, and other gas or gases are mixed in the manifold at the top of the flowmeter bank, and they flow to a concentration-calibrated anesthesia vaporizer (Fig. 38–2).

ANESTHESIA VAPORIZERS

A vapor is the gas phase of an agent that is normally a liquid at room temperature and atmospheric pressure. Vaporizers facilitate the change of a liquid anesthetic into its vapor phase and add a controlled amount of this vapor to the flow of gases passing to the patient circuit.

Vapor, Evaporation, and Vapor Pressure

Consider isoflurane in a closed container at 1 atm pressure (760 mm Hg) and room temperature 20°C. Although most is in liquid form, some isoflurane molecules escape from the surface of the liquid to enter the space above as a vapor. Under steady-state conditions of temperature, an equilibrium is estab-

lished between the molecules in the vapor phase and those in the liquid phase. The vapor phase molecules are in constant motion, striking the walls of the container to exert a vapor pressure. If the temperature is increased, more isoflurane molecules enter the vapor phase (evaporate), resulting in an increase in vapor pressure. When the gas phase above the liquid contains all the isoflurane vapor that it can hold at that temperature, it is said to be saturated and the pressure exerted by the isoflurane is called its saturated vapor pressure (SVP) at that temperature.

The SVP exerted by the vapor phase of a potent volatile agent depends only on the volatile agent and the ambient temperature (Fig. 38–6). The temperature at which SVP becomes equal to atmospheric pressure and at which all the liquid agent changes to the vapor phase is the liquid's boiling point. The most volatile agents are those with the highest SVPs for any given temperature, and they also have the lowest boiling points (e.g., desflurane and diethyl ether boil at 22.8°C and 35°C, respectively, at an ambient pressure of 760 mm Hg). Boiling point decreases with decreasing ambient pressure, such as occurs at increasing altitude.

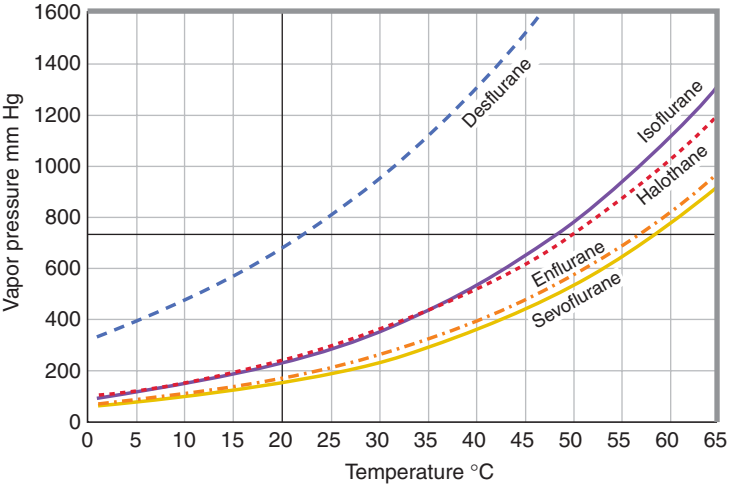

FIGURE 38–6. Vapor pressure curves for the potent inhaled anesthetics.

Units of Vapor Concentration

Anesthetic vapor presence may be quantified either as an absolute pressure (or tension), expressed in millimeters of mercury (mm Hg), or in volumes percent of 1 atm (i.e., volumes of vapor per 100 volumes of total gas).

By applying Dalton's law, volumes percent is similar to the agent's fractional partial pressure:

$$\text{Vols \%} = (\text{Partial pressure of agent} / \text{Total ambient pressure}) \times 100$$

Dalton's Law of Partial Pressures

Dalton's law states that in a mixture of gases (or vapors) the pressure exerted by each gas is the same as that it would exert if it alone occupied the container.[7] Each gas (or vapor) exerts its pressure independently of the pressure of the other gases present. For example, in a container of dry air at atmospheric pressure (760 mm Hg), if O_2 represents 21% of all gases present, the pressure exerted by the O_2 (its partial pressure) is 21% of 760, or 159.6 mm Hg.

Now consider air, which is fully saturated with water vapor at 37°C (normal body temperature). Vapor pressure depends on temperature. The SVP for water at 37°C is 47 mm Hg. O_2 now represents 21% of what remains (i.e., 713, or 760 – 47), having a partial pressure of 21% of 713, or 149.3 mm Hg.

Volumes percent expresses the ratio of gas molecules in a mixture, whereas partial pressure is an absolute value. Anesthetic uptake and potency are directly related to partial pressure and only indirectly to volumes percent. This distinction will become more apparent when the use of vaporizers under hyperbaric and hypobaric conditions is considered in a later section (see Changes in Barometric Pressure).

Minimum Alveolar Concentration

The minimum alveolar concentration (MAC) of a potent inhaled anesthetic agent that produces immobility in 50% of patients undergoing a surgical incision is used as a measure of anesthetic potency or depth. MAC is typically expressed as volumes percent of alveolar (end-tidal) gas at 1 atm pressure at sea level (760 mm Hg). Table 38–1 shows how MAC in familiar volumes percent can be expressed as a partial pressure in millimeters of mercury.[12] The reader is encouraged to think of MAC in terms of minimum alveolar pressure (MAP) or minimum alveolar partial pressure (MAPP) rather than volumes percent because it is the partial pressure (tension) of the anesthetic in the brain that determines the depth of anesthesia.[13,14] The term P_{MAC1} (Table 38–1) is used to express the partial pressure of a potent inhaled agent at a concentration of 1 MAC. Thus 1 MAC of sevoflurane is equivalent to a P_{MAC1} of 16 mm Hg.

TABLE 38–1.

Expression of Minimum Alveolar Concentration of Anesthetic Agent (MAC) as Partial Pressure at Concentration of 1 MAC (P_{MAC_1}) Assuming Ambient Pressure of 760 mm Hg

Anesthetic Agent	MAC (vol %)		P_{MAC_1} (mm Hg)
Halothane	0.75 × 760	=	5.7
Enflurane	1.68 × 760	=	12.8
Isoflurane	1.15 × 760	=	8.7
Methoxyflurane	0.16 × 760	=	1.2
Desflurane[a]	6.0 × 760	=	45.6
	7.25 × 760	=	55.1
Sevoflurane	2.1 × 760	=	16.0

[a]MAC of desflurane is age-dependent: 18–35 years = 7.25%; 31–65 years = 6.0%. See Rampil et al.[15]

Latent Heat of Vaporization

Energy in the form of heat is needed to transfer molecules from the liquid to the vapor phase. This energy is called the *latent heat of vaporization*, and is defined as the amount of heat (calories) required to convert unit mass (grams) of the liquid into vapor.[7] For example, the latent heats of vaporization of volatile anesthetics at room temperature are 35 cal/g for halothane; 41 cal/g for enflurane and isoflurane; and 58 cal/g for methoxyflurane.[16]

The heat of vaporization is inversely related to ambient temperature so that the lower the temperature, the more heat that is required. Heat required to vaporize anesthetic agents is drawn from the remaining liquid and the surroundings. As vapor is generated, the temperatures of the vaporizer and remaining liquid fall. This causes the vapor pressure to decrease and would result in decreased vaporizer output if no compensatory mechanism were provided.

Specific Heat

Specific heat is the quantity of heat (calories) required to raise the temperature of unit mass (grams) of a substance by 1°C.[7] Heat must be supplied to the liquid anesthetic in the vaporizer to maintain its temperature while heat is being lost in the process of evaporation.

Specific heat is also important to vaporizer construction material. Thus materials with high specific heat change temperature more gradually than those with low specific heats for the same amount of heat lost through vaporization. Thermal capacity is defined as the product of specific heat and mass and represents the total quantity of heat stored in the vaporizer body.[7]

The vaporizer construction material's ability to conduct heat from the environment through to the contained liquid anesthetic is also of importance. This is called thermal conductivity, defined in terms of how quickly heat is transmitted through a substance. The ideal material for vaporizer construction would have a high specific heat and high thermal conductivity. In this respect, copper comes close to the ideal (thus the Copper Kettle vaporizer). More recently, bronze and stainless steel have been used in vaporizer construction.

Regulating Vaporizer Output: Measured Flow versus Variable Bypass

The SVPs of the four potent inhaled agents halothane, isoflurane, enflurane, and sevoflurane at room temperature are 243, 238, 175, and 160 mm Hg, respectively, and far in excess of those required for clinical anesthesia (Fig. 38–6 and Table 38–2). Consequently, the vaporizer first creates a saturated vapor that must then be diluted by the bypass gas flow to result in clinically useful concentrations. If this were not done, a lethal concentration of agent could be delivered.

Contemporary anesthesia vaporizers for halothane, isoflurane, enflurane, and sevoflurane are concentration-calibrated and of the variable-bypass design.[2] The vaporizers for desflurane (Datex-Ohmeda Tec 6; Dräger D-Vapor) are of a different design and are described separately in a later section (see Desflurane and the Tec 6 Vaporizer). In a variable-bypass vaporizer (e.g., Datex-Ohmeda Tec series, Dräger Vapor 19.n series) the total fresh gas flow from the anesthesia machine flow meters passes to the vaporizer. The vaporizer splits the incoming gas flow into both a smaller flow, which enters the vaporizing chamber to emerge with the agent at its saturated vapor concentration, and a larger bypass flow, which when mixed with the vaporizing chamber output, results in the desired or "dialed-in" concentration (Fig. 38–7).

In the now rarely used measured-flow (i.e., not concentration-calibrated)

TABLE 38–2.

Physical Properties of Potent Volatile Agents

Parameter/Agent	Halothane	Enflurane	Isoflurane	Methoxyflurane	Sevoflurane	Desflurane

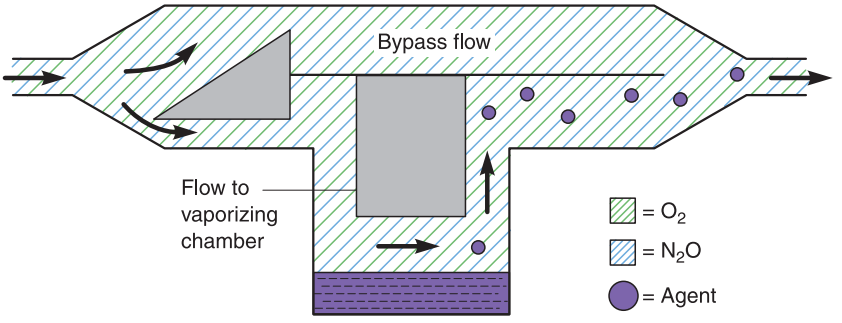

FIGURE 38–7. Variable bypass vaporizer principle. These are concentration-calibrated and are of the flow-over design (see text).

vaporizers, such as the Copper Kettle (Foregger/Puritan-Bennett) or Verni-Trol (Datex-Ohmeda), a measured O_2 flow is set on a separate flowmeter to pass to the vaporizer, from which vapor at its SVP emerges. This is then diluted by a larger measured flow of gases from other (main) flowmeters on the anesthesia machine (Fig. 38–8). In this type of arrangement, several calculations are necessary to determine the anesthetic vapor concentration in the emerging gas mixture.

With either type of vaporizing arrangement, an efficient system must exist to create a saturated vapor concentration in the vaporizing chamber. This is achieved by having a large surface area for evaporation of the liquid agent. In flow-over vaporizers (e.g., Dräger Vapor series, Datex-Ohmeda Tec series) the area is increased by the use of wicks and baffles. In bubble-through vaporizers (e.g., Copper Kettle, Verni-Trol), O_2 is bubbled through the liquid agent. The tiny bubbles, which in the Copper Kettle are created by passage of O_2 through a sintered bronze disk, represent large areas of liquid–gas interface over which evaporation of the liquid agent can quickly occur.

Desflurane, because of its high saturated vapor pressure at room temperature (669 mm Hg at 20°C), and its low boiling point (22.8°C at 1 atm), cannot be safely delivered using the vaporizing systems described in the preceding paragraphs. The physical properties of desflurane require that a special design of vaporizer (e.g., Datex-Ohmeda Tec 6; Dräger D-Vapor) be used to deliver this agent in a controlled fashion (see Desflurane and the Tec 6 Vaporizer).

Calculation of Vaporizer Output for Agents Other Than Desflurane

Assume that room temperature is kept constant at 20°C. The SVPs of each agent are as follows: halothane, 243 mm Hg; isoflurane, 238 mm Hg; enflurane, 172 mm Hg; and sevoflurane, 160 mm Hg (Table 38–2). If ambient pressure is 760 mm Hg, these vapor pressures represent 243/760, or 32% for halothane; 238/760, or 31% for isoflurane; 175/760, or 23% for enflurane; and 160/760, or 21% for sevoflurane, in terms of volumes percent of each agent at 1 atm.

In a variable-bypass vaporizer, a given volume of carrier gas flowing into the vaporizing chamber over time will exit the chamber over the same period. In the vaporizing chamber, however, anesthetic vapor at its SVP constitutes a mandatory fractional volume of the atmosphere (e.g., 32% by volume in a halothane vaporizer at 20°C and 760 mm Hg ambient pressure). Thus the volume of carrier gas entering the vaporizing chamber constitutes the difference between 100% of the atmosphere in the vaporizing chamber and that which results from the anesthetic vapor.

With halothane at 20°C and ambient pressure 760 mm Hg the volume of carrier gas at any time represents 68% of the atmosphere in the vaporizing chamber. Thus if 100 mL of carrier gas enters a vaporizing chamber containing halothane, the carrier gas represents 68% (i.e., 100% – 32%) of the atmosphere, and the remaining 32% is halothane vapor. By simple proportions, the latter can be calculated to be 47 mL of halothane vapor ([100/68] × 32).

Another way of expressing this is by applying Dalton's law:

$$\frac{\text{SVP}_{\text{agent}}\ (\text{mm Hg})}{\text{Total Pressure (mm Hg)}} = \frac{\text{Agent vapor } (x\ \text{mL})}{\text{Carrier gas } (y\ \text{mL}) + \text{Agent vapor } (x\ \text{mL})}$$

For halothane in the previous example, y = 100 mL/min. Therefore:

$$\frac{243}{760} = \frac{x}{100 + x}$$

from which x can be calculated to be 47 mL. Conversely, if x is known, the carrier gas flow (y) can be calculated. Thus a larger total volume of gas leaves the vaporizing chamber than enters it, the additional volume being anesthetic vapor at its saturated vapor concentration.

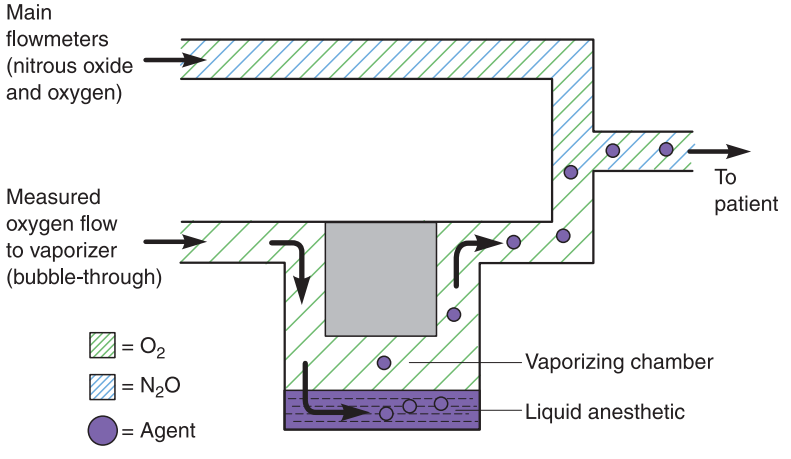

FIGURE 38–8. Measured flow vaporizer principle. These are not concentration-calibrated and are of the bubble-through design (see text).

Measured-Flow Vaporizers

Although measured-flow vaporizers are not included in the recent anesthesia machine and workstation standards,[1,2] it is instructive to first review the function of a measured-flow vaporizer (e.g., Copper Kettle).

Assume that 1% (vol/vol) halothane is required at a total fresh gas flow rate to the patient circuit of 5 L/min (Fig. 38–9). This requires that 50 mL halothane vapor be evolved per minute by the vaporizer (1% × 5000 mL). In the vaporizing chamber, halothane represents 32% of the atmosphere by volume, assuming temperature is kept constant at 20°C and therefore SVP is maintained at 243 mm Hg. Now if 50 mL of halothane vapor represents 32% by volume, the carrier gas (O_2) must represent the other 68%, or 106 mL (50/32 × 68).

Alternatively:

$$\frac{243}{760} = \frac{50}{y + 50}$$

where y is carrier gas (O_2) flow, or 106 mL. Thus if 106 mL/min of O_2 flows into a measured-flow vaporizer, 156 mL/min of gas emerges, of which 50 mL is halothane vapor and 106 mL is the carrier gas O_2 supplied to the vaporizer. This vaporizer output of 156 mL/min must be diluted by an additional fresh gas flow of 5000 – 156 = 4844 mL/min, to create a precise 1% halothane mixture (as 50 mL of halothane diluted in a total volume of 5000 mL = 1% by volume).

In clinical practice, however, the anesthetist would likely set flows of 100 mL/min to the measured-flow vaporizer and 5 L/min of fresh gas on the main flowmeters, which results in slightly less than 1% halothane (47/5147 = 0.91%). Multiples of either of these numbers (100 mL and 5 L) are used to create other concentrations of halothane from a measured-flow vaporizing system. Thus a 100-mL/min O_2 flow to the vaporizer and 2500 mL/min on the main flowmeters would produce approximately 2% halothane (actually 1.78%). It is important to realize that if there is O_2 flow only to the vaporizer and no diluent gas flow is set on the main flowmeters, potentially lethal concentrations (approaching 32%) of halothane would be delivered to the anesthesia circuit, albeit at low flow rates.

Because halothane and isoflurane have similar vapor pressures at 20°C (Table 38–2), the gas flows required for halothane are essentially the same as those to be set for isoflurane if similar concentrations of isoflurane were to be produced from a measured-flow vaporizing system.

Variable Bypass

In the foregoing example discussing measured-flow vaporizing systems, it was necessary to calculate both the O_2 flow to the vaporizer and the total bypass gas flow needed to produce the desired output concentrations of vapor. This is inconvenient and can give rise to errors, but it is helpful to understand the principles underlying the calculations.

In the concentration-calibrated variable-bypass ("Tec-type") design, the vaporizer splits the incoming total flow of gas arriving from the machine flowmeters between a variable-bypass and the vaporizing chamber that contains the anesthetic agent (Fig. 38–7). The ratio of these flows—the splitting ratio—depends on the anesthetic agent, the temperature, and the dialed-in vapor concentration set to be delivered. Figure 38–10 shows the schematic of a contemporary concentration-calibrated vaporizer, the Dräger Vapor 19.1. Anesthetic output concentration is increased by turning the concentration dial, which raises the control cone, allowing more saturated anesthetic vapor to leave the vaporizing chamber.

Review of the previous section for accurately delivering 1% halothane from a measured-flow vaporizer reveals that 4950 mL/min of incoming total gas flow must be split so that 106 mL enters the vaporizing chamber and 4844 mL enters the bypass (Fig. 38–9). This results in a splitting ratio of 4844/106, or 46:1 (at a temperature of 20°C). A variable-bypass vaporizer (e.g., Dräger Vapor 19.1), when set to deliver 1% halothane, is, in effect, set to a splitting ratio of 46:1 (bypass flow-to-vaporizing chamber flow).

Concentration-calibrated vaporizers are agent-specific and designed to be used only with the agent for which the unit is designed and calibrated. To produce a 1% vapor concentration, an isoflurane vaporizer makes a flow split of 44:1, whereas a sevoflurane vaporizer makes a flow split of 25:1 (Table 38–3). If an empty sevoflurane vaporizer set to deliver 1% were filled with isoflurane, the concentration of the isoflurane vapor emerging would exceed 1% (44/25 = 1.7%). An understanding of splitting ratios enables fairly accurate prediction of the concentration output of an agent-specific variable-bypass vaporizer that has been erroneously filled with an agent for which it was not designed (see Incorrect Filling of Vaporizers below).

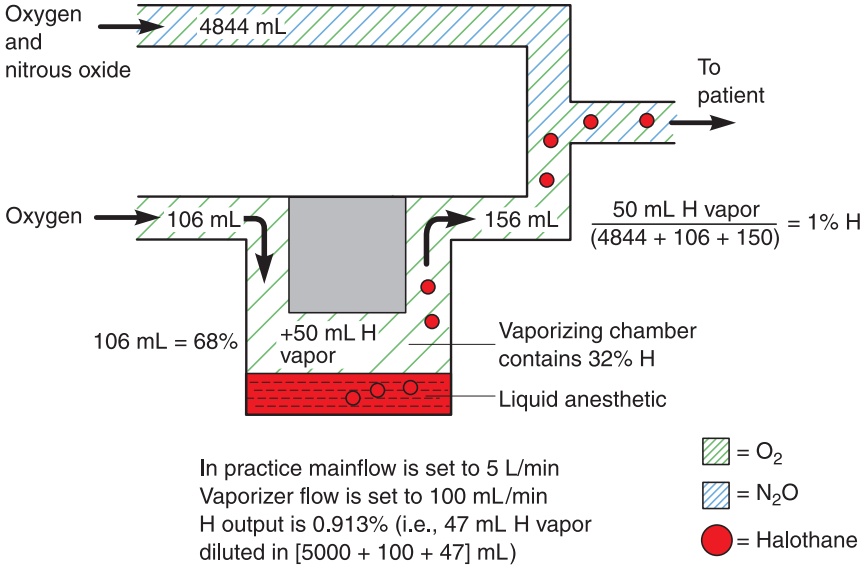

FIGURE 38–9. Preparation of 1% (vol/vol) halothane by measured-flow vaporizer.

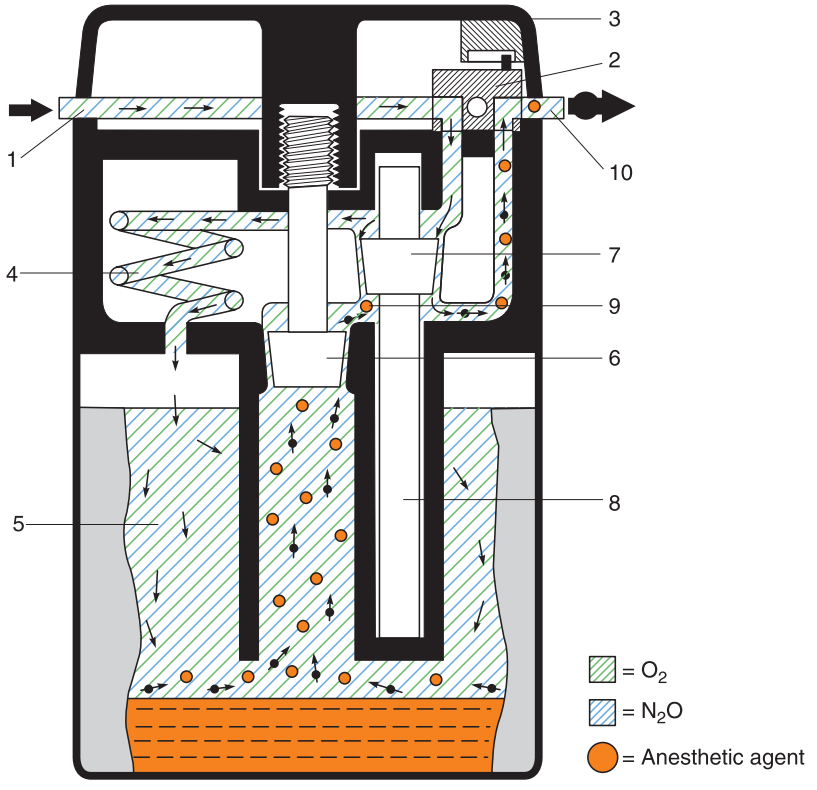

FIGURE 38–10. Schematic of Dräger Vapor 19.1 vaporizer. When concentration knob (*3*) is in 0 (zero) position, on/off switch (*2*) is closed. Gas mixture enters vaporizer at fresh gas inlet (*1*) and leaves through fresh gas outlet (*10*) without entering the vaporizer's interior. When concentration knob (*3*) is turned to any volume (%) concentration above 0.2 vol%, the on/off switch (*2*) automatically opens and allows fresh gas to enter the vaporizer's interior. Gas is immediately divided and follows two different routes. One part of the fresh gas moves through a thermostatically controlled bypass (*7*), which compensates for temperature changes and maintains correct volumes percent concentration vapor output as selected with concentration knob (*3*). The other part of the fresh gas moves through a pressure compensator (*4*), which prevents pressure changes that occur upstream or downstream from the vaporizer to be transmitted into the vaporizer and thus affect volumes percent vapor output. From the pressure compensator, gas continues into vaporizing chamber (*5*). This chamber contains liquid anesthetic agent, which is absorbed and evaporated by a special wick assembly. As fresh gas moves through the vaporizing chamber, it is fully saturated with anesthetic vapor. Saturated gas leaves the chamber through a control cone (*6*). The cone is adjustable with concentration knob (*3*). Saturated vapor and fresh gas that did not pass through the vaporizing chamber are combined and leave through the fresh gas outlet (*10*). Combination of the bypass opening (*7*) and control cone opening (*6*) determines volumes percent vapor output. The expansion element (*8*) reduces vaporizing chamber gas flow as temperature increases.

Efficiency and Temperature Compensation

Agent-specific, variable-bypass, concentration-calibrated vaporizers are located in the fresh gas path between the flow meters (e.g., rotameters) on the anesthesia machine and the machine common gas outlet (Fig. 38–2). The vaporizers must be efficient and produce steady concentrations of the agent over a fairly wide range of incoming gas flows. However, as the agent is vaporized and the temperature falls, SVP also falls and vaporizing chamber output tends to decrease.

Measured-flow vaporizers (e.g., Copper Kettle, Verni-Trol) incorporate a thermometer that measures the temperature of the liquid agent in the vaporizing chamber. A lower temperature translates to a lower SVP in this chamber, and reference to the vapor pressure curves (Fig. 38–6) enables a resetting of vaporizer gas flow, bypass gas flows, or both to ensure correct output at the ambient temperature. Such an arrangement can be tedious but if done correctly does ensure the most accurate and rapid temperature compensation.

Most of the contemporary variable-bypass vaporizers (e.g., Datex-Ohmeda Tec series, Dräger Vapor 19.1) have automatic temperature compensation achieved by a temperature-sensitive valve in the bypass gas flow. When temperature increases, the valve in the bypass opens wider to create a greater splitting ratio. More gas flows through the bypass, and less gas enters the vaporizing chamber. A smaller volume of a higher concentration of vapor emerges from the vaporizing chamber. When mixed with an increased bypass gas flow, this volume maintains a reasonably constant vaporizer output when temperature changes are gradual and not extreme.

The design of the temperature-sensitive valve varies among the different types of vaporizer. Datex-Ohmeda Tec series vaporizers use a bimetallic strip; a flap valve situated in the bypass flow composed of two different metals that have different coefficients of expansion (defined as change in length per unit length per unit change in temperature). As temperature increases, one surface of the flap expands more than the other, causing the flap to bend in such a way that the valve orifice opens wider.[17] The principle of differential expansion of metals is applied similarly in the Dräger Vapor 19.1 vaporizers, in which an expansion element increases bypass gas flow as temperature increases (Fig. 38–10, component 8).

The vapor pressures of the potent volatile anesthetics vary nonlinearly as a function of temperature (Fig. 38–6). The automatic temperature compensation mechanisms described are linear in terms of expansion coefficients of materials. When these affect the size of the orifice that they control, however, the compensation mechanisms also become nonlinear. The situation is complex, depending on the geometry of the valves and the nature of the gas flow through them. The result is that the vapor output concentration at any given vaporizer setting remains constant only within a certain range of temperatures. For example, the Dräger Vapor 19.1 vaporizers are specified as accu-

TABLE 38–3.

Gas Flow Splitting Ratios at 20°C[a]

	Halothane	Enflurane	Isoflurane	Methoxyflurane	Sevoflurane
1%	46:1	29:1	44;1	1.7:1	25:1
2%	22:1	14:1	21:1	0.36:1	12:1
3%	14:1	9:1	14:1	[b]	7:1

[a]Ratios are not given for desflurane, because the vaporizer for this agent (Datex-Ohmeda Tec 6; Drager D-Vapor) uses a different design from that used for the above agents.
[b]Maximum possible concentration is 2.7% at 20°C; see Table 38–2.

rate to ± 15% of the concentration set when used within the temperature range of 15°C to 35°C at normal atmospheric pressure.[9,11] At temperatures outside this range, the resulting concentration increases beyond the upper tolerance limit despite continuing compensation. The boiling point of the volatile agent must never be allowed to be reached in the current variable-bypass vaporizers designed for enflurane, halothane, isoflurane, and sevoflurane, as the vapor output concentration would otherwise be totally uncontrolled and potentially lethal.

Incorrect Filling of Vaporizers

Modern vaporizers are agent-specific. If an empty vaporizer designed for one agent is filled with an agent for which it was not designed, the vaporizer output may be erroneous for both agent and delivered vapor concentration.

A dangerous situation would result if a vaporizer designed for methoxyflurane (very low SVP of 20.3 mm Hg at 20°C) were erroneously filled (Table 38–2). A methoxyflurane vaporizer filled with halothane and set to deliver 1% methoxyflurane (albeit 6 MAC; Table 38–2) would deliver 14.8% (20 MAC) halothane. Set to 1 MAC (0.16%) methoxyflurane, the vaporizer makes a flow split of 16:1, similar to that of a halothane or isoflurane variable-bypass vaporizer set to deliver 2.7%.

Table 38–4 lists the outputs of erroneously filled vaporizers. Erroneous filling affects the output concentration and consequently the MAC (MAP, MAPP) or potency output of the vaporizer. Thus an enflurane vaporizer set to deliver 2% (1.19 MAC) but filled with halothane at 22°C will deliver 3.21% (4.01 MAC) halothane, that is, 3.3 times the anticipated anesthetic potency output.[18]

TABLE 38–4.

Output in Percent and Minimum Alveolar Concentration (MAC) in O_2 of Erroneously Filled Vaporizers at 22°C

Vaporizer	Liquid	Setting (%)	Output (%)	Output MAC
Halothane	Halothane	1.0	1.00	1.25
	Enflurane	1.0	0.62	0.37
	Isoflurane	1/0	0.96	0.84
Enflurane	Enflurane	2.0	2.0	1.19
	Isoflurane	2.0	3.09	2.69
	Halothane	2.0	3.21	4.01
Isoflurane	Isoflurane	1.5	1.50	1.30
	Halothane	1.5	1.56	1.95
	Enflurane	1.5	0.97	0.57

Reproduced with permission from Bruce DL, Linde HW. Vaporization of mixed liquids. Anesthesiology 1984;60:342.

Erroneous filling of vaporizers can be prevented by careful attention to the specific agent and the vaporizer when filling is performed. In the United States, agent-specific keyed filling mechanisms are available as options on modern vaporizers; in Canada, keyed filling is a standard. Liquid anesthetic agents are commercially available packaged in bottles that have an agent-specific collar. One end of the agent-specific filling device fits the collar on the agent bottle, and the other end fits only the vaporizer designed for that agent. An agent-specific filling system assumes even greater importance with desflurane (see Desflurane and the Tec 6 Vaporizer and Table 38–2). Keyed filling systems also decrease contamination of the operating room atmosphere during vaporizer filling.

Vaporization of Mixed Anesthetic Liquids

A more likely scenario is that an agent-specific variable-bypass vaporizer partially filled with correct agent is topped off with an incorrect agent.[18] The situation here is more complex, vaporizer output is less-easily predicted, and large errors in vapor administration can occur. Halothane, enflurane, and isoflurane, when mixed, do not react chemically but do influence the extent of each other's ease of vaporization. Halothane facilitates the vaporization of both enflurane and isoflurane and in the process is itself more likely to vaporize.[19] The clinical consequences depend on the potencies of each of the mixed agents as well as the delivered vapor concentrations. If a halothane vaporizer 25% full is refilled to 100% with isoflurane and set to deliver 1%, the halothane output is 0.41% (0.51 MAC) and the isoflurane output is 0.9% (0.78 MAC) (Table 38–5).[18] In this case, the output potency of 1.29 MAC is not far from the 1.25 MAC (1% halothane) expected.

However, an enflurane vaporizer 25% full and set to deliver 2% (1.19 MAC) enflurane that is filled to 100% with halothane has an output of 2.43% (3.03 MAC) halothane and 0.96% (0.57 MAC) enflurane (Table 38–5).[19] This represents a total MAC of 3.6, or more than twice that intended. In any event, it is important that erroneous filling of vaporizers be avoided, and that if suspected, the vaporizer be

TABLE 38–5.

Vaporizer Output after Incorrectly Refilling from 25% to 100% Full

			Vaporizer Outputs						
			Halothane		Enflurane		Isoflurane		
Vaporizer	Setting(%)	Refill liquid	%	MAC	%	MAC	%	MAC	Total MAC
Halothane	1.0	Enflurane	0.33	0.41	0.64	0.38	—	—	0.79
	1.0	Isoflurane	0.41	0.51	—	—	0.90	0.78	1.29
Enflurane	2.0	Halothane	2.43	3.03	0.96	0.57	—	—	3.60
Isoflurane	1.5	Halothane	1.28	1.60	—	—	0.57	0.50	2.10

emptied, serviced, purged, and refilled with the correct agent.

Filling of Vaporizers

Vaporizers should only be filled as directed in their accompanying instructions. Overfilling or tilting of a vaporizer (free-standing or by tilting the whole anesthesia machine) may result in liquid agent entering parts of the anesthesia delivery system (e.g., vaporizer bypass flow) designed for gases or vapors only and might give rise to lethal concentrations of the agent. If a vaporizer has been tilted and there is concern that liquid agent has leaked into the gas delivery system, then with no patient connected to the system, the vaporizer should be purged with a high flow rate of O_2 (10 L/min) from the machine flowmeter (not the O_2 flush, which bypasses the vaporizer) and with the vaporizer concentration dial set to the maximum concentration setting.[20] The most recent models of vaporizer (Datex-Ohmeda Tec 7; Dräger Vapor 2000 series) are designed with antispill mechanisms. Thus to remove a Vapor 2000 vaporizer from the mounting manifold, the concentration dial must be turned past the OFF setting to the T setting, or transport mode. In this setting, the sump that contains liquid agent is completely isolated from the other parts of the vaporizer, which can then be safely tilted.

Table 38–2 shows that 1 mL of liquid volatile anesthetic agent produces approximately 200 mL of vapor at 20°C. Thus if small volumes of liquid agent enter parts of the delivery system intended for gas or vapor only, it is easy to see how potentially lethal concentrations of vapor could arise. For example, if 1 mL of liquid halothane entered the patient breathing system, it would require 22.6 L of fresh gas to dilute the resulting vapor to a 1% concentration (1.3 MAC).

Effect of Carrier Gas on Vaporizer Output

The carrier gas used to vaporize the volatile agent in the vaporizing chamber may also affect vapor output concentration. Thus when the carrier gas flow through a variable-bypass Ohio enflurane vaporizer (Fig. 38–11) was changed from N_2/O_2 to N_2O/O_2, the vapor concentration decreased for about 15 minutes and then returned to normal.[21] Once the output concentration is stable with a carrier gas of N_2O/O_2, changing back to N_2/O_2 resulted in an increase in vapor concentration for about 15 minutes.

The explanation for this observed effect is the solubility of N_2O in the liquid volatile agents. When N_2O/O_2 first enters the vaporizing chamber, some N_2O gas physically dissolves in the liquid agent, and the vaporizing chamber output decreases until the liquid has become saturated with N_2O. Conversely, when N_2O is discontinued as the carrier gas, the N_2O gas that is dissolved in the liquid anesthetic comes out of solution and represents, in effect, additional gas flow to the vaporizing chamber. The solubility of N_2O is approximately 4.5 mL per mL of liquid anesthetic. Thus 100 mL of halothane liquid, when fully saturated with N_2O, can dissolve approximately 450 mL of N_2O. Such a volume of N_2O, being added to the vaporizing chamber flow over a brief period when N_2O has been discontinued, causes the observed increase in vaporizer output concentration. This effect is not ob-

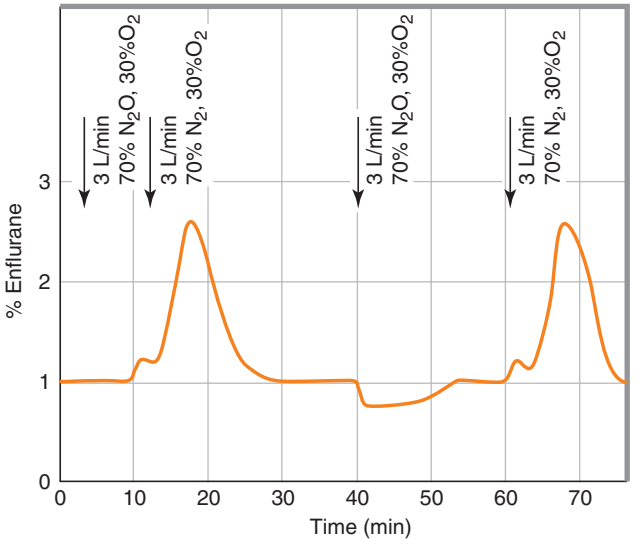

FIGURE 38–11. Effect of carrier gas composition on output of Ohio enflurane variable-bypass vaporizer (see text for details).

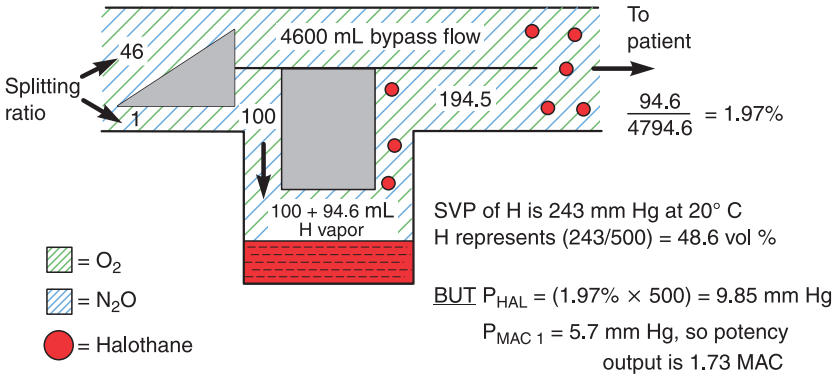

FIGURE 38–12. Use of variable-bypass halothane vaporizer under hypobaric conditions. Vaporizer is set to 1% (vol/vol) and is being used at ambient pressure of 500 mm Hg.

served with measured-flow vaporizers (e.g., Copper Kettle, Verni-Trol), as in this type of arrangement the carrier gas is always O_2.[21]

Changes in Barometric Pressure

Although vaporizers are most often used at ambient pressures of approximately 760 mm Hg (1 atm at sea level), they may be used under hypobaric (e.g., at increased altitude) or hyperbaric (e.g., in a hyperbaric chamber) conditions.[22]

Hypobaric Conditions

Because few reports discuss the use of vaporizers under hypobaric conditions, the theoretic considerations applying to such use are discussed here. Consider a variable-bypass vaporizer set to deliver 1% halothane (1.3 MAC at 760 mm Hg atmospheric pressure) that is being used at an ambient pressure of 500 mm Hg (equivalent to an altitude of 10,000 feet above sea level) and at a temperature of 20°C (Fig. 38–12). In the vaporizing chamber, halothane has an SVP of 243 mm Hg (at 20°C), but this now represents 243/500 = 48.6 vol%. The vaporizer, set to deliver 1% under normal conditions, creates a splitting ratio of 46:1 (Table 38–3) between bypass and vaporizing chamber flows. If the total gas flow to the vaporizer is 4700 mL/min (Fig. 38–12), 4600 mL/min enter the bypass and 100 mL/min of carrier gas enter the vaporizing chamber. This 100 mL represents 51.4% of the volume there because halothane represents the other 48.6 vol% (100% – 51.4%). Emerging from the chamber is 100 mL/min of carrier gas plus ([100/51.4] × 48.6) = 94.6 mL/min of halothane vapor. When the vaporizing chamber and bypass flows merge, the 94.6 mL/min of halothane vapor are diluted in a total volume of 4794.6 mL/min (4600 + 100 + 94.6), giving a halothane concentration of 1.97 vol%, or approximately 2%. This would appear to be double the dialed-in concentration in terms of volumes percent.

Now consider partial pressures. If halothane represents 1.97% of the gas mixture by volume, its partial pressure in the emerging mixture is 1.97 × 500, or 9.85 mm Hg. In terms of anesthetic potency, this represents 9.85/5.7, or 1.73 MAC, because the P_{MAC1} of halothane is 5.7 mm Hg (Table 38–1). Thus in theory, when used at an ambient pressure of 500 mm Hg, the variable-bypass halothane vaporizer set to 1% (vol/vol) would deliver twice the dialed-in concentration in terms of volumes percent but only 1.73/1.33 MAC, or 1.3 times the anesthetic potency expected.

Hyperbaric Conditions

Consider a variable-bypass isoflurane vaporizer set to deliver 2% (1.74 MAC at 760 mm Hg atmospheric pressure) isoflurane vapor used at 20°C and 3 atm (3 × 760 = 2280 mm Hg), as may exist in a hyperbaric chamber (Fig. 38–13).

In the vaporizing chamber, the SVP of isoflurane is 238 mm Hg (Table 38–2) and the isoflurane concentration is 10.4 vol% ([238/2280] × 100). A variable-bypass isoflurane vaporizer set to deliver 2% creates a splitting ratio of 21:1 for the fresh gas flow (Table 38–3). If the total gas flow to the vaporizer is 2200 mL/min, 2100 mL enter the bypass and 100 mL of carrier gas enter the vaporizing chamber per minute (Fig. 38–13). This 100 mL represents 89.6% (100 – 10.4) of the total gas there; the remainder is isoflurane vapor. The amount of isoflurane vapor evolved is ([100/89.6] × 10.4) = 11.6 mL/min. This volume, diluted in 2100 + 100 + 11.64 gives 11.6/2211.6, or 0.52% isoflurane vapor by volume. This is 0.26 (0.52/2.0) of what was set on the concentration dial in terms of volumes percent.

How about potency? The partial pressure of isoflurane in the emerging gas mixture is 11.9 mm Hg (0.52% × 2280). Dividing by the P_{MAC1} for isoflurane of 8.7 mm Hg (Table 38–1) gives a potency output of 1.37 MAC (11.9/8.7). Thus the isoflurane vaporizer, set to deliver 1.74 MAC under conditions of 1 atm pressure, delivers 1.37 MAC at 3 atm, or about 0.80 times the anesthetic potency expected.

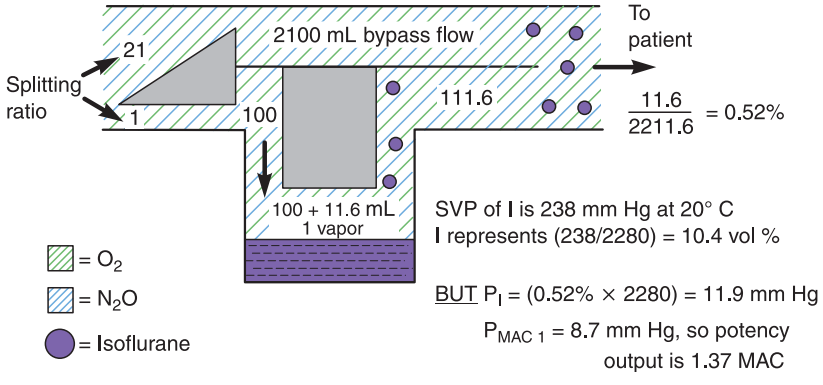

FIGURE 38–13. Use of variable-bypass isoflurane vaporizer under hyperbaric conditions. Vaporizer is set to 2% (vol/vol) and is being used at ambient pressure of 2280 mm Hg (3 atm).

These examples show that although changes in ambient pressure may have a great effect on vapor concentration output in terms of volumes percent, the anesthetic potency (MAC) output is changed less drastically. In the examples discussed, it was assumed that the set splitting ratios (Table 38–3) would be maintained constant as ambient pressure changed. In reality, changes in gas density occur with changes in ambient pressure and may affect the splitting ratios slightly. The anesthetic potency output expected for any given vaporizer setting is relatively unchanged, by ambient pressure, even though vapor concentration (vol/vol) may be altered considerably.[22] Again, vaporizer output concentration expressed in volumes percent is of limited value unless converted to MAC units using the concept of pressures as described in the foregoing examples.[12,22]

Arrangement of Vaporizers

Old anesthesia machines had up to three variable-bypass vaporizers arranged in series such that fresh gas from the flowmeters passed through each vaporizer to reach the common gas outlet of the anesthesia machine. Without an interlock system, which permits only one vaporizer to be in use at any time, it was possible to have all three vaporizers turned on simultaneously. Apart from potentially overdosing the patient, the agent from the upstream vaporizer could contaminate the liquid agent(s) in the downstream vaporizer(s). During subsequent use, the output of the downstream vaporizer would be contaminated. The resulting concentrations in the emerging gas and vapor mixture would be indeterminate and might even be lethal.[12]

With modern workstations, only one vaporizer can be on at any time. The recent standards require that, to prevent cross-contamination of the contents of one vaporizer with an agent from another, a system must be provided that isolates the vaporizers from each other and prevents gas from passing through the vaporizing chamber of one vaporizer and then through that of another.[1,2] This specification is met by use of an interlock system. Contemporary Dräger and Datex-Ohmeda anesthesia machines incorporate manufacturer-specific interlock systems.[23,24]

Calibration and Checking of Vaporizer Outputs

Vaporizers should be regularly serviced according to manufacturer's recommendations and their outputs checked to ensure that a malfunction does not exist. Thus the vaporizer dial is set to deliver a certain concentration. The actual output concentration is measured by an anesthetic agent analyzer that samples gas via a connector placed at the common gas outlet of the anesthesia machine.

Desflurane and the Tec 6 Vaporizer

Box 38–1 lists the physical properties of desflurane. With an SVP of 669 mm Hg at 20°C and a boiling point of 22.8°C, this agent is extremely volatile. Clearly, this agent cannot be administered using the conventional variable-bypass design of vaporizer used for halothane, enflurane, isoflurane, and sevoflurane. If such a variable-bypass vaporizer were somehow filled with desflurane, an increase in temperature to above 22.8°C would result in the desflurane boiling in the vaporizing chamber and uncontrolled output from the vaporizer. The consequences of misfilling contemporary agent-specific variable-bypass vaporizers with desflurane at 22°C have been predicted.[23] Thus an enflurane vaporizer set to deliver 3 MAC (approximately 5% enflurane) would deliver 16 MAC (approximately 96%) desflurane at 22°C.[25]

Datex-Ohmeda (Steeton, UK) designed the Tec 6 concentration-calibrated vaporizer for the controlled administration of desflurane. It was designed to make the practical aspects of the clinical administration of desflurane no different from that of other potent inhaled agents using their Tec series of vaporizers (Fig. 38–14).[24,25]

The principle of operation of the Tec 6 is that liquid desflurane is heated in a chamber (the sump) to 39°C to produce vapor under pressure (~1500 mm Hg or 2 atm absolute) analogous to having a reservoir of compressed gas in a tank (Fig. 38–14). The vapor leaves the sump (item 9) via a variable pressure-regulating valve (item 7), the opening of which is continuously adjusted according to the output from pressure transducers (items 3 and 4) to ensure that the pressure of the desflurane vapor entering the rotary valve in the user-controlled concentration dial is the same as the pressure generated by the fresh gas inflow (from the anesthesia machine flowmeters) into a fixed restrictor. The concentration dial and rotary valve control the quantity of desflurane vapor added to the fresh gas flow so that what emerges from the vaporizer outlet is the dialed-in concentration of desflurane. Unlike other concentration-calibrated vaporizers (e.g., Datex-Ohmeda Tec 5, Dräger Vapor 19.1) which are of variable-bypass design, no fresh gas enters the desflurane sump in the Tec 6.

The Tec 6 is calibrated by the manufacturer using 100% oxygen as the fresh gas. As the oxygen enters the vaporizer it flows through a fixed restrictor (Fig. 38–14, item 2, and Fig. 38–15). This is a device that offers a fixed resistance, resistance being defined as change in pressure per unit of flow. The resistance is approximately 10 cm H_2O/L/min over a wide range of gas flows. The back pressure created by gas flowing through the fixed restrictor is therefore proportional to the main gas flow (as set on the machine flowmeters) and changes according to Poiseuille's law (see Gas Flow Control Systems [Knobs, Needle Valves, Rotameters, Etc.] above). By sensing this back pressure (via a pressure transducer) and ensuring that the pressure of the desflurane vapor entering the variable restrictor is always made equal to this pressure (via the control electronics and variable pressure control valve), the variable restrictor provides a means to control

the concentration of desflurane (Fig. 38–15).

Thus,

$$\text{Resistance} = \frac{\Delta \text{ Pressure}}{\Delta \text{ Flow}} \quad (38\text{–}1)$$

For the main gas flow of oxygen entering the fixed restrictor,

$$\text{Resistance (main)} = \frac{\text{Pressure(main)}}{\text{Flow(main)}} \quad (38\text{–}2)$$

or

$$\text{Flow (main)} = \frac{\text{Pressure(main)}}{\text{Resistance(main)}} \quad (38\text{–}3)$$

But Resistance(main) is a constant, K (10 cm H_2O/L/min), so Flow(main) is proportional to Pressure(main).

For the desflurane flow entering the concentration dial variable restrictor,

$$\text{Flow(des)} = \frac{\text{Pressure(des)}}{\text{Resistance(main)}}$$

$$\text{Concentrations(des)} = \frac{\text{Flow(des)}}{\text{Flow(main)} + \text{Flow(des)}} \quad (38\text{–}4)$$

If Flow(des) is small compared to Flow(main), we can ignore Flow(des) in the denominator of equation 38–4, thus:

$$\text{Concentrations(des)} = \frac{\text{Flow(des)}}{\text{Flow(main)}} =$$

$$\frac{\text{Pressure(des)} \times \text{K}}{\text{Pressure(main)} \times \text{Resistance(des)}} \quad (38\text{–}5)$$

The pressure transducer, control electronics and variable pressure control valve ensure that Pressure(des) = Pressure(main), therefore:

$$\text{Concentration(des)} = \frac{\text{Flow(des)}}{\text{Flow(main)}}$$

which is approximately equal to:

$$\frac{1}{\text{Resistance(des)}} \quad (38\text{–}6)$$

Thus it becomes apparent that the variable restrictor in the concentration dial [i.e., Resistance(des)], can be calibrated in terms of desflurane concentration. The calibration of the variable restrictor is not linear, however, and equation 38–6 above is an approximation because the value of Flow(des) in the denominator of equation 1 cannot always be ignored.

Some examples of vaporizer concentration dial and gas flow settings will illustrate the application of these principles.

Example 1 Consider a Tec 6 vaporizer set to deliver 10% desflurane at a fresh gas flow of O_2 of 5 L/min (Fig. 38–16).

$$\text{Concentrations(des)} = \frac{\text{Flow(des)}}{\text{Flow(main)} + \text{Flow(des)}}$$

$$10\% = 0.10 = \frac{\text{Flow(des)}}{5000 + \text{Flow(des)}} \quad (38\text{-}7)$$

Thus,

$$0.10 \times (5000 + \text{Flow(des)}) = \text{Flow(des)}$$

$$0.9 \times \text{Flow(des)} = 500 \text{ mL}$$

$$\text{Flow(des)} = \frac{500}{0.9} = 556 \text{ mL/min} \quad (38\text{-}8)$$

Consequently, at a 5 L/min flow of O_2 and set to deliver 10% desflurane, the Tec 6 is adding 556 mL/min of desflurane vapor to the main gas flow, that is,

$$\frac{556}{5000 + 556} = \frac{556}{5556} = 0.10 = 10\% \quad (38\text{-}9)$$

Once the main flow (in this case 5 L/min O_2) and the desflurane flow (calculated as above) are known, the ratio of resistances of the variable resistor (Resistance(des), in the concentration dial) to the fixed resistor (Resistance(main), in the main gas flow) may be calculated:

$$\text{Resistance(des)} = \frac{\text{Pressure(des)}}{\text{Flow(des)}}$$

$$\text{Resistance(main)} = \frac{\text{Pressure(main)}}{\text{Flow(main)}} \quad (38\text{-}10)$$

But, Pressure(des) = Pressure(main), therefore,

$$\frac{\text{Flow(main)}}{\text{Flow(des)}} = \frac{\text{Resistance(des)}}{\text{Resistance(main)}} = \frac{5000}{556} = 9{:}1 \quad (38\text{-}11)$$

Resistance(des) may also be calculated as follows:

Pressure(des) = Pressure(main), which is 50 cm H_2O (because main gas flow is 5 L/min)

$$\text{Flow(des)} = 556 \text{ mL/min}$$

$$\text{Resistance(des)} = \frac{\text{Pressure(des)}}{\text{Flow(des)}} = \frac{50}{0.556} = 90 \text{ cm } H_2O\text{/L/min} \quad (38\text{-}12)$$

Example 2 Increase fresh gas flow to 10 L/min. Increasing Flow(main) from 5 L/min to 10 L/min causes a temporary imbalance of pressures

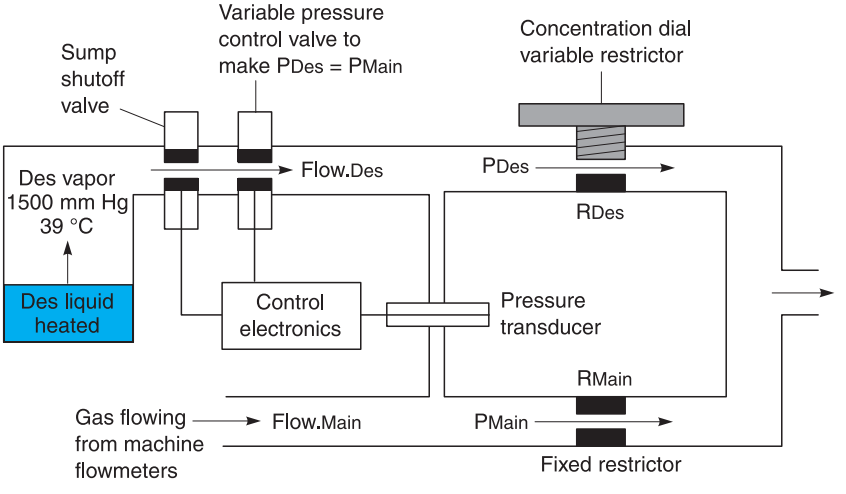

FIGURE 38–15. Tec 6 vaporizer simplified to illustrate principles. See text for details.

FIGURE 38–16. **A.** Tec 6 vaporizer (Datex-Ohmeda) for desflurane. **B.** Close-up to show status warning lights and LCD indicating agent level.

across the differential pressure transducer because Pressure(main) increases from 50 cm H_2O to 100 cm H_2O (Fig. 38–15). (Remember that Resistance(main) is 10 cm H_2O/L/min.) The imbalance is sensed by the differential pressure transducer and the control electronics cause the variable pressure control valve to open wider (i.e., decrease its resistance to desflurane vapor flowing from the sump at a pressure of 1500 mm Hg) so that the pressure of desflurane vapor into the concentration dial variable restrictor increases until Pressure(des) is also 100 cm H_2O. The increase in Flow(des) and, thereby, Pressure(des) ensures that the Tec 6 continues to deliver the 10% concentration as set on the dial.

Example 3 Increase concentration dial setting from 10% to 15% while maintaining gas flow of 10 L/min. Increasing the concentration dial setting to 15% causes a decrease in Resistance(des). The resulting decrease in Pressure(des) relative to Pressure(main) is sensed by the differential pressure transducer and the control electronics cause the variable pressure control valve to open wider (i.e., decrease its resistance to desflurane vapor flowing from the sump) so that Pressure(des) is increased to once again be equal to Pressure(main). The resulting increase in Flow(des) ensures that the vapor concentration increases to the desired greater concentration.

Example 4 Decrease concentration dial setting from 15% to 5% at 10 L/min gas flow. Changing the concentration dial setting from 15% to 5% creates an increase in Resistance(des), which causes an increase in Pressure(des). The latter is sensed by the differential pressure transducer because Pressure(des) is now greater than Pressure(main) and the control electronics cause the variable pressure control valve to decrease its opening (i.e., increase its resistance to desflurane vapor flowing from the sump), thereby decreasing Flow(des) until Pressure(des) once again equals Pressure(main).

Special Considerations

Design Features of the Tec 6 (Figs. 38–14 and 38–16) The sump, when full, contains 450 mL desflurane. Because the sump is pressurized to 1500 mm Hg, the agent level is sensed electronically and shown on a liquid crystal display (LCD), rather than the sight-glass used in variable-bypass vaporizers. When the vaporizer is energized by connecting the power cord to an electrical outlet, a heater in the sump heats the agent to 39°C and maintains that temperature via thermostatic controls. While the agent is being heated, the sump shut-off valve is held closed, keeping the agent in the sump. During the warmup period, the vaporizer is not operational because the sump shut-off valve remains closed, and a solenoid-locking device prevents the concentration dial from being turned to on. Once operational (i.e., at 39°C), the dial lock is released and when the dial is turned on, the sump shut-off valve is opened, permitting desflurane vapor to flow to the pressure regulating valve.[24,25]

To prevent condensation ("rain out") of desflurane vapor, in addition to the heater in the sump, there are heaters in the rotary valve and in the vicinity of the pressure transducers that sense the back pressures caused by the main gas flow and by desflurane.

The Tec 6 thus differs considerably from variable-bypass vaporizers. None of the fresh gas flow enters the vaporizing chamber. The Tec 6 requires electrical power and incorporates sophisticated electronics to ensure normal operation and a display panel to inform the user about its operational status. It also has alarms to alert to any malfunction, in the event of which the sump shut-off valve closes (Fig. 38–16).

Filling System Because of its high saturated vapor pressure, desflurane is supplied in plastic-coated glass bottles

to which an agent-specific filling device is firmly attached. The vaporizer incorporates an agent-specific filling system that permits filling of the sump at any time, including when the vaporizer is in use. This may be important because of desflurane's low blood-to-gas partition coefficient.

During filling the bottle is locked to the vaporizer-filling system and the high pressure of vapor in the sump at 39°C is transmitted to the interior of the bottle, which helps to drive liquid desflurane from the bottle into the sump. When filling is complete, the bottle is disconnected from the vaporizer fill system and the valve on the bottle closes to avoid loss or spillage of agent. At this time the bottle contains vapor at 39°C and a pressure of 1500 mm Hg. As the bottle and its contents cool to room temperature, the pressure in the bottle decreases toward atmospheric (760 mm Hg at 22.8°).

Effect of fresh gas composition on performance. The Tec 6 is calibrated at the factory using 100% O_2. Performance accuracy at 5 L/min oxygen is specified as ± 0.5% of delivered agent or ± 15% of dial setting, whichever is greater.[24]

Using Poiseuille's law, laminar flow through a resistor is determined as:

$$\text{Flow} = \frac{\pi \times P \times r^4}{8 \times \eta \times L}$$

where $\pi = 3.142$, P is the pressure difference, r is the radius, η is the viscosity of the gas, and L is length

Thus,

$$\text{Flow} = \frac{P}{\eta}$$

or

$$P \approx \text{Flow} \times \eta$$

The Tec 6 design uses back pressure from gas flow through the fixed restrictor to infer flow (Fig. 38–15). If the viscosity of the gas flowing through the fixed resistor were to decrease, then the same flow would result in a lower back pressure. This back pressure is used to determine the pressure of desflurane into the variable restrictor in the concentration dial. A lower pressure results in a lower flow of desflurane vapor through the variable restrictor.

Of the gases on the anesthesia machine, O_2 is the most viscous and N_2O the least viscous. Thus, changing the main gas flow composition from O_2 to O_2/N_2O decreases gas viscosity and the output concentration of desflurane from that setting on the dial. Differences between the actual concentration produced and the dial setting are greatest (up to 20% of dial setting) with high concentrations of N_2O at low gas flow rates. The clinical implications of this are minimal, however, because the anesthetic effect lost by the decrease in desflurane is offset by the effect of the N_2O.[24]

Effects of Altitude on Output

The Tec 6 accurately delivers the dialed-in concentration of desflurane in terms of volumes percent, even at altitudes different than sea level. At sea level, 7% desflurane (1 MAC) creates a P_{des} of (7% × 760 mm Hg) = 53 mm Hg (the P_{MAC1}; Table 38–2). At altitude, if the ambient pressure were 500 mm Hg, the same 7% desflurane creates a P_{des} of only 35 mm Hg (7% × 500), which is only 0.66 of the P_{MAC1}. To compensate for this decrease in potency output at increased altitude, a higher concentration must be set on the dial. Conversely, at higher ambient pressures, a lower concentration dial setting would be indicated. Recommendations as to how the dial setting should be changed at altitude are provided in the operator's manual.[24]

Interlock System

Although the Tec 6 is manufactured by Datex-Ohmeda and is mountable on their patented Select-a-Tec manifold on a Datex-Ohmeda anesthesia machine, a version is also available for mounting on Dräger Narkomed anesthesia workstations. Recently, Dräger introduced the D-Vapor desflurane vaporizer to its Vapor 2000 series (Fig. 38–17). The operating principles are the same as in the Datex-Ohmeda Tec 6 but it weighs significantly less. Similar to other vaporizers in their Vapor 2000 series, the D-Vapor is hermetically sealed when removed from an anesthesia system, allowing transport in any position, even when filled. The 300-mL reservoir capacity of the tank can hold the entire contents of a standard anesthetic agent bottle. Like the Tec 6, the D-Vapor is electrically powered, but it also features 5 minutes of emergency battery operation which ensures that dose settings remain constant even during a brief power failure. Penlon (UK) has also exhibited a desflurane vaporizer addition to their Sigma series of vaporizers, but at the time of writing it is not being marketed in the United States.

Aladin Vaporizing System

Advances in technology and computerization of the workstation have led to the development of a new design of

FIGURE 38–17. ***Left:*** Dräger D-Vapor desflurane vaporizer. ***Right:*** Dräger Vapor 2000 sevoflurane vaporizer. Note the T position (for Transport mode) on the concentration dial.

variable-bypass, electrically powered Aladin vaporizing system that is used in the Datex-Ohmeda S5 /ADU and Aisys workstations. The principles of operation differ from those of earlier variable-bypass vaporizers and from the Tec 6 design of vaporizers discussed above.

The Aladin vaporizer consists of two separate parts that must be joined to produce a functioning vaporizer. One is a sump, the detachable agent-specific Aladin cassette, that can hold up to 250 mL of liquid agent. Each anesthetic agent, including desflurane, has its own cassette made unique by means of an agent-specific fill system (e.g., Saf-T-Fil for desflurane; key fill or Quick-Fill for other agents). Thus five different cassettes are available, one for each of the presently available potent inhaled agents. The second part of the vaporizer is a component of the ADU or Aisys workstation and contains the concentration-control hardware and software. The agent-specific cassette identifies itself to the second part of the vaporizer by the arrangements of signature magnets at the top of the cassette. The ADU and Aisys workstations monitor and control gas and vapor at several points. They monitor and control flow through the N_2O, O_2 and air flowmeters and will not permit the delivered oxygen concentration to fall below 25% at the workstation's common gas outlet. Gas flow from these sources is delivered to, or bypasses, the anesthetic in the sump. The flow of agent at its saturated vapor concentration issuing from the sump, and the bypass flows are monitored and adjusted by hardware, as governed by software algorithms to produce the dialed-in concentration of anesthetic. The algorithms take into account the anesthetic agent, temperatures and gas pressures in the sump and by pass (each separately measured).

The agent wheel (an electronic control) on the front panel of the ADU or Aisys workstation is used to set the desired concentration of agent to be delivered to the breathing system (Fig. 38–18). A green light-emitting diode (LED) indicates that the vaporizer is on (Fig. 38–19). The vaporizer is controlled via a central processing unit (CPU). See Figure 38–20 for principles of operation.[26] The flow restrictor in the bypass causes fresh gas from the gas flow controls to be split into a bypass flow and a flow, that passes through a unidirectional valve (which prevents backflow) to the Aladin cassette. The latter is an agent-specific cartridge that contains liquid anesthetic at its saturated vapor concentration at the ambient temperature (e.g., [160/760] × 100% = 21 vols% for sevoflurane at 20°C). Continuous monitoring of temperature and pressure in the cassette means that the agent vapor concentration there is always known. The concentration of anesthetic vapor delivered to the common gas outlet of the machine is determined by the concentration of agent vapor in the cassette, and the ratio of cassette outflow to the bypass flow, both of which are measured continuously. The delivered concentration is controlled by the position of the agent proportional valve, which is set continuously according to information from the agent controller (CPU).

Each Aladin cassette is essentially a flow-over vaporizer because it contains liquid agent that is vaporized as fresh gas flows between the agent-soaked wicks and baffles. It is equiva-

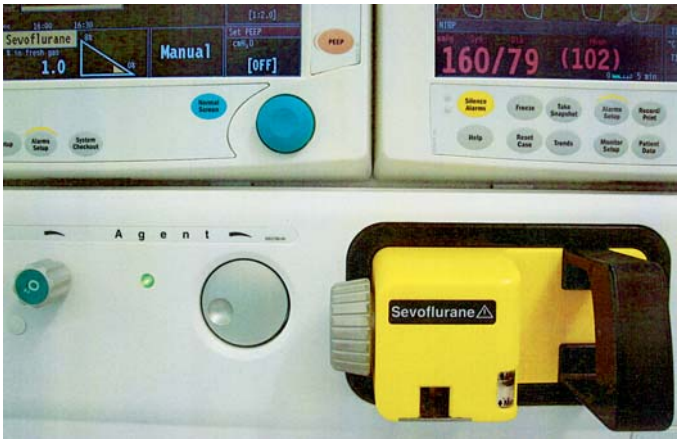

FIGURE 38–18. Aladin vaporizing system shown here on a Datex-Ohmeda ADU workstation. The cassette is agent-specific (in this case sevoflurane). The dial to the left of the cassette is the concentration control. The (green) pilot light to the left of the dial indicates that the vaporizer is on. The dialed-in agent concentration is shown at the bottom of the left-hand screen.

FIGURE 38–19. Enlarged view of concentration dial and agent display box on screen. Although this is an electronically controlled vaporizing system, agent concentration is *increased* by turning the dial in a *counterclockwise* direction, analogous to the dial on a traditional variable-bypass vaporizer (e.g. Tec 7, Dräger Vapor 2000.)

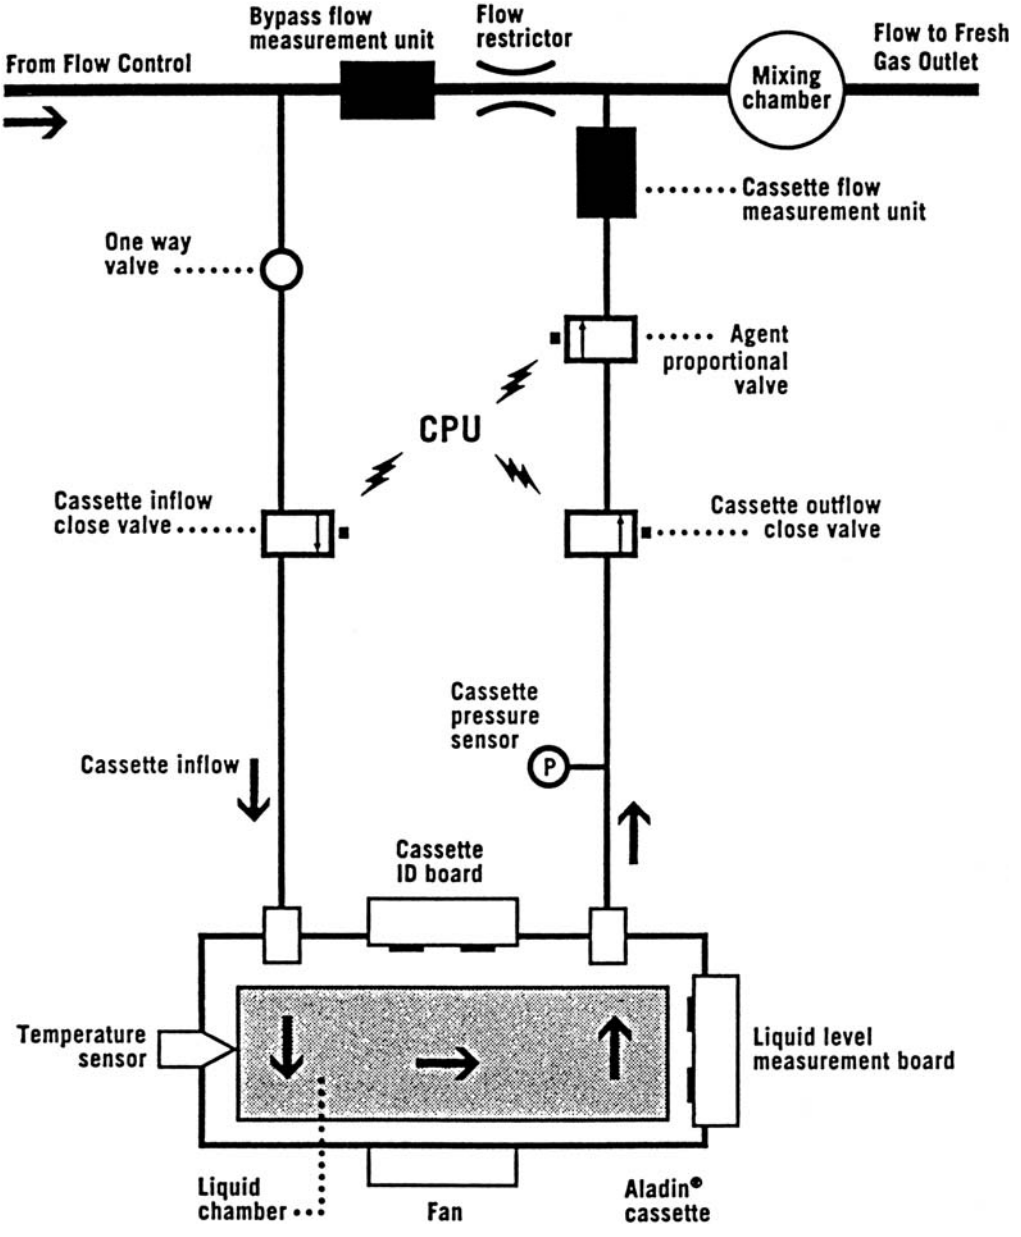

FIGURE 38–20. Schematic showing principles of operation of the Aladin vaporizing system used on the Datex-Ohmeda ADU and Aisys workstations.

lent to the sump of a traditional variable-bypass vaporizer but because it does not incorporate bypass flow channels, tilting the cassette during handling, changing, or filling is not hazardous (Figs. 38–21A,B).

The Aladin cassette for desflurane incorporates an electronic liquid level measuring device so that if <10% liquid desflurane (<25 mL) remains, an alarm message is displayed. If the temperature is <22.8°C (boiling point of desflurane) fresh gas must enter the cassette for vapor to be delivered via the exit connection. If the temperature is >22.8°C, no fresh gas inflow is needed and the desflurane vapor is released by controlling the outflow valve. A fan is mounted inside the fresh gas control unit beneath the Aladin cassette housing and is required to heat the cassette when large amounts of agent are being vaporized. The fan operates when the cassette temperature is <17°C and stops when it is >20°C.

The Aladin vaporizing system offers certain advantages, the greatest of which is that the CPU can control the concentration of any of the commonly used potent inhaled anesthetic agents. Separate vaporizers (or at least their flow-splitting mechanisms) are not required for each agent. An obvious disadvantage is that in the event of a prolonged power loss (i.e., after the backup battery has been depleted) delivery of the volatile agent will cease. In contrast, conventional mechanical Tec-type vaporizers will function as long as there is a source of compressed gas to the machine. An Aisys workstation with the Aladin system is shown in Figure 38–22.

COMMON GAS OUTLET AND OUTLET CHECK VALVES

The fresh gas mixture produced by the settings of the flow controls for O_2, N_2O, and other gases, and vapor from one concentration-calibrated vaporizer exit the anesthesia machine via the common gas outlet. Situated between the vaporizer and the common gas outlet, Datex-Ohmeda Modulus I and Modulus II machines have an outlet check valve,

FIGURE 38–21A. A. Aladin cartridge specific for isoflurane. The electronic bus (electrical contacts) allows the agent fill status to be monitored by the CPU. *(continued)*

and a pressure relief valve that opens at a pressure of 120–150 mm Hg (2.3–2.9 psig) (Fig. 38–2). The pressure-relief valve, as its name suggests, prevents the buildup of excessive pressures upstream of the outlet check valve. These components are located upstream from where the O_2 flush flow would join to pass to the common gas outlet. The Datex-Ohmeda Excel and Aestiva machines have an outlet check valve and a pressure relief valve (opening pressure threshold: 5 psig) that is located downstream of the outlet check valve.

The purpose of the outlet check valve, where present (Datex-Ohmeda Modulus I, Modulus II, Excel and Aestiva but not Modulus II Plus or Modulus CD machines), is to prevent reverse gas flow, which would permit gas to go back into the variable-bypass (Tec-type) vaporizer if the latter did not have its own outlet check valve or specialized design. This "pumping" effect, if not prevented, could cause increased vaporizer output concentrations.[27]

Dräger Narkomed models 2, 3, and 4 are designed so as not to require an outlet check valve. Any pumping effect is eliminated by special design of the Vapor vaporizer (Fig. 38–10, component 4). The Datex-Ohmeda Modulus II Plus and Modulus CD machines are equipped with Datex-Ohmeda Tec 4 or Tec 5 vaporizers, which incorporate a baffle system and specially designed manifold to prevent the pumping effect, making an outlet check valve unnecessary on these machines. Nevertheless, the Datex-Ohmeda Modulus II Plus and Modulus CD machines do have a pressure-relief valve (Fig. 38–2). Dräger Narkomed 2, Narkomed 3, and Narkomed 4 machines do not require a separate pressure-relief valve.[9] In these machines, pressure-relief opening (threshold approximately 18 psig), if required, takes place through the specially designed Dräger Vapor vaporizers. The presence or absence of an outlet check valve and pressure-relief valve is important when considering how to test the low-pressure system of the anesthesia machine for leaks.

The workstation standard requires that when the common gas outlet is connected to the breathing system by a fresh gas supply hose (the usual arrangement in most workstations), the common gas outlet should be provided with a manufacturer-specific retaining device. It may have a 15-mm female fitting or a 15/22-mm coaxial fitting. Machines should have only one common gas outlet. The retaining device's purpose is to help prevent disconnection or misconnections between the machine common gas outlet and the patient circuit, which could result in patient injury. Dräger Narkomed machines have a bar-type retaining device, whereas Datex-Ohmeda machines use a spring-loaded, bayonet-fitting retaining device.

Datex-Ohmeda Aestiva and Aespire machines do not have a visible CGO and hose connection between machine and circle system. There is, however, an auxiliary CGO that can be accessed if other than a circle system is used (e.g., Bain), or to leak check the low-pressure system of the machine (see Anesthesia Machine Checkout; Testing for Leaks in the Anesthesia Machine and Breathing System).

ANESTHESIA BREATHING SYSTEMS

The anesthesia breathing system or circuit represents a mini-environment for respiratory gas exchange. The fresh gas flow from the anesthesia machine delivers known volumes and concentrations of O_2, N_2O (and possibly air or helium), and potent inhaled anesthetic to the circuit, and gases are vented from the circuit to the scavenging system. In some arrangements, high fresh gas flows are used, in which case the patient's inspired gas concentrations approximate those in the fresh gas supply. Other circuits, such as the adult circle system, use lower fresh gas flows and rely on an absorption system for CO_2. In the circle breathing system, when low fresh gas flows are used, the composition of the inspired gas may be quite different from that of the fresh gas inflow.

All adult anesthesia circuits are composed of corrugated 22-mm-diameter tubing, a reservoir bag, and connecting piece or elbow to the patient's airway. They may or may not also

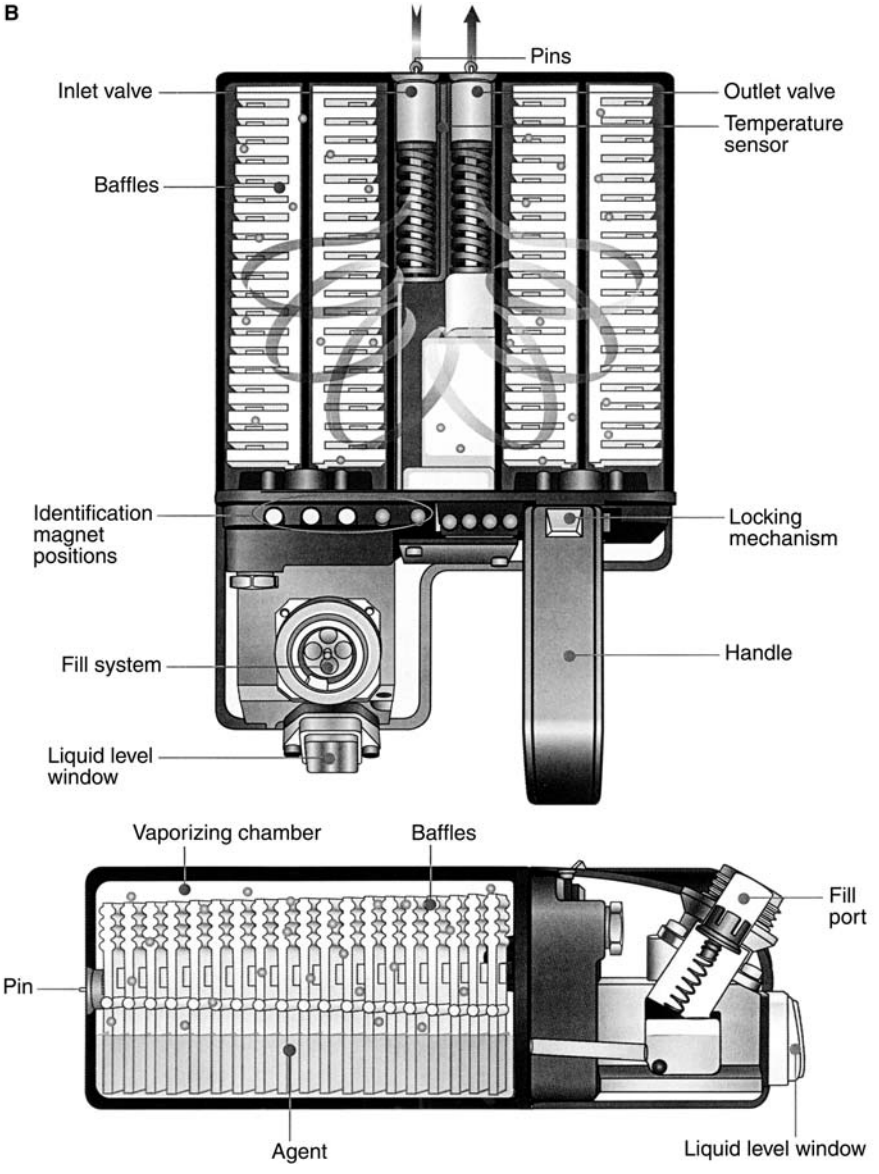

FIGURE 38–21B. (Continued) **B.** Schematic cross-section of Aladin cartridge showing that it is the same as the agent specific sump of a standard variable-bypass vaporizer, with wicks and baffles to increase the surface area for evaporation of the anesthetic agent. include a valve or valves. How these items are arranged gives the resulting circuit its functional characteristics. Breathing systems are generally classified as rebreathing, having no CO_2 absorption system (i.e., Mapleson classification circuits A to F), or nonrebreathing, having a CO_2 absorber (e.g., circle system).

Rebreathing Systems

Figure 38–23 illustrates the circuits assigned letters according to the Mapleson classification.[28] In circuits A, B, and C, the APL (pop-off) valve is located close to the patient, whereas circuits D, E, and F are T-piece arrangements with gas leaving the circuit at a distance from the patient. Because there is no CO_2 absorber in any of these systems, the potential exists for the patient to inhale alveolar gas that has been previously exhaled and contains CO_2. The extent of rebreathing depends on the circuit anatomy, the patient's minute ventilation, pattern of ventilation, fresh gas flow rate, and whether ventilation is spontaneous or controlled.[29,30]

Mapleson A: Magill Attachment

The Magill attachment (circuit A) is illustrated in Fig. 38–23. Fresh gas from the anesthesia machine enters at the end of the system farthest from the patient and closest to the reservoir bag and leaves via a spring-loaded adjustable pop-off valve located close to the patient. The system functions very differently during spontaneous than during controlled ventilation. During spontaneous ventilation, as the patient begins to exhale, dead space gas enters the tubing and passes toward the reservoir bag. Meanwhile, fresh gas entering the system from the machine is stored in the reservoir bag. As exhalation continues, pressure increases in the system, and the pop-off valve opens to preferentially vent alveolar gas. If the fresh gas flow rate is high, dead space gas stored in the tubing may also be vented via the pop-off valve. During the next spontaneous inspiration the patient breathes in any dead space gas stored in the tubing, followed by fresh gas from the anesthesia machine and that stored in the reservoir bag. Mapleson[28] calculated and others[32] confirmed that during spontaneous ventilation, a fresh gas flow rate equivalent to alveolar ventilation (i.e., approximately 70% of minute ventilation) will prevent rebreathing. However, as the fresh gas flow rate approaches alveolar ventilation, the system's vulnerability to producing rebreathing, as a result of an uneven ventilatory pattern, is increased.

When used during controlled ventilation, the Magill attachment becomes very inefficient in terms of fresh gas requirements. During controlled inspiration, when the bag is squeezed, the pop-off valve opens, causing release of fresh gas.[29] Previously exhaled alveolar gas is not vented efficiently and is rebreathed. With controlled ventilation the most efficient removal of CO_2 occurs with a short inspiratory-to-expiratory (I:E) ratio, a large tidal volume, and a high fresh gas flow.[28,31] Consequently, fresh gas flow rates of 3 times the estimated minute ventilation are recommended during controlled ventilation with the Magill attachment.[32] Such high flows are wasteful of anesthetic gases and pose additional problems for waste gas scavenging.

Enthusiasm for the Magill attachment resulted in potential modifications to address these problems. Thus, during controlled ventilation, the fresh gas requirement can be reduced by keeping the pop-off valve closed during inspiration. This is achieved by the

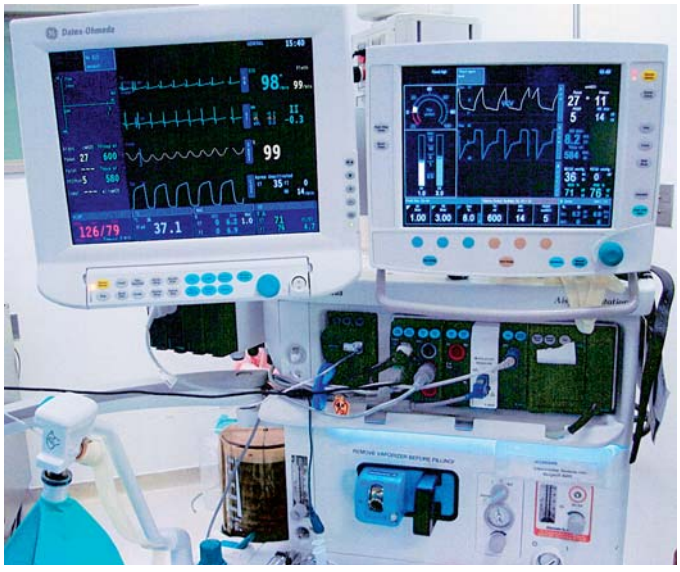

FIGURE 38–22. The Aladin vaporizing system is also used in the Datex-Ohmeda Aisys workstation. Note the agent-specific desflurane cassette. In this workstation, agent concentration is adjusted using the com wheel that is just below the lower right corner of the screen on the right hand side. In this workstation, agent concentration is *increased* by turning the com wheel in a *clockwise* direction.

Enclosed Magill System or the Miller modification (Fig. 38–24).[33] A system somewhat analogous to that used in contemporary double-circuit anesthesia ventilators (see Anesthesia Ventilators). This modified system is reported to be as efficient during controlled ventilation as the Magill attachment is during spontaneous ventilation.[33,34]

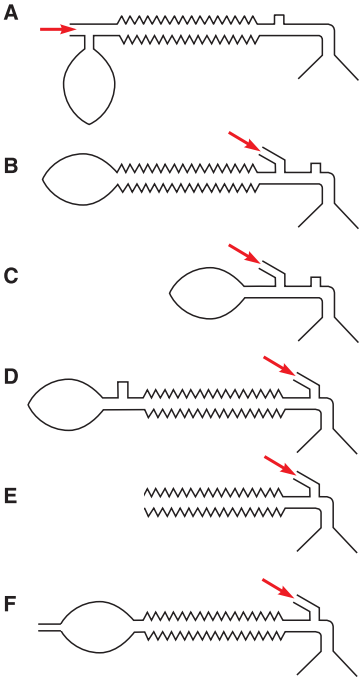

FIGURE 38–23. Mapleson classification of rebreathing systems (see text for details on A to F circuits). The Mapleson A circuit is also known as the Magill attachment.

As noted, because the pop-off valve in the Magill attachment is close to the patient, waste gas scavenging is a potential problem. This is addressed in the coaxial Mapleson A or Lack Breathing System (Fig. 38–25), which is functionally similar to the Mapleson A.[35]

Mapleson B and C Systems

In the Mapleson B and C systems (Fig. 38–23B and C) the site of fresh gas inflow and the pop-off valve are near the patient, whereas the circuit tubing and reservoir bag form a cul-de-sac in which a mixture of dead space, alveolar, and fresh gas may collect. The Mapleson C system, with a shorter length of tubing between patient and bag, is also known as the Waters to-and-fro system without absorber. These systems function similarly during both spontaneous and controlled ventilation. Rebreathing is prevented with fresh gas flows of at least twice the minute ventilation.[28,29] In contemporary anesthesia practice, the Mapleson B and C systems are rarely used.

Mapleson D System

The Mapleson D system (Fig. 38–23D) is basically a T piece with a long expiratory limb, the end of which has a reservoir bag and a pop-off valve. During spontaneous ventilation it is less efficient than the A system, but more efficient than the B or C systems.[28,29] On spontaneous exhalation, dead space, alveolar, and fresh gas enter the tubing, and as pressure increases, some of this gas mixture is vented. During the next spontaneous inspiration the patient inhales fresh gas from the anesthesia machine mixed with gas from the tubing, the composition of which depends on fresh gas flow, tidal volume, and duration of the patient's expiratory pause.

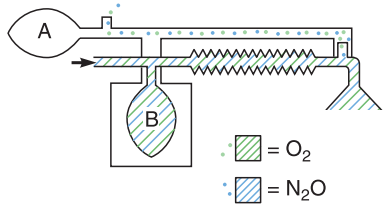

FIGURE 38–24. The enclosed Magill system. Squeezing reservoir bag (**A**) causes the pop-off valve to be held closed and results in compression of enclosed reservoir bag (**B**).

If the latter is long, the tubing is flushed with fresh gas, which is then available to be inhaled on the next inspiration. If the pause is short, less flushing occurs and rebreathing of CO_2 becomes more likely. Large tidal volumes result in more alveolar gas entering the tubing, which also predisposes to rebreathing. Mapleson[28] calculated that a fresh gas flow of at least twice the minute ventilation was required to prevent rebreathing. This has been confirmed by others.[29,31]

When used during controlled ventilation, gas is distributed similarly in the circuit. Thus manual compression of the reservoir bag ensures that alveolar and dead space gas is released via the pop-off valve during inspiration and that fresh gas enters the patient's airway. During exhalation, dead space gas and fresh gas tend to enter the reservoir bag first before the pop-off valve opens to vent the remaining (mainly alveolar) gas. As with spontaneous ventilation, a fresh gas flow of 2 to 3 times the minute ventilation prevents rebreathing.[29,31]

The Mapleson D circuit originally described is rarely used now in the United States. However, a coaxial mod-

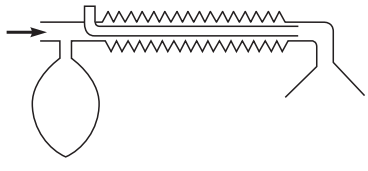

FIGURE 38–25. Coaxial Mapleson A or Lack Breathing System.

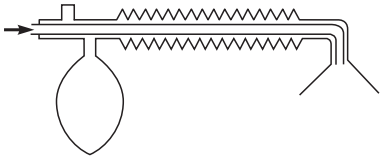

FIGURE 38–26. Bain circuit: coaxial Mapleson D.

ification, the Bain circuit, is sometimes used in pediatric anesthesia practice.

Bain Circuit: Coaxial Mapleson D

This system, introduced by Bain and Spoerel in 1972,[36] is shown in Figure 38–26. Fresh gas from the anesthesia machine enters the inner (smaller-bore) tubing and is delivered to the patient end. Exhaled gas is carried via the outer tubing to the reservoir bag and pop-off valve. Both reusable and disposable versions are available. The outer tubing is now made from transparent material so that the inner tubing can be inspected for kinking or disconnection. Clearly, if disconnection occurred at the machine end, the whole system would become apparatus dead space and result in excessive rebreathing.

The Bain system may be used for spontaneous or assisted ventilation, or the reservoir bag may be removed and an anesthesia ventilator hose attached to the bag mount for mechanical ventilation. Several studies have evaluated the fresh gas flow requirements of the Bain system. Although some have found that during spontaneous ventilation, an fresh gas flow of 100 mL/kg/min produces normocapnia at the cost of increased minute ventilation,[36] another study reported that an fresh gas flow of 2.5–3 times the minute ventilation prevents rebreathing during spontaneous ventilation.[37] The slightly higher fresh gas flow requirement of the Bain circuit compared with the basic Mapleson D system may be caused by turbulence at the patient end of the coaxial system, in turn causing failure to store fresh gas in the outer corrugated tubing. During controlled ventilation, the Bain circuit behaves more as a Mapleson D system, and a fresh gas flow of 70 mL/kg/min results in normocapnia, provided minute ventilation is adequate (120 mL/kg/min). This applies in patients weighing more than 40 kg.[36]

A ventilation nomogram has been produced for the Bain circuit during controlled ventilation (Fig. 38–27).[37] This shows that the alveolar CO_2 tension (and therefore $PaCO_2$) can be estimated from a combination of fresh gas flow and minute ventilation ($\dot{V}_E$). At high fresh gas flow, $PaCO_2$ becomes independent of fresh gas flow and dependent on minute ventilation. At high minute ventilation, $PaCO_2$ is independent of minute ventilation and becomes dependent on fresh gas flow.

The Bain circuit can thus be used to provide controlled rebreathing with hyperventilation, resulting in normal $PaCO_2$. Such predictive nomograms, while useful guides, have become of less importance as monitoring of end-tidal CO_2 by capnometry has become the standard of care. Because the pop-off valve in the Bain circuit is located close to the machine, scavenging from the Bain circuit is not a problem.

A preuse check of the Bain circuit is essential to ensure that the inner gas delivery tube has not become disconnected. If this occurred, it would lead to rebreathing. Two checkout methods have been described. In one (Pethick's method) the patient end of the whole system is occluded, the pop-off valve is closed, and the system is filled with O_2 until the reservoir bag is distended. The patient end is then unoccluded, and O_2 is flushed into the circuit via the inner tube. The high O_2 flow produces a Venturi effect at the patient end of the circuit. The low pressure created at the end of the outer tubing causes O_2 to be drawn along the outer tubing from the bag, causing the reservoir bag to deflate. If a disconnection or a leak occurs in the inner tubing, flushing the circuit with O_2 would allow the high pressure to be transmitted from the inner to the outer tubing, and the reservoir bag would remain inflated or distend further.

A second method (Seed's method) for checking the Bain circuit is to set 50 mL/min of flow on the O_2 flowmeter and then occlude the distal (patient) end of the inner tube using the plunger of a small syringe. If the inner tube is intact, this should cause the gas flow to cease and the flowmeter bobbin to fall. This (Seed's) method is preferred because if the inner tube has been omitted, Pethick's method may give no indication that anything is wrong.

Mapleson E and F Systems

The Mapleson E and F systems are valveless, T-piece arrangements (Fig. 38–23E and F). The E system is modified from Ayre's original T-piece by the addition of corrugated tubing to the expiratory limb, which thereby becomes a reservoir of fresh gas during inspiration. During inspiration the patient breathes fresh gas from the machine and gas stored in the expiratory limb. The latter should have a capacity greater than the patient's expected tidal volume, to prevent entrainment of room air during inspiration. During exhalation, exhaled gas enters the expiratory limb; during the expiratory pause, this limb is flushed with fresh gas, which is then available for the next inspiration.

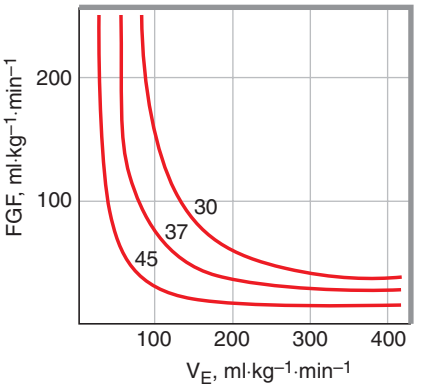

FIGURE 38–27. Nomogram for predicting $Paco_2$ from given combination of fresh gas flow and minute ventilation for Bain system. Three isopleths indicate $Paco_2$ of 30, 37, and 45 mm Hg.

The E system may be used for either spontaneous or controlled ventilation, the latter being achieved by intermittent occlusion of the expiratory limb by a "mechanical thumb" ventilator. With the E system, rebreathing is avoided if a fresh gas flow of 3 times the minute ventilation is used.[29]

The Mapleson F circuit is a modification by Jackson-Rees[38] of the Ayre's T-piece (Mapleson E) system (Fig. 38–23E and F). In this system a two-tailed reservoir bag and a means for venting waste gases are added to the end of the expiratory limb tubing. The venting piece is usually a valve with an adjustable orifice that is connected to a waste gas scavenging system.

The Mapleson F system functions similarly to the Mapleson E, except that during exhalation a mixture of exhaled and fresh gas collects in the bag. On the next inspiration the patient inhales fresh gas from the machine and that stored in the expiratory limb. Addition of the reservoir bag to the E system provides a means to qualitatively monitor ventilation during spontaneous breathing, as well as a

means to control ventilation by manually squeezing the reservoir bag. Prevention of rebreathing is achieved using fresh gas flows of 2–3 times the minute ventilation.[29]

The Ayre's T-piece and Jackson-Rees' systems have been popular for pediatric anesthesia because they are simple to assemble, inexpensive, and, being valveless, offer low resistance to breathing. However, because relatively high fresh gas flows are needed, all T-piece systems are less desirable for use in adults. They also cause greater loss of moisture from the airway if dry gases are used.[29,31]

Circle System

In this system, the components form a circle into which fresh gas can enter and from which excess gas can leave. Figure 38–28 shows the arrangement of the components of a contemporary circle system. Fresh gas enters just upstream from the inspiratory unidirectional valve and during inspiration passes down the circle's inspiratory limb to the Y-piece connector. During expiration, gas passes along the expiratory limb to the expiratory unidirectional valve. Just beyond the expiratory valve are the adjustable pressure limit (APL or pop-off) valve and a reservoir bag. Gas then passes through a canister containing a CO_2 absorbent (e.g., soda lime) and emerges to rejoin fresh gas entering the circuit from the anesthesia machine just upstream from the inspiratory valve.

In the system described, rebreathing of CO_2 is prevented by its absorption from exhaled gas before it is reinspired. At high fresh gas flows, however, CO_2 absorption becomes unnecessary, and some older circle systems even permitted bypass of the absorber canister. At lower fresh gas flows, CO_2 absorption is necessary. Eger[39] proposed 3 basic rules for minimizing CO_2 rebreathing in a circle system: (1) a unidirectional valve must be present between the reservoir bag and the patient on both inspiratory and expiratory sides; (2) fresh gas must not enter the system between the expiratory unidirectional valve and the patient; and (3) the overflow (APL) valve must not be placed between the patient and the inspiratory unidirectional valve.

Unidirectional gas flow occurs only in that part of the circle between the unidirectional valves and the patient. In the part of the circuit between the fresh gas inlet and the APL valve, gas flow is bidirectional (Fig. 38–28). Incompetence of either unidirectional valve permits bidirectional gas flow in the corrugated patient circuit tubing, leading to rebreathing of previously exhaled CO_2.

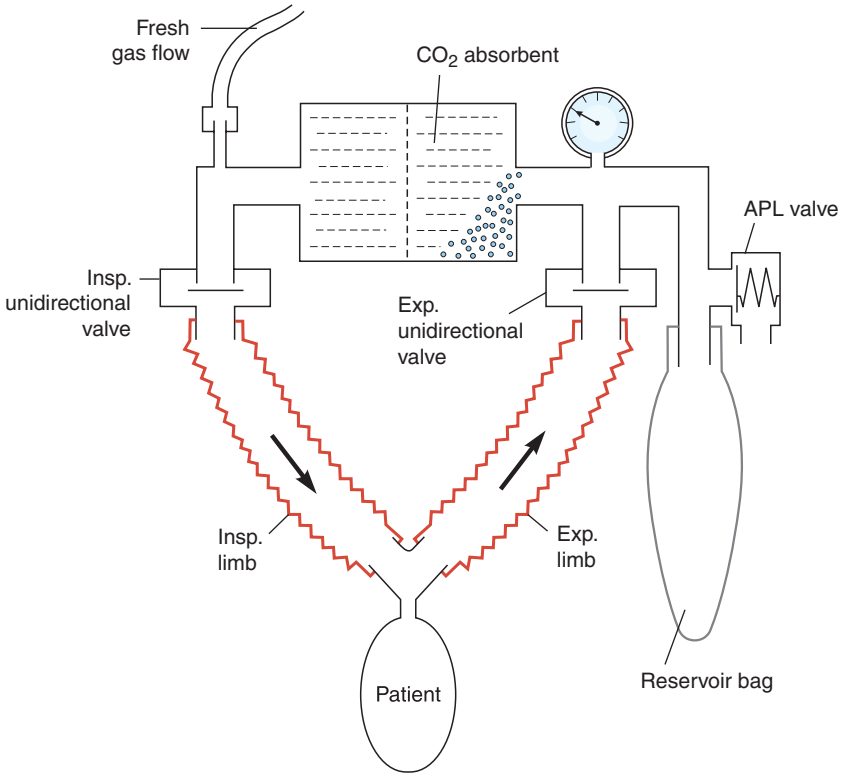

FIGURE 38–28. Contemporary anesthesia circle system arrangement.

The circle system is currently the most popular anesthesia system in use in the United States. It has the advantages of permitting low fresh gas flows, reduction of operating room pollution, and conservation of heat and humidity. Disadvantages of the circle system include a somewhat complex design with multiple components that could malfunction or possibly be arranged incorrectly. It is also difficult to predict inspired gas composition within the circle, particularly if low fresh gas flows are being used. The latter may cease to be a problem as monitoring of anesthetic gas and vapor concentrations becomes more common.

Absorption of Carbon Dioxide

The CO_2 absorber is the central component in a circle system. Traditional absorber canisters are large, with a minimal gas space equal to the largest expected patient tidal volume. This design permits low gas flow rates, long dwell times, and, as a result, more complete removal ("scrubbing") of CO_2. Traditional absorber canisters usually have 2 chambers so that half of the absorbent (that in the upstream chamber) can be completely exhausted before removal. The chambers are then reversed so that the previously downstream chamber now becomes upstream (Fig. 38–29).[40]

The CO_2 absorbent most commonly used is soda lime. The once popular absorbent Baralyme is no longer available. Soda lime consists of 4% NaOH, 1% KOH, 14–19% H_2O, and the remainder $Ca(OH)_2$.[49] In addition, small amounts of silica or kieselguhr are added for hardening, to reduce the formation of dust. The absorptive efficacy of soda lime is inversely related to its hardness. The reaction of CO_2 with soda lime is as follows[40]:

$$(1)\ CO_2 + H_2O \rightarrow H_2CO_3$$

$$(2)\ H_2CO_3 + 2NaOH \rightarrow Na_2CO_3 + 2H_2O$$

$$(3)\ H_2CO_3 + 2KOH \rightarrow K_2CO_3 + 2H_2O$$

$$(4)\ Na_2CO_3 + Ca(OH)_2 \rightarrow 2NaOH + CaCO_3$$

or

$$K_2CO_3 + Ca(OH_2) \rightarrow 2KOH + CaCO_3$$

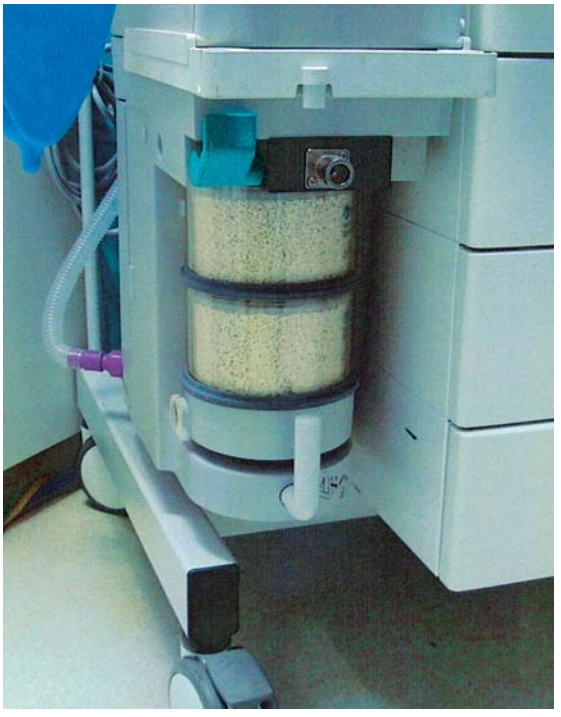

FIGURE 38–29. Traditional two-compartment absorber canister as used on a Datex-Ohmeda Aestiva machine.

Considerable heat is liberated during the course of this reaction. The preservation of heat and moisture within the system is considered to be a desirable feature.

Absorptive surface area and gas flow through soda lime are a function of granule size. The smaller the size, the larger the area for absorption but the greater the resistance to gas flow. Conversely, large granules decrease absorption surface area, offer less resistance to flow, and may encourage channeling of gases through the soda lime, thereby decreasing CO_2 absorption. The most frequently used size of soda lime granule is 4–8 mesh (i.e., 0.25-inch to 0.125-inch diameter). In theory, 100 g of CO_2 absorbent (soda lime) can absorb 26 L of CO_2. In practice, the amount of CO_2 actually absorbed is less because of the channeling of gas through the absorber.

Indicators are added to the absorbent granules to show when they are becoming exhausted. These indicators are pH sensitive and are colorless when soda lime is fresh but become colored when pH decreases. The most frequently used indicator is ethyl violet, which changes to purple as absorption proceeds. It was chosen because the color change is conspicuous even under poor lighting conditions.[40]

Ethyl violet may be deactivated by fluorescent lighting and may possibly be temporally deactivated after a container is opened, even with storage in the dark. Such deactivation increases the hazard of using CO_2 absorption, but such a hazard would be offset by continuous capnography.

When using CO_2 absorption, the absorbent must be compatible with the anesthetic gases in use. Sevoflurane is degraded by both soda lime and the now discontinued Baralyme.[41]

Prolonged exposure of desflurane, enflurane, and isoflurane to desiccated CO_2 absorbents may result in anesthetic degradation, leading to the production of CO.[42] Use of dry absorbent produces more CO than standard absorbent with normal amounts of water. For any given water content, the now discontinued Baralyme produced more CO than does soda lime. Increased temperature increases CO production, as does use of higher anesthetic concentrations. Although there were no reports of patient harm resulting from CO found in the breathing system, CO is of concern because there is the potential for injury. To minimize exposure to CO from the degradation of anesthetics in the breathing system, only an absorbent with the full complement of water should be used. Drying of the absorbent can be minimized by using low fresh gas flow rates. Liquid water may be added to the top of the absorbent; this was found to decrease degradation of the anesthetic.[42]

New Absorbents and the Problems Associated with Strong Bases

Baralyme was a very popular absorbent and used safely for many years. In late 2004, Allied Health Care, the manufacturer of Baralyme, halted its distribution. This was because desiccated Baralyme acting on sevoflurane can produce great amounts of heat that could result in temperatures in excess of 400°C, fires, and explosions.[43–45] Animal studies and a bench model have demonstrated fires and explosions with sevoflurane.[43–45] In August 2004, several reports documented fires and explosions in clinical practice with sevoflurane, but none with desflurane or isoflurane.[46–49] In a bench study of the action of desiccated Baralyme on potent inhaled anesthetics at 1.5 MAC, sevoflurane degradation by Baralyme produced temperatures >300°C, and fires, whereas degradation of desflurane or isoflurane produced temperatures of approximately 100°C and no fires.[50]

Monovalent bases (potassium hydroxide and sodium hydroxide) in absorbents cause the exothermic degradation of potent inhaled anesthetics to compound A and carbon monoxide. In new absorbents, such as Amsorb, Drägersorb, and Drägersorb Free,[51,52] the elimination of such bases (but not calcium hydroxide) minimizes compound A or CO production with both moist and desiccated absorbents (Table 38–6).[51–55] Although the new absorbents appear to be safer, compared to soda lime they are more expensive and absorb less CO_2. It is likely that the withdrawal of Baralyme (with its high content of KOH) from clinical use will minimize or eliminate the problem of fires and explosions. Amsorb has the additional advantage that it turns from white to purple when it becomes desiccated or when its capacity to absorb CO_2 is exhausted. Drägersorb Free, which contains no monovalent bases, may not only cause less anesthetic degradation, but also may have a greater absorptive capacity for CO_2.[53–55]

TABLE 38–6.

More than one manufacturer reported variable absorption capacity based on canister design, shape, volume FGF, hydration, and carbon dioxide concentration. Nearly all reported price variability dependent upon marketing and type of fill.
Reproduced with permission from Anesthesia Patient Safety Foundation (APSF) Newsletter, Volume 20, No. 2, Summer 2005.

In April 2005, the Anesthesia Patient Safety Foundation (APSF) convened a conference to discuss the safety of CO_2 absorbents. The stated goal of the conference, was "to develop a consensus statement to share with anesthesia professionals on the use of carbon dioxide absorbents so as to reduce the risk of adverse interactions with volatile anesthetic drugs." The conclusions of the attendees were as follows.

> The APSF recommends use of carbon dioxide absorbents whose composition is such that exposure to volatile anesthetics does not result in significant degradation of the volatile anesthetic.
>
> The APSF further recommends that there should be institutional, hospital, and/or departmental policies regarding steps to prevent desiccation of the carbon dioxide absorbent should they choose conventional carbon dioxide absorbents that may degrade volatile anesthetics when absorbent desiccation occurs.

In such circumstances of using absorbents that may degrade volatile anesthetics, conference attendees generally agreed that users could take the following steps, consistent with Emergency Care Research Institute (ECRI) recommendations:

1. Turn off all gas flow when the machine is not in use.
2. Change the absorbent regularly, on Monday morning for instance.
3. Change absorbent whenever the color change indicates exhaustion.
4. Change all absorbent, not just 1 canister in a 2-canister system.
5. Change absorbent when uncertain of the state of hydration, such as if the fresh gas flow has been left on for an extensive or indeterminate time period.
6. If compact canisters are used, consider changing them more frequently.

There was also support for the APSF to create an "Expert Task Force" to define further the characteristics of carbon dioxide absorbents that do not significantly degrade volatile anesthetics.

Mini-Absorbers

While traditional circle systems used large absorber canisters, some recent workstations such as the Datex-Ohmeda ADU, Aisys, and Dräger Apollo workstations use smaller volume (600 mL) compact or "mini-absorbers" that contain soda lime or one of the new absorbents shown in Table 38–6. These compact absorber canisters can be replaced without causing a leak in the breathing system because the absorber mount block is self-sealing (Fig. 38–30).

ANESTHESIA VENTILATORS

Anesthesia ventilators have evolved considerably over the last several years. The traditional anesthesia ventilator is a pneumatically powered, electronically controlled device. The visible bellows acts as a "counterlung" that

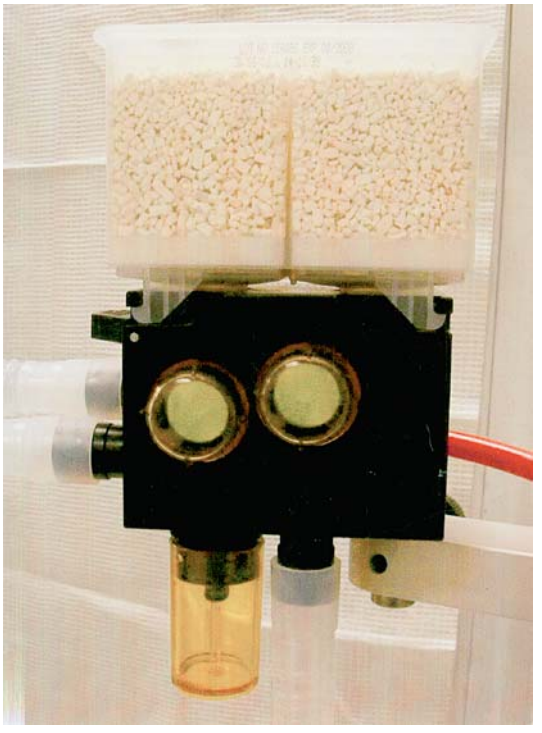

FIGURE 38–30. Datex-Ohmeda ADU Carestation Compact Block and mini-absorber. In this design of circle breathing system the fresh gas flow from the CGO enters the circuit *downstream* (i.e., on the patient side) of the inspiratory unidirectional valve (rather than upstream as shown in Fig. 38–28). With this design, changes in fresh gas composition are reflected more rapidly at the patient's airway. Also the dry fresh gas cannot flow back into the absorbent, which helps to prevent desiccation.

exchanges with the gas in the patient's lungs via the breathing circuit. Examples of traditional ventilators include the Dräger AV-E and the Datex-Ohmeda 7900 and ADU models. These are sometimes described as "bag-in-a-bottle" respirators. The basic principle is that the reservoir bag of the anesthesia circle system is replaced by a bellows in a bellows housing, and the APL ("pop-off") valve is replaced by a ventilator pressure-relief valve (Fig. 38–31). Inspiration occurs when compressed (driving) gas enters the bellows housing. The bellows is compressed, and the pressure-relief valve is held closed (Fig. 38–32). Gas contained within the bellows, as well as fresh gas entering the patient circuit from the anesthesia machine, are forced into the patient's lungs. At end-inspiration the bellows housing is no longer pressurized, the bellows refills (by gravity in the case of a hanging bellows, as in Figs. 38–31 and 38–32), and the pressure-relief valve is able to open, permitting excess gas in the patient circuit to be vented to the waste gas scavenging system.

The traditional "bag-in-a-bottle" anesthesia ventilators are also described as double-circuit ventilators, one circuit being the driving gas circuit and the other the patient breathing system. The interface between these two circuits is the ventilator bellows itself.

In some recent models of Dräger anesthesia workstation (Narkomed 6400, Apollo) the ventilator bellows, bellows housing and driving gas circuit are replaced by a piston in a cylinder. The movements of the piston are precisely controlled by a microprocessor and electric motor. This design is described in a later section (New Designs of Anesthesia Ventilator and Patient Breathing Systems).

Traditional Anesthesia Ventilators

Although the Dräger AV-E and the Datex-Ohmeda 7000 series, 7900 series, and ADU model ventilators are of the double-circuit design, their mechanisms of action differ in certain details.

Datex-Ohmeda 7000

The Datex-Ohmeda 7000 ventilator is shown in Fig. 38–33. It consists of two basic units: a bellows housing and assembly, and a control unit. The former may be separate from, or be mounted on, the control unit, as in Fig. 38–33. The driving gas circuit is considered first (Fig. 38–34).[56]

The driving gas supply of this ventilator, O_2 at a nominal pressure of 50 psig, passes to a pressure regulator whose output is set to 38 psig at 24 L/min of flow. From here the pressure-regulated O_2 flow passes to a block containing 5 solenoid flow-control valves connected in parallel. These flow-control valves are electronically opened during the inspiratory phase to

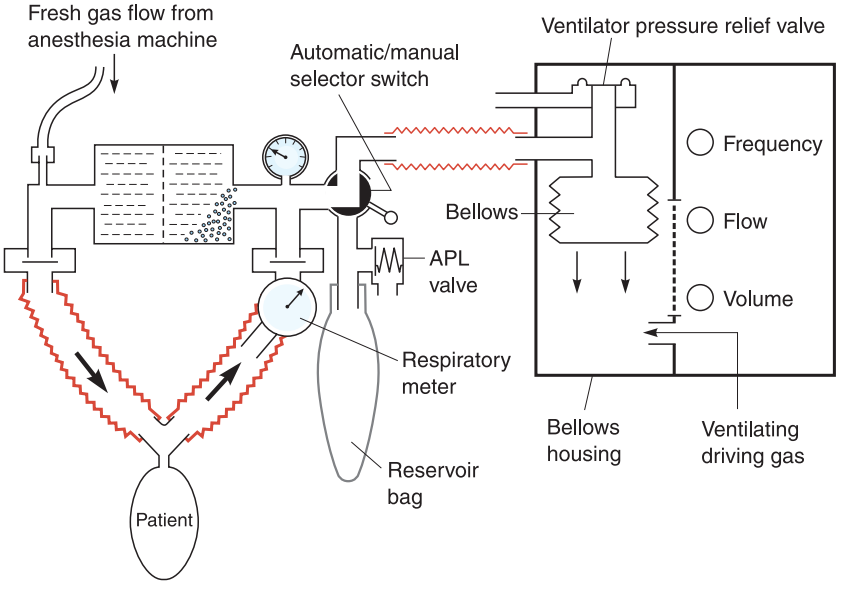

FIGURE 38–31. Schematic of typical "bag-in-a-bottle" double-circuit design of anesthesia ventilator. Reservoir bag and APL valve are switched out of circuit and replaced by ventilator bellows (bag) in bellows housing (bottle).

FIGURE 38–32. direct O_2 flow through tuned orifices, which are calibrated for flows of 2, 4, 8, 16, and 32 L/min. The possible range for flow selection is 4–60 L/min in 2 L/min increments. By controlling the duration of opening of each of the 5 solenoid valves, the control module determines the O_2 volume that passes into the collection chamber. This metered O_2 volume then enters the bellows housing, where it exerts pressure on the bellows and displaces an equal volume of anesthesia gas mixture from the bellows into the patient circuit. This displaced volume is the ventilator tidal volume.

The Datex-Ohmeda 7000 ventilator uses a standing bellows. According to the settings on the ventilator panel, V_T equals set MV divided by set RR, or V_T = MV/RR; the bellows empties until the predetermined tidal volume has been delivered. The bellows therefore does not empty completely unless a tidal volume of 1600 mL or greater is selected (Fig. 38–34). During inspiration the exhaust valve in the collection chamber (Fig. 38–34) is closed so that the driving gas does not escape. A ventilator pressure-relief valve (pop-off valve) located in the base of the bellows is held closed by the driving gas pressure during inspiration so that gas passes from within the bellows to the patient circuit (Fig. 38–35).

Exhalation begins when the driving gas exhaust valve located in the control module opens, permitting driving gas to be vented from the bellows housing. This occurs because this gas is displaced by the bellows refilling with anesthesia gases from the patient's lungs during passive exhalation, and the fresh gas flow from the anesthesia machine. During exhalation, for the bellows to refill with anesthesia gases, a slight positive pressure must be maintained in the circuit. If the circuit were kept at atmospheric pressure during exhalation, circuit gas would preferentially flow out to the scavenging system, and the bellows would not reexpand. The ventilator pressure-relief valve therefore also incorporates a positive end-expiratory pressure (PEEP) valve that exerts a pressure of about 2.5 cm H_2O on the gas contained within the patient circuit. At end-expiration, when the bellows has reached its limit of expansion and the circuit pressure has risen to greater than 2.5 cm H_2O, the ventilator pressure-relief valve opens, and

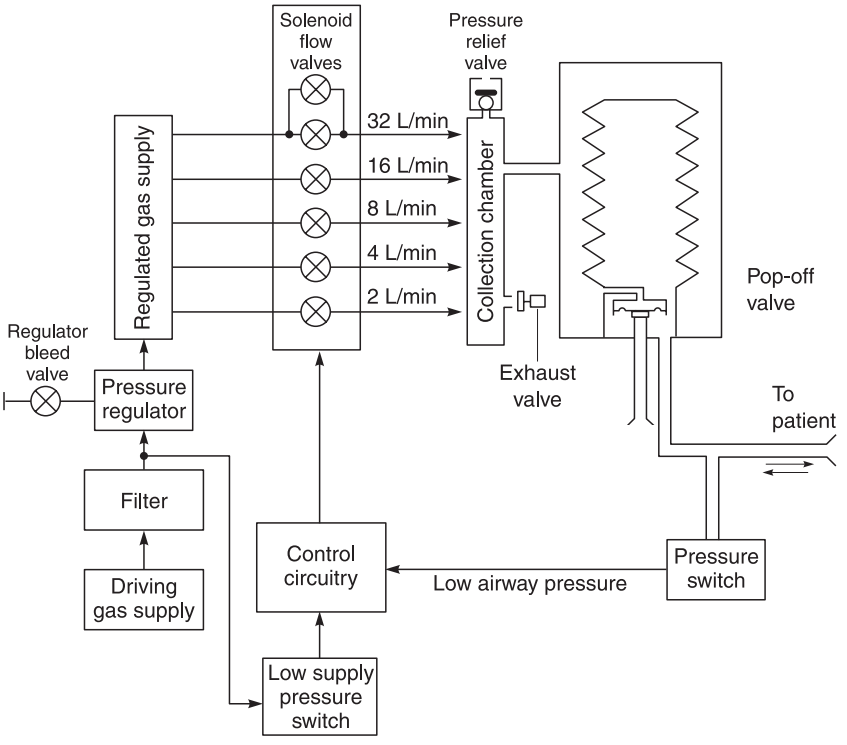

FIGURE 38–34. Ohmeda 7000 electronic anesthesia ventilator. Schematic of driving gas circuit. (Courtesy of Ohmeda, BOC Health Care, Madison, WI.)

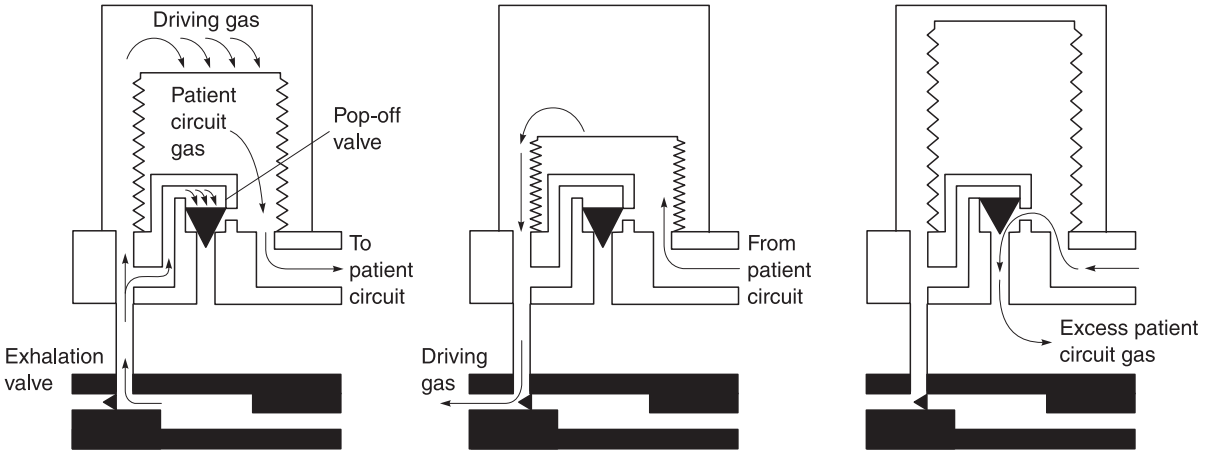
excess gas from the patient circuit is vented to the waste gas scavenging system.

The pressure-relief valve in the driving gas collection chamber (Fig. 38–34) represents a safety feature such that if the pressure in the driving gas circuit becomes too high (greater than 65 cm H_2O), the valve opens to relieve the excess pressure. This prevents such excessive pressure from being applied to the patient's airway.[56] The Ohmeda 7000 ventilator is electronically controlled and time cycled. Operator controls (Fig. 38–33) are for minute volume, respiratory rate (thus VT = MV/RR), and I:E ratio.

Datex-Ohmeda 7810

The Datex-Ohmeda 7810 ventilator (Fig. 38–36) is very similar to the model 7000 but differs in certain features.[57] Driving gas is O_2 at 50 psig nominal pressure (Fig. 38–37). The O_2 passes to a primary regulator whose output is controlled to 26 psig. From here the O_2 passes to a pneumatic manifold, where its flow into the bellows housing is controlled by a flow-control valve. This sophisticated mass flow valve varies the opening of a flow orifice according to the current supplied to the valve's coil, thereby controlling O_2 flow. A combination of the current supplied to the coil and the time for which it is applied (valve opening size and time) is determined by the microprocessor and based on the operator control settings.

The pneumatic manifold in the model 7810 replaces the 5 solenoid valves and tuned orifices of the model 7000 (Fig. 38–34). The operator controls also differ in that the model 7810 the limits of tidal volume, rate, inspiratory flow, and inspiratory pressure (maximum, 100 cm H_2O) may be set directly (Fig. 38–36). The I:E ratio, how-



Start of inspiration. Control module closes the exhalation valve and delivers driving gas to the area around the bellows.

Beginning of expiration. Exhalation valve opens and gas flow in the breathing circuit and driving-gas circuit reverses. Driving gas is released into the atmosphere as the bellows extends.

If during the expiratory cycle (when the bellows has extended completely) the pressure inside the bellows exceeds about 2.5 cm H_2O, the pop-off valve opens, releasing any excess breathing system gas through the bellows assembly's exhaust port.

ever, is not set directly but is calculated by the unit and displayed. The control unit contains an O_2 analyzer and displays the O_2 concentration sensed in the patient circuit. It also incorporates pressure and volume alarms. In other respects, the 7810 ventilator functions are similar to the model 7000.

Datex-Ohmeda 7900

The Datex-Ohmeda 7900 ventilator is similar to the 7810 in that it consists of a control unit (Fig. 38–38) and a separate bellows housing assembly. It uses compressed oxygen and a precision control valve to control the flow and pressure of gas delivered to the patient circuit. Inspiration may be volume or pressure preset and during exhalation, the ventilator controls the PEEP by regulating the exhalation pressure at the ventilator pressure-relief valve. Using signals from pressure, flow, and oxygen sensors, microprocessor circuits in the ventilator monitor the patient breathing circuit and display the measured variables. By comparing the operator set values for ventilatory parameters with those measured by the sensors, the ventilator automatically compensates for gas losses because of compression of gases in the ventilator, ventilator circuit, and absorber system, but not for losses in the patient circuit. The system also compensates for gas gains as a result of anesthesia machine fresh gas flow (see Tidal Volume below). Thus the user-set tidal volume is delivered to the patient circuit even when fresh gas flow, respiratory rate, or I:E ratios are altered. Some of the most recent model Datex-Ohmeda workstations (Aestiva, Aespire, Aisys) use the 7900 series ventilator.

Dräger AV-E

The Dräger AV-E ventilator (used on the Narkomed 2, 3, 4, GS, and Mobile machines) is also a double-circuit, pneumatically powered design.[38,39] It consists of a control unit mounted above the flowmeters and vaporizers on a Dräger Narkomed machine and a bellows assembly (Fig. 38–39). A schematic illustration of this ventilator is shown in Fig. 38–40. The following numbers in parentheses refer to Figs. 38–40 and 38–41. The driving gas circuit is described first.[58]

The ventilator is powered by O_2 at a driving pressure of 50 psig (2). When the ventilator on/off switch (3) is turned on, O_2 pressure is supplied to a 1 psig switch (4), which is activated and energizes the electronic circuit. The respiratory rate (7) and I:E ratio (6) controls (Fig. 38–39 inset) are set as desired. Inspiration (Fig. 38–40) occurs when the solenoid valve (9) receives an electrical signal from the control unit (5). This signal remains throughout inspiration and activates the solenoid valve (9) to allow O_2 at 50 psig to pass through it to activate the control valve (10). Opening the control valve allows O_2 that has passed through the adjustable flow regulator (11) to pass through the control valve (10) to the venturi (13). The inspiratory flow rate is adjusted by the flow regulator (11) (flow-control knob, Fig. 38–39), and the flow rate is monitored on a flow indicator gauge (12). This indicator is really a pressure gauge, measuring pressure downstream from the flow regulator. The display on the gauge shows flow in three zones: high, medium, and low (Fig. 38–39). During inspiration, back pressure from the venturi (13) is conducted to a pilot actuator (15), which is held closed. As the O_2 flows from the venturi (13), room air is entrained through the muffler and entrainment port (14).

The mixture of O_2 and entrained air is directed into the bellows chamber (16). As pressure rises in the bellows chamber, the bellows is compressed. Anesthetic gases within the bellows are forced into the patient circuit via the breathing connector (22). At the same time, driving gas pressure from the bellows housing (16) is transmitted via the relief valve pilot line (20) to hold the ventilator pressure-relief valve (21) closed as long as the bellows housing is under pressure (i.e., throughout inspiration). In this ventilator the bellows is emptied completely with each inspiratory cycle. Thus tidal volume is determined by the extent to which the bellows is allowed to expand during exhalation, which in turn is adjusted by the tidal volume control knob (19) and bellows plate (18). During the inspiratory pause the O_2 continues to flow from the venturi (13). Because the bellows is now fully compressed, no further air is entrained, and pressure is maintained in the bellows housing by the pressure of the O_2 jet from the venturi. Meanwhile, the chamber (16) contains a mixture of air and O_2 with an average O_2 concentration of 33%.

Expiration (Fig. 38–41) begins when the electrical signal from the control unit (5) to the solenoid valve (9) stops. The solenoid valve is deactivated and closes, interrupting the supply of 50 psig O_2 to the control valve (10), which therefore also closes. The preset O_2 flow from the flow regulator (11) is interrupted by the control valve (10), causing a pressure drop at the venturi

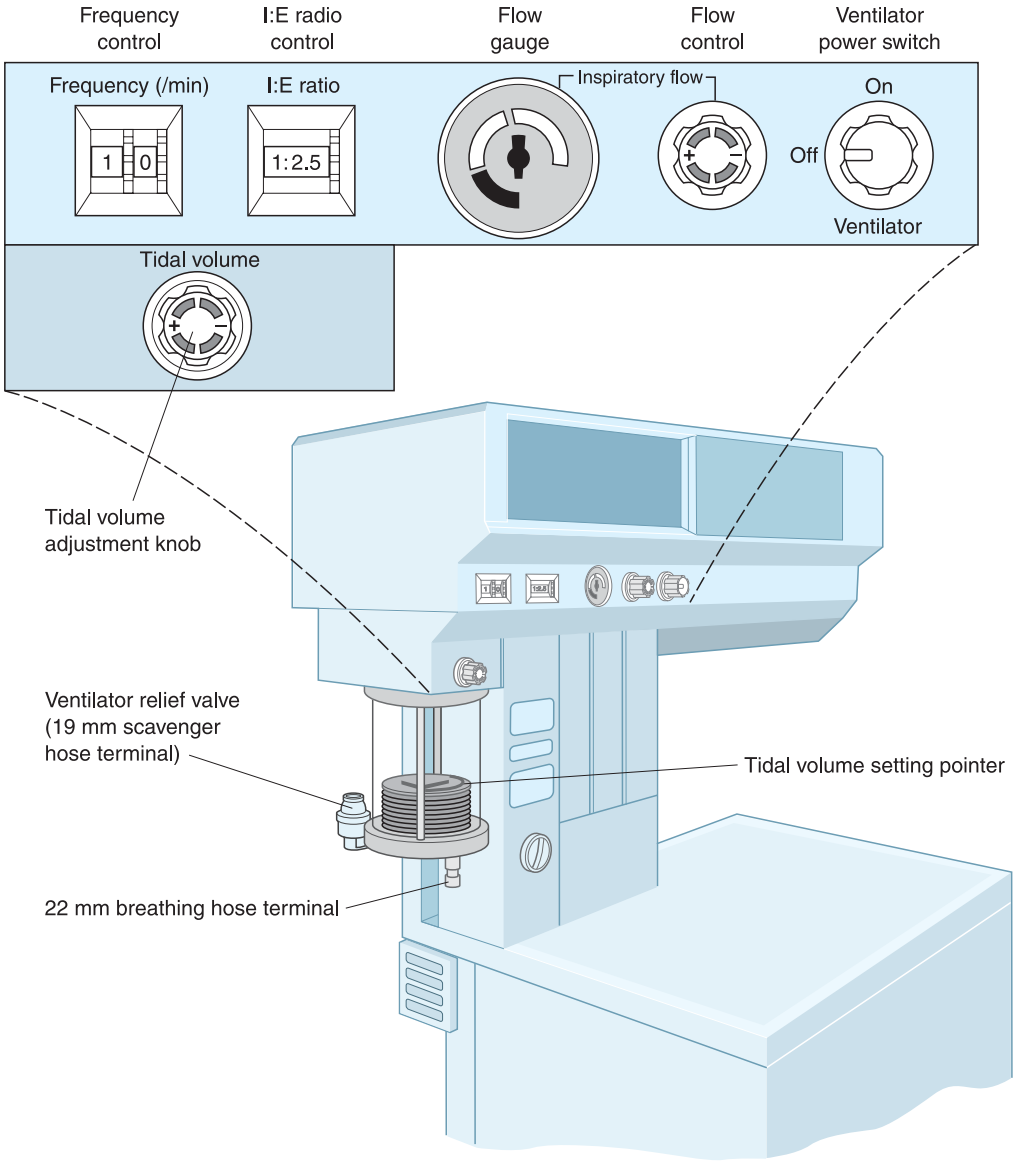

FIGURE 38–39. Dräger AV-E anesthesia ventilator. Note the standing bellows arrangement in this diagram. Figures 38–31 and 38–40 show a hanging bellows version. (Courtesy of North American Dräger, Telford, PA.)

(13), and no back pressure is supplied to the pilot actuator (15). The latter opens to allow gas from the bellows chamber (16) to be vented through the pilot actuator (15) and the entrainment port (14) of the venturi (13). This exhausted driving gas leaves the ventilator through a muffler. A clean, dry muffler is essential for normal function of this ventilator. As the pressure falls in the bellows chamber (16), the bellows (17) begins to refill. As long as any pressure remains in the bellows chamber (16), the ventilator relief valve (2) is also pressurized and held closed.

Figures 38–42 and 38–43 are schematic illustrations of the standing bellows version of the Dräger AV-E during inspiration and expiration, respectively. As with the standing bellows arrangement in the Datex-Ohmeda ventilators, the Dräger AV-E ventilator relief valve applies about 2.5 cm H_2O PEEP to the gas in the patient circuit. Once the standing bellows has reached its preset limit of expansion (the next tidal volume) and circuit pressure exceeds 2.5 cm H_2O, the PEEP valve opens, permitting excess circuit gas to enter the waste gas scavenging system (Fig. 38–43).

In the Dräger AV-E, the ventilator pressure-relief valve is controlled via an external relief valve pilot line (Figs. 38–40 and 38–41, item 20), which is essentially a short length of plastic tubing. Kinking this tubing can cause ventilator malfunction. Occlusion during inspiration, when the valve is being held closed, causes it to remain closed thereafter and excess gas cannot leave the anesthesia circuit. Consequently, pressure in the circuit rises and, if not relieved, could result in barotrauma.[59] A circuit continuing pressure or high-pressure alarm should alert the clinician to such a situation. If the tubing is occluded during exhalation when the valve is not held closed, during the next inspiratory cycle, pressure cannot be transmitted through to the valve to hold it closed. Patient circuit gas can then leak out to the scavenging system

rather than entering the patient circuit, which might result in hypoventilation. Incompetence of the pressure-relief valve itself may also result in hypoventilation.[60] Again, contemporary circuit pressure, volume, or ventilation (CO_2) alarms should alert one to these situations. More recent versions of Dräger ventilator (AV 2+) incorporate a high-pressure limit control, capable of inverse I:E ratios with a built-in safety mechanism that allows application to a wider range of patient conditions.

Differences Among Traditional Double-Circuit Ventilator Designs

Standing versus Hanging Bellows Ventilators

Contemporary traditional anesthesia ventilators are of the standing bellows design; that is, they rise (ascend as the bellows fills) during exhalation and descend (empty) during inspiration. With a disconnection in which circuit pressure becomes equal to atmospheric pressure, the bellows cannot refill during exhalation. Some consider this to be a desirable safety feature.

In the (older) hanging bellows design (Figs. 38–31 and 38–32), the bellows fills by gravity during exhalation so that the ventilator pressure-relief valve does not require a PEEP design. With a circuit disconnection, room air is entrained into the patient circuit via the leak and the bellows refills, emptying through the leak on the next inspiration. For this reason the standing bellows design is preferred, although it is not required by the standard describing specifications for anesthesia ventilators.[61] The standard states that if the ventilator incorporates a weighted descending bellows, the manufacturer shall specify the maximum negative pressure created both when the fresh gas flow to the circuit is shut off and when the patient connecting port of the delivery system is obstructed just after a tidal volume is described and the ventilator shut off.

Dräger AV-E versus Datex-Ohmeda: Driving Gas

The gas entering the bellows housing in a Datex-Ohmeda ventilator is 100% O_2 (Figs. 38–33 and 38–37), whereas in the Dräger AV-E, the gas is an air/O_2 mixture (Fig. 38–40). With a leak (hole) in the bellows, driving gas enters the patient circuit and dilutes the

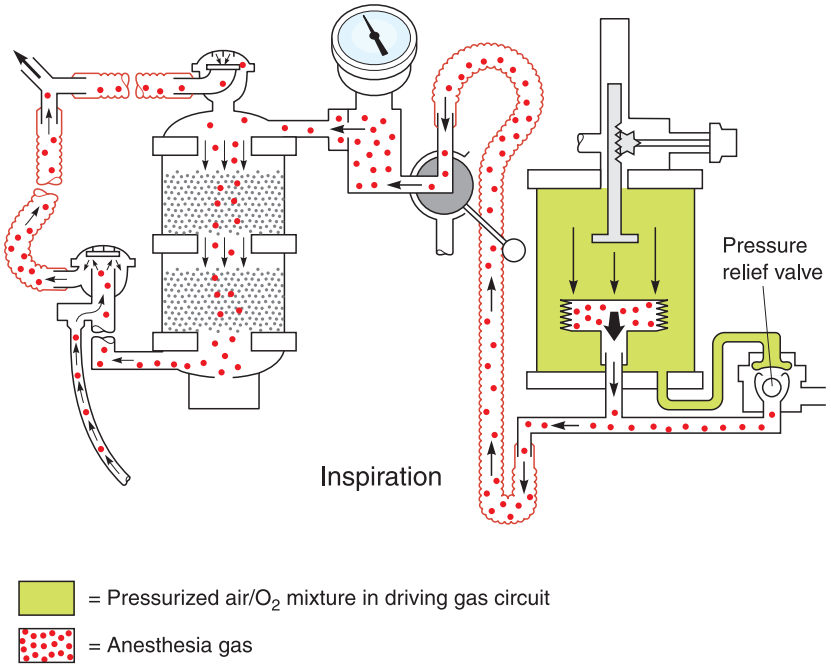

FIGURE 38–42. Dräger AV-E standing bellows design showing events during inspiration. (Courtesy of Dräger, Telford, PA.)

gases there. This can cause O_2 enrichment with a Datex-Ohmeda ventilator but a decrease in the F_IO_2 with a Dräger AV-E if an F_IO_2 < 0.4 were set at the machine flowmeters.

In the Dräger ventilator, the tidal volume is determined by setting the expansion limit of the bellows during expiration, because the bellows is emptied completely during inspiration. The bellows (Figs. 38–42 and 38–43) is graduated from 0 mL below to 2000 mL at the top of the housing. In the Datex-Ohmeda design, the bellows is graduated from 0 mL at the top to 1600 mL at the bottom of the bellows housing, as the tidal volume is displaced from the bellows by a metered volume of compressed O_2 during inspiration (Fig. 38–33).

The Dräger AV-E ventilator uses a venturi and an air/O_2 mixture to compress the bellows. This economizes on the use of compressed O_2. In the Datex-Ohmeda ventilator, O_2 consumption as the driving gas is a little greater than the set minute ventilation.[62]

In the Datex-Ohmeda 7000 and 7800 series ventilators, the circuit pressure-relief ("pop-off") valve is flush-mounted inside the bellows (Fig. 38–35). The design does not use a relief valve pilot line and is therefore not vulnerable to the effects of this line kinking (Fig. 38–40, item 20).[59] In the Datex-Ohmeda ADU workstation, the ventilator pressure-relief valve is visible but there is a direct rather than a pilot tube connection to the driving gas circuit.

Datex-Ohmeda ventilators incorporate a pressure-relief valve in the driving gas circuit (Figs. 38–32 and 38–34). This may be preset to 65 cm H_2O (as in the Datex-Ohmeda 7000 model) or may be adjustable (Fig. 38–36, Ohmeda 7810 model, "Inspiratory Pressure Limit") as on the 7900 series. Most of the original Dräger AV-E ventilators do not have a pressure-relief valve in the driving gas circuit. Such a valve (Dräger Pressure Limit Control), with variable relief pressure settings, is available and may be retrofitted to standing bellows versions of these ventilators, thereby providing a pressure limit.[63] It is now standard with the more recent model, the Dräger AV 2+.

Because the Dräger AV-E ventilator venturi requires entrainment of air (Figs. 38–40 and 38–41), a clean (unoccluded) muffler is essential. If the muffler becomes blocked for any reason, room air is no longer entrained and inspiration cannot be completed. If blockage occurs during exhalation, gas cannot leave the ventilator bellows housing, and the bellows remain collapsed.[64]

Tidal Volume

During inspiration the anesthesia ventilator pressure-relief valve is held closed so that gas contained in the bellows enters the patient circuit rather than the scavenging system (Fig. 38–42). Meanwhile, because the anesthesia machine is a continuous flow machine, fresh gas continues to enter

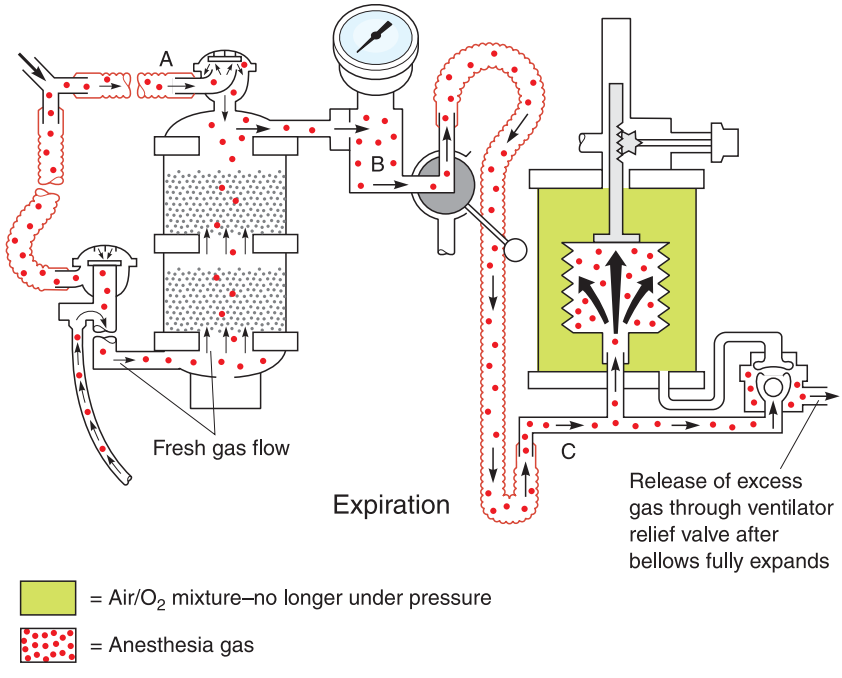

FIGURE 38–43. Dräger AV-E standing bellows design showing events during expiration. A, B, and C represent possible positions for positive end-expiratory pressure (PEEP) valve placement (see text for details). (Courtesy of Dräger, Telford, PA.)

the patient circuit from the anesthesia machine throughout the ventilatory cycle, according to the (O_2, N_2O, air) gas flow-control settings.

In the traditional design of anesthesia ventilator, when setting a certain VT to be delivered from the bellows in order to achieve a certain VT delivered to the patient's lungs, one must consider the fresh gas flow rate from the anesthesia machine to the patient circuit.[65,66]

Consider an anesthesia ventilator set to a frequency of 10 breaths/min, an I:E ratio of 1:2, and a fresh gas flow of 6 L/min (or 100 mL/sec) to the anesthesia circle. Each breath lasts 6 seconds (60 sec/10 breaths), with inspiration lasting 2 seconds and expiration 4 seconds (I:E = 1:2). During inspiration, the ventilator pressure-relief valve is closed so that both gas from the emptying bellows and fresh gas flow from the machine enter the patient circuit (Fig. 38–42). Because fresh gas flow is 100 mL/sec and each inspiration lasts 2 seconds, the VT set on the ventilator bellows is potentially augmented by 200 mL. Consequently, changing the fresh gas flow, respiratory rate, or I:E ratio may have a profound effect on circuit VT, alveolar ventilation, and $Paco_2$.[65,66] Figure 38–44 illustrates the effect on $Paco_2$.

The additional minute ventilation to the patient circuit when using an anesthesia ventilator is approximated by the formula:

$$\text{Additional ventilation} = (I/[I + E]) \times \text{fresh gas flow}$$

This is divided by the respiratory rate to determine the augmentation of each ventilator bellows VT.

In terms of VT actually delivered to the patient's airway, this formula provides an approximation only. The actual augmentation of VT also depends on the patient's total thoracic compliance compared with that of the anesthesia circuit components. If the patient's total thoracic compliance is low, additional fresh gas inflow from the machine may be accommodated mainly by compression in the circuit. Thus patient MV is given by:

$$\text{Set MV} + (\text{fresh gas flow} \times [I/I + E]) - (\text{gas volume compressed in circuit at peak inspiratory pressure} \times f)$$

where f is the respiratory rate in breaths per minute. The compressed gas volume term can be calculated as the product of circuit compliance and peak inspiratory pressure. Thus volume compressed in the circuit equals compliance of circuit (mL/cm H_2O) times peak inspiratory pressure. These considerations do not apply to intensive care unit ventilators, which are designed to be minute volume dividers and whose VT is not affected by fresh gas flow, I:E ratio, or rate. The Datex-Ohmeda 7900 ventilator uses the SmartVent compensation system to compensate automatically for changes in fresh gas flow, I:E ratio, and RR as far as they affect the tidal volume delivered to the patient circuit. However, because the inspiratory flow transducer (which senses the inspired volume) is located at the inspiratory connection to the circuit, compression losses experienced in the patient circuit itself are not compensated. The uncompensated loss is the product of the peak inspiratory pressure and the compliance of the patient circuit.

Positive End-Expiratory Pressure

The deliberate application of PEEP to the patient's airway is not uncommon during anesthesia. PEEP may be applied by adding a free-standing PEEP valve between the circle system's expiratory limb and the expiratory valve (e.g., Boehringer PEEP valve, Boehringer Laboratories, Wynnewood, PA). Although free-standing PEEP valves function well when used correctly, they are occasionally used erroneously and may totally occlude the circuit if incorrectly placed in the circle's inspiratory limb.[67] Because of this potential hazard, the use of free-standing PEEP valves is not recommended.

The machine manufacturers, Dräger and Datex-Ohmeda, now provide PEEP valves that are an integral component of their contemporary anesthesia delivery systems. These purpose-designed valves are convenient to use and should also avoid the risk of erroneous valve placement. However, one must consider the possible effects of placement positions of a PEEP valve in the anesthesia circuit.

At end-exhalation the pressure in an anesthesia circuit during positive-pressure ventilation using a standing bellows ventilator is +2.5 cm H_2O because of the PEEP effect of the ventilator pressure-relief valve (Fig. 38–43). If a 10-cm H_2O PEEP valve is now added by the expiratory unidirectional valve

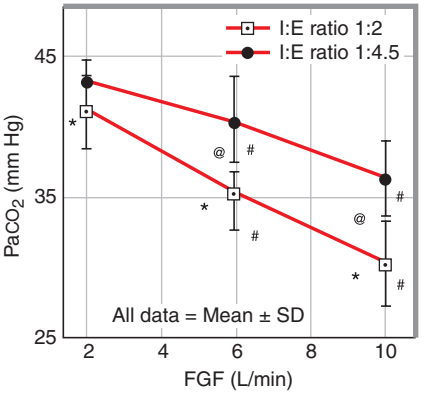

FIGURE 38–44. Effect of fresh gas flow and inspiratory-to-expiratory (I:E) ratio on arterial CO_2 tension ($Paco_2$) in patients ventilated with anesthesia ventilator set to constant tidal volume (VT). Increasing fresh gas flow or I:E ratio causes an increase in delivered VT, an increase in alveolar ventilation, and a decrease in $Paco_2$.

(Fig. 38–43, position A), that part of the circuit between the inspiratory and PEEP valves is at +10 cm H_2O compared with pressure beyond the valve. That part of the circuit between the PEEP valve and the ventilator is at +2.5 cm H_2O. On the next inspiration, gas from the compressed bellows enters the circuit and must compress that gas in the patient circuit that is at +2.5 cm H_2O by an additional +10 cm H_2O before any entering gas will flow past the inspiratory unidirectional valve to enter the circle's inspiratory limb. The volume of gas that leaves the ventilator bellows and is compressed in the part of the circuit that was at +2.5 cm H_2O represents wasted bellows VT because it is not available to ventilate the patient's lungs. If the PEEP valve is placed close to the ventilator bellows (Fig. 38–43, position C), at end-exhalation most of the gas in the patient circuit is now at +10 cm PEEP. In this case, a much smaller volume of gas leaving the bellows during inspiration must be compressed in the circuit before the patient begins to receive a VT. Thus once a VT has been set to be delivered from an anesthesia ventilator bellows, addition of PEEP to the basic patient circuit may decrease delivered VT, depending on the position of the PEEP valve in the circuit. In Fig. 38–43, bellows VT loss would be greatest with position A and least with position C; position B is intermediate.[68] Decreases in VT may be reflected in spirometer readings or in other monitors of patient ventilation (e.g., $Paco_2$; end-tidal CO_2).

Advantages of placing the PEEP valve near to the expiratory unidirectional valve (see Fig. 38–43, position A or B), however, are that in these positions PEEP may be applied during spontaneous as well as during mechanical ventilation. The decrease in patient V_T on application of PEEP at position A in Fig. 38–43 (such as would be obtained with insertion of a free-standing PEEP valve) is greatest at low bellows V_T settings.[68] It is also more significant with the Datex-Ohmeda design of ventilator (models 7000, 7810) than with the Dräger AV-E. This is because the Dräger AV-E bellows empties completely during each inspiration, whereas the Datex-Ohmeda bellows empties only the set V_T into the circuit. Because a Datex-Ohmeda bellows has a capacity of 1600 mL (Fig. 38–33), the compression volume in the circuit at end-inspiration is greater than in the Dräger AV-E ventilator system by a volume of [1600 mL V_T].

Because with the Datex-Ohmeda 7900 ventilator and the ADU, the PEEP is applied at the level of the ventilator pressure relief valve, the whole circuit is at positive-end expiratory pressure and the tidal volume loss caused by application of PEEP at positions A, B, and C (shown in Fig. 38–43) does not apply. Furthermore, any deviation from the tidal volume set would be sensed by the inspiratory flow transducer and a correction would be made via the SmartVent Compensation System.

New Designs of Anesthesia Ventilator and Patient Breathing Systems

As discussed above, there were several problems inherent in the design of the traditional anesthesia ventilator. There was often a discrepancy between what was set as V_T and what was delivered. Thus with a Datex-Ohmeda 7000 ventilator and GMS absorber system, one might set a V_T of 500 mL, observe a different value on the bellows housing graduations (which are inaccurate), and yet another value from the spirometer on the expiratory side of the circuit. The ventilators were not very accurate in small pediatric patients, where changes in fresh gas flow, I:E ratio, and RR could have profound effects that might lead to barotrauma.

Two basic approaches have been taken to compensate for unintentional changes in V_T; computerized compensation and fresh gas decoupling. These require a more detailed discussion of some of the newer workstations.

Computerized Compensation: Datex-Ohmeda Anesthesia Delivery Unit (ADU) and 7900 SmartVent

The Datex-Ohmeda ADU uses conventional needle valves to control gas flows (O_2, N_2O, air) but the flows are measured electronically and the information fed to the CPU. Information from the Aladin vaporizing system is also fed to the CPU. The total fresh gas flow and vapor leaving the CGO is therefore constantly measured. It may pass through an optional conventional rotameter that reassures the user that O_2 is flowing in the event electrical power is lost.

The ADU uses a circle system with fresh gas inflow on the patient side of the inspiratory unidirectional valve. The ADU ventilator controls are integrated with the CPU so that when a V_T is set to be delivered by the ventilator, the CPU can adjust the excursion of the bellows, adjusting it accordingly if fresh gas flow, RR, or I:E ratio is changed. If a high fresh gas flow is set at the gas flow controls and a small V_T is set on the ventilator, the bellows may move only slightly because most of the V_T is now being provided by the fresh gas flow. If the fresh gas flow is decreased, this is sensed by the CPU, which automatically increases the V_T delivered from the ventilator bellows. In addition, during the automated preuse checkout the user occludes the Y-piece and the workstation measures the compliance of the breathing system so that this is also taken into account by the ventilator. The ADU Carestation achieves PEEP by controlling the ventilator pressure-relief valve.

The latest addition to the Datex-Ohmeda line is the Aisys workstation. Although it incorporates totally electronic gas flow control using a gas mixer (the user selects N_2O or air, F_IO_2, and total gas flow) and Aladin vaporizer controls, the ventilator used is the Datex-Ohmeda 7900. The SmartVent feature monitors the patient's breathing system by signals from pressure, flow and O_2 transducers. Inspiratory and expiratory flow sensors measure the flow of gas to and from the patient circuit. By comparing the operator set value with the actual delivered inspired V_T, the ventilator compensates for gas compression losses and contributions from fresh gas flow.

Fresh Gas Decoupling

Fresh gas decoupling is used in the Datascope Anestar workstation, which has a hanging bellows design. Fresh gas decoupling is also used in the Dräger Narkomed 6400, Fabius GS, and Apollo (Fig. 38–45) workstations, which use an electrically driven piston in place of the traditional gas-driven bellows.

The principle of fresh gas decoupling is that during the inspiratory cycle of positive-pressure ventilation, a decoupling valve diverts fresh gas flow into the reservoir bag of the circle system so that only gas from the ventilator (piston or bellows) flows to the patient. Figure 38–46 shows fresh gas decoupling in the Anestar circuit. During inspiration, the decoupling valve closes, bellows gas flows to the patient, and fresh gas is diverted into the reservoir bag. If the fresh gas flow is high such that the bag's capacity is exceeded, the excess flows through the absorber and is vented to the waste gas scavenging system. In other designs the bellows can be replaced in function by an electric motor-driven piston (Fig. 38–47). During the expiration phase (Fig. 38–48), the fresh gas decoupling valve opens, permitting the descending bellows to fill with fresh gas from the bag, and fresh gas flow from the machine, followed by exhaled gas that has passed through the absorber. Once the bellows has descended completely, additional exhaled gas (mainly alveolar) is vented to the scavenging system.

In the fresh gas decoupling ventilator circuits that use a piston (Fig. 38–49) or a hanging bellows, negative pressure could potentially be applied during exhalation if fresh gas flow is inadequate. This is of particular concern with the piston ventilator when the piston withdraws as it attempts to refill the cylinder. To protect against possible negative pressure barotrauma, fresh gas decoupling circuits incorporate a negative pressure relief valve through which room air can be drawn when the negative pressure exceeds approximately –2 cm H_2O. When this occurs, an alarm sounds because unrecognized entrainment of room air could lead to

FIGURE 38–45. Dräger Apollo Anesthesia workstation. (Courtesy of Dräger, Telford, PA.)

an unintended low F_IO_2 and dilution of the anesthetic. Consequently, monitoring of F_IO_2 and anesthetic agent concentration at the airway is of particular importance. During the preuse checkout of the workstation the integrity of the breathing system is pressure checked for leaks. A leak could result in anesthetic gases being released into the atmosphere, as well as room air being entrained as just described. In one report, the workstation was checked out correctly. The users then noted that the patient was latex allergic and so the reservoir bag was replaced with one that was latex free. It was then noted that the F_IO_2 and the anesthetic agent concentration were decreasing. The users concluded that air was being entrained and a large hole was found in the latex-free bag. No alarm sounded, however, because the air entrainment was not occurring through the negative pressure relief valve (Fig. 38–49).[69]

WASTE GAS SCAVENGING SYSTEMS

The anesthesia workstations in common use are all continuous flow devices, that is, fresh gas flows continuously from the common gas outlet to the breathing system. Because the fresh gas flow is usually more than that required either by the patient or to compensate for small leaks, the excess gas must be allowed to exit the breathing system and be scavenged by the waste gas scavenging system. Trace concentrations of anesthetic (waste) gases have neither been fully incriminated nor fully exonerated as a health hazard to operating room personnel. However,

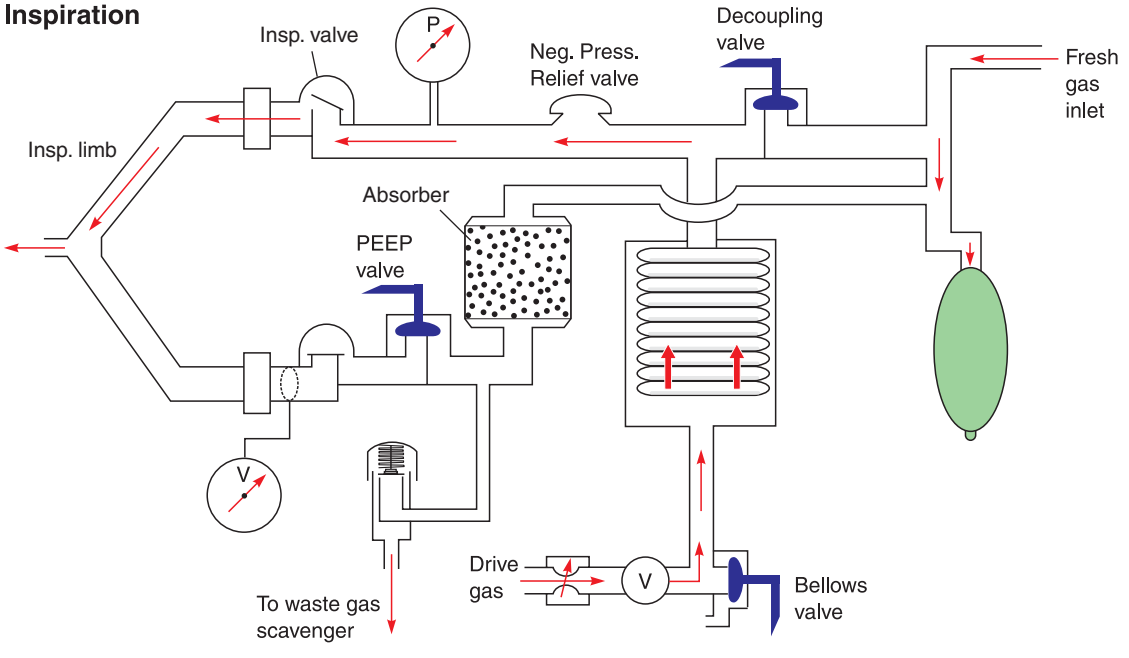

FIGURE 38–46. Fresh gas decoupling during the inspiratory phase of positive pressure ventilation. During this phase the decoupling valve, positive end-expiratory pressure (PEEP) valve and bellows valve are held closed. Fresh gas entering the breathing system is diverted into the reservoir bag, which therefore distends. Reproduced with permission from Abromovich A. Fresh gas decoupling minimizes complexity. APSF Newsletter 2005;20:35.

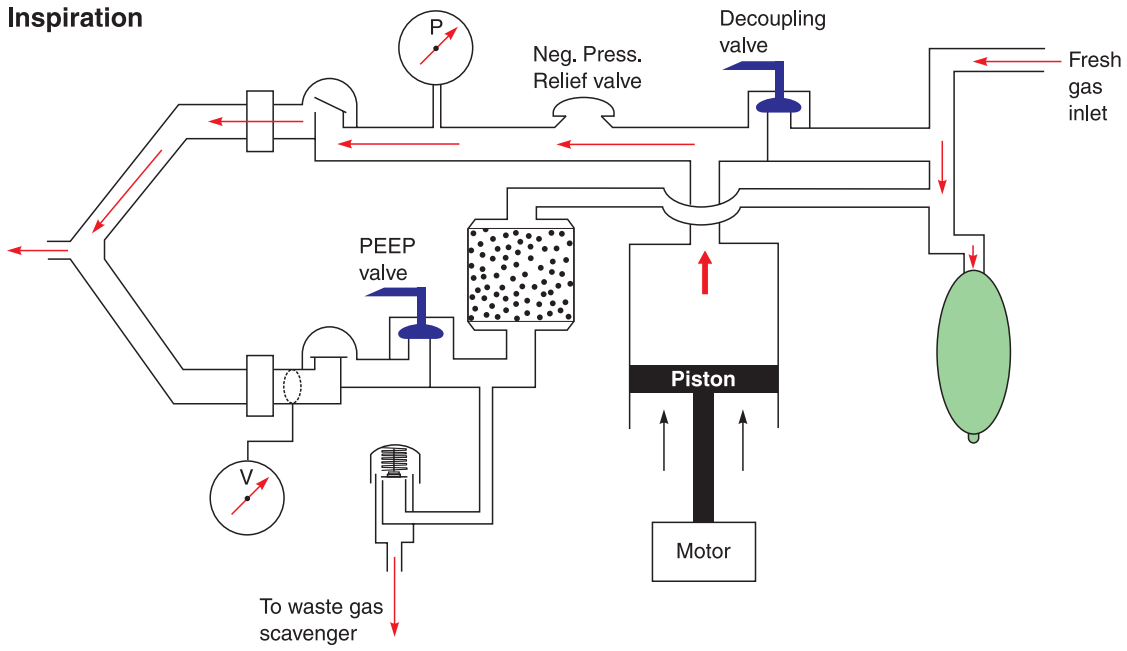

FIGURE 38–47. This figure shows that the function of the ventilator bellows can be performed by a piston in the same location. Piston ventilators are used in the Dräger Narkomed 6400 (Divan ventilator, horizontal piston), Fabius GS, and Apollo workstations (vertical pistons). Several advantages are afforded by a piston ventilator. Because they are driven by an electric motor there is no need for a driving gas circuit, which economizes on the use of oxygen, particularly if a cylinder supply is in use. The electric motor can control the piston very accurately and provide versatility in ventilatory modes such as offered in ICU ventilators. These ventilators are silent in operation and many anesthetists are used to the familiar sounds of a pneumatic ventilator. Some models offer variable tones to simulate inspiration and expiration. Adapted with permission from Abromovich A. Fresh gas decoupling minimizes complexity. APSF Newsletter 2005;20:35.

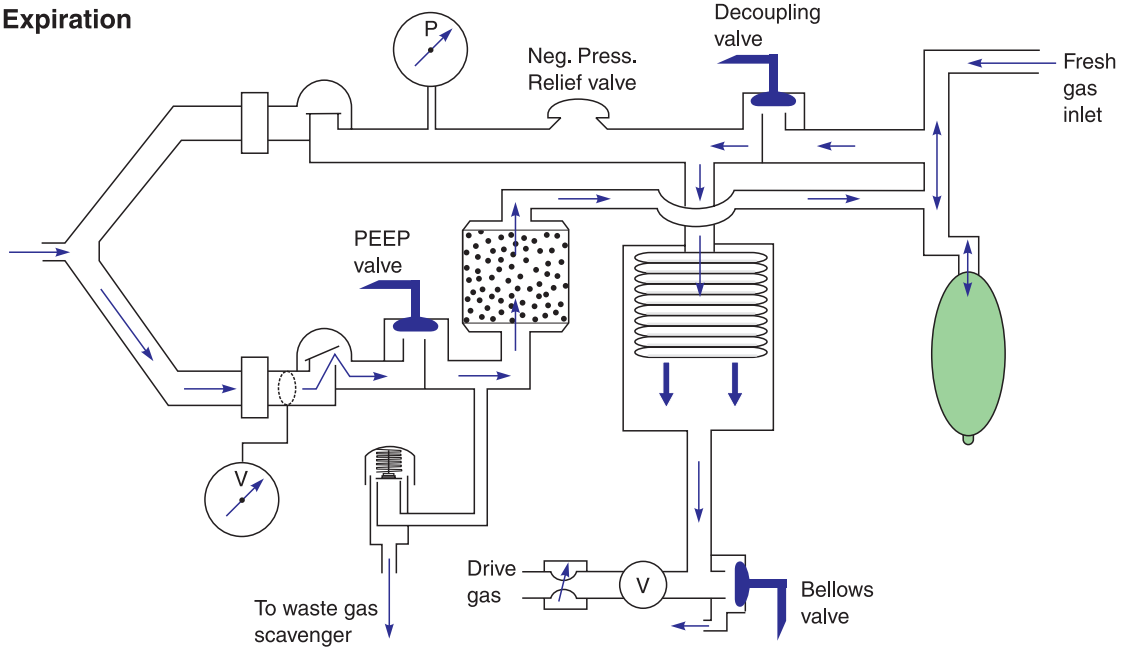

FIGURE 38–48. Fresh gas decoupling circuit during exhalation. The bellows refills (in this example by descending) and draws in fresh gas from the fresh gas inlet, and fresh gas that was stored in the reservoir bag during the previous inspiration. Reproduced with permission from Abromovich A. Fresh gas decoupling minimizes complexity. APSF Newsletter 2005;20:35.

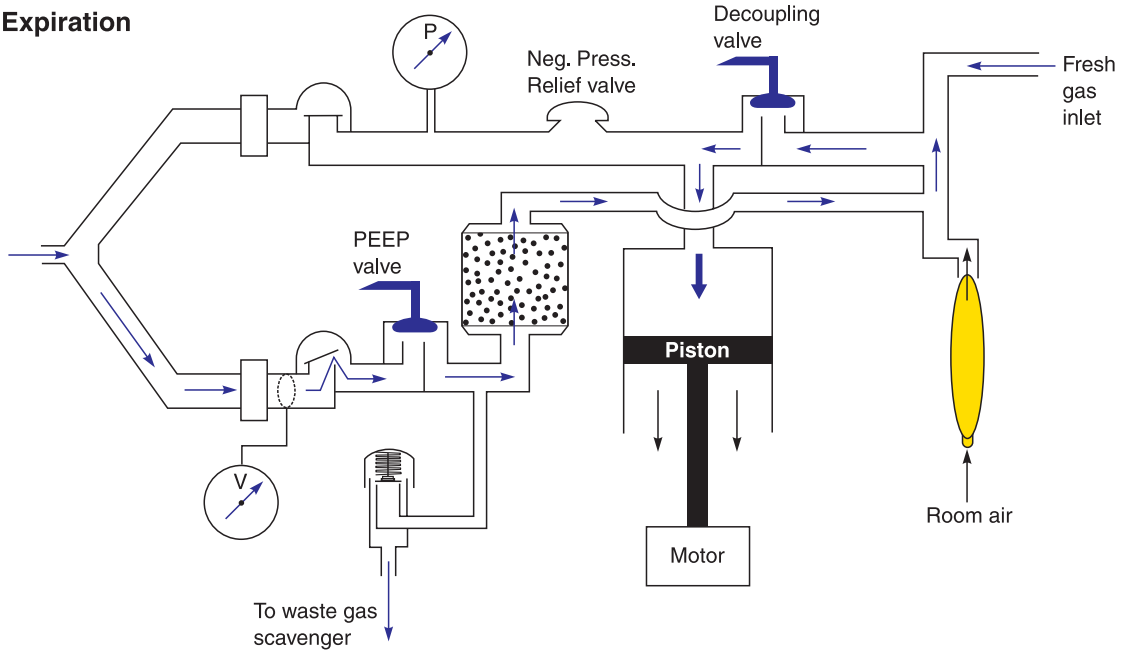

FIGURE 38–49. Figure shows in principle the situation reported by Sandberg and Kaiser.[69] The reservoir bag that passed the machine checkout is replaced by one that has a large hole in it. During exhalation, room air is entrained into the circuit via the hole as the piston descends to refill the cylinder with anesthetic gas mixture. Because the circuit is now at atmospheric pressure (due to the hole in the bag, no air is entrained through the negative pressure relief valve and no alarm is annunciated. Adapted with permission from Abromovich A. Fresh gas decoupling minimizes complexity. APSF Newsletter 2005;20:35.

all the concerned agencies, such as the National Institute for Occupational Safety and Health (NIOSH), the American Hospital Association (AHA), the Joint Commission on Accreditation of Healthcare Organizations (JCAHO), and the American Society of Anesthesiologists (ASA), encourage reduction of exposure to waste gases, which includes waste gas scavenging and monitoring of measures to reduce exposure.

In a 1977 publication that to date has not been superseded, NIOSH recommended environmental limits for the upper boundary of exposure[70]:

> Occupational exposure to halogenated anesthetic agents shall be controlled so that no worker is exposed at concentrations greater than 2 parts per million (ppm) of any halogenated anesthetic agent....When such agents are used in combination with nitrous oxide, levels of the halogenated agent well below 2 ppm are achievable. In most situations, control of nitrous oxide to a time-weighted average (TWA) concentration of 25 ppm during the anesthetic administration period will result in levels of approximately 0.5 ppm of the halogenated agent....Occupational exposure to nitrous oxide, when used as the sole anesthetic agent, shall be controlled so that no worker is exposed at TWA concentrations greater than 25 ppm during anesthetic administration. Available data indicate that with current control technology, exposure levels of 50 ppm and less for nitrous oxide are attainable in dental offices.

These recommended exposure limits were based on two reports. Whitcher et al.[71] showed that these levels were readily attainable in the operating room when certain precautionary measures were taken. Bruce and Bach found no decrement in the psychomotor capacities of volunteers exposed for 4 hours at these levels.[72]

Because trace concentrations of anesthetic gases have never been proven to be a health hazard, the NIOSH-recommended limits were never promulgated into law and are therefore not enforceable by OSHA. In 1998, the ASA convened a Task Force on Trace Anesthetic Gases (of which this author was a member) to evaluate the status of this subject and make recommendations.[73] The opinion and recommendations of the Task Force are summarized as follows:[73]

> Studies have not shown an association between trace levels of waste anesthetic gases found in scavenged anesthetizing locations and adverse health effects to personnel.
>
> Recommendations of ASA Task Force on Waste Anesthetic Gases are:
> 1. Waste anesthetic gases should be scavenged.
> 2. Appropriate work practices should be used to minimize exposure to waste anesthetic gases.
> 3. Personnel working in areas where waste anesthetic gases may be present should be educated regarding current studies on health effects of exposure to waste anesthetic gases, appropriate work practices to minimize exposure, and machine checkout and maintenance procedures.
> 4. There is insufficient evidence to recommend routine monitoring of trace levels of waste anesthetic gases in the operating room and postanesthesia care unit.
> 5. There is insufficient evidence to recommend routine medical surveillance of personnel exposed to trace concentrations of waste anesthetic gases, although each institution should have a mechanism for employees to report suspected work-related health problems.

Waste gases may leave the anesthesia circuit via the APL valve or via the

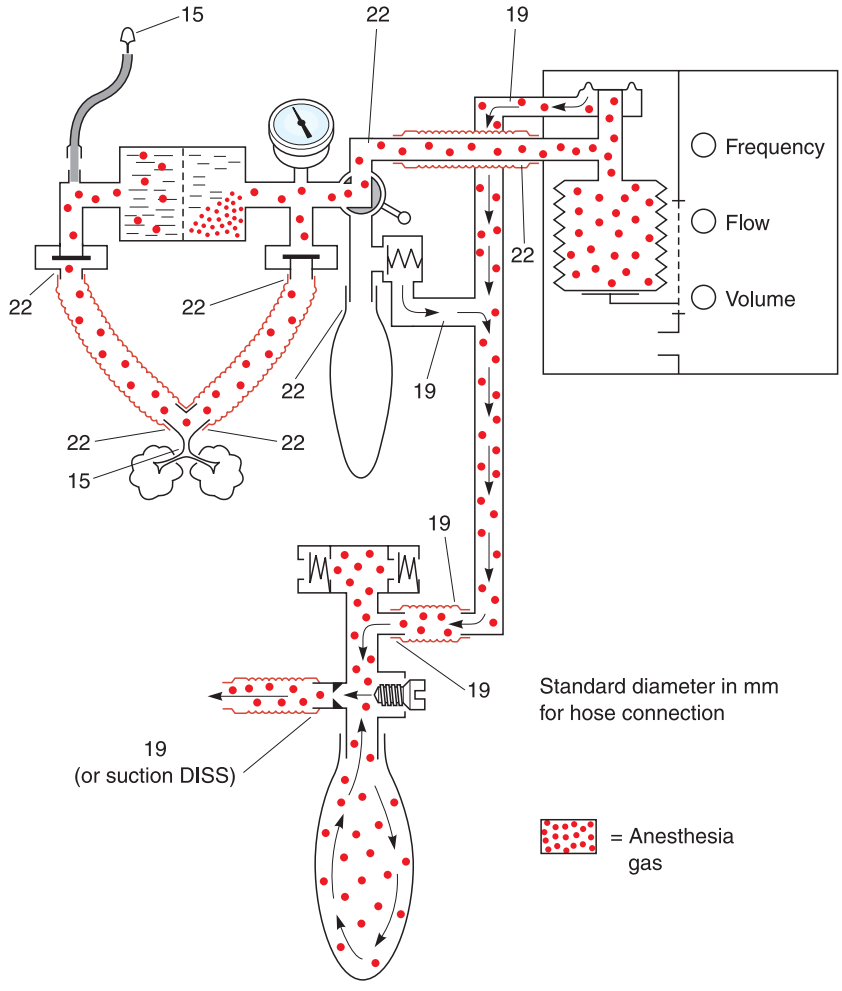

FIGURE 38–50. Schematic of anesthesia circuit and scavenging system tubing showing diameters for hose connections. (Courtesy of Dräger, Telford, PA.)

ventilator pressure-relief valve. In either case, tubing of either a 19-mm or 30-mm internal diameter is used, as distinct from the 22-mm internal diameter with anesthesia circuit and ventilator tubing, and the 15-mm internal diameter common gas outlet and tracheal tube connector sizes (Fig. 38–50). The scavenging system interfaces the gas flow out of the patient circuit with the hospital suction system.[8] Scavenging systems may be open or closed.

Closed systems use spring-loaded valves to ensure that excessively high or low pressures are not applied to the patient circuit (Fig. 38–51).[74,75] Thus if not connected to negative pressure (suction), excess pressure in the closed interface caused by gas entering it from the circuit is vented via the positive-pressure (pop-off) relief valve, which opens at about +5 cm H_2O. If excessive suction might be applied to the circuit, one (Ohmeda interface) or two (North American Dräger closed interface, Fig. 38–50) negative-pressure relief ("pop-in") valves (–0.25 to –1.80 cm H_2O, depending on the system) would open to preferentially draw in room air. This would minimize the potential for application of negative pressure to the patient circuit.

Open-reservoir scavenging interfaces are valveless (Fig. 38–52) and use continually open relief ports to provide pressure relief.[76] Waste gas that exits from the breathing circuit (via the APL or ventilator pressure-relief valve) is directed to the bottom of the canister (all anesthetic gases are more dense than air), and the hospital suction system aspirates gas from the bottom of the canister. In this type of interface, the reservoir canister contains the excess waste gas and thereby accommodates a range of waste gas flow rates from the patient circuit. Because this type of interface depends on open relief ports for pressure relief, care must be taken to ensure that these ports remain unoccluded at all times. Items 8a through 8e of the 1993 FDA checklist describe, in principle, how the scavenging system should be checked out (see Box 38–2 in Anesthesia Machine Checkout below).

In some recent models of workstation (e.g., ADU) the waste gas scavenging interface is internal to the machine and invisible to external inspection by the user. The principle of operation is that of an open reservoir system and the checkout requires that the machine's scavenging connector is connected to the hospital vacuum and that the scavenging flowmeter indicates that flow is present. With the flowmeter indicator ball floating between the two lines, the vacuum is drawing about 25 L/min from the interface.

ANESTHESIA MACHINE CHECKOUT

The anesthesia delivery system should be checked each day before administering anesthesia to the first patient and whenever any change has been made to the system. Such changes include replacing the ventilator bellows, replacing the anesthesia circuit, changing the absorbent, and moving the anesthesia workstation, even within the same operating room. Moving the machine may cause kinking or compression of tubing, which, in turn, may produce interference with gas delivery, ventilator function, or waste gas scavenging. Thus, in addition to a complete checkout at the start of each day, a shortened checkout of the delivery system should precede each administration of an anesthetic.

The Food and Drug Administration (FDA) first published its anesthesia apparatus checkout recommendations, which had 24 steps, in August 1986.[77] A subsequent study reported that the mere introduction of the FDA 1986 checklist did not improve the ability of anesthesiologists to detect anesthesia machine faults.[78]

A revised version of the FDA preuse checkout with 18 steps was published in 1993 (Box 38–2).[79] Many potential problems with the machine can be detected if the FDA checkout is performed correctly, although the best checkout is always that recommended by the manufacturer for its particular model of machine.

FDA Anesthesia Apparatus Checkout Recommendations—1993

Anesthesia Apparatus Checkout Recommendations, 1993

This checkout, or a reasonable equivalent, should be conducted before administration of anesthesia. These recommendations are only valid for an anesthesia system that conforms to current and relevant standards and includes an ascending bellows ventilator and at least the following monitors: capnograph, pulse oximeter, oxygen analyzer, respiratory volume monitor (spirometer), and breathing system pressure monitor with high and low pressure alarms. This is a guideline which users are encouraged to modify to accommodate differences in equipment design and variations in local clinical practice. Such local modifications should have appropriate peer review. Users should refer to the operator's manual for the manufacturer's specific procedures and precautions, especially the manufacturer's low pressure leak test (step #5).

Emergency Ventilation Equipment

*1. Verify Backup Ventilation Equipment is Available & Functioning

High Pressure System

*2. Check Oxygen Cylinder Supply
   a. Open O_2 cylinder and verify at least half full (about 1000 psi).
   b. Close cylinder.

*3. Check Central Pipeline Supplies
   a. Check that hoses are connected and pipeline gauges read about 50 psi.

Low Pressure Systems

*4. Check Initial Status of Low Pressure System
   a. Close flow control valves and turn vaporizers off.
   b. Check fill level and tighten vaporizers' filler caps.

*5. Perform Leak Check of Machine Low Pressure System
   a. Verify that the machine master switch and flow control valves are OFF.
   b. Attach "suction bulb" to common fresh gas outlet.
   c. Squeeze bulb repeatedly until fully collapsed.
   d. Verify bulb stays fully collapsed for at least 10 seconds.
   e. Open one vaporizer at a time and repeat "c" and "d" as above.
   f. Remove suction bulb, and reconnect fresh gas hose.

*6. Turn On Machine Master Switch and All Other Necessary Electrical Equipment.

*7. Test Flowmeters
   a. Adjust flow of all gases through their full range, checking for smooth operation of floats and undamaged flow tubes.
   b. Attempt to create a hypoxic O_2/N_2O mixture and verify correct changes in flow and/or alarm.

Scavenging System

*8. Adjust and Check Scavenging System
   a. Ensure proper connections between the scavenging system and both APL (pop-off) valve and ventilator relief valve.
   b. Adjust waste gas vacuum (if possible).
   c. Fully open APL valve and occlude Y-piece.
   d. With minimum O_2 flow, allow scavenger reservoir bag to collapse completely and verify that absorber pressure gauge reads about zero.
   e. With the O_2 flush activated allow the scavenger reservoir bag to distend fully, and then verify that absorber pressure gauge reads <10 cm H_2O.

Breathing System

*9. Calibrate O_2 Monitor
   a. Ensure monitor reads 21% in room air.
   b. Verify low O_2 alarm is enabled and functioning.
   c. Reinstall sensor in circuit and flush breathing system with O_2.
   d. Verify that monitor now reads greater than 90%.

10. Check Initial Status of Breathing System
   a. Set selector switch to "Bag" mode.
   b. Check that breathing circuit is complete, undamaged and unobstructed.
   c. Verify that CO_2 absorbent is adequate.
   d. Install breathing circuit accessory equipment (e.g. humidifier, PEEP valve) to be used during the case.

11. Perform Leak Check of the Breathing System
   a. Set all gas flows to zero (or minimum).
   b. Close APL (pop-off) valve and occlude Y-piece.
   c. Pressurize breathing system to about 30 cm H_2O with O_2 flush.
   d. Ensure that pressure remains fixed for at least 10 seconds.
   e. Open APL (pop-off) valve and ensure that pressure decreases

Manual and Automatic Ventilation Systems

12. Test Ventilation Systems and Unidirectional Valves
   a. Place a second breathing bag on Y-piece.
   b. Set appropriate ventilator parameters for next patient.
   c. Switch to automatic ventilation (Ventilator) mode.
   d. Fill bellows and breathing bag with O_2 flush and then turn ventilator ON.
   e. Set O_2 flow to minimum, other gas flows to zero.
   f. Verify that during inspiration bellows delivers appropriate tidal volume and that during expiration bellows fills completely.
   g. Set fresh gas flow to about 5 L/min.
   h. Verify that the ventilator bellows and simulated lungs fill and empty appropriately without sustained pressure at end-expiration.
   i. Check for proper action of unidirectional valves.
   j. Exercise breathing circuit accessories to ensure proper function.
   k. Turn ventilator OFF and switch to manual ventilation (Bag/APL) mode.
   l. Ventilate manually and assure inflation and deflation of artificial lungs and appropriate feel of system resistance and compliance.
   m. Remove second breathing bag from Y-piece.

Monitors

13. Check, Calibrate, and/or Set Alarm Limits of all Monitors
Capnometer Pulse Oximeter
Oxygen Analyzer Respiratory Volume Monitor (Spirometer)
Pressure Monitor with High and Low Airway Alarms

Final Position

14. Check Final Status of Machine
   a. Vaporizers off
   b. AFL valve open
   c. Selector switch to "Bag"
   d. All flowmeters to zero
   e. Patient suction level adequate
   f. Breathing system ready to use

*If an anesthesia provider uses the same machine in successive cases, these steps need not be repeated or may be abbreviated after the initial checkout.

Updated May 12, 1997

Testing for Leaks in the Anesthesia Machine and Breathing System

Item 5 in the 1993 FDA checkout recommendations (Box 38–2) describes how to check for leaks in the low-pressure system.[79] This checkout evaluates the components of the delivery system that are downstream of the gas flow control and should detect gross leaks that may result from cracked rotameter tubes, leaking gaskets, and vaporizers. This leak check evolved from that in the 1986 checkout. In the 1986 test, the APL ("pop-off") valve is closed and the patient circuit is occluded at the patient end. The system is then filled via the O_2 flush until the reservoir bag is just full, but negligible pressure exists in the system. Oxygen flow is set to 5 L/min and the oxygen flow is slowly decreased until pressure no longer rises above about 20 cm H_2O (Fig. 38–53). This set flow is said to approximate the total gas leak rate, which should be no greater than a few hundred ml/min. The reservoir bag should then be squeezed to a pressure of about 50 cm H_2O to verify that the system is gas tight. If a large enough leak is present, the circuit pressure may decrease to zero (Fig. 38–54).

The advantages of this test routine are that it can be performed quickly and that it checks the patient circuit as well as the low-pressure parts of the machine in those models without an outlet check valve. Disadvantages of this routine are that it is relatively insensitive to small leaks and that in those machines with an outlet check valve (e.g., Datex-Ohmeda Modulus I, Modulus II, Aestiva and Excel models), only the patient circuit downstream of the outlet check valve is tested for leaks (Fig. 38–55).

The FDA 1986 generic leak check also is insensitive because it is volume dependent. Thus in this test, a large volume of gas (i.e., that contained in the circuit tubing, absorber, and reservoir bag) is compressed, and a change in reading on the pressure gauge is sought. The term *compliance* expresses the relationship between volume and pressure and is defined as change in volume per unit change in pressure. Because of the large volume of gas compressed and the high compliance of the distensible reservoir bag, relatively large changes in volume (i.e., leaks) may exist with minimal changes in pressure. The anesthetist performing the check is seeking a pressure decrease as an indicator of gas

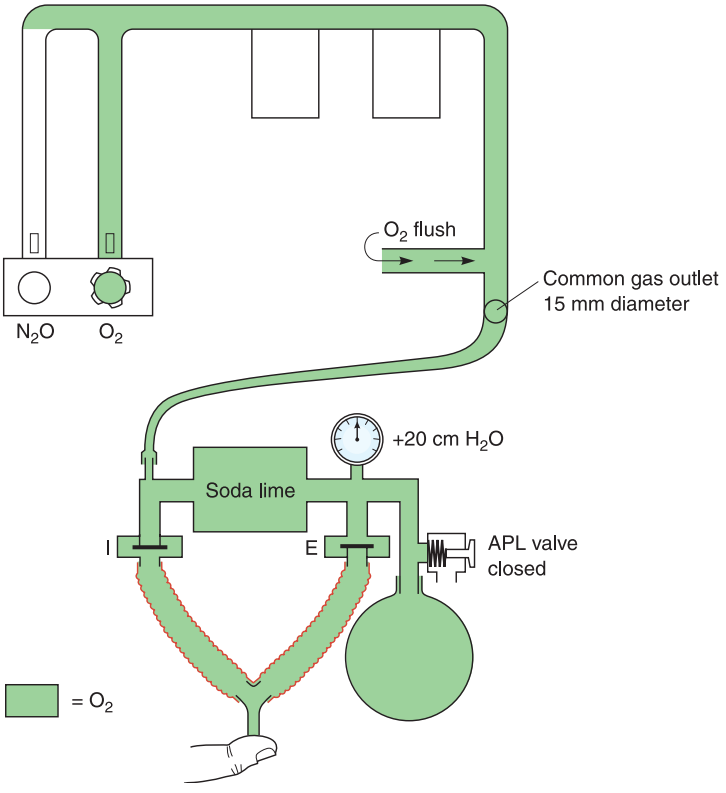

FIGURE 38–53. FDA 1986 generic leak test in a machine without an outlet check valve In this case, a pressure of 20 cm H_2O is held with no gas flow, indicating both patient circuit and low-pressure parts of machine are gas tight.

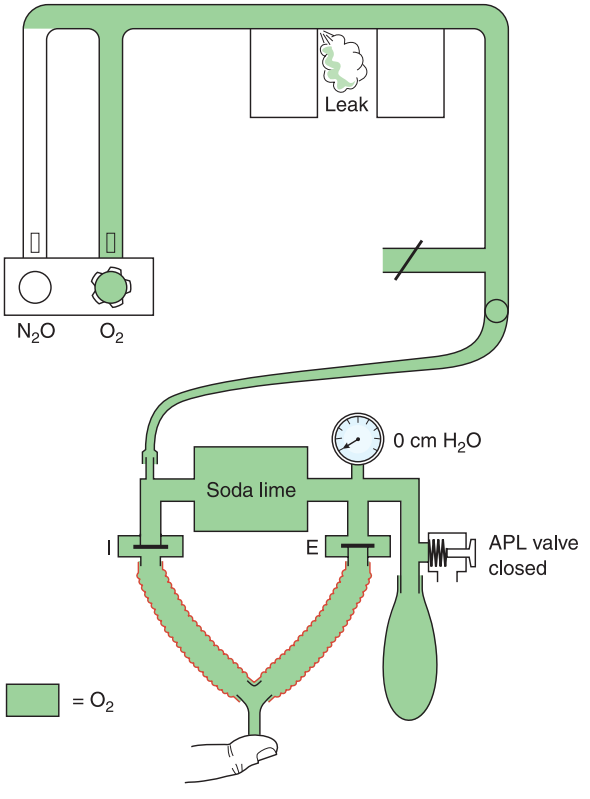

FIGURE 38–54. In absence of outlet check valve, a leak at the vaporizer mount results in failure of the system to hold pressure, which in this case falls to zero. Such a leak would not be detectable by this test if an outlet check valve (see Fig. 38–55) were present.

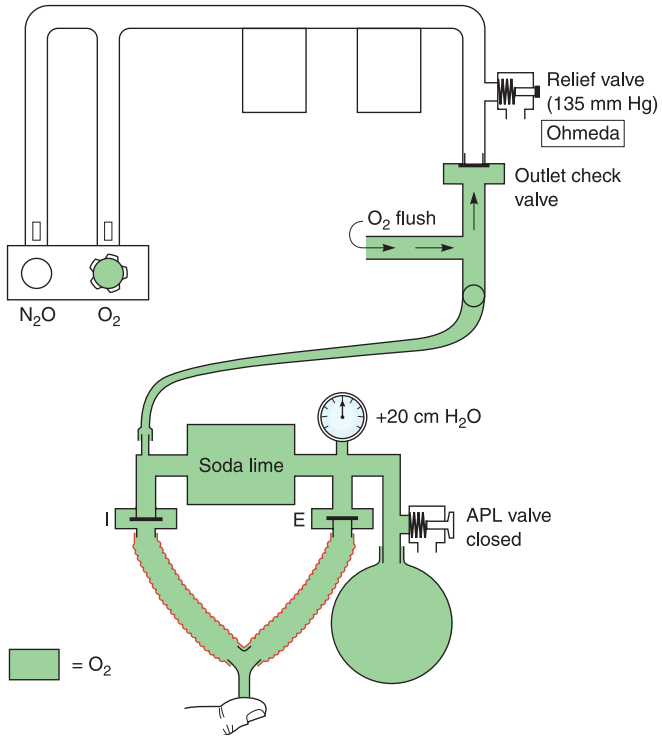

FIGURE 38–55. Application of generic checkout to a system with an outlet check valve. In this case, application of positive back pressure of 20 cm H_2O causes the check valve to close so that only components downstream (i.e., the circuit) are being tested for leaks.

leakage, but large leaks may go undetected by this test. Such leaks may be unimportant while high fresh gas flows are used, but become more significant if gas flow rates are reduced subsequently during the maintenance of anesthesia.

The second limitation of the FDA 1986 generic checkout is related to the presence or absence of an outlet check valve, which, if present, separates the low-pressure part of the machine from the common gas outlet and circuit components downstream (Fig. 38–2). Application of the generic leak check in this situation may fail to detect leaks in components downstream of the outlet check valve (Fig. 38–55). In the past, certain anesthesia delivery systems configured by the user placed a free-standing vaporizer in series between the common gas outlet of the machine and the fresh gas inlet of the patient circuit. Some of these free-standing vaporizers incorporated their own outlet check valve to prevent a pumping effect on the vaporizer. If such an arrangement were to be used, the generic leak check would test only as far proximally as the location of this check valve in the vaporizer outlet.

The use of in-series, free-standing vaporizers is not described in the ASTM F1161–88 and subsequent standards and should be prohibited. Furthermore, because free-standing vaporizers are placed downstream of the machine's common gas outlet, use of the O_2 flush would deliver a "bolus" of the potent inhaled agent to the patient circuit. This assumes that the tubing connections are not disrupted by the potentially high pressures associated with use of the O_2 flush. A disconnect between the machine's common gas outlet and the free-standing vaporizer could also cause a low-concentration O_2 mixture to develop in the patient circuit during controlled ventilation (if a hanging bellows ventilator is being used), thus the current requirement for a retaining device. In addition, any vaporizer exclusion system (interlock) would be compromised with a free-standing arrangement. Again, it is emphasized that the use of a free-standing vaporizer downstream of the common gas outlet is not recommended and may be hazardous.

The limitations of the FDA 1986 generic leak check demand that specialized leak checks of the low-pressure system must be used and that the machine operator's manual be consulted for details. The tests described for the traditional Dräger Narkomed and Datex-Ohmeda machines are briefly reviewed to illustrate the differences in system design, function, and checkout.

Dräger Narkomed 2, Narkomed 3, Narkomed 4, and Narkomed GS Machines: No Outlet Check Valve

Dräger recommends the following procedure for checking the anesthesia breathing system and fresh gas delivery system.[11] In this test, all gas flow-control (flowmeter) valves are closed, and the machine system's main power switch is turned to standby or off. This way, no gas should flow to the flowmeters or from the common gas outlet. All vaporizer concentration dials are set to zero. The inspiratory and expiratory valves are interconnected using a 22 mm-diameter circuit hose (Fig. 38–56). The shortest possible length of hose should be used to minimize contained gas volume. The "manual/automatic" selector valve is set to the manual (bag) position. The APL (pop-off) valve is closed (turned fully clockwise). The reservoir bag is removed, and the "test terminal" is attached to the bag mount. A sphygmomanometer squeeze bulb is connected to the hose barb on the test terminal.

The total volume of the circuit components has now been drastically reduced by removing the circle system tubing (a circle with each limb measuring 152 cm in length has a volume of about 1200 mL) and the reservoir bag (3 L). The sphygmomanometer bulb is then squeezed by hand until the pressure shown on the breathing system pressure gauge indicates a pressure higher than 50 cm H_2O. The

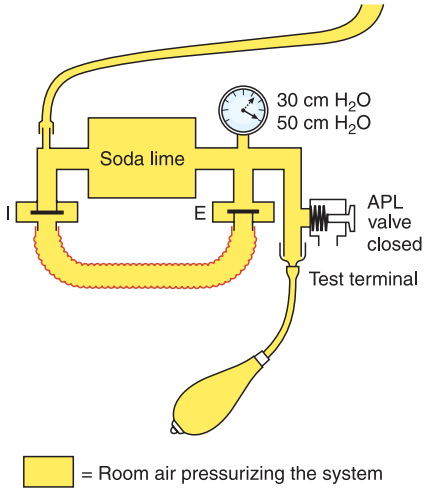

FIGURE 38–56. Dräger Narkomed positive-pressure leak check. It should take 30 seconds or longer for the pressure to decrease from 50 to 30 cm H_2O.

gauge is then observed for a pressure decrease. The manufacturer specifies that 30 seconds or longer is required for a pressure decrease from 50 to 30 cm H_2O.[11] Because the volume of gas being compressed in this test is minimal, small gas leaks result in decreased pressure, which is observable on the circuit pressure gauge.

The positive-pressure leak check should be repeated sequentially with each vaporizer turned on and set at any concentration above 0.4%. This will check for leaks in individual vaporizers (e.g., filler caps, selector switches, vaporizer mounts).

The test specifications given in this section apply to an anesthesia breathing system without accessories (e.g., spirometer, sidestream gas analyzer, other adapters).[11] Test limits are exceeded when accessory items are included in the test. (The supplier of the accessory items should be contacted for leak specifications.)

Leaks in the patient circuit components can be distinguished from leaks in the low-pressure part of the Dräger Narkomed machine (no outlet check valve) as follows. If a leak has been identified using the combined circuit/machine positive-pressure leak check just described, the sphygmomanometer bulb can be connected to the machine's common gas outlet using a 15-mm connector and to a pressure gauge using a 3-way stopcock. With this arrangement, only the machine (as opposed to machine and circuit in the previous test) is pressurized to 50 cm H_2O. A decrease in pressure then indicates a leak within the machine upstream of the common gas outlet. This test is possible because no outlet check valve is present in Dräger Narkomed machines.

Leaks in the patient circuit can be detected by systematically examining each component and connection in the circuit. If necessary, soap solution can be applied over joints suspected of leaking, with bubbles indicating the leakage site(s).

Datex-Ohmeda Machines: Outlet Check Valve Present

In certain Datex-Ohmeda anesthesia machines (Modulus I, Modulus II, Excel, and Aestiva) an outlet check valve complicates positive-pressure testing of the machine's low-pressure system (Fig. 38–55).

Application of positive pressure downstream from the valve causes it to close, and only components downstream of this valve (i.e., beyond the common gas outlet) would then be checked for leaks. Positive-pressure ventilation and opening of the O_2 flush valve cause the check valve to close. For this reason, Datex-Ohmeda describes a negative-pressure leak test using a special suction bulb device that is supplied with each machine to which this test applies (Fig. 38–57).

First, the adequacy of the leak-testing device should be checked by sealing the bulb's inlet connector and squeezing the bulb until it is collapsed. The bulb is then released and the time taken to reinflate observed. If reinflation occurs in less than 60 seconds, the device should be replaced.[8,10,80] The device is checked periodically (at times of machine servicing) to ensure that the vacuum produced by the evacuated bulb is at least –65 mm Hg (Fig. 38–57).

The device is then used to check the machine. The anesthesia machine system's master switch and all vaporizers are turned off so that no gases flow into the machine's low-pressure system. Each gas supply is then opened by turning on the cylinder valves or by connecting the pipeline supply. The flow-control valves (rotameters) are turned fully open. The negative-pressure leak-testing bulb is attached to the machine's common gas outlet via a 15-mm connector. The hand bulb is repeatedly squeezed and released until it remains collapsed. If the bulb reinflates within 30 seconds or less (Fig. 38–57), a leak of as little as 30 mL/min is present. The test procedure is repeated with each vaporizer on in turn to seek leaks in individual vaporizers. If the source is not obviously correctable, the machine should be withdrawn from service.

When the leak tests are completed, the negative-pressure bulb is removed from the common gas outlet, and residual vapors are purged from the machine by turning on O_2 flow at 1 L/min for 1 minute with all vaporizers off. Use of the O_2 flush control following this check does not purge vapors from the machine, because the O_2 flush flow enters the system downstream from the vaporizers and from the outlet check valve. Because the leak check described is conducted with all the flow-control valves open, components up to and including the machine's main on/off control switch are also tested for leaks.

The negative-pressure leak check described for Datex-Ohmeda machines results in the outlet check valve being held open by the –65 mm Hg vacuum (Fig. 38–58) and air or gas being sucked into the system through any leaks. If such leaks were present while the machine was in service, anesthesia gases would escape from the system through such leaks.

Considering the basic internal arrangement of the Datex-Ohmeda machines that have an outlet check valve, one might suggest that an internal machine leak could be detected by occluding the common gas outlet (by thumb or by clamping the fresh gas delivery tubing, as shown in Fig. 38–59). The machine is then turned on and the O_2 flow rate observed, which is possible at the rotameter, assuming that the O_2 flow rate indicates the leakage rate (compare with FDA 1986 checkout procedure). The procedure described does not necessarily indicate the true leakage rate, because these Datex-Ohmeda machines also have a pressure-relief valve located between the vaporizers

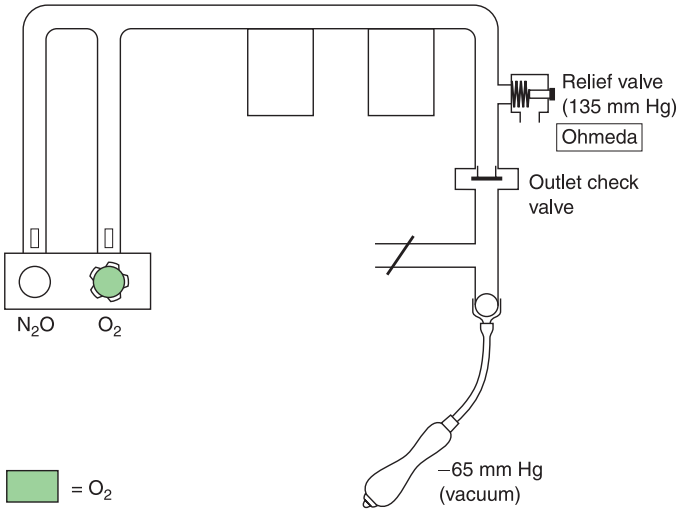

FIGURE 38–57. Datex-Ohmeda negative-pressure leak check. See text for details.

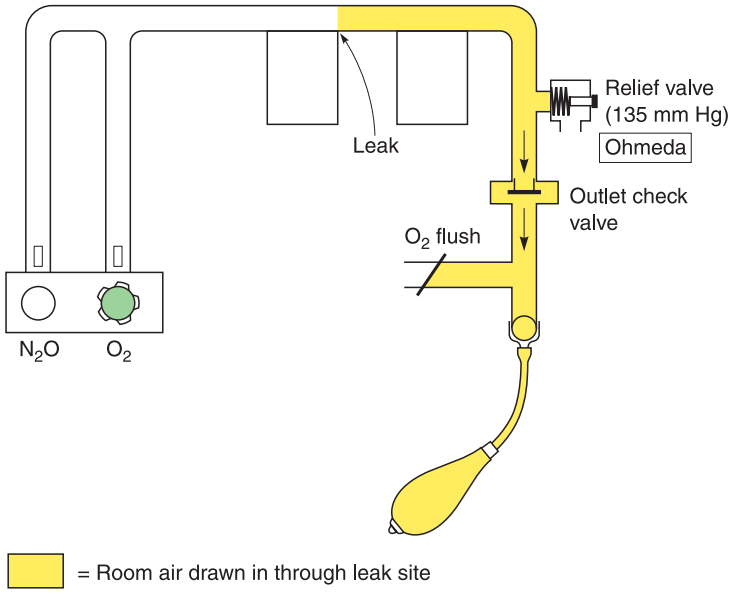

FIGURE 38–58. Datex-Ohmeda negative-pressure leak check. With a leak in the machine, the evacuated bulb reinflates. See text for details.

and the outlet check valve (see Figs. 38–57, 38–58, and 38–59). This pressure-relief valve opens at a pressure of 135 ± 15 mm Hg (approximately 2.3–2.9 psig) to release gas and prevent pressure buildup proximal to the outlet check valve. Datex-Ohmeda Excel machines have a pressure-relief valve located downstream from the outlet check valve, between this valve and the common gas outlet. This pressure-relief valve has an opening pressure of 5 psig. A pressure-relief valve limits the use of the procedure just described to testing for machine leaks only at pressures below the pressure-relief valve's opening pressure. Consequently, only the negative-pressure test described by Datex-Ohmeda in its operator's manual for the particular model should be used.

If, following testing, the anesthesia machine is found to have a leak, it should be withdrawn from use until an authorized agent has repaired the leak, rechecked the system, and certified that it is ready to be put back into clinical service.

Datex-Ohmeda Modulus II Plus and Modulus CD Machines: No Outlet Check Valve

Although the more recently introduced Datex-Ohmeda models (Modulus II Plus, Modulus CD) do not have an outlet check valve (Fig. 38–2), Datex-Ohmeda recommends the negative-pressure leak-test procedure previously described to check for leaks in these models.[10] The negative-pressure leak check device can, in principle, be used to check for leaks in a Dräger Narkomed machine, but Dräger has not provided specifications for using such a device on their products. Indeed, Myers et al. reported that the negative-pressure leak test could be used to detect leaks in all traditional anesthesia machines, whether they have an outlet check valve or not.[81] Item 5 of the FDA 1993 preuse checkout recommendations describes the use of the negative-pressure leak check bulb, and states that it should stay fully collapsed for at least 10 seconds.

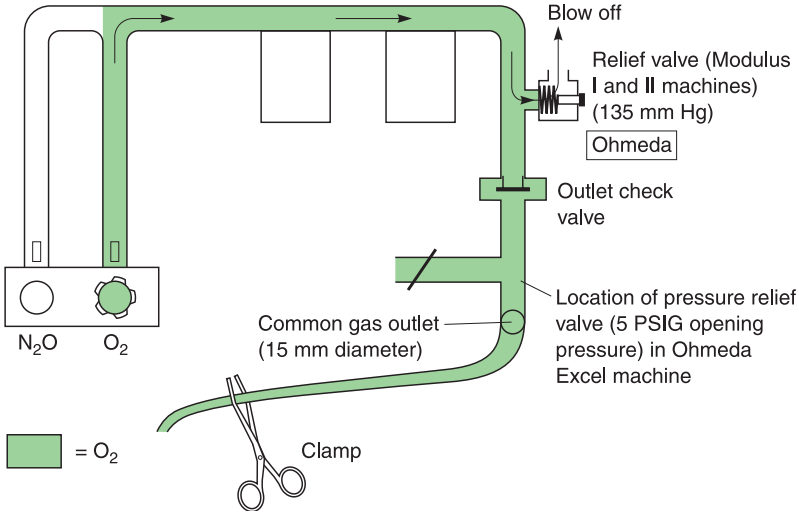

FIGURE 38–59. Datex-Ohmeda system. The effect of occluding the common gas outlet and turning on the O_2 flowmeter is shown. Flow shown does not necessarily indicate leakage rate but may indicate rate of gas flow (blow-off) through pressure relief valve (pressure-relief valve). See text for details.

Automated Preuse Checkouts

Although the preuse checkout of the workstation is very important, it is apparent that it is often performed inadequately. The most recently introduced anesthesia workstations (e.g., ADU, Aisys, Narkomed 6400, Apollo) use an automated checkout of many of the important functions. Advantages of an automated checkout are that it is performed correctly and alerts the user to faults and potential problems; the results are recorded in the memory of the workstation; and it enables certain parts of the checkout to be performed by an anesthesia technician so that an anesthetist who subsequently uses the workstation can see what has been checked and when.

Automated checkouts cannot, however, check all aspects of the workstation function. Certain procedures must still be performed by the user. The computerized checkout screen prompts and educates the user to perform certain checkout actions and to log that the actions have been done. For example, the user is expected to correctly assemble the breathing system and connect it to the workstation. The automated checkouts require that the Y-piece of the circuit be occluded so that the system can be pressurized to test for leaks and to measure compliance. This must be performed each time a change is made to the circuit. Thus there may not be a leak in the circuit used in the first case, but there may be a leak in the next used disposable circuit. Breathing circuit function, as opposed to integrity, can be checked by attaching a second reservoir bag to the circuit Y-piece to act as a model lung, and ventilating the bag in both manual and ventilator modes (see

Box 38–2, FDA 1993 checkout, step 12, above). This is important because the circuit may pass an automated pressure check but not a functional flow check.

With the introduction of the new workstations, the specific procedures recommended in the FDA 1993 checkout may not always be applicable, although the principles still apply. At the time of writing, an ASA subcommittee is reviewing the 1993 checkout with a view to suggest updated recommendations.

Studies of critical incidents and adverse outcomes in relation to anesthesia gas delivery equipment have consistently shown that use error is the most common cause of such incidents and outcomes.[82–84] Because intensive training of anesthetists improves their ability to detect problems with anesthesia equipment, educational efforts must be emphasized.[85] User education is a major concern and priority of the manufacturers as new and increasingly sophisticated workstations are introduced. Human patient simulation has been reported to be an effective training device to ensure that practitioners are competent to use new equipment in both straightforward and crisis situations before using the equipment with real patients.[85]

SUMMARY

A basic understanding of the anesthesia delivery system and its components is important to the provision of safe patient care. The reader is encouraged to trace the flow of gases and vapors from their sources of storage, through the reader's own particular delivery system, to waste gas scavenging. One should also consider the structure and function of each component in the gas pathway. In this way, malfunctions can be more readily identified and often more easily corrected by the user.

The reader is also strongly encouraged to review the operator's manual accompanying the reader's anesthesia delivery system and, in particular, to understand the rationale behind the specific checkout procedures described.

CHAPTER 39

Principles of Pharmacokinetics and Pharmacodynamics: Applied Clinical Pharmacology for the Practitioner

Ken B. Johnson, MD, and
Talmage D. Egan, MD

CLINICAL PHARMACOLOGY: WHY BOTHER?

Clinical pharmacology is the science of predicting the magnitude and time course of drug effect. Given that anesthesiologists and other anesthesia providers spend their day administering low therapeutic index agents, clinical pharmacology is perhaps more important to anesthesiology than any other specialty. From a practical aspect, the ultimate goal of clinical pharmacology is to provide anesthesia practitioners with the information they need to make rational decisions about the selection and administration of anesthetics.

Anesthesia and reanimation necessitate a standard of precision and accuracy in drug administration not required in most areas of clinical medicine. Practitioners must profoundly depress the central nervous system in order to maintain the anesthetized state but then rapidly reanimate patients after an operation is complete. Although overdosing every patient within the constraints of acceptable hemodynamic variables is one approach to assuring the patient is adequately anesthetized, it comes at the cost of slow emergence from anesthesia, among others. Therefore, clinicians must target drug levels that are within a relatively narrow therapeutic window to achieve the competing clinical imperatives of adequate anesthesia (without toxicity) and rapid emergence.

Once an agent is selected (presumably because the agent's pharmacologic profile is well suited to the proposed application), the next challenge is the formulation of a scientifically grounded dosing strategy. What does the anesthetist need to know? Table 39–1 catalogues some of the important considerations in determining the proper drug administration scheme in the context of anesthesia practice.

KEY POINTS

1. The ultimate goal of *pharmacokinetic–pharmacodynamic* study is accurate prediction of the time course and magnitude of drug effect so that the clinician can answer a very simple and important question: "What is the appropriate dosing scheme for my patient?"
2. *Pharmacokinetics*, often thought of as "what the body does to the drug," is the study of the relationship between the drug dose and the drug concentrations that are produced over time.
3. *Pharmacodynamics*, often thought of as "what the drug does to the body," is the study of the relationship between the drug concentration and the drug effects that are produced.
4. Pharmacokinetic–pharmacodynamic models can be constructed that characterize drug behavior. These models are mathematical expressions of the relationship between drug dose and concentration (pharmacokinetics) and drug concentration and effect (pharmacodynamics). The models are composed of individual parameters (e.g., *clearance, distribution volume, effective concentration for 50% of maximal effect*, etc.). Because of the complex interaction of the parameters, drawing conclusions about drug behavior from a single parameter is difficult.
5. Because it is a mathematically based discipline, pharmacokinetics–pharmacodynamics is a distinctly unpopular subject among clinical anesthesiologists. This unpopularity is ironic considering there is no medical specialty for which accurate prediction of the time course and magnitude of drug effect is more important (anesthesiologists produce profound, potentially dangerous drug effects that must be "turned on and off" in a rapid fashion).
6. Fortunately, the clinical implications of pharmacokinetic–pharmacodynamic models can be easily understood and conveyed through the use of *computer simulation*. Using computer simulation, a proposed dosing scheme can be "input" into a pharmacokinetic–pharmacodynamic model, producing a "*picture*" of the drug levels and drug effects that are expected to occur. These pictures (i.e., computer simulations) are intuitively understandable and are easily applied to clinical situations.
7. The "*biophase*" is the theoretical site of drug action or "*effect site*" (e.g., the brain, the neuromuscular junction, the spinal cord, etc.). It is important to consider drug concentrations in the biophase (and not just the plasma) because most drugs do not exert their effect in the blood. Pharmacokinetic–pharmacodynamic models account for this problem by linking the concentrations in the blood to theoretical concentrations in the biophase.
8. Because anesthetics are rarely administered alone (i.e., anesthesia usually is at least a two-drug process consisting of an analgesic and a sedative), characterizing the interaction between drugs is also an important goal of pharmacokinetic–pharmacodynamic study. Most anesthetics commonly used in combination, such as fentanyl and propofol, interact in a profoundly synergistic way (i.e., where 2 + 2 = 7 or more...) so that much less of each drug is required (compared to the doses necessary when the drugs are used alone). Drug interaction models using "*response surface*" methods can be used to visualize these *synergistic interactions* and identify optimal dosing regimens.
9. Anesthesiologists have long recognized the need to adapt their anesthetic to account for differences in demographic factors and disease processes that influence drug disposition or effect. Comorbidities such as obesity, blood loss, presence of opioid tolerance, and differences in age are referred to as *covariates*. Covariates are descriptors of demographic factors or pathophysiologic states that impact anesthetic drug behavior.

TABLE 39–1.

Questions to Consider When Formulating a Dose of Intravenous Anesthetic

1. What is an appropriate dose for my particular patient? Should I give the dose as a bolus or as a continuous infusion?
2. How soon will the intended effect start?
3. How long will it last?
4. How do the onset and duration of effect change in the presence of other anesthetics?
5. How do I minimize sedation yet optimize analgesia following surgical procedures associated with a painful postoperative course?
6. Do I know how to account for body weight, age, or other important factors that may alter dosage requirements (e.g., blood loss, heart failure, kidney failure, etc.) in how I determine the dose?
7. How can I tailor my anesthetic to account for opioid tolerance in patients who chronically consume opioids and/or benzodiazepines?

Adapted from Sheiner[90] with permission.

Anesthesiologists have long recognized that conventional, often simplified approaches to describing drug behavior, such as "half-life" or "peak and trough," are not useful in answering these questions.[1] Perhaps no other specialty in medicine is more dependent on accurate predictions of a drug's pharmacokinetic and pharmacodynamic profile than is anesthesiology. Most settings in clinical medicine do not require immediate onset and rapid offset of pharmacologic effect. When an internist prescribes an oral medication for treatment of hypertension, for example, the fact that several days may be required for the development of a steady-state level of drug effect is of little consequence. The anesthetist, however, must rely on drugs with rapid onset and predictable offset of effect to ensure maintenance of an anesthetic state with return of responsiveness and other vital functions at the appropriate time. In summary, an understanding of fundamental pharmacokinetic and pharmacodynamic concepts is of critical importance to the clinical practice of anesthesiology.

Modern clinical pharmacology techniques and concepts provide the scientific foundation to answer the questions listed in Table 39–1. Clinical pharmacologists have created tools using principles of pharmacokinetics and pharmacodynamics to construct models that predict drug behavior. Unfortunately, the often puzzling mathematical manipulations involved in estimating pharmacokinetic and pharmacodynamic parameters and the complex mathematics required to build models that predict drug behavior have made these techniques distinctly unpopular among most practitioners. Most practitioners have been slow to integrate the intricacies of kinetics and dynamics into their clinical practice, instead relying on training and experience to determine dosing. Thus, determination of the proper dose in clinical anesthesia often is little more than a sophisticated guess based on the anesthesiologist's gestalt impressions.

So why bother with clinical pharmacology? It is because this discipline provides the core scientific foundation for optimizing doses of intravenous anesthetics and should be a part of every practicing anesthetist's knowledge base. Fortunately, advances in pharmacologic computer *simulation* have revolutionized the way we apply complex pharmacokinetic and pharmacodynamic models. Simulations can be used to create meaningful *pictures* of drug behavior that are useful when considering the questions given in Table 39–1. Pharmacokinetic and pharmacodynamic model simulations get beyond the clinically unappealing mathematics associated with this area, providing an intuitively interpretable picture of drug behavior that clinician can grasp and apply in day-to-day practice. Relying almost entirely on simulations (and not math), the purpose of this chapter is to empower practitioners with key concepts in pharmacokinetics and pharmacodynamics that influence the answer to the question: "What is an appropriate dose for my patient?"

PHARMACOLOGIC MODELING

Pharmacokinetics

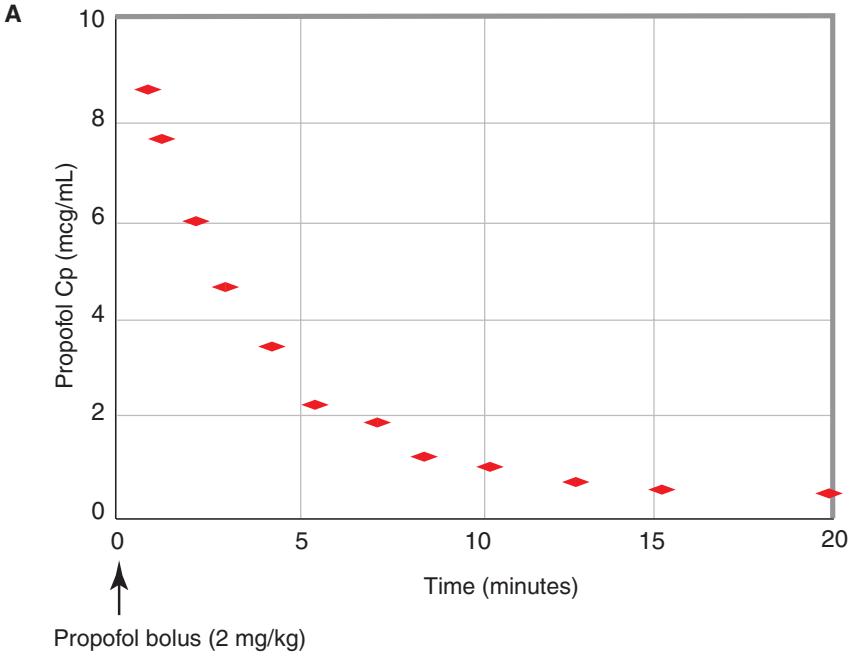
To develop a *pharmacokinetic* model, clinical pharmacologists administer a drug and then repeatedly measure drug levels until the concentration is undetectable. The raw data are drug concentrations over time (Fig. 39–1). Using computerized pharmacokinetic tools, an equation is fit to the raw data. The equations used are simply a mathematical expression of the shape of the concentration versus time curve. The equations are composed of parameters such as fractional coefficients and rate constants, which are not much use to most providers.

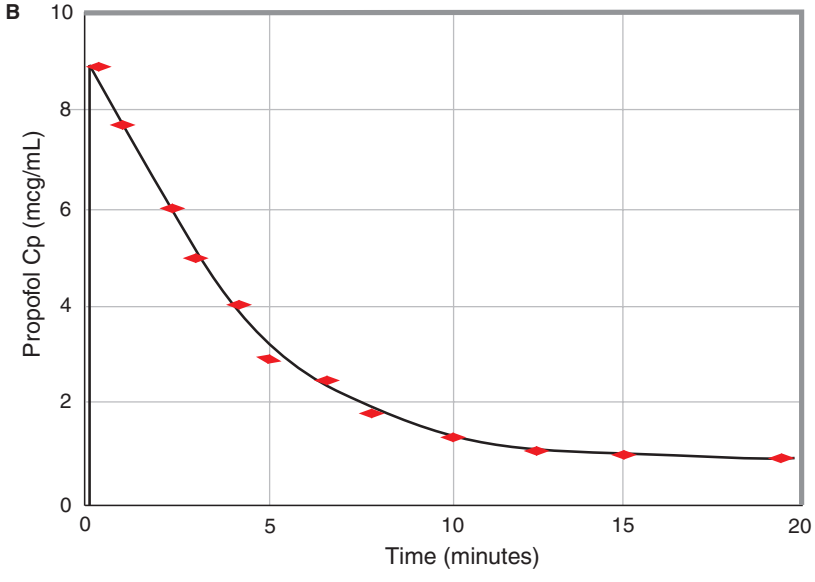
To make parameters more meaningful, these equations often are reparameterized (converted) in terms of *distribution volumes* and *clearances* or intercompartmental micro *rate constants*. Distribution volumes and clearances are used to create compartmental models that provide a schematic representation of drug behavior (Fig. 39–2A).

Unimportance of Individual Parameters

It is difficult for clinicians to take advantage of compartment models and the mathematical equations that represent them in a clinical setting. Consideration of individual volumes of distribution or clearance parameters in formulating a dose of anesthetic that accounts for the complex interplay of the parameters is impossible for humans to do in real time.

As an example of this complexity, consider the illustration in Fig. 39–2B. As a metaphor of a compartment model, tracking loans and bank accounts over time provides insight into what is required to estimate drug concentrations in the body over time. Consider a person with an income of $2,900 that is deposited into his/her bank account each month. From this bank account there are two monthly withdrawals to pay for credit card debt and mortgage payments. The credit card debt has a high interest rate (18%) with a debt load of $10,000. The mortgage has a low interest rate (5.5%) and a balance of $100,000. The monthly payments to each are $200 and $900 to the credit card and mortgage companies, respectively. In addition, each month there is a monthly expenditure of $1,000 for savings and daily living operating costs. Assuming no other expenses, how much money will be in the bank (central compartment) in 21 months? It is clear that without the use of a computer, calculating the answer to this question is impossible. Hence, using compartmental models without computer support makes them not very useful in a clinical environment.





C

$$C_p(t) = Ae^{-\alpha t} + Be^{-\beta t}$$

FIGURE 39–1. Development of a pharmacokinetic model, using propofol as an example. **A.** Raw data. Drug levels (*red diamonds*) are repeatedly measured over time. **B.** Analyzed data. A drug disposition curve (*black line*) is fit to the raw data using an exponential equation based on a computerized nonlinear regression analysis. **C.** The equation is simply a mathematical representation of curves of the general shape that "fit" the data. The nonlinear regression "curve fitting" exercise results in a set of parameters (in this example, A, B, α, and β) that, when plugged into the equation, reproduces the curve through the data. Cp(t) represents the plasma propofol concentration as a function of time (t). This is the mathematical basis of the pharmacokinetic model that clinicians need not worry about!

Importance of Simulations

The real power from these pharmacokinetic parameters and compartment models comes through simulation. Because little insight into a drug's pharmacokinetic profile can be gleaned from simple inspection of its multicompartment pharmacokinetic parameters, computer simulation of the expected rise and fall of drug concentrations using a drug's pharmacokinetic parameters has assumed an important role in modern pharmacokinetic research and analysis. Making use of population pharmacokinetic parameters estimated in research studies, computers can be programmed to simulate the concentration versus time profile that results from any combination of boluses and/or continuous infusions. Although such simulations are subject to certain limitations, they are intuitive graphic representations of the time course of drug concentration.[2]

For example, Fig. 39–3 illustrates a set of simulations of propofol using pharmacokinetic parameters from the literature.[3] In these simulations, the temporal profile of plasma propofol levels that result from various bolus doses is plotted over time. From these plots it is possible to visualize the peak plasma propofol concentration attained and the time propofol levels remain present in the plasma.

Without the aid of a computer, these simulations would be impossible. Although the simulations are limited by the quality of the original research from which the pharmacokinetic parameters were estimated and the inherent variability of pharmacokinetic parameters from patient to patient, the simulations are nonetheless a graphic representation of a drug's expected clinical pharmacokinetic profile and provide an excellent framework within which to formulate a rational dosing strategy.

Context-Sensitive Half-Times

Computer simulation has been useful in demonstrating how estimating drug behavior based on individual kinetic parameters such as terminal half-lives can be misleading.[1] Clinicians have traditionally relied on terminal half-lives as a reflection of the duration of drug action when, in fact, terminal half-life alone is not a very useful pharmacokinetic parameters.[4] To that end, techniques have been used to predict the time necessary to achieve a 50% decrease in drug concentration after termination of variable-length continuous infusions. Approaches in simulation have been developed to provide a *context-sensitive-half time* or *50% decrement time* where "context" refers to the duration of a continuous infusion.[5] Such simulations are intended to provide more clinically relevant parameters than "half-life" or "volume of distribution."[6]

Fig. 39–4 is a graphical representation of context sensitive half-times for selected opioids and sedatives using

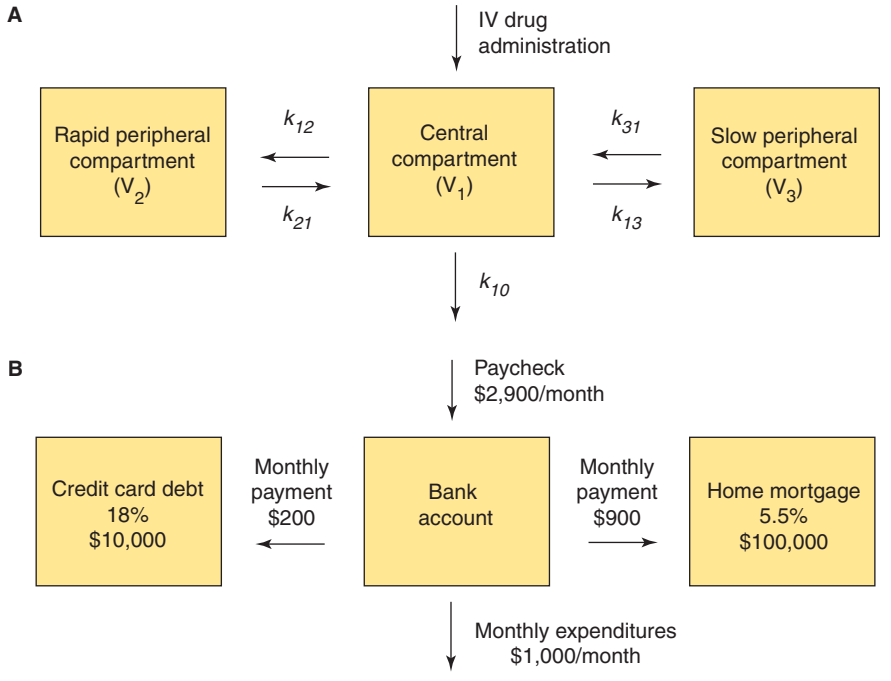


FIGURE 39–2. Mathematical complexity of the three-compartment model. **A.** Schematic of a three-compartment model. The k parameters represent rate constants. The V parameters represent the compartment volumes. **B.** Metaphor of a three-compartment model: cash flow through multiple accounts.

parameters from the literature.[3,7–11] As can be appreciated in Fig. 39–4A, clinically relevant information is easily gleaned from the plot that compares the context-sensitive half-times for propofol, etomidate, and midazolam. Here propofol and etomidate have a more rapid decrement time than midazolam for any continuous infusion of duration >30 minutes. This illustrates why a prolonged continuous infusion of midazolam is a poor choice if rapid emergence is an important anesthetic goal. By contrast, propofol and etomidate have a much more forgiving profile for prolonged continuous infusions. Even for infusions lasting >8 hours, for example, the time required for propofol to decrease by 50% is <20 minutes. This feature of propofol makes it an attractive drug when delivering prolonged intravenous anesthetics. Although etomidate has a favorable pharmacokinetic profile for prolonged infusions in comparison to midazolam, it has other features that make it unattractive for prolonged use, such as nausea and vomiting, hemolysis, and adrenal suppression.[12]

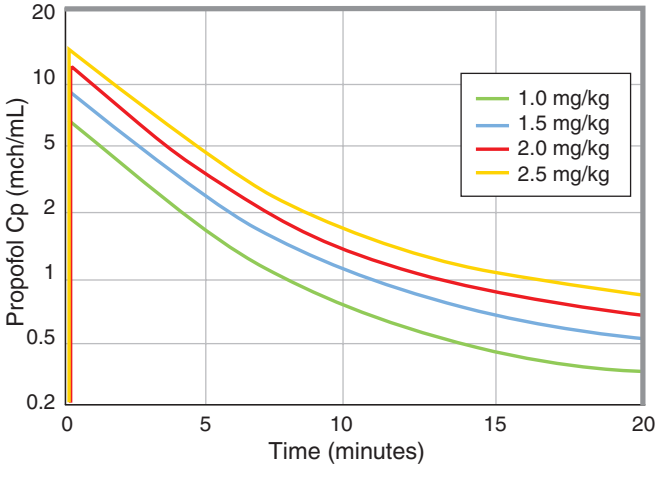

FIGURE 39–3. Simulations of four different bolus doses of propofol ranging from 1–2.5 mg/kg. The vertical axis is on a log scale.

With regard to opioids, sufentanil appears to have more favorable pharmacokinetics for infusions lasting <8 hours compared to fentanyl when the goal is to achieve a rapid 50% decrease in concentration. This difference can be explained by the fact that sufentanil's pharmacokinetic model has a large, slowly equilibrating peripheral compartment that continues to fill after termination of an infusion, thus contributing to the faster decrease in sufentanil central compartment concentration. In other words, central compartment sufentanil concentrations (which is the compartment that drives drug effect) fall rapidly after an infusion <8 hours is stopped because of continued elimination and distribution.[5,13]

Unlike sufentanil, fentanyl exhibits an early time-dependent increase in the context-sensitive half-time. Although fentanyl would be a poor choice for clinical situations where a rapid decrease in concentration after infusion termination is desirable, it might well be the drug of choice in clinical scenarios where prolonged opioid effect is the goal. For example, fentanyl is well suited for cases after which the patient's trachea will remain intubated for a period of time after the procedure in order to promote a gradual emergence from anesthesia and a long-lasting level of significant analgesia.

Note that for cases of very brief duration, the context-sensitive half-times for sufentanil and fentanyl are nearly identical. Thus, for brief applications, when the opioid is administered by infusion (or by frequent, small bolus doses), there would be no substantial differences among these drugs in the time to a 50% decrease in concentration after stopping a continuous infusion.

Remifentanil, in contrast to both sufentanil and fentanyl, has a very short context-sensitive half-time for infusions of any duration. This feature may be attractive during procedures associated with varied surgical stimuli where giving longer-acting opioids such as fentanyl or sufentanil to blunt the response to noxious stimulation may prolong emergence or increase the chance of unwanted respiratory depression. Remifentanil's short context-sensitive half-time may be useful in cases

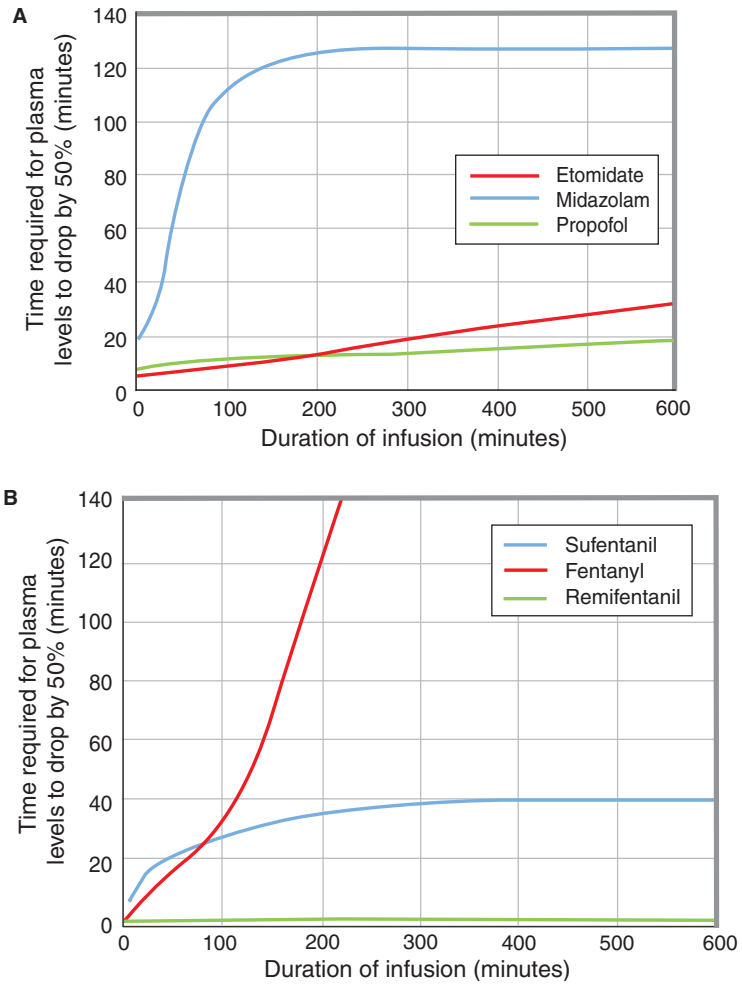

FIGURE 39–4. Simulations of the context-sensitive half-life (or 50% decrement time) for selected sedatives (**A**) and opioids (**B**). The vertical axis represents the time required for plasma concentrations to decrease by 50% once a continuous infusion is terminated. The horizontal axis represents the duration of a continuous infusion.

where timely postoperative neurologic assessments are warranted to rule out developing neurologic deficits following neurosurgical procedures. Remifentanil, on the other hand, may be a poor choice as a prolonged infusion in cases associated with significant postoperative pain (e.g., total hip arthroplasty). In this setting, once a continuous infusion of remifentanil is terminated, without the addition of a "transition" analgesic, patients can become remarkably uncomfortable once remifentanil plasma levels wane.

Although the 50% decrement time is an improvement compared with the use of the terminal half-life for estimating how anesthetic drugs will behave, it is not always relevant. Depending on the dose and pharmacokinetic features of a particular drug, the 50% decrement time may not adequately describe drug behavior that is of clinical interest (i.e., when will the analgesic effect of my intravenous opioid infusion dissipate after the infusion is terminated?). To get beyond this limitation, other decrement times can be used, such as the 20% or the 80% decrement time, to tailor the pharmacokinetic description of drug behavior to a clinical end point of interest.[6,13]

Importance of Biophase

Biophase refers to the equilibration delay between peak drug levels in the blood or plasma and peak drug effect. The time lag (or *hysteresis*) between peak concentration in the plasma and peak drug effect is a function of drug movement into and action within the effect site.[14–16] The effect site represents a theoretical space without any definitive anatomic analogue where drug exerts its effect. The lag time represents a summation of events that can impact the onset of pharmacologic effect, such as drug diffusion to the effect site, receptor binding, etc. (Fig. 39–5A). The hysteresis is important to account for when forecasting drug effect. It is particularly important to consider when simulating bolus injections of drug, whereas for long infusions the time lag assumes less importance because the effect site and plasma are generally closer to equilibrium.

Consider again a 2 mg/kg bolus of propofol and the observed changes in a processed electroencephalographic (EEG) parameter such as the bispectral index scale (BIS). The maximal decrease in the BIS lags behind the peak plasma propofol level (Figure 39–5B). The time delay, or hysteresis, represents the time required for propofol to go from the plasma to the site where it exerts an effect. In other words, most drugs do not work in the plasma.

For many drugs, including propofol, the equilibration delay between peak concentration in the plasma and peak effect has been characterized by estimating a parameter called k_{eo}. The k_{eo} represents the rate constant for elimination of drug from a virtual compartment called the *effect site* (Fig. 39–5C).[15,17] The effect site concept is schematically represented as an additional compartment in the three-compartment model (Fig. 39–6). When the k_{eo} parameter is available for a drug, theoretical effect compartment concentrations can be simulated along with plasma concentrations, thus making the effect of the time lag easily appreciated. In essence, the time course of effect site concentrations should accurately predict the time course of drug effect.

One of the useful clinical features of simulating the effect site concentration is that the time required to reach peak effect can be easily visualized. Fig. 39–7 presents simulations of the effect concentration over time for selected sedatives and opioids following commonly used doses for each drug. It is readily apparent that some intravenous anesthetics reach their peak effect site concentrations for a given dose much later than do others (Table 39–2).

Midazolam, for example, requires up to 9 minutes to reach peak effect in contrast to propofol and etomidate. This may explain why the early use of midazolam for endoscopic procedures was associated with adverse events related to excessive sedation.[18–20] One misleading characteristic of midazolam is that it has a rapid onset of effect (i.e., some effect is apparent soon after injection) but a latency to peak effect that is slower

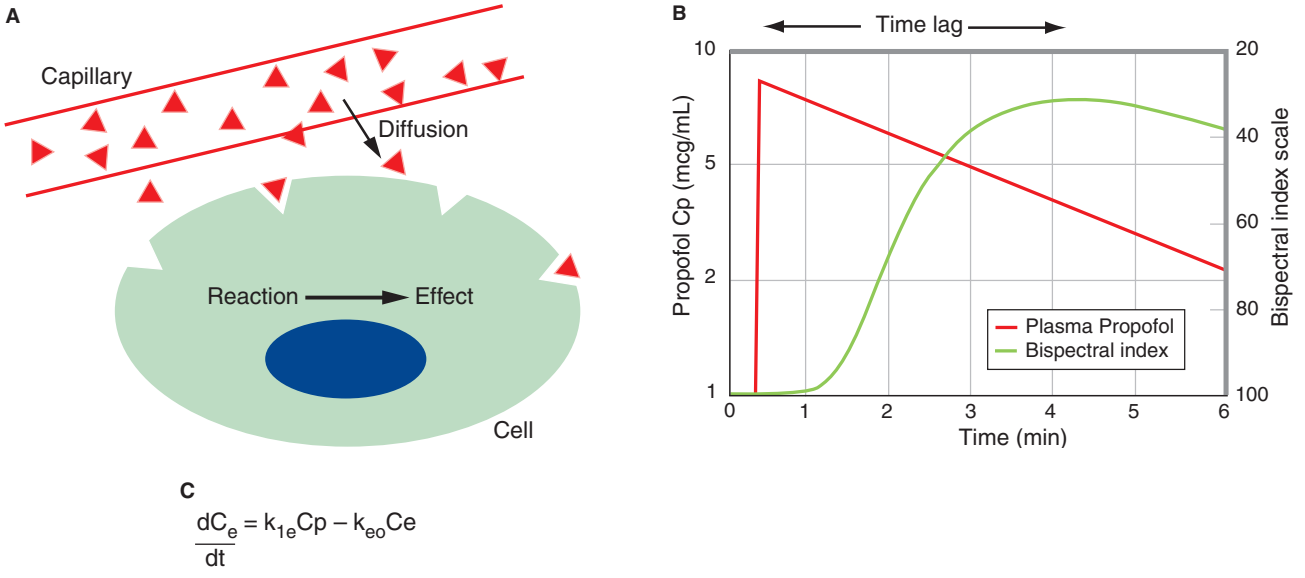

FIGURE 39–5. Biophase concept. **A.** Schematic of drug (*blue triangles*) diffusion from a blood vessel to the site of action (effect site), in this case, a cell membrane. Drug interaction with a cell membrane receptor produces a biochemical reaction that leads to a drug effect. **B.** Simulation of plasma propofol levels and bispectral index scale (BIS) following a 2 mg/kg propofol bolus to a 70-kg person. The red and green lines represent the plasma propofol concentration and BIS, respectively. The right-side vertical axis for BIS has been reversed. Note the time (hysteresis) lag between the peak propofol plasma level and the peak BIS value. **C.** Mathematical expression used to compute the effect site concentration. k_{1e} and k_{eo} represent the elimination rate constants from the central (Cp) and effect site (Ce) compartments, respectively. Although important for modeling, this is another mathematical detail that the clinician need not worry about!

relative to some other sedatives. In instances where a desired effect has not been reached within 90 seconds, practitioners may be tempted to administer additional midazolam. This may lead to a peak effect site concentration that is excessive and, by comparison to other sedative–hypnotics, delayed in presentation. This underscores the importance of using caution when administering large doses of intravenous midazolam.

By contrast to midazolam, etomidate and propofol, given as a bolus dose under normal hemodynamic conditions, reach their peak effect within 2 minutes following administration and then quickly dissipate. With these agents, if a desired effect has not been achieved within 120 seconds, practitioners may be inclined to give additional drug knowing that the previous doses are already waning.

With regard to opioids, following a bolus dose, the time required to reach peak effect site concentrations for remifentanil is considerably quicker than that of fentanyl and sufentanil. The clinical implications of this difference may be considerable when these drugs are administered to patients breathing spontaneously. Remifentanil by bolus injection may lead to a more pronounced respiratory depression when compared to equipotent doses of sufentanil or fentanyl. With the slower onset of effect for fentanyl and sufentanil, blood PCO_2 levels are given time to rise, providing some offset to the respiratory depression associated with opioids. With remifentanil, the onset of effect outpaces the accumulation of blood PCO_2, leading to more pronounced respiratory depression.[21–23]

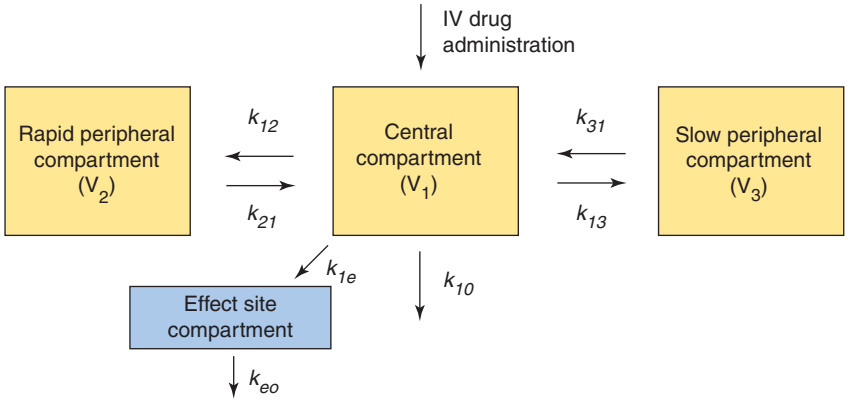

FIGURE 39–6. Effect site compartment concept. Addition of the effect site to a three-compartment model. k_{1e} and k_{eo} (in blue) represent the elimination rate constants from the central and effect site compartments, respectively. Drug effect correlates with the concentration in the effect compartment.

Pharmacodynamics

Pharmacodynamic models have been constructed to describe the relationship between drug effect site levels and drug effect. Some important features of pharmacodynamic models are presented in Fig. 39–8. In this figure, a schematic illustrates how drug, once it reaches the effect site, interacts with a receptor to produce effect (Fig. 39–8A). This process is typically characterized graphically using a sigmoidal curve (Fig. 39–8B). Parameters used to describe the pharmacodynamic model (i.e., the sigmoid curve) include C_{50} and gamma (γ). C_{50} represents the effect site concentration at which 50% of the maximal drug effect will be elicited, and γ represents the slope of the concentration–effect curve. The most important part of the sigmoid curve, the steep section of the curve, represents the dynamic range of drug effect. The dynamic range charts the concentration–effect relationship from E_0 (baseline effect) to E_{max} (maximal ef-

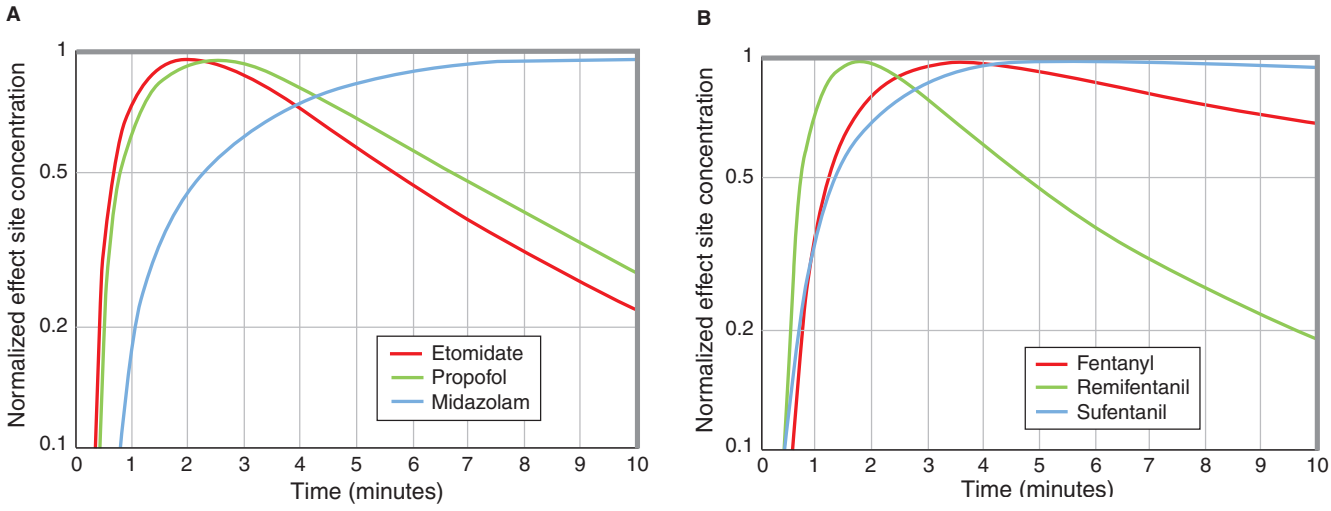

FIGURE 39–7. Latency to peak effect site concentration. Effect site concentrations over time for selected opioids (**A**) and sedatives (**B**) following conventional doses for each drug. The vertical axis has been normalized for all drugs such that 1 indicates the maximal effect site concentration.

fect). In this region, small changes in drug concentration lead to large changes in drug effect. This is the region of particular interest to anesthesia providers. Increasing effect site concentrations beyond the dynamic range leads to minimal changes in drug effect. The mathematical expression that uses C_{50} and γ to estimate drug effect is presented in Fig. 39–8C.

A surfing analogy is helpful in conceptualizing the application of pharmacodynamic models to rational drug administration.[24] Just as a surfer attempts to ride just in front of the crest of a wave in order to slide down the front edge of the wave, practitioners attempt to maintain their anesthetic drugs at effect site concentrations near the "crest" of the concentration–effect relationship (Fig. 39–8B). In so doing, clinicians maintain significant drug effect but can "slide down" the concentration curve to promote recovery at the end of an anesthetic. From an efficacy and toxicity perspective, there is no advantage of being on the flat part of the concentration–effect relationship near E_{max}.

As an example, consider three bolus doses of propofol (0.5, 2, and 7 mg/kg). The resultant effect site concentrations for each bolus are presented in Fig. 39–9. Using a pharmacodynamic model for propofol, the effect of these boluses is plotted on a sigmoid curve. The C_{50} for this curve (1.8 µg/mL) represents the effect site concentration at which there is a 50% probability of loss of responsiveness.[25] Dosing regimens that maintain drug concentrations along the lower left portion of the sigmoid curve (i.e., below the wave) are too low to be effective, as illustrated by the low-dose propofol bolus (0.5 mg/kg). Dosing regimens that maintain drug concentrations to the right side of the sigmoid curve (i.e., before the wave breaks) are excessive and may produce unwanted hemodynamic depression or prolonged recovery. In this region, increasing drug concentration does not increase drug effect. This phenomenon is illustrated by the 7 mg/kg bolus dose of propofol. The ideal dosing strategy targets the upper portion of the steep part of the concentration–effect relationship, a concentration that produces considerable drug effect but from which drug effect will recover quickly once drug administration is terminated as illustrated by an intermediate dose of propofol (2 mg/kg).

One practical aspect of anesthesia care that makes pharmacologic "surfing" difficult is that the concentration–effect relationship is not consistent across various stimuli. For some stimuli, much less drug is required to achieve a desired effect compared to other stimuli. For example, skin incision typically is less noxious than laryngoscopy.[26–28] In an effort to characterize how different stimuli vary, numerous pharmacodynamic models have been built for selected stimuli.

The schematic presented in Fig. 39–10 plots out the relative difference between pharmacodynamic models for opioids across various stimuli. Effect measures used to characterize opioid behavior include mild to moderate analgesia (i.e., blunting response to a noxious stimulus), respiratory depression, significant analgesia (i.e., blunting response to laryngoscopy), and suppression of EEG activity. As expected, the pharmacodynamic relationship for each stimulus is very similar (a sigmoid curve), but the C_{50} values are shifted from left to right with increasing stimulus. Several important points flow from this schemat-

TABLE 39–2.

Time to Peak Effect for Selected Opioids and Sedative–Hypnotics

Drug	Dose	Peak Effect Site Concentration	Time Required to Reach Maximal Effection
Opioids			
Fentanyl	150 µg	1.5 ng/mL	39 min
Sufentanil	15 µg	0.2 ng/mL	5.5 min
Remifentanil	150 µg	8.6 ng/mL	1.5 min
Sedatives			
Propofol	2 mg/kg	4.8 µg/mL	2.3 min
Etomidate	0.2 mg/kg	0.6 µg/mL	2.0 min
Midazolam	2 mg	22.0 ng/mL	9.5 min

Simulations based on a body weight of 70 kg.

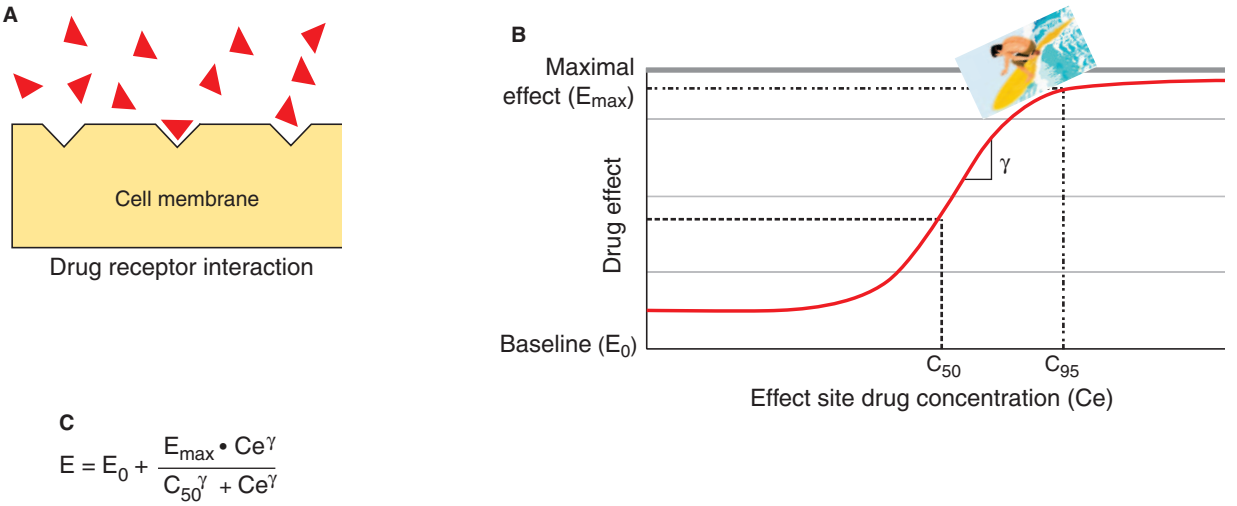

FIGURE 39–8. Typical pharmacodynamic model. **A.** Schematic of the pharmacodynamic process. Drug (*red triangles*) interact with receptors in the effect site to elicit a drug effect. **B.** Graphic expression of pharmacodynamic drug behavior. E represents drug effect, C_{50} represents the effect site concentration necessary to produce 50% of the maximal drug effect, E_0 represents the baseline effect (with no drug present), and E_{max} represents the maximal effect. The vertical axis is on the log scale. The sigmoid shape of the concentration versus effect curve is characteristic of intravenous anesthetics. γ represents the maximal slope of the concentration versus effect curve. A surfing analogy is useful to understand the application of the pharmacodynamic model. As the surfer rides just below the crest of a wave, anesthesia providers attempt to dose their anesthetics to achieve near maximal effect just at the point where the sigmoid curve starts to flatten out. The dashed line represents the concentration at which 50% of the maximal effect is achieved. The dash-dot-dash line represents the concentration at which 95% of the maximal effect is achieved. **C.** Mathematical expression of the pharmacodynamic model used to render the concentration versus effect curve in B. This is the mathematical basis of the pharmacodynamic model that clinicians need not worry about.

ic, especially for the meticulous clinician who seeks to "surf" near the ideal Ce and thus achieve the desired drug effect without administering a relative overdose. (1) Significant analgesia is required to blunt the response from laryngoscopy compared to other stimuli encountered in the operating room. (2) The C_{50} for the effect site concentration necessary to blunt a response to laryngoscopy is higher than the C_{50} for respiratory depression. (3) Dosing anesthetics requires an appreciation of ongoing and anticipated stimuli. (4) There is a window in opioid levels between which analgesia can be achieve yet excessive respiratory depression can be avoided. Investigators have demonstrated that the C_{50} for analgesia is approximately 30% of the C_{50} for respiratory depression.[26] This may be especially important during emergence from anesthesia.

Importance of Combining Kinetic and Dynamic Models

In order to depict a patient's response to a dose of drug, it is necessary to combine pharmacokinetic–pharmacodynamic models and provide a quantitative description of each. Because most drugs do not act in the blood, pharmacokinetic and pharmacodynamic models must be linked so that concentrations in the plasma can be translated into effect site concentrations and thus drug effect. One approach to visualize the link between pharmacokinetics and pharmacodynamic models is to plot a horizontal line on the pharmacokinetic plot of effect site concentrations over time

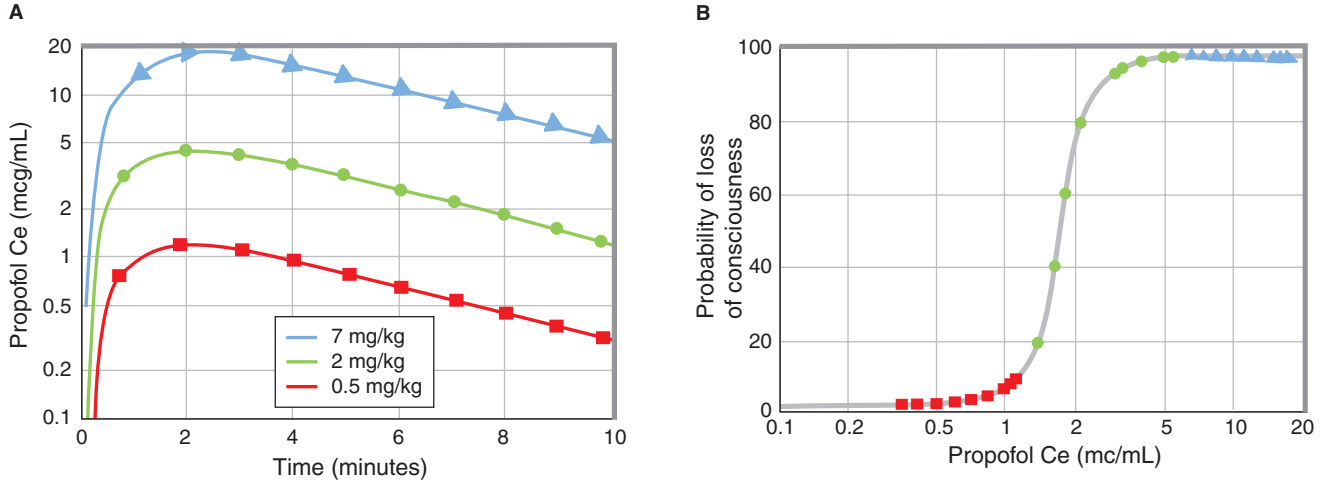

FIGURE 39–9. Simulation integrating pharmacokinetic and pharmacodynamic models illustrating the interplay between the dose–concentration (pharmacokinetic) relationship and the concentration–effect (pharmacodynamic) relationship. **A.** Simulation of propofol effect site concentrations over time for bolus doses of 0.5 mg/kg (*red squares*), 2 mg/kg (*green circles*), and 7 mg/kg (*blue triangles*). **B.** Corresponding concentration versus effect of the bolus doses shown in A superimposed over a pharmacodynamic model for propofol.

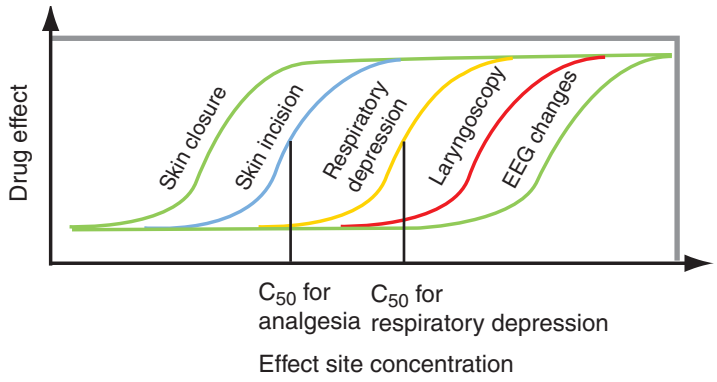

FIGURE 39–10. Schematic of the concentration–effect relationship for various stimuli.[26] Anesthesia is a dynamic process that requires frequent adjustments of drug levels.

that represents the C_{50} for a desired drug effect. Two key points of interest are now easily visualized through computer simulation: (1) the time to onset of effect and (2) the duration of drug effect.[4,29,30]

For example, using linked pharmacokinetic and pharmacodynamic models, the simulations of propofol bolus doses ranging from 1–2.5 mg/kg presented in Fig. 39–3 can be reperformed for effect site concentrations rather than plasma concentrations (Fig. 39–11). To visualize the onset and duration of effect, the C_{50} for loss of responsiveness is overlaid on the simulations of propofol effect site concentrations. Several investigators have estimated propofol effect site concentrations required for loss of responsiveness with C_{50} values ranging from 1.8–2.4 μg/mL.[25,31–33] For simulation and discussion purposes, the C_{50} for loss of responsiveness to be used in these simulations and throughout the remainder of this chapter is 1.8 μg/mL. A summary of the time to onset and duration of effect for each propofol bolus dose is presented in Table 39–3. It is important to point out that this C_{50} for loss of responsiveness, like all pharmacokinetic and pharmacodynamic parameters, is a population estimate for the typical patient and as such is subject to intersubject variability and will not perfectly predict unresponsiveness in individuals.

Guided by simulations, the clinical implications of a given propofol dosing strategy become apparent. For example, using a higher dose of propofol as part of a rapid sequence induction, if hemodynamically tolerable, may prove useful in minimizing the time when the airway is unsecured because of faster onset of effect. By contrast, a lower dose may be useful when providing anesthesia for brief procedures associated with a noxious stimulus, such as a retrobulbar block, where only brief unresponsiveness is required. When using the lower dose, however, practitioners need to recognize that it will take up to 50 seconds longer to achieve loss of responsiveness.

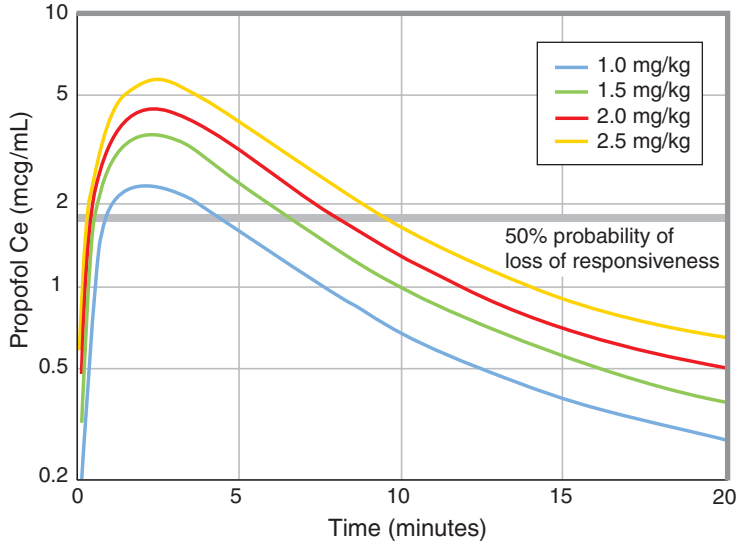

FIGURE 39–11. Simulations of propofol effect site concentrations in response to bolus doses ranging from 1–2.5 mg/kg for a 70-kg person. The vertical axis is on the log scale. The gray line represents the propofol effect site concentration associated with a 50% probability of loss of responsiveness.[25,31–33] Note the time to loss of responsiveness and the duration of the loss of responsiveness for varying doses.

TABLE 39–3.

Onset and Duration of Effect Following a Propofol Bolus

Dose	Time to Onset	Duration of Effect
1.0 mg/kg	80 sec	3.7 min
1.5 mg/kg	50 sec	6.9 min
2.0 mg/kg	40 sec	8.0 min
2.5 mg/kg	30 sec	9.5 min

Simulations may also be useful in illustrating how drugs behave in relation to an unwanted toxic effect. Consider a plot of fentanyl effect site concentrations for various doses of fentanyl and the concentration at which probability of substantial respiratory depression exceeds 50% (i.e., somewhere around 3.5 ng/mL) in 60-, 80-, and 100-kg people (Fig. 39–12).[34] In this simulation, the bolus of 100- and 150-mg fentanyl prevents respiratory depression for each weight. However, the 250-μg bolus exceeds the effect site concentrations associated with a 50% probability of respiratory depression for people weighing 60 and 80 kg for 7 and 13 minutes, respectively. According to these simulations, persons weighing 100 kg or more briefly approach the fentanyl effect site concentration associated with a 50% probability of respiratory depression but do not exceed it.

Linked pharmacokinetic–pharmacodynamic models can provide insight into how drugs behave following termination of continuous infusions. Factors that influence the duration of effect following termination of an infusion include (1) the infusion rate and (2) the duration of the infusion. For example, consider the time required to regain responsiveness following termination of a continuous infusion of

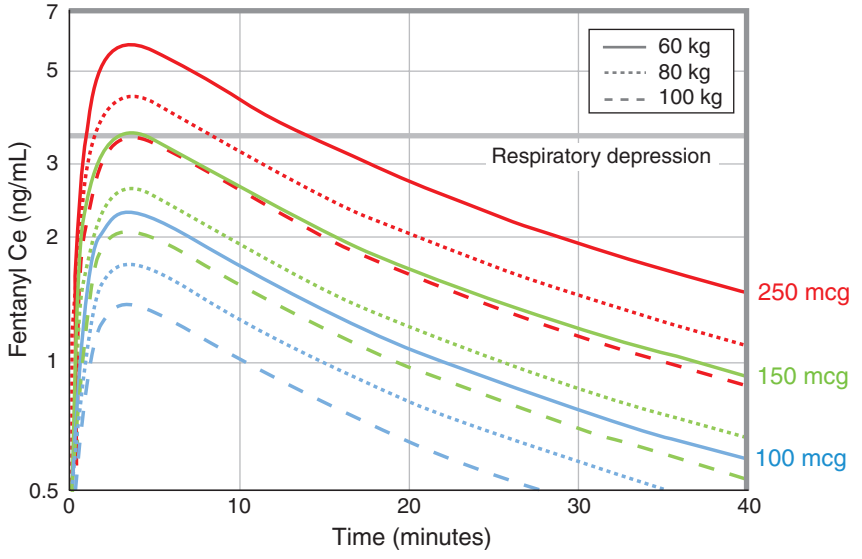

FIGURE 39–12. Simulations of the fentanyl effect site concentration following a 100-, 150-, and 250-μg bolus in a 60-, 80-, and 100-kg person. The fentanyl effect site concentration associated with a 50% probability of substantial respiratory depression is plotted as a gray line (3.5 ng/mL).[34] The vertical axis is on a log scale. Note the implication of dose on respiratory depression.

propofol. Fig. 39–13 shows a series of simulations of the resultant propofol effect site concentration following continuous infusions at rates between 50 and 150 μg/kg/min for 1, 2, and 3 hours. As with the previous simulations of bolus dosing of propofol, the plot also charts the propofol effect site concentration associated with a 50% probability of loss of responsiveness (1.8 μg/mL).[25]

The area of interest is the segment of time from when the infusion is terminated until the propofol effect site concentration falls below the level associated with a loss of responsiveness. The results of these simulations are summarized in Table 39–4. Once the infusion was terminated, longer propofol infusions at equivalent dosages required more time for propofol levels to drop below a level associated with unresponsiveness. As expected, once the infusion was terminated, higher propofol infusion rates required more time to drop below a level associated with unresponsiveness. With higher infusion rates, the time to regaining responsiveness can be quite long (i.e., up to 13 minutes).

Conceptualizing this clinical issue in terms of compartmental models, these simulations illustrate how during prolonged infusions propofol gradually "fills" the slowly equilibrating peripheral compartments (extravascular tissues). When the infusion is terminated, the propofol in the peripheral compartments serves as a reservoir to maintain plasma propofol concentrations, thereby slowing the decline in drug effect. This may be clinically evident as a delay in emergence. These simulations also suggest that running a propofol infusion at a single continuous rate throughout an anesthetic will lead to propofol effect site levels that are higher than desired. Therefore, a prudent approach to dosing prolonged propofol infusion is to reduce the infusion rate over time to minimize drug accumulation. This accumulation phenomenon emphasizes the advantage of target controlled infusions that, instead of delivering drug at a set rate (i.e., micrograms per kilogram per minute), deliver drug to achieve and maintain a set effect site concentration (i.e., 2.5 μg/mL for propofol). In so doing, they avoid accumulation of drug yet maintain an appropriate drug level for the desired duration. These types of infusion systems are widely used throughout the world, but they have not attained regulatory approval within the United States.[24]

This form of analysis may be useful when exploring the duration of analgesic effect from fentanyl following surgical procedures of various durations. A common practice is to administer intermittent boluses of fentanyl starting at induction and then throughout a general anesthetic with the goal of providing perioperative analgesia during and following a stimulating procedure. Consider an anesthetic where fentanyl, in addition to a potent inhaled agent, is given as a bolus (3 μg/kg or approximately 200 μg for a 70-kg patient) on induction and then intermittently (i.e., 1.5 μg/kg or approximately 100 μg for a 70-kg patient every 20 minutes) throughout a surgical procedure associated with significant painful stimuli.

Simulations of this fentanyl dosing regimen for anesthetics lasting 1, 2, and 3 hours reveal several clinical points of interest (Fig. 39–14). For a 1-hour anesthetic with an induction dose of 200 μg of fentanyl followed by two supplemental 100-μg doses during the anesthetic, the total fentanyl dose administered is 400 μg (8 mL). With this dosing regimen, the fentanyl effect site concentration intermittently rises above the fentanyl effect site concentration associated with analgesia (1.6 ng/mL)[35] but rapidly drops below the analgesic level once the anesthetic is terminated.

Simulations of the 2- and 3-hour anesthetics using a similar dosing scheme result in total fentanyl doses of 700 and 1000 μg (14 and 20 mL). With the longer duration, the fentanyl concentration rises above the effect site level associated with analgesia. In this simulation, it becomes apparent that repetitive doses increase the fentanyl concentration at the end of a 3-hour anesthetic; the resulting effect site concentration of fentanyl is much higher than after the 1-hour anesthetic. Following termination of the anesthetic, the time required for the fentanyl effect site concentrations to decrease below the level associated with analgesia was 9 and 57 minutes for a 2- and 3-hour anesthetic, respectively. Similar to what was learned from the simulations of the context-sensitive half-time for fentanyl, prolonged infusions or repetitive dosing of fentanyl over prolonged periods can lead to high fentanyl effect site concentrations. High fentanyl levels may be of clinical benefit (i.e., adequate analgesia following a painful surgical procedure) or be a detriment (prolonged respiratory depression) in the early postoperative period. These simulations demonstrate the potential benefit of visualizing fentanyl effect site concentrations in real time when caring for patients for whom the anesthetic goals upon termination of a general anesthetic include adequate analgesia yet avoidance of unwanted respiratory depression.

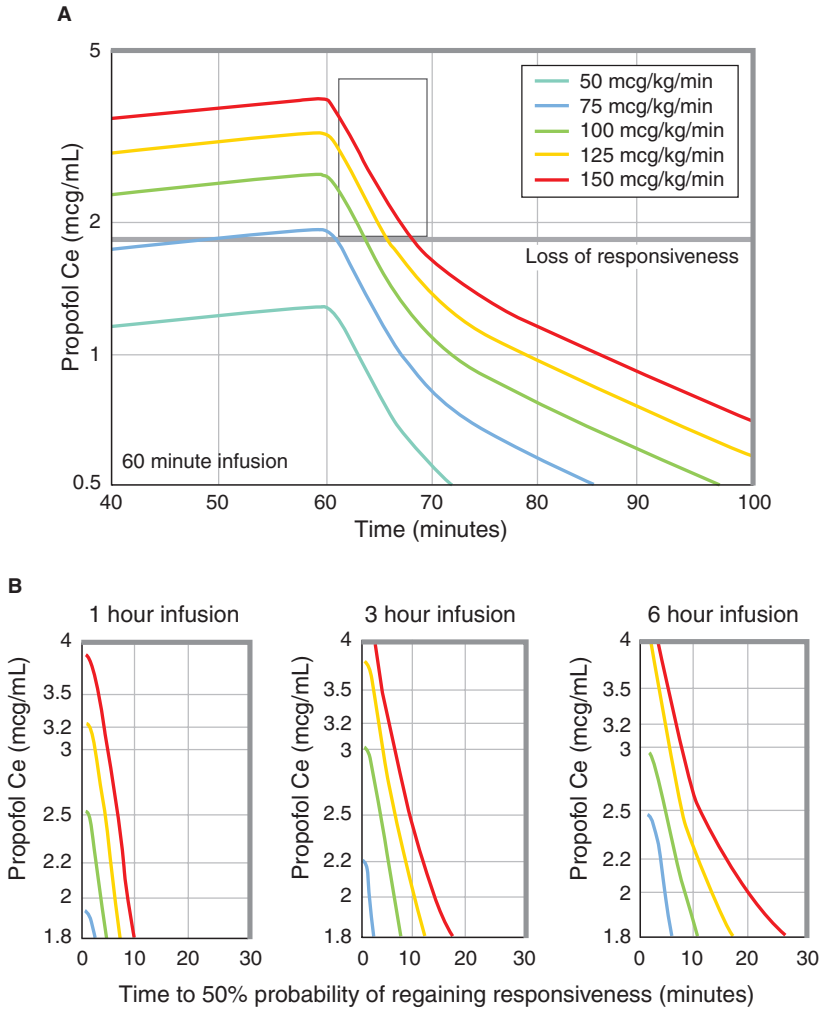

FIGURE 39–13. **A.** Simulation of a 60-minute infusion of propofol at rates ranging from 50–150 µg/kg/min. At 60 minutes the infusion is terminated. Superimposed on this plot is the effect site concentration (Ce) associated with a 50% probability of loss of responsiveness (*gray line*).[25,31–33] Of interest is the time required once the infusion is terminated for the propofol effect site concentration to fall below the concentration associated with loss of responsiveness (*black box*). **B.** Plot within the black box expanded for three different infusion durations (1–6 hours). Following termination of the continuous infusion, the time on the x axis has been reset to 0 for each plot. Each plot illustrates the time required for propofol effect site levels to drop below the propofol concentration associated with a loss of responsiveness for infusion rates commonly used in clinical practice. Simulations used pharmacokinetic and pharmacodynamic parameters for propofol reported by Marsh et al.[8] and Kern et al.,[25] respectively.

TABLE 39–4.

Time Required for Propofol Effect Site Concentrations to Fall Below Levels Associated with Loss of Responsiveness for Various Infusion Rates Running for 1, 3, and 6 Hours

Infusion Rate (mg/kg/min)	Time Required for Propofol Ce to Fall Below Ce Associated with Loss of Responsiveness (min)		
	60-Min Infusion	180-Min Infusion	360-Min Infusion
50	—	—	—

Ce, Effect site concentration.

One important limitation of these simulations is that painful surgical procedures are rarely, if ever, performed with fentanyl alone. Other anesthetics, such as potent inhaled agents or intravenous sedatives, are used as well. Inhaled agents and intravenous sedatives accentuate the analgesic effect of opioids in a synergistic fashion. This limitation is addressed in Drug Synergism below. Thus, these simulations chart the effect of fentanyl alone and at best are representative of analgesic effect once other anesthetics that have been coadministered with the fentanyl have been allowed to dissipate. Hence, the segment of this simulation set reflective of the actual analgesic state is the fentanyl effect site concentrations well beyond (i.e., 20–30 minutes) the termination of the anesthetic.

Drug Synergism

Anesthetics typically are administered as a combination of several different types of drugs to achieve a desired complete anesthetic. Anesthesiologists have long appreciated that the administration of one type of drug may enhance and prolong the effect of another type of drug. The concept of minimum alveolar concentration (MAC) reduction is well established and used to describe how the addition of an intravenous opioid reduces the amount of a potent inhaled agent required to achieve and maintain a desired MAC. This line of thinking is especially important when trying to prevent unwanted side effects associated with high doses of a single anesthetic, such as hemodynamic depression, prolonged emergence from anesthesia, and persistent respiratory depression.

As clinical pharmacologists have become more sophisticated in their approach to characterizing the interaction between different anesthetic drug types, several tools have been developed to describe drug–drug interactions. One simple tool characterizes drug–drug interactions as additive (i.e., 2 + 2 = 4), antagonistic (e.g., 2 + 2 = 1), or synergistic (e.g., 2 + 2 = 8). These can be graphically illustrated to allow visualization of the extent of antagonism or synergism present between two drugs (Fig. 39–15). These drug interaction plots present the effect site concentrations for two drugs that are necessary to achieve specified

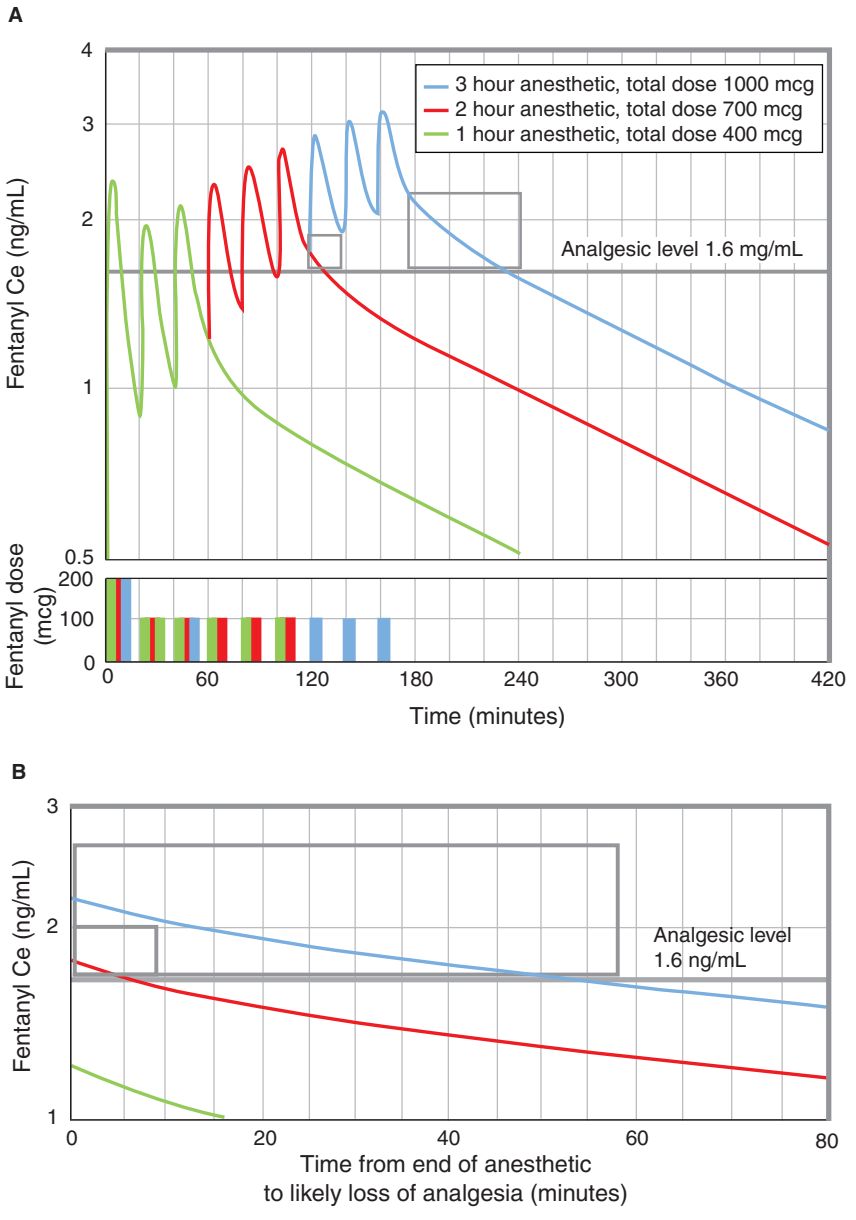

FIGURE 39–14. **A.** Simulation of intermittent doses of fentanyl for anesthetics lasting 1, 2, and 3 hours. The red line represents the fentanyl effect site concentration (Ce) that results from a 200-mcg bolus on induction followed by intermittent 100-mg boluses throughout the remainder of the anesthetic. The green bars just above the x axis represent the fentanyl dosing regimen. The red and blue lines represent the fentanyl Ce for similar dosing schemes that last for 2 and 3 hours, respectively. Superimposed on this plot is the Ce associated with analgesia (*gray line*). Of interest is the time required once the anesthetic is terminated for the fentanyl Ce to fall below the concentration associated with analgesia (*gray boxes*). **B.** Plots within the gray boxes have been expanded. Following termination of the anesthetic, the time on the horizontal axis has been reset to 0. This plot illustrates the time required for fentanyl Ce to drop below the fentanyl concentration associated with analgesia. These simulations used pharmacokinetic and pharmacodynamic parameters for fentanyl reported by Shafer et al.[9] and fentanyl Ce associated with analgesia (1.6 ng/mL) reported by Scott et al.[65] Simulations were based on a patient weight of 70 kg.

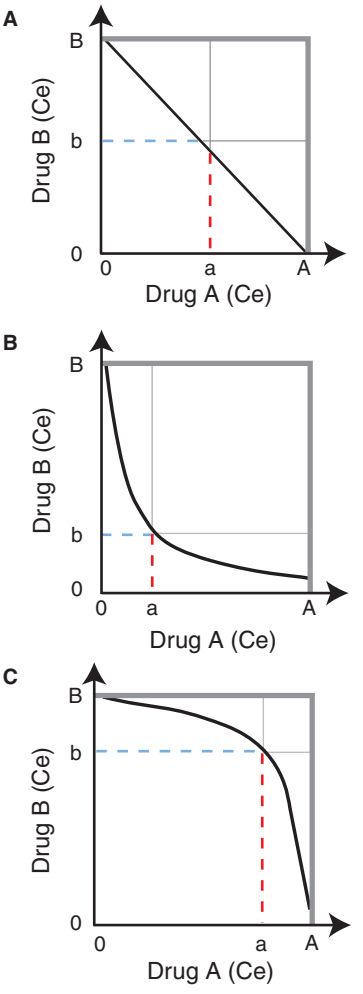

FIGURE 39–15. Schematic representation of drug–drug interactions. **A.** Additive interaction. **B.** Synergistic interaction. **C.** Antagonistic interaction. The horizontal and vertical axes represent the effect site concentration (Ce) of drugs A and B, respectively. A and B represent the concentrations of each drug required to achieve a similar effect when used alone. a and b represent the concentrations of drugs A and B that result in a similar effect when combined. The black lines represent an isobologram. An *isobologram* is a plot of all the drug–drug concentration pairs that result in the same level of drug effect. These schematics are patterned after schematics originally described by Minto et al.[36]

drug effects. In this schematic, a desired effect is achieved at point A on the horizontal axis and point B on the vertical axis. The points labeled a and b represent the concentrations of *both* drugs required to achieve a similar effect to either drug A or B alone. As can be appreciated, an infinite number of drug–drug combinations can result in a similar drug effect. The line that runs through all the possible drug–drug concentration pairs and that connects points A and B is known as an *isobologram*. The isobologram represents drug concentration pairs that would result in the same drug effect when the two drugs are used alone or in combination.

With drug–drug interactions that are additive, the isobologram is a straight line indicating that as drug A increases, proportionally less of drug B is required to achieve the same degree of effect (Fig. 39–15A). With drug–drug interactions that are synergistic, the isobologram is a curved line bowing toward the origin of the graph (Fig. 39–15B), indicating that when both drugs A and B are used, much less of both is required to achieve the same degree of desired effect. Conversely, with drug–drug inter-

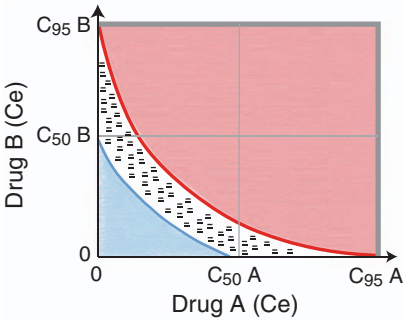

FIGURE 39–16. Schematic representation of a synergistic drug–drug interaction of drugs A and B for the probability of no response to a noxious stimulus. The red line represents the 50% isobole, and the blue line represents the 95% isobole. Area to the right of the 95% isobole (*shaded red*) represents drug–drug pairs that are higher than the 95% isobole. Area to the left of the 50% isobole (shaded blue) represents drug–drug pairs that are less than the 50% isobole. Area contained within the 50% and 95% isobole (*black hash marks*) represents drug–drug pairs that are between the two isoboles. The C_{50} and C_{95} effect site concentrations for drugs A and B are marked on the horizontal and vertical axes, respectively. Any of the infinite number of combinations of drugs A and B along the isoboles yields the same probability of drug effect.

actions that are antagonistic, the isobologram is a curved line bowing away from the origin of the graph (Fig. 39–15C), indicating that when both drugs A and B are used, much more of each is required to achieve the same degree of desired effect. Most interactions between anesthetic drugs are synergistic.

Common anesthetic goals can be characterized in terms of isobolograms. For example, isobolograms can be used to plot effect site concentration pairs necessary to achieve a 50% or 95% probability of achieving a desired drug effect (i.e., no response to laryngoscopy) or when a worrisome side effect may occur (i.e., onset of respiratory depression). Using these isobolograms, it is possible to explore through computer simulations how well an anesthetic performs in terms of meeting desired anesthetic goals.

For example, consider a schematic of a combined anesthetic technique using drug A (an opioid) and drug B (a sedative), which are known to have a synergistic interaction (Fig. 39–16). Drug delivery that yields concentration pairs to the left of the 50% isobole for no response to painful stimuli do not meet analgesic goals. With drug pairs in this region, patients most likely will respond to painful stimuli. Drug delivery that yields concentration pairs between the 50% and 95% isoboles likely will meet analgesic goals, but some patients may respond to a painful stimulus. In this region, once the anesthetic is terminated, the analgesic effect will quickly dissipate. With drug delivery that yields concentration pairs to the right of the 95% isobole, a patient is very likely to be unresponsive to painful stimuli, and increasing the anesthetic target will not substantially increase the probability of adequate effect. A key point with regard to this region of the isobole plot is that administering additional anesthetic will not provide more analgesia but rather will only prolong the time required for drug effect to dissipate, especially if the resultant concentrations have far exceeded the 95% isobole. A prolonged duration of effect may be a desired outcome (e.g., adequate analgesia following a surgery associated with significant postoperative pain) or an undesired outcome (e.g., delayed emergence following a prolonged surgery).

Because visualization of these complex interactions currently is not feasible in the clinical setting and clinicians are justifiably more frequently concerned with preventing awareness while patients are under anesthesia or exaggerated responses to painful stimuli than they are in promoting rapid emergence from anesthesia, most anesthetic techniques target concentration pairs that are substantially above the 95% isobole. In summary, to prevent unwanted consequences of light anesthesia, most practitioners tend to administer relatively excessive doses of anesthetics. For the majority of anesthetics, this practice is well tolerated. However, in patients who are sensitive to adverse consequences of excessive anesthesia, administering an anesthetic beyond the 95% isobole may be associated with adverse consequences.

In order to visualize the concentration interaction that two drugs have on a particular drug effect, such as analgesia, work has focused on the development of three-dimensional plots called *response surfaces*. Response surfaces portray the concentration–effect relationship for each drug individually (similar to a simple pharmacodynamic model) as well as paired concentration–effect (drug–drug interaction). Plotted on these surfaces are the effect site concentrations for two drugs (i.e., an opioid and a potent inhaled agent) over a range of concentrations of clinical interest and a measure of drug effect. The measure of drug effect typically is presented as a probability ranging from 0–1 (i.e., the probability of loss of responsiveness with a selected drug pair is 0.8). Many investigators have characterized response surfaces for a variety of drug–drug pairs and clinical relevant drug effects in human volunteers and patients. For example, surfaces have been developed for analgesia, loss of responsiveness to verbal and tactile stimulation, and laryngoscopy for propofol and remifentanil[25,31,33,36–41] and sevoflurane and remifentanil.[42]

To illustrate the visual power of response surfaces, consider a simulation of 90-minute total intravenous anesthetic using continuous infusions of propofol and remifentanil (Fig. 39–17). Simulated infusion rates are consistent with dosing recommendations for each drug. The resultant effect site concentrations for both drugs are plotted over time. With a bolus dose administered prior to starting a continuous infusion, therapeutic levels for each drug are quickly achieved and then maintained throughout the anesthetic. To visualize the combined analgesic effect of remifentanil and propofol, this anesthetic technique has been plotted out on a previously established response surface for analgesia (Fig. 39–18).[25]

With the concentration pairs of remifentanil and propofol plotted for the entire anesthetic on this response surface, two important features of the anesthetic technique are easily observed. First, remifentanil and propofol have a pronounced synergistic interaction. When given together, much less of both drugs is required to achieve a desired analgesic effect than if each drug were given individually. This is best illustrated by the 50% and 95% isoboles in Fig. 39–18B. Here, the isoboles bow inward and reveal that propofol when dosed to produce an effect site concentration of 1 μg/mL decreases the remifentanil needed to meet an analgesic goal by more than half. Of note, a propofol effect site concentration of 1 μg/mL by itself typically is enough to sedate patients but is not enough to render them unconscious.

Second, the dosing used in this total intravenous technique results in a combined drug–drug analgesic effect that, for the majority of the anesthetic, exceeds the 95% isobole for analgesia. The trajectory of the dosing regimen is

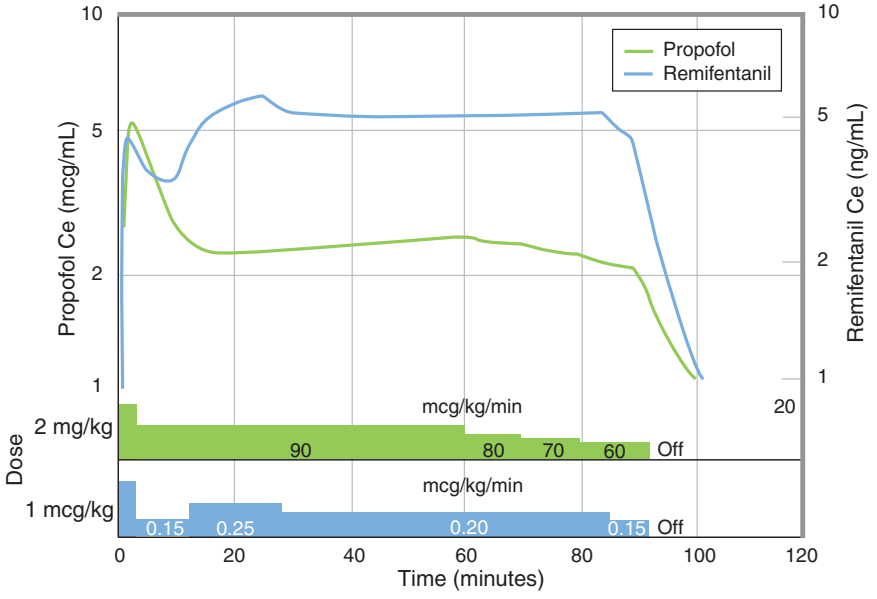

FIGURE 39–17. Simulation of a 90-minute total intravenous anesthetic with propofol and remifentanil. The propofol and remifentanil dosing regimens are presented along the horizontal axis. They include the induction bolus dose (in milligrams per kilogram for propofol and micrograms per kilogram for remifentanil) followed by the continuous infusion rates (in micrograms per kilogram per minute) for each drug. The propofol and remifentanil effect site concentrations that result from the dosing regimens are plotted over time.

color coded into three segments: *induction* (i.e., bolus doses of both drugs), *maintenance* (continuous infusions of both drugs), and *emergence* (termination of both drug infusions). It is interesting to note that the maintenance phase of the anesthetic exclusively occupies the relatively flat region on the surface. Maintaining an anesthetic that is so far removed from the 95% isobole is essentially unnecessary. With regard to analgesia, in this region additional anesthetic would not be expected to increase the analgesic effect. In the case of remifentanil and propofol, this practice may not be overly worrisome because both drugs exhibit a rapid decline in drug effect once infusions are terminated. With other opioid–sedative drug pairs, however, overdosing an anesthetic onto the flat portion of the response surface in most instances will slow the decline of drug effect.

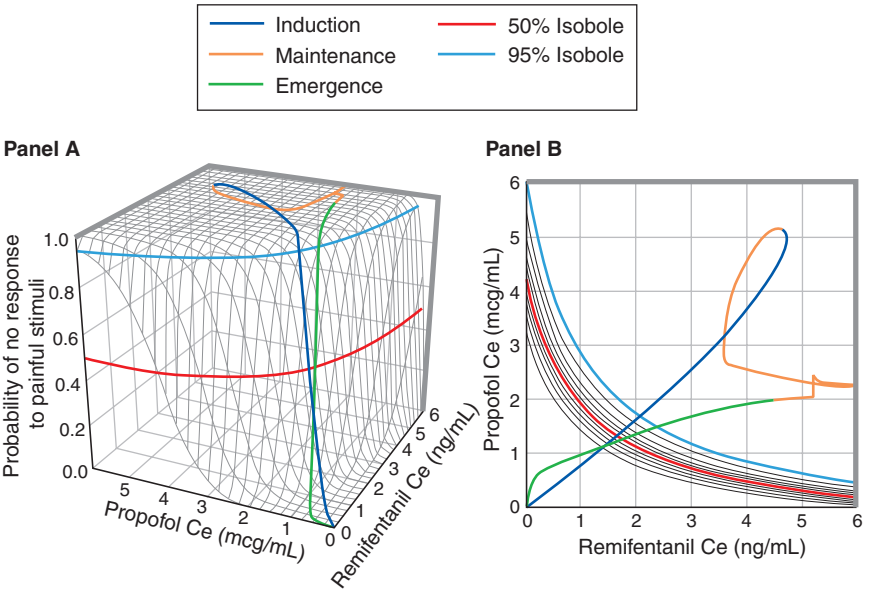

FIGURE 39–18. A. Response surface for remifentanil and propofol effect site concentration pairs and the probability of no response to a painful stimulus. **B.** Isobologram of the response surface presented in A. Superimposed on both plots are the remifentanil and propofol effect site concentrations that result from the simulated total intravenous anesthetic shown in Figure 39–17. Segments of the anesthetic are color coded to depict the induction, maintenance, and termination of anesthetic delivery.

One of the challenges of drug synergism is quantifying the magnitude of drug–drug interactions in a clinically meaningful manner that will allow clinicians to reliably modify their dosing regimens to optimize a desired drug effect. Although response surfaces and isoboles provide useful tools for characterizing drug interactions, their clinical utility when delivering an anesthetic in real time has not been explored. Suspecting that anesthesia providers may have difficulty interpreting response surfaces and isoboles, investigators have explored other means of visually presenting synergistic effects in real time. Work has focused on plotting the contribution of simultaneously administered sedatives or potent inhaled agents and opioids to the overall analgesic and sedative effects over time.[43] With this approach, the overall analgesic effect, for example, is plotted over time as a function of the C_{50} for no response to a painful stimulus. Using this technique, the total intravenous anesthetic introduced in Fig. 39–17 has been replotted in terms of the contribution of remifentanil alone (blue) and remifentanil and propofol (gray) to the overall analgesic effect (Fig. 39–19).

To gain a perspective of how synergistic these two drugs are with regard to analgesia, consider the contribution of remifentanil without propofol to analgesia. The bolus and infusion of remifentanil rendered an effect site concentration that approached half of the effect site concentration (4–5 ng/mL) necessary to reach the C_{50} for analgesia (8.8 ng/mL).[25] By contrast, when added to the bolus and continuous infusion of propofol, the cumulative effect of both drugs exceeds the C_{50} for analgesia 8-fold during most of the anesthetic.

An important limitation of these simulations used to describe drug synergy is that they are inherently restricted by pharmacokinetic and pharmacodynamic parameter variability within the population that was used to estimate them.[44,45] Population pharmacokinetic parameters thus should be viewed as an estimate of the population's typical parameters, recogniz-

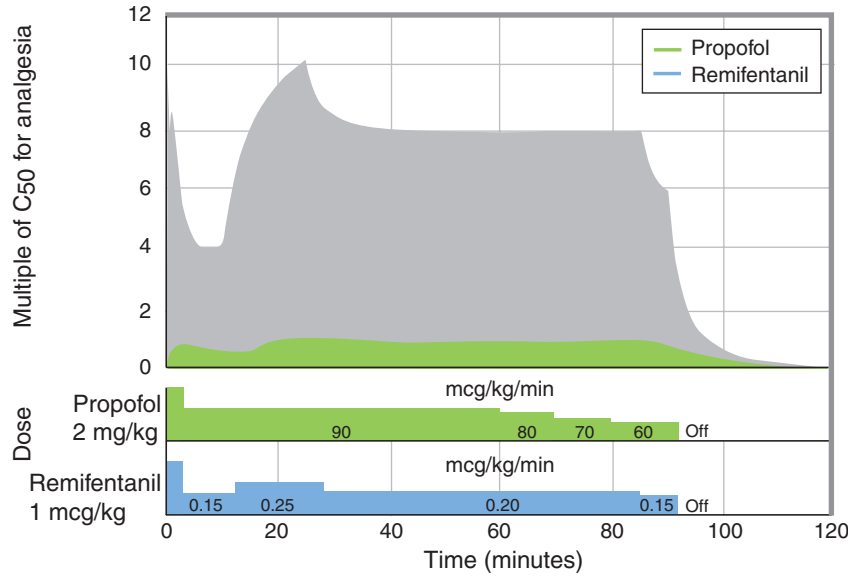

FIGURE 39–19. Simulation of the analgesic effect of remifentanil (*blue*) and synergistic effect of remifentanil and propofol on analgesia (*gray*) over time. The analgesic effect is presented as multiples of the C_{50} for analgesia (8.8 ng/mL[25]). The dosing regimens for propofol and remifentanil are presented on the horizontal axis.

ing that each individual likely will vary from the population parameters to some degree.[46] Some patients, of course, will vary greatly from the population mean. For these patients, the simulations are admittedly of little value. For most patients, however, the prediction based on the population pharmacokinetic and pharmacodynamic parameters are a good starting point for initial therapy. Adjustments in dosing scheme are then made on the basis of patient response.

In summary, most practitioners tend to relatively overdose patients with their anesthetic technique because the current surrogate measures of anesthetic depth (e.g., changes in heart rate and blood pressure, patient movement, processed EEGs) and display tools for visualizing the time course of anesthetic drug concentrations over time are inadequate. Given that variations in surgical stimulus often are difficult to predict and that pharmacologic interpatient variability is substantial, clinical experience mandates that practitioners continue to administer generous doses of anesthetics. As pharmacokinetic and pharmacodynamic display systems become more effective at reliably communicating useful information regarding clinical end points of interest in a timely manner, perhaps anesthesiologists will be more inclined to tailor their technique to the precise needs of each patient and the demands of a given surgical procedure or, in other words, surf the 95% isobole.

SPECIAL POPULATIONS

Anesthesiologists have long recognized the need to adapt their anesthetic to account for differences in demographic factors and disease processes that influence drug disposition or effect. Increasingly, the scientific rationale supporting these dosing changes is taking shape. Comorbidities in these special populations. such as obesity, renal failure, heart failure, liver failure, blood loss, presence of opioid tolerance, and differences in age. are referred to as *covariates.* Covariates are descriptors of demographic factors or pathophysiologic states used to estimate the impact of these states on anesthetic drug behavior. Although a significant amount of research has been dedicated to describing covariates and how they can be used to optimize dosing, there are still many gaps in our knowledge base, making the development of guidelines and dosing recommendations for commonly used anesthetics difficult. Nevertheless, as newer intravenous anesthetics have expanded the array of drugs available to the practitioner, covariate analysis has become an increasingly useful tool for describing potential dosing pitfalls associated with these anesthetics.

The next segment of this chapter reviews the comorbidities and demographic factors that have been described, with covariate analysis for selected intravenous anesthetics (propofol, fentanyl, and remifentanil) as an example of how to account for (1) disease states such as obesity and blood loss and (2) commonly occurring patient conditions such as advanced age and opioid tolerance when formulating a dosing regimen. Unfortunately, our pharmacologic database is incomplete and does not allow us to generalize these examples to all intravenous anesthetics. Furthermore, some of the studies were performed in animal models and therefore are difficult to translate to clinical practice. Nevertheless, this body of work does provide some insight into how intravenous anesthetics behave in the presence of commonly occurring covariates and are important to consider when formulating a dosing regimen.

Body Weight and Intravenous Anesthetic Pharmacology: Developing Rational Dosing Strategies

The clinical relevance of accounting for differences in body mass is a result of the prevalence of obesity in western culture. Obesity is a major public health problem throughout the developed world. Since the early 1970s the proportion of the US population that is overweight has steadily increased.[47] Among US adults aged 20–74 years, approximately 25% are overweight, with a slightly higher prevalence among women.[48] Almost 5% of US adults are morbidly obese, that is, they weigh twice their ideal weight. Anesthesia providers thus frequently encounter obese patients in everyday practice.

Many investigators have explored the impact of weight on drug dosing for opioids[46,49–51] and sedatives[52] and have offered strategies on how doses should be formulated for patients who are overweight. Nonetheless, despite the high prevalence of obesity, practitioners often formulate dosage regimens for many drugs based on total body weight (TBW). However, dosing according to TBW in obese patients can lead to large doses and prolonged or toxic effect. Clinicians should recognize that most studies designed to determine appropriate doses of intravenous anesthetics have been conducted in healthy patients or in volunteers at or

TABLE 39–5.

Ideal Body Weights for Selected Heights in Men and Women

Height	Women	Men
4 ft 9 in (145 cm)	85 lb (39kg)	
5 ft 1 in (155 cm)	105 lb (48 kg)	115 lb (52 kg)
5 ft 6 in (165 cm)	130 lb (59 kg)	140 lb (63 kg)
5 ft 9 in (175 cm)	145 lb (66kg)	155 lb (70 kg)
6 ft 1 in (185 cm)	165 lb (75 kg)	174 lb (79 kg)
6 ft 5 in (196 cm)		194 lb (88kg)

near their ideal body weight (IBW). A unique attribute of IBW is that it represents an estimate of appropriate body weight based on height only. For example, popular formulas for estimating IBW are IBW = 49.9 + 0.89 × (Height – 152.4) kg for men and IBW = 45.4 + 0.89 × (Height – 152.4) kg for women.[53]

To illustrate the resultant weights using these formulas, IBWs for several common heights are presented in Table 39–5. It is important to point out that when using these formulas for any given height, the IBW is the *same* regardless of weight. Formulating a dose according to the IBW for patients of equivalent height who weigh 70, 100, and 150 kg would be the same. By contrast to dosing patients according to their TBW, dosing according to the IBW has the potential for significant *underdosing*.

To get around the limitations of IBW for dosing anesthetics, investigators have used lean body mass (LBM) instead. Advantages of LBM are that it excludes weight associated with adipose tissue and accounts for patient height and TBW. For example, LBM has been used to scale pharmacokinetic parameters (i.e., volumes and clearances) for remifentanil to predict drug levels in lean and obese patients (Table 39–6).[49]

TABLE 39–6.

Pharmacokinetic Population Model Scaled to Lean Body Mass

Parameter Name	Scale Pharmacokinetic Parameter
V1 (L)	(0.121 × LBM) – 0.0731
V2 (L)	(0.165 × LBM) – 0.0731
Cl1 (L/min)	(0.0185 × LBM) – 1.88
Cl2 (L/min)	1.04

Equations used to describe lean body mass (LBM) are LBM = 1.1 × Weight – 128 × (Weight/Height)² for men and LBM = 1.07 × Weight – 148 × (Weight/Height)² for women.

Using these weight-adjusted pharmacokinetic parameters, simulations of remifentanil effect site concentrations in obese and lean patients can be compared when dosed according to TBW versus LBM (Fig. 39–20). This set of simulations was performed for a lean woman (125 lb) and an obese woman (220 lb) of the same height (5 feet 5 inches). The simulations used dosing regimens typical for remifentanil as part of a combined technique with a potent inhaled agent, nitrous oxide, or a continuous infusion of a sedative–hypnotic. The dosing scheme included a bolus dose (1 μg/kg) followed be a continuous infusion at 0.25 μg/kg/min for 20 minutes and then 0.15 μg/kg/min for 60 minutes.

Key points illustrated by these simulations include the following. (1) Dosing obese patients according to their TBW can yield remifentanil effect site concentrations that are substantially higher than in equivalently dosed lean patients. The peak effect site concentrations after 20 minutes of the anesthetic were 9.5 and 5.4 ng/mL for the obese and lean patient, respectively. (2) With the dosing scaled to LBM, the resultant simulated effect site concentrations for both lean and obese patients were *lower* than the effect site profile for a lean patient dosed to the TBW. These simulations suggest that dosing intravenous anesthetics to

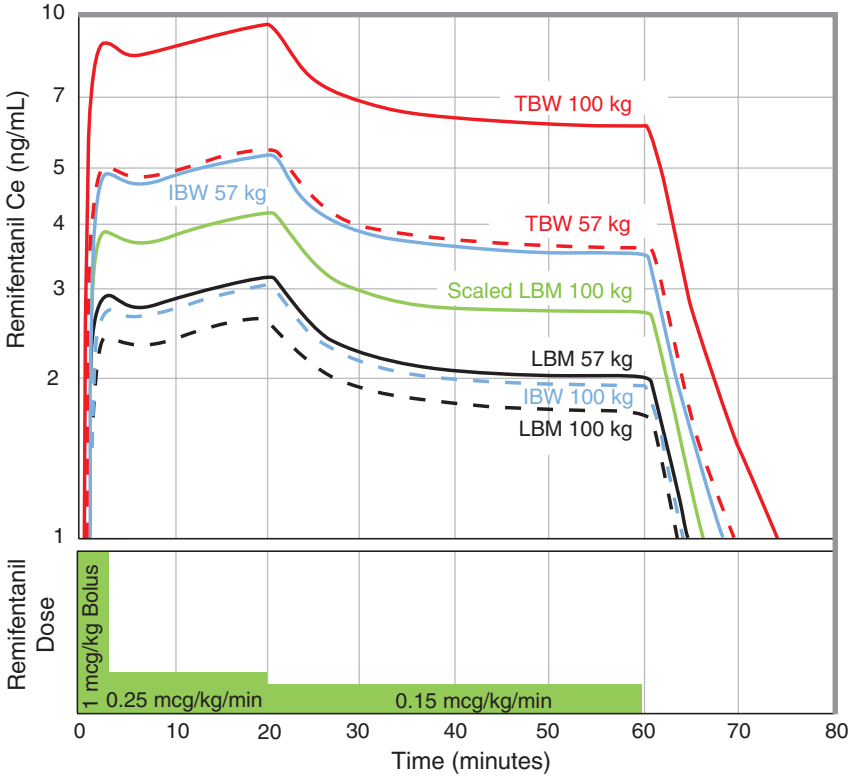

FIGURE 39–20. Computer simulation of a remifentanil infusion for two patients: a 5-foot 5-inch (165-cm) lean (57-kg) female, and a 5-foot 5-inch obese (100-kg) female. Solid lines represent dosing to 100 kg, and dashed lines represent dosing to 57 kg. The dosing regimen is presented along the horizontal axis. The red, blue, and black lines represent the resultant remifentanil effect site concentration when dosed according to total body weight (TBW), ideal body weight (IBW), and lean body mass (LBM). The green line represents the resultant effect site concentration when remifentanil is dosed according to the scaled LBM for the 100-kg patient. The effect site concentration when remifentanil is dosed according to the scaled LBM for the lean patient is equivalent to the concentration for the lean patient dosed to TBW.

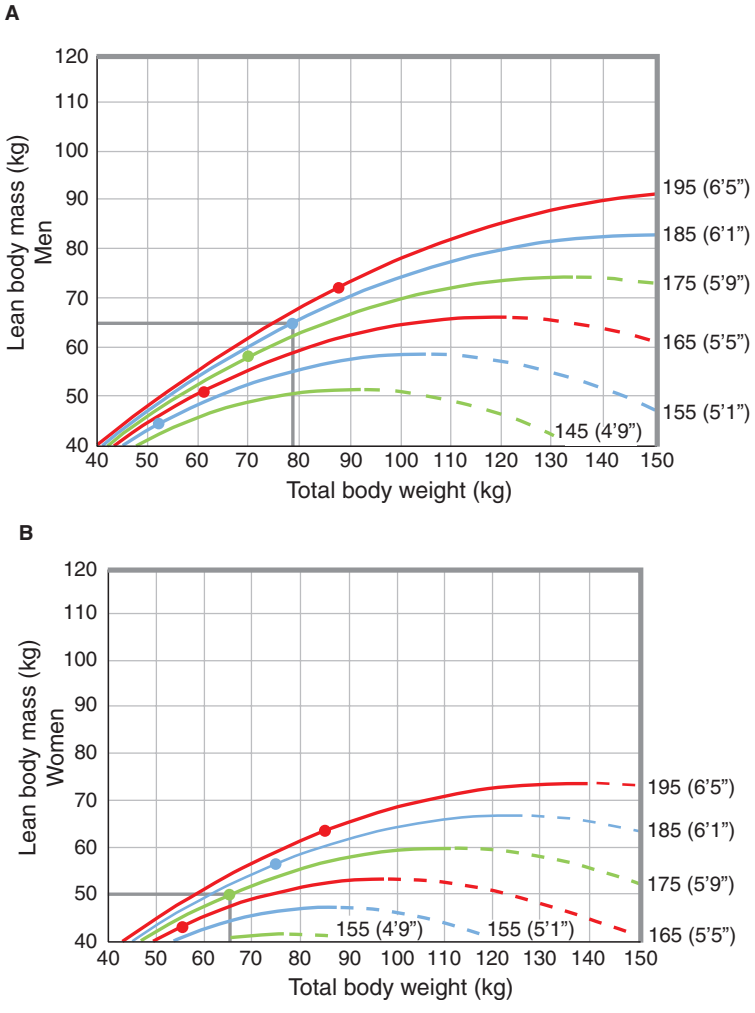

FIGURE 39–21. Normogram by height of the lean body mass over a range of total body weights for men (**A**) and women (**B**). The height is presented in centimeters, with feet and inches in parentheses. The dots represent the ideal body weight at each height. The solid lines illustrate the lean body mass for an ideal body weight for a 6-foot 1-inch man and a 5-foot 9-inch woman. The dashed lines represent the segment of each normogram where the formula for lean body weight begins to generate lean body masses that are smaller for increasing total body weight. Ideal body weights and lean body mass were calculated from standard formulas presented in the text.[53] These normograms are patterned after normograms originally described by Bouillon and Shafer[54] using different heights and weights.

LBM, similar to IBW, may lead to significant underdosing.

LBM has an additional limitation. In instances where the patient's weight approaches morbid obesity, dosing according to the LBM becomes increasingly inaccurate.[54] A unique and somewhat worrisome feature to the LBM equation is that, for any given height, there is a maximum LBM. For TBWs that are above the maximum LBM, the LBM decreases. In Fig. 39–21, an LBM normogram, the LBM estimates that correspond to TBWs where the LBM decreases with increasing TBW are plotted as a dashed line. This most likely is an artifact of the LBM equation. If not accounted for, very large patients would receive smaller doses than patients of equivalent height but not as large. Another limitation of using the LBM normogram for dosing is that the LBM reports the patient mass in the absence of any fat tissue. The LBM is always lower than the IBW. This is illustrated in the normogram with solid gray lines. These lines point out the resultant LBM for an IBW for a 6-foot 1-inch man and a 5-foot 9-inch female. Because even lean people have some fat, this would suggest that using the LBM for dosing anesthetics, as observed in Fig. 39–20, results in some degree of underdosing. Hence, for clinical purposes, the LBM equation is perhaps useful only until the maximum LBM for a given height is reached, with the expectation that many patients may require additional anesthetic.

With this limitation in mind, Bouillon and Shafer[9] recommend that estimates of the *ideal* dosing weight from which to formulate dosing regimen use a modified normogram of LBM. Their modified normogram uses the following guidelines. (1) Conventional LBM scales are adjusted to IBW (in other words, for a patient that is at his/her IBW, the LBM at a given height should be the IBW). In effect, this shifts the original normograms presented in Fig. 39–21 up and to the left. (2) The scaled or modified LBM normograms are truncated at the maximal estimates of LBM. This approach relies on the assumptions that recommended doses printed on package inserts are appropriate for patients who are their IBW. The scaled normogram of LBM is presented in Fig. 39–22. Again, the dashed lines represent the point where the scaled LBM decreases with increasing weight. Scaled LBM estimates in this region should not be used to estimate the proper dosing weight.

Using this scaled normogram for dosing remifentanil when a person's weight is at or below his/her IBW is unnecessary. Using their actual weight will suffice. When a person's weight is above the IBW, using the normogram shown in Fig. 39–22 may be useful but probably is not immediately practical if it is not readily available in the clinical setting. A more simplified approach, based on the normograms presented in Fig. 39–22, is to use a patient's IBW or, if the patient is approaching morbid obesity, to consider using his/her IBW *plus* some fraction of the difference between TBW and IBW.[54] A simplified summary of scaled LBM normograms is presented by gender in Table 39–7. To account for height and weight, suggested scaled weights to use for dosing are presented as a function of the body mass index (BMI).

In Fig. 39–20, the green line represents the resultant remifentanil effect site concentration when dosing the 5-foot 5-inch (165-cm), 220-lb (100-kg) patient according to the suggested dosing weight in Table 39–6. Her IBW is 57 kg. Her BMI was calculated as 37. Twenty percent of the difference between TBW and IBW is 8.6 kg. Therefore, the suggested dosing weight is 65.6 kg. The resultant effect site concentrations are between the concen-

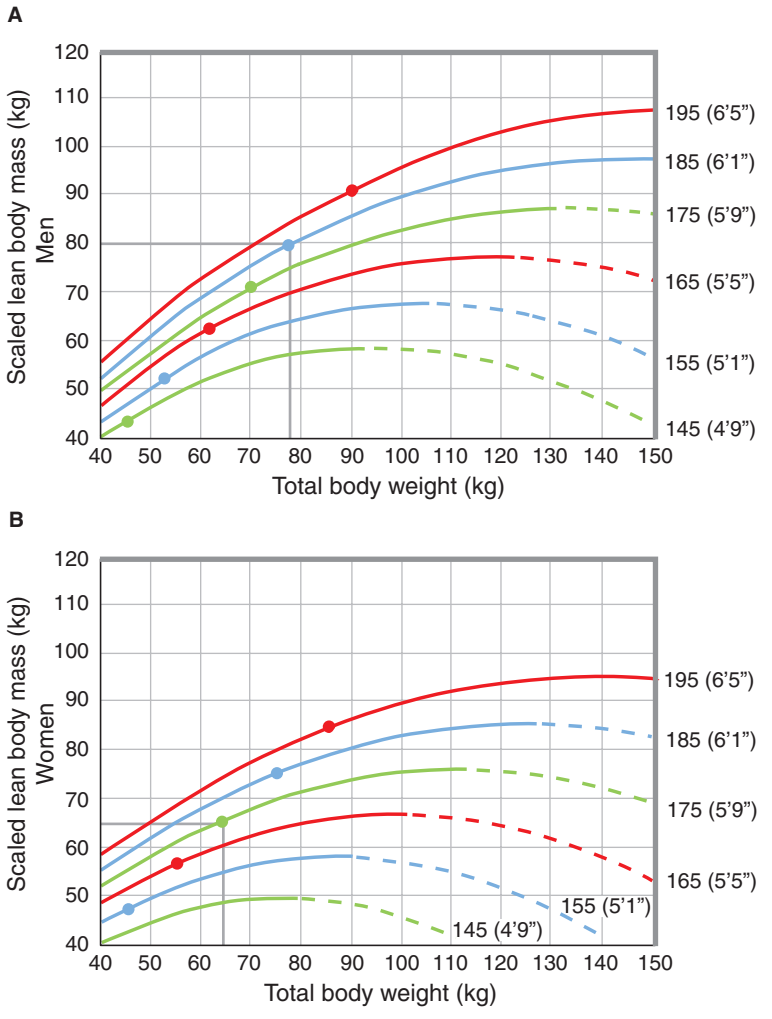

FIGURE 39–22. Modified normogram by height of the *scaled* lean body mass over a range of total body weights for men (**A**) and women (**B**). This normogram represents weights that should be used when formulating a dosing regimen by weight. The normogram assumes that published dosing recommendations are correct for persons of ideal body weight. The height is presented in centimeters, with feet and inches in parentheses. The dots represent the ideal body weight at each height. Note that with the scaled normogram, the ideal body weight plotted on the horizontal axis corresponds to the same scaled lean body mass on the vertical axis. The solid lines illustrate that the scaled lean body mass and the ideal body weight for a 6-foot 1-inch man and a 5-foot 9-inch woman are the same. The dashed lines represent the segment of each normogram where the formula for scaled lean body weight begins to generate scaled lean body masses that are smaller for increasing total body weight.

trations when dosing her according to her TBW and LBM, respectively. Using this approach avoids the inherent risks of underdosing using the LBM and overdosing using the TBW, as well as the limitations of dosing according to the IBW.

Age and Intravenous Anesthetic Pharmacology: Developing Rational Dosing Strategies

Considering the aging of the world's population, the clinical significance of age in the practice of anesthesia is obvious. Practitioners are frequently faced with the clinical challenge of anesthetizing older adults, sometimes even patients in their ninth or tenth decade. Clinicians have long recognized that elderly patients usually require a smaller dosage of most intravenous anesthetics to produce the desired therapeutic effect while minimizing adverse effects.

Of the frequently considered patient covariates (e.g., gender, age, body weight, kidney function, hepatic function, etc.), age is perhaps one of the most valuable in terms of developing a therapeutic, nontoxic dosage strategy for many intravenous anesthetics. Age is easily measured (i.e., just ask the patient), and its influence on the pharmacokinetics and pharmacodynamics of many intravenous anesthetics has been described in some detail.

With regard to age, both remifentanil and propofol can serve as a prototype to examine the impact of age on anesthetic pharmacology. Studies specifically designed to assess the influence of age on remifentanil and propofol pharmacokinetics and pharmacodynamics have been conducted and complex models constructed that characterize the influence of age in quantitative terms.[11,32,52,54,55]

With regard to remifentanil, it is clear that the elderly do require less drug to produce the desired spectrum of opioid effects. The reduced dosage requirement is a function of both pharmacokinetic and pharmacodynamic mechanisms, although pharmacodynamic factors dominate.[55] The concentration of remifentanil necessary for 50% of maximal effect as measured by the EEG is markedly decreased in the elderly (C_{50} for EEG changes); in addition, remifentanil's clearance and volume of distribution are also decreased.[11] These age-related changes translate clinically into the need for a very substantial dosage reduction in the elderly that is based largely on the increased potency of remifentanil in older patients (i.e., a pharmacodynamic difference).

Using the pharmacokinetic–pharmacodynamic parameters from age-adjust-

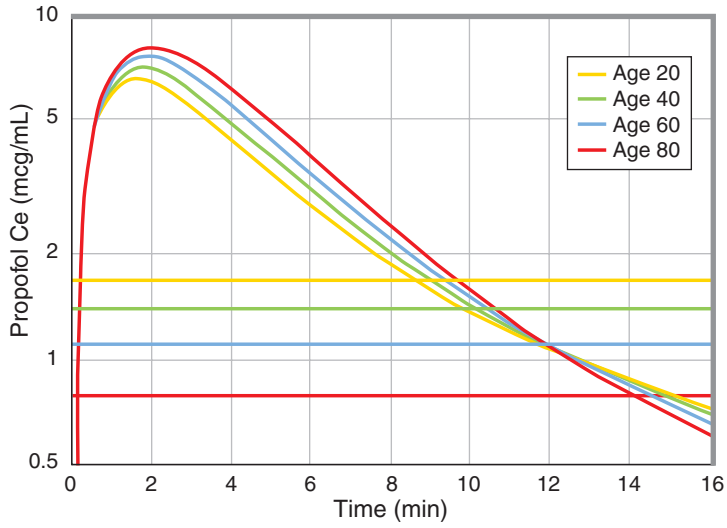

FIGURE 39–23. Plot illustrating a combined pharmacokinetic and pharmacodynamic simulation of the propofol effect site concentration that results from a 2 mg/kg bolus. The simulated patient is an 80-kg, 183-cm male. Simulations were performed for patients aged 20, 40, 60, and 80 years. The horizontal lines represent the effect site concentrations associated with a 50% probability of loss of responsiveness, which are 1.7, 1.4, 1.1, and 0.8 µg/mL for ages 20, 40, 60, and 80 years, respectively. Pharmacokinetic and pharmacodynamic parameters for propofol by age were adapted for simulation from Schnider et al.[32,52]

ed pharmacologic models of propofol and remifentanil, computer simulations can be performed to explore the suitability of various dosage schemes. Fig. 39–23 presents a set of simulations of propofol's pharmacologic behavior following an induction dose of propofol. Using age-adjusted pharmacokinetic and pharmacodynamic parameters,[32,52] four simulations of a 2 mg/kg propofol bolus for a 20-, 40-, 60-, and 80-year-old patient demonstrate, with the same dose, a subtle rise in the peak propofol effect site concentration and a small delay in reaching the peak with increasing age. By contrast, the concentration at which there is a 50% probability of losing unresponsiveness (C_{50} for unresponsiveness) drops by 50% from age 20 to 80 (Table 39–8). Combining the pharmacokinetic and pharmacodynamic models, the duration of propofol effect (time above the effect site concentration associated with a loss of responsiveness) substantially increases with increasing age.

Similarly Fig. 39–24 is an illustration of simulations of remifentanil's pharmacologic behavior following a 1-hour infusion. Using age-adjusted pharmacokinetic and pharmacodynamic parameters,[11,55] four simulations are presented of a 1-hour continuous infusion at a rate of 0.2 mg/kg/min for a 20-, 40-, 60-, and 80-year-old patient. At the same infusion rate, the remifentanil effect site concentration develops a substantial increase over time with increasing age (Table 39–8). Estimates of the C_{50} for analgesia allow for prediction of the duration of analgesic effect following termination of the 1-hour infusion. In Fig. 39–24, the C_{50} for each simulated age is presented as a horizontal line. Following termination of the infusion, the duration of analgesic effect markedly increases with age (more than 3-fold increase from age 20 to 80).

Additional simulations can be used to estimate the percent reduction in dose as a function of age for both propofol and remifentanil. As shown in Table 39–8, to achieve equipotent doses in 20- and 80-year-old individuals requires that the 80-year-old person receive a dose that has been reduced by 55–65% of that which would be given to a 20-year–old person. These simulations emphasize the importance of considering age when formulating an appropriate dose in elderly patients.

Although the physiologic mechanism of the pharmacodynamic changes in elderly people remains largely unexplored, the pharmacokinetic changes may be due at least in part to decreased cardiac output. The lower cardiac output associated with advanced age[56] presumably results in slower drug mixing and therefore higher peak concentrations after a bolus dose.[57–59] Lower cardiac output may decrease drug delivery to metabolic organs, resulting in lower clearance for some drugs.

When generalizing to other drugs, whether reduced cardiac output is the primary underlying mechanism responsible for the pharmacokinetic

TABLE 39–8.

Influence of Age on Pharmacologic Behavior of a 2 mg/kg Bolus of Propofol and 1-Hr Remifentanil Infusion Set at 0.2 kg/min

Age (y)	20	40	60	80
Propofol				
Peak propofol Ce (µg/mL)	6.5	7.0	7.6	8.2
Time to peak Ce (min)	1.7	1.8	2.0	2.0
C_{50} for LOR (µg/mL)	1.7	1.4	1.1	0.8
Time above the C_{50} for LOR (min)	9	10	12	14
Percent reduction in dose	0	25	56	65
Remifentanil				
Remifentanil Ce (ng/mL) upon termination of infusions	5.6	6.6	8.0	10.2
C_{50} for analgesia (ng/mL)	2.0	1.6	1.3	0.9
Upon termination of infusion time above C_{50} for analgesia (min)	8	13	19	29
Percent reduction in dose	0	18	37	55

Ce, effect site concentration; C_{50} for analgesia, effect site concentration associated with 50% probability of analgesia; C_{50} for LOR, effect site concentration associated with 50% probability of loss of responsiveness.
Pharmacokinetic and pharmacodynamic parameters for propofol by age were adapted for simulation from Schnider et al.[32,52] Pharmacokinetic and pharmacodynamic parameters for remifentanil by age were adapted for simulation from Minto et al.[11,55]

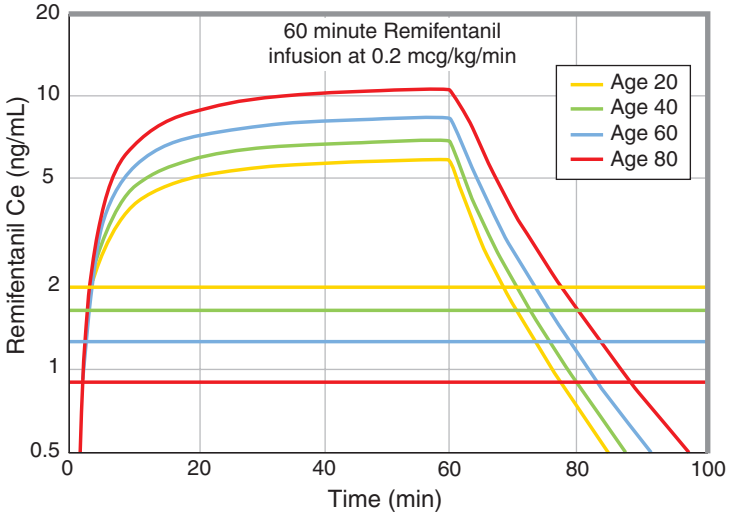

FIGURE 39–24. Plot illustrating a combined pharmacokinetic and pharmacodynamic simulation of the remifentanil effect site concentration that results from a 1-hour infusion set at 0.2 μg/kg/min. The simulated patient is an 80-kg, 183-cm male. Simulations were performed for patients aged 20, 40, 60, and 80 years. The horizontal lines represent the effect site concentrations associated with an analgesia. The analgesic levels are 2, 1.6, 1.3, and 0.9 ng/mL for ages 20, 40, 60, and 80 years, respectively. Pharmacokinetic and pharmacodynamic parameters for propofol by age were adapted for simulation from Minto et al.[11,55]

changes observed in the elderly, it is consistent with the observation that many intravenous anesthetics (thiopental, propofol, etomidate) appear to have a smaller distribution volume or slower clearance in the elderly.[10,52,60,61]

It is, however, important to point out that reduced cardiac output is not a ubiquitous finding in the elderly, particularly in the absence of heart disease in well-conditioned individuals.[62] This recognition perhaps has led to the common clinical notion of identifying a patient's "physiologic" age instead of relying on chronologic age alone.[63,64] Significant reductions in dosage may not, therefore, be necessary for physically robust elderly patients with normal body habitus and without substantial coexisting disease.

It is more difficult to generalize with regard to age-induced pharmacodynamic changes to other intravenous anesthetics. Although the elderly clearly have a "left-shifted" concentration-effect relationship for opioids (i.e., the opioids are more potent in the elderly),[11,65] a good deal of data suggests that the elderly are not more pharmacodynamically sensitive to the sedative–hypnotics. For example, there is no difference between old and young in terms of the EEG C_{50} for etomidate or thiopental.[10,60,61] On the other hand, published data suggest that both propofol and midazolam are more potent in the elderly.[32,66] Thus, although there certainly is general consensus that the elderly require less medication than do younger patients, whether this reduced dosage requirement can be attributed to pharmacokinetic or pharmacodynamic mechanisms remains unclear for some individual agents.

Blood Volume and Intravenous Anesthetic Pharmacology: Developing Rational Dosing Strategies

Dr. F. Halford,[67] a surgeon, wrote a letter to the editor of *Anesthesiology* after caring for several trauma victims following the attack on Pearl Harbor in 1941. He noticed that anesthetists had started using the intravenous anesthetic sodium pentothal. His comments are as follows:

> "Then let it be said that intravenous anesthesia is also an ideal form of euthanasia.... With this heterogeneous mass of emergency anesthetists, it is necessary to choose an anesthetic involving the *WIDEST MARGIN OF SAFETY* for the patient.... Stick with *ETHER*."

Anesthesiologists have long recognized the need to select certain IV anesthetics over others, to incrementally dose these anesthetics, and to moderate the overall dose for patients who have significant blood loss before or during surgery. Through experience, clinicians have learned that a full dose of selected intravenous anesthetics can lead to pronounced and often unwanted side effects with potentially disastrous consequences.

In the recent past, several researchers have attempted to quantify how the extent of blood loss impacts intravenous anesthetic pharmacokinetics and pharmacodynamics to include work with opioids,[68–70] sedative–hypnotics,[71–75] benzodiazepines,[76,77] and local anesthetics.[78] The most important finding consistent throughout this body of work is that equivalent dosing leads to higher drug concentrations with severe blood loss when compared to unbled controls. In addition, although derived volumes and clearances from pharmacokinetic analyses do not reflect true organ drug distribution and clearance, they do indicate that, in severe blood loss, blood flow to muscle, gut, liver, and connective tissue is markedly decreased such that anesthetics delivered intravenously are most likely pumped straight to the brain in higher concentrations. This phenomenon leads to higher brain concentrations of anesthetic drugs and a more pronounced and/or prolonged anesthetic effect.[79]

As an example, Fig. 39–25 illustrates the differences in blood concentrations that result from identical doses of remifentanil in bled and unbled swine.[70] Following severe blood loss (42 mL/kg), resultant remifentanil blood levels were 2-fold higher during and after a10-minute remifentanil infusion. Of note in this study, the dose (10 μg/kg/min) is approximately 50- to 100-fold more than a typical dose of 0.1 to 0.2 μg/kg/min, yet all animals survived despite losing more than half of their blood. A decrease in blood volume and cardiac index (5–1.7 L/min/m^2) along with compensatory changes in regional blood flow are the likely physiologic mechanisms explaining these pharmacokinetic changes. Pharmacokinetic analyses revealed that the volumes of distribution and clearances were decreased in bled animals when compared to unbled controls. Spectral edge changes in the EEG were used to measure drug effect. By contrast to the pharmacokinetic analysis, no difference was observed in the pharmacodynamics between groups. As has been observed with fentanyl[69] and morphine,[68] these findings with remifenta-

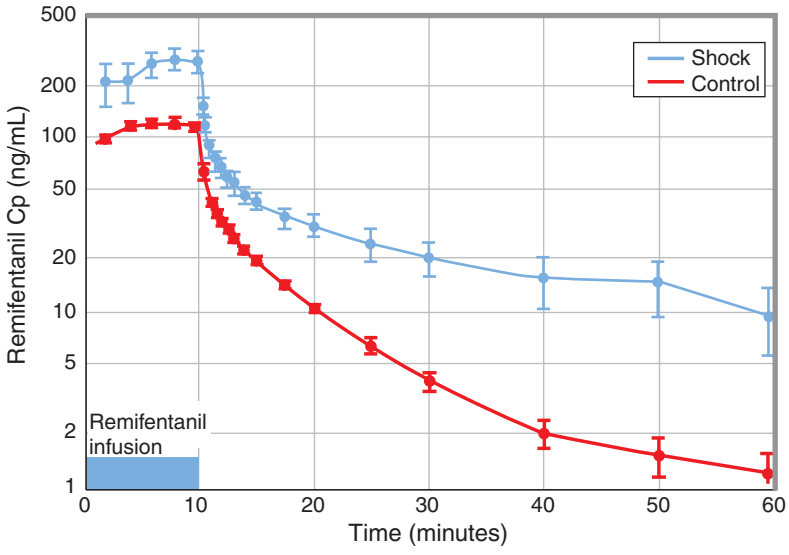

FIGURE 39–25. Resultant mean blood drug concentrations versus time from equivalent dosing of remifentanil in bled (42 mL/kg) and unbled swine. The blue and green lines represent the mean levels for bled and unbled animals, respectively. The blue box at the lower left corner represents the duration of the 10 µg/kg/min remifentanil infusion. The error bars indicate the standard error. The vertical axis is on the log scale.

nil corroborate the relative forgiving posture of high-dose opioids on cardiovascular function even when used in the setting of hemorrhagic shock.

In contrast to opioids, blood loss has a more worrisome impact on propofol pharmacokinetics and pharmacodynamics. Similar to the experimental design used with remifentanil described earlier, investigators have bled animals and then administered propofol. Two major differences were observed when compared to remifentanil. First, the administration of propofol following severe hemorrhage (42 mL/kg) led to certain cardiovascular collapse. Second, the dose found to elicit a pharmacologic effect (i.e., a change in the BIS of at least 50) in unbled animals was in no way tolerated in bled animals. In order to conduct experiments in bled animals, the propofol dose had to be reduced by more than 50% and the extent of hemorrhage had be markedly reduced to 30 mL/kg. In this case, hemorrhage led to a decrease in the cardiac index from 5 to 2.6 L/min/m^2. Subsequently animals received a 10-minute propofol infusion at 200 µg/kg/min. Of interest, with equivalent dosing, the hemorrhaged animals exhibited approximately 2-fold greater plasma concentrations of propofol throughout the study period. A pharmacokinetic analysis revealed that, similar to remifentanil, propofol compartmental clearances and volumes were decreased in bled animals.

The BIS was used as a surrogate measure of propofol effect. As expected, changes in the BIS lagged behind the changes in plasma propofol concentrations. These data were used to estimate the k_{eo} for bled and unbled animals and to construct previously described pharmacodynamic models to include estimates of C_{50} and γ. Comparison of pharmacodynamic parameters between bled and unbled animals revealed a similar k_{eo} and γ but a 2.7-fold decrease in C_{50} (4.6 µg/mL vs 1.7 µg/mL for the control and shock groups, respectively). This is emphasized by the leftward shift (green arrow) in the C_{50} for each study group (Fig. 39–26).

Perhaps one of the more dangerous uses of intravenous anesthetics is during the induction of anesthesia. Here bolus doses are used to rapidly render a patient analgesic or unconscious, but these doses can be associated with significant morbidity if dosing does not account for large changes in blood volume. For purposes of discussion, consider an induction dose of propofol. The pharmacokinetic and pharmacodynamic findings related to propofol during blood loss described earlier will be used to illustrate how blood loss impacts conventional dosing of sedative–hypnotics.

In Fig. 39–11, using pharmacokinetic parameters previously described in humans,[3] the onset and duration of loss of responsiveness following a propofol bolus of 2 mg/kg was 1 and 8 minutes, respectively, assuming that the necessary propofol effect site concentrations required for loss of responsiveness was near 1.8 µg/mL.[25] Conducting a propofol bolus simulation following moderate blood loss (35% of the blood volume) yields a significantly different result (Fig. 39–27). Based on the impact of blood loss on propofol pharmacokinetics and pharmacodynamics, this simulation takes into account the 2.5-fold increase in effect site propofol concentration and the 2.7-fold decrease concentration required for loss of responsiveness.

With this simulation, the impact of moderate blood loss on the duration of effect is easily appreciated. Of note,

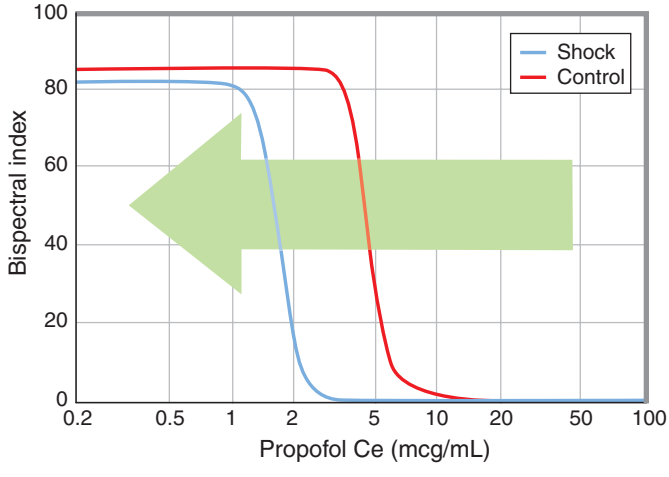

FIGURE 39–26. Concentration–effect relationship of propofol to the bispectral index scale (BIS) in bled (30 mL/kg) and unbled swine as characterized by a pharmacodynamic model. The red and blue lines represent the mean change in BIS over a range of propofol effect site concentrations for unbled and bled swine, respectively. The green arrow illustrates the shift in C_{50} between groups.

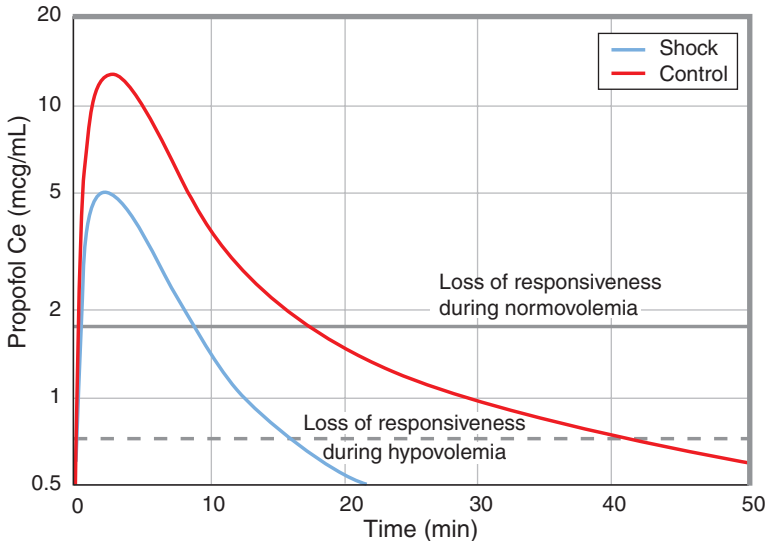

FIGURE 39–27. Combined pharmacokinetic and pharmacodynamic simulations of a propofol 2 mg/kg bolus dose under normal hemodynamic conditions and following moderate blood loss. The blue and red lines represent the effect site concentrations under normal and hypovolemic conditions. The gray solid and dashed lines represent the propofol effect site concentration associated with loss of responsiveness under normal and hypovolemic conditions.

with blood loss there is more than a 5-fold increase in the duration of effect (from 8 to 44 minutes). These simulations suggest that propofol should be used, if at all, with extreme caution! Estimating the dose that would provide an equivalent effect in a person suffering from severe blood loss with a person with normal cardiovascular physiology yields a propofol dose reduction of 80% (i.e., 0.4 mg/kg). Although the impact of blood loss on propofol is dramatic, it is important to recognize that this is a simulation of a single propofol bolus and does not reflect the common practice of combining propofol with an opioid during the induction of anesthesia. In this scenario, it is likely that the pronounced increase in peak effect and duration of effect would only be larger and potentially more dangerous.

Perhaps the most important consequence of blood loss on propofol behavior is the exaggerated hemodynamic response following a bolus dose. Propofol is a peripheral vasodilator and suppresses contractility.[80] As observed in these simulations, a propofol bolus dose yields higher effect site concentrations that remain elevated for a prolonged period of time, thus amplifying propofol's cardiovascular depression. Sodium pentothal has a similar profile of cardiovascular depression, which likely explains why Dr. Halford was so adamant about the dangers associated with the induction of anesthesia with sodium pentothal.

What about resuscitation? Does volume resuscitation restore drug disposition and effect to baseline? In typical clinical practice, some fluid resuscitation usually is under way prior to administration of an anesthetic. Based on the premise that resuscitation will restore cardiac output and systemic blood flow, the shock-induced pharmacokinetic and pharmacodynamic changes may be reversed. In a similar set of experiments, a comparison was made between unbled controls and bled and then partially resuscitated swine.[81] Hemorrhage was severe (42 mL/kg), and resuscitation constituted an infusion of crystalloid to maintain a mean arterial blood pressure of 70 mm Hg for 60 minutes. This resulted in a resuscitation volume of 59 mL/kg.

Following a 10-minute, high-dose (750 μg/kg/min) propofol infusion, the propofol plasma concentrations were nearly identical. Resuscitation restored the shock-induced changes in propofol pharmacokinetics to near baseline values. However, the pharmacodynamic parameters remained altered. As with severe blood loss, the C_{50} was decreased 1.5-fold following hemorrhage and resuscitation. Although the mechanism for this phenomenon is not well understood, one explanation for the increase in end-organ sensitivity to propofol may be, at least in part, attributable to an unrecognized increase in unbound propofol. Thus, the leftward shift in the C_{50} of propofol may represent an undetected *pharmacokinetic* difference between groups. Although the plasma propofol levels were similar between the bled then resuscitated animals and the unbled animals, the amount of unbound propofol available to exert a pharmacologic effect may have been increased.[82] After removing >50% of the estimated blood volume and replacing it with crystalloid, plasma protein content most likely would be decreased. Furthermore, alterations in organ blood flow, capillary wall integrity, and plasma pH may influence the levels of unbound propofol. Given that plasma protein content, propofol-plasma protein binding, or unbound propofol levels were not measured or estimated, the extent that changes in unbound propofol played in altering the observed differences in end-organ sensitivity remains unknown.

With this protocol, 60% of the estimated blood volume was removed, and 140% of the shed blood volume was replaced with lactated Ringer solution to maintain a near normotensive blood pressure. *The near normal blood pressure was deceiving!* Although hemodynamic function appeared near normal (i.e., central venous pressure and cardiac index were similar to values in unbled animals), the cardiovascular response to propofol remained exaggerated. During the propofol infusion, the cardiac index decreased by 1.7 L/min/m^2 in the shock-resuscitation group but by only 0.2 L/min/m^2 in the control group. The large hemodynamic changes in the shock-resuscitation group illustrate how severe blood loss followed by partial resuscitation can lead to potentially large cardiovascular changes with the administration of propofol. In fact, a significant clinical correlate from this analysis is that, despite a near normal hemodynamic profile following partial resuscitation for severe blood loss, resuscitation should continue in order to minimize the potentially severe hemodynamic depression that can be associated with the administration of propofol.

Fig. 39–28 shows a simulation of the propofol effect site concentration following a propofol bolus dose in a patient suffering from severe blood loss followed by partial resuscitation with crystalloid (1.5 mL of crystalloid per 1 mL of estimated blood loss). This simulation accounts for the pharmacodynamic changes as manifest by a 1.5-

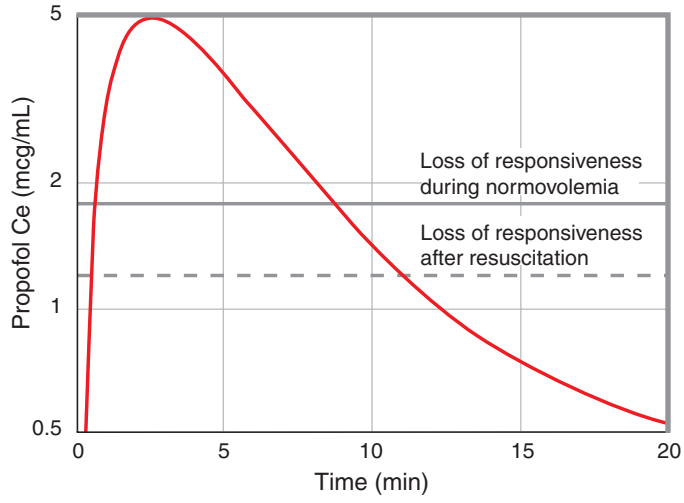

FIGURE 39–28. Combined pharmacokinetic and pharmacodynamic simulation of a propofol 2 mg/kg bolus dose following severe blood loss and resuscitation. The solid and dashed blue lines represent the effect site concentrations at which there is a loss of responsiveness under normal and bled then resuscitated conditions.

fold decrease in the effect site concentration required for loss of responsiveness. The duration of effect increases from 8 to 11 minutes.

By comparison to propofol, both ketamine and etomidate have greater acceptance among clinicians who care for patients with significant blood loss. This is largely because the cardiovascular depression known to be exaggerated with propofol and sodium pentothal is not as apparent with etomidate and to an even lesser extent with ketamine. Although etomidate is a known to produce mild cardiovascular depression, prior work surprisingly has revealed minimal cardiovascular change following a high-dose, brief continuous etomidate infusion[73,74] during moderate hemorrhagic shock (30 mL/kg). In a similar fashion, the pharmacokinetic and pharmacodynamic profile of etomidate following blood loss was minimally influenced by blood loss. This suggests that dosing requirements for etomidate do not require adjustment following moderate blood loss. This finding is in accordance with the widely held view that etomidate is a good choice in hemodynamically unstable patients.

What remains unknown is the impact of blood loss on ketamine. Preliminary work has revealed that, as with etomidate, blood loss does not significantly impact the pharmacokinetics of ketamine. Ketamine is known to increase sympathetic tone, serve as a potent analgesic, and perform favorably in patients with poor cardiovascular function. These preliminary findings support the widely held view that ketamine is an important drug to maintain in our pharmacologic armamentarium when caring for patients suffering from life-threatening blood loss.

The pharmacodynamic properties of ketamine are difficult to assess. This is largely because ketamine is a racemic mixture that, when metabolized, has an active metabolite, nor-ketamine. Hence, the contribution of both enantiomers and nor-ketamine must be considered when assessing the overall drug effect of ketamine. Another complication with measuring ketamine's drug effect is that it is difficult to identify a surrogate measure for ketamine's effect. For example, the BIS is not a reliable measure of ketamine's sedative effects.

In summary, as clinicians manage patients suffering from blood loss through often perilous anesthetics, hemorrhage and even hemorrhage followed by resuscitation that appears to restore hemodynamic function to near normal can lead to dramatic alterations in the pharmacologic behavior of commonly used sedative–hypnotics and opioids. Duration of effect, peak effect site concentrations, and extent of cardiovascular depression all should be considered when selecting an intravenous anesthetic and formulating an appropriate dose. The hemodynamically compromised patient is especially susceptible to the cardiovascular suppression of selected sedative–hypnotics, whereas other patients appear to be much safer. Propofol and sodium pentothal are an especially poor choice even after some degree of resuscitation. By contrast, ketamine and etomidate tend to be immune to the deleterious effects of moderate to severe blood loss on their pharmacokinetic profiles. Severe blood loss alters opioid pharmacokinetics, leading to higher plasma concentrations, but opioids, by contrast to propofol and sodium pentothal, enjoy a wider therapeutic margin in the presence of blood loss. What remains unexplored is the impact of blood loss on the resultant effect from simultaneous administration of multiple drugs. As illustrated in the section on Drug Synergism, opioids and sedative–hypnotics can dramatically influence one another. How this interaction behaves in the presence of intravascular volume depletion remains unknown.

The Opioid-Tolerant Patient

One of the most vexing problems facing an anesthetist is providing care for patients who chronically consume opioids (see Chapter 23 for a general review of substance abuse and anesthesia practice). With chronic consumption of opioids, tolerance develops, and more drug is required to achieve a desired analgesic effect. This becomes especially problematic in the perioperative period when opioid dosing requirements for these patients often reach thresholds associated with significant morbidity in the nonopioid-tolerant population. Out of concern for patient safety, opioid doses often are administered in more conventional doses to avoid unwanted side effects associated with opioid toxicity leading to often dramatically poor pain control in the postoperative period. In these types of patients, the population-based pharmacodynamic models used to describe opioid concentration–effect relationships become obsolete. Performing simulations to estimate opioid behavior either alone or in combination with other types of anesthetics using pharmacodynamic models built from studies evaluating an opioid-naïve population is bound to provide a faulty estimate of drug effect in patients who chronically consume opioids. The essential problem is that the magnitude of the right shift in C_{50} and C_{95}, which are key parameters used to build the pharmacodynamic models, is unknown (Fig. 39–29).

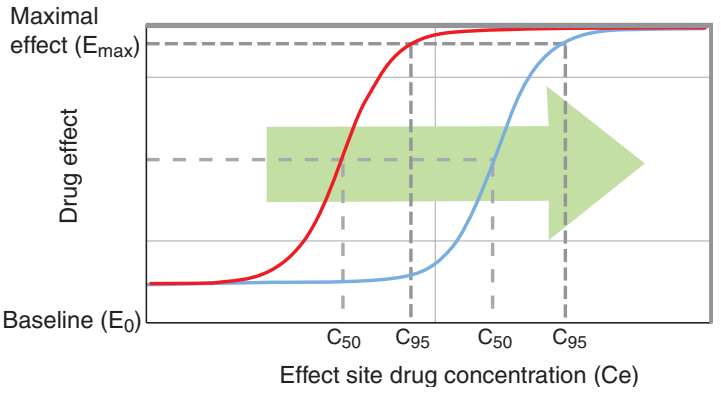

FIGURE 39–29. Effect of opioid tolerance on the concentration–effect relationship characterized by pharmacodynamic modeling. C_{50} and C_{95} are shifted to the right, indicating that more drug is required to achieve the same level of drug effect.

With the widespread use of oral short-acting and time-contingent opioids, transdermal opioid delivery systems, and implantable opioid infusion pumps, opioid tolerance is recognized as a growing challenge in the perioperative environment. Nevertheless, there is a paucity of literature examining the phenomenon of opioid tolerance as a covariate in pharmacodynamic models. One potential reason for this is that opioid tolerance is a difficult feature of drug behavior to quantify and most likely varies substantially among persons based on duration of opioid consumption and opioid dose.

With this problem in mind, investigators have explored methods of identifying the concentration–effect relationship for opioid on an individual basis.[83–85] Using principles of pharmacokinetics and pharmacodynamics, a technique called the "fentanyl challenge" has been developed. The fentanyl challenge was designed for use in patients with a known history of chronic opioid consumption who are scheduled to undergo surgical procedures associated with significant postoperative pain that will require a general anesthetic and are of moderate to long duration (i.e., multilevel lumbar spine instrumentation). The fentanyl challenge protocol calls for administration of a rapid continuous infusion of fentanyl (2 μg/kg/min) until the onset of respiratory depression in the absence of any other sedatives, anxiolytics, or opioids (Fig. 39–30). The optimal setting in which to perform the challenge is just prior to the induction of general anesthesia. The onset of respiratory depression as defined within the fentanyl challenge is a respiratory rate < 6 breaths/min. A critical component of the challenge is to measure the time from the onset of fentanyl infusion until the onset of respiratory depression.

With the duration of high-dose fentanyl infusion until respiratory depression identified, a pharmacokinetic simulation of the infusion is made to identify the fentanyl effect site concentration that is associated with respiratory depression. This process redefines the pharmacodynamic relationship between fentanyl effect site concentrations and drug effect that is unique to a particular patient. A major assumption of this protocol is that more drug will be required to achieve analgesia.

As described in the Pharmacodynamics section, a series of pharmacodynamic relationships over an array of noxious stimuli is encountered in the perioperative environment (Fig. 39–10). One interesting feature of this array of concentration relationships is that they can be quantified in terms of a percentage of the amount of drug required to elicit EEG changes.[26] For example, the fentanyl effect site concentration associated with C_{50} for changes in the spectral edge, a measure of EEG activity, is approximately 9 ng/mL.[35,65,86,87] The fentanyl effect site concentration C_{50} values associated with analgesia and respiratory depression are 1.6 and 5.4 ng/mL, respectively. Hence, the fentanyl effect site concentrations for analgesia and respiratory depression are 17% and 60%, respectively, of the C_{50} for EEG changes. Taking advantage of this linearity, the analgesic fentanyl effect site concentrations are approximately 30% of those associated with respiratory depression.[88,89]

Although not well established, preliminary work has indicated that the linear relationship between analgesia, respiratory depression, and EEG changes remains intact despite a rightward shift in the concentration–effect relationships associated with opioids in the chronic opioid-consuming patient.[83–85] Using this linearity, the fentanyl challenge is able to predict analgesic effect site concentrations from estimated concentrations of fentanyl required to produce respiratory depression. For example, the fentanyl effect site concentration associated with analgesia

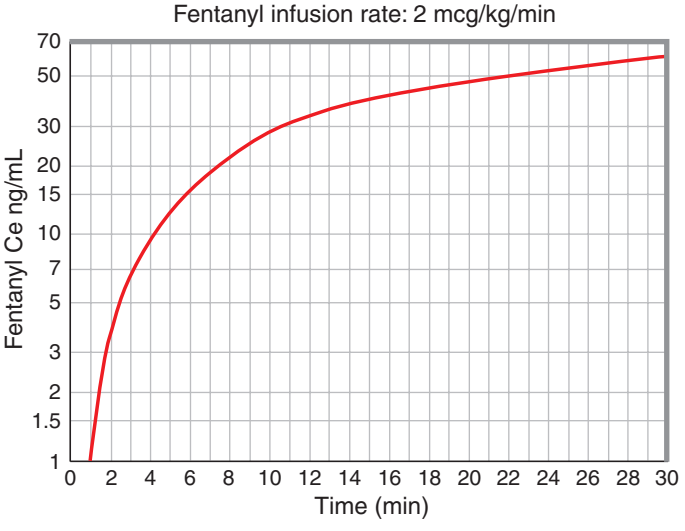

FIGURE 39–30. Computer simulation of the fentanyl challenge. Plot illustrates the fentanyl effect site concentration that results from a continuous infusion of 2 μg/kg/min. Plot is used to estimate the fentanyl effect site concentration at the onset of respiratory depression. For example, if 8 minutes elapses prior to the onset of respiratory depression (i.e., respiratory rate <6 breaths/min), the associated fentanyl effect site concentration is approximately 20 ng/mL.

will be 30% of the effect site concentration associated with respiratory depression regardless of the fentanyl effect site concentration required to achieve respiratory depression.

With the analgesic effect site concentration identified as a percentage of the concentration required for respiratory depression, the next step is to develop fentanyl dosing regimens to achieve and maintain analgesia. Dosing goals may be directed at providing intraoperative analgesia as part of a combined anesthetic technique and/or postoperative analgesia until the patient is able to take oral analgesics. Additional simulations are used to identify optimal infusion rates that will produce the target analgesic effect during the course of the anesthetic and into the postoperative period.

Unique features of fentanyl pharmacokinetics that are important to consider when initiating an infusion following a fentanyl challenge include the following: (1) With prolonged continuous infusions (i.e., >2 hours), effect site concentrations continue to rise. Simulations of continuous infusions reveal that effect site concentrations do not reach near steady state for at least 24 hours. Thus, it is important to anticipate the duration of a postoperative continuous fentanyl infusion and select an infusion rate that will not exceed the effect site concentrations associated with respiratory depression. (2) Upon completion of the fentanyl challenge prior to the induction of anesthesia, a significant amount of fentanyl can be delivered, depending on the duration of the challenge. For example, an 8-minute infusion at 2 μg/kg/min in a 90-kg patient will result in the delivery of 1440 μg (29 mL) of fentanyl. This initial dose should be accounted for when formulating an intraoperative fentanyl infusion rate.

In Fig. 39–31, a set of simulations illustrate the fentanyl effect site concentrations that result from a fentanyl challenge. In this case, an 8-minute infusion was required to reach the onset of respiratory depression. Following the challenge are six simulations of a fentanyl infusion ranging from 1–6 μg/kg/h for a 5-hour anesthetic. At 8 minutes, the fentanyl effect site concentration associated with respiratory depression is 20 ng/mL, giving a target effect site concentration of 6 ng/mL (i.e., 30% of 20). Using this simulation, the fentanyl infusion that best approximates the target effect site concentration of 6 ng/mL is a continuous infusion at 3 μg/kg/h.

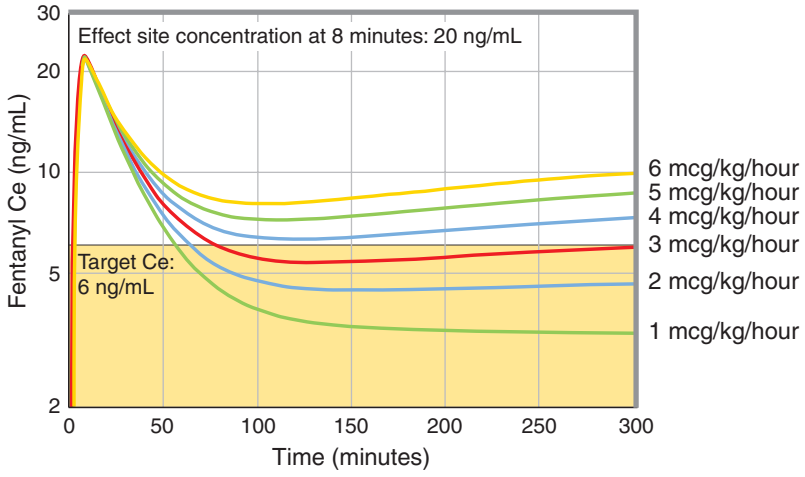

FIGURE 39–31. Computer simulation of the fentanyl challenge (2 μg/kg/min) for 8 minutes, followed by continuous infusions at various rates for 5 hours. Plot is used to estimate the fentanyl infusion rate necessary to achieve analgesia. The target Ce is estimated as 30% of the fentanyl effect site concentration (Ce) associated with the onset of respiratory depression (20 ng/mL). For a 5-hour anesthetic, a continuous infusion of 3 μg/kg/h best achieves the target Ce.

Information obtained from pharmacokinetic simulations following a fentanyl challenge can be used to improve intraoperative dosing of fentanyl to ensure adequate analgesia in the early postoperative period. This same information can be used to identify intravenous fentanyl dosing regimens for the first 24–48 hours following selected surgical procedures associated with significant postoperative pain and no or inadequate ability to use oral analgesics.

To improve intraoperative dosing of fentanyl, prior work has found that administering a continuous infusion of fentanyl that maintains the analgesic effect site concentration throughout the duration of a surgical procedure leads to an adequate level of analgesia in the early postoperative period yet allows for timely emergence from anesthesia in patients who chronically consume opioids.[84] With regard to postoperative dosing of fentanyl, information gained from the fentanyl challenge can be used to identify dosing regimens for patient-controlled analgesia (PCA) combined with a basal continuous infusion to maintain analgesia while avoiding respiratory depression.[83–85] Infusion rates (in micrograms per kg per hour) used intraoperatively to target the fentanyl concentrations associated with analgesia are divided in half. Half the infusion rate is administered as a continuous infusion, and the other half is administered as intermittent boluses using a PCA pump.

Preliminary exploration into the efficacy and safety of this technique has been encouraging. In a cohort of patients who reported chronic consumption of opioids, a fentanyl challenge was used to identify the intraoperative and postoperative dosing regimens for fentanyl. The number of interval doses delivered via the PCA pump was used as a metric of pain control. Interval dose requirements of less than two doses or less per hour was considered to provide adequate analgesia. No use of the PCA pump over a 4-hour period was considered to be an aggressive basal infusion and was decreased by 20%. PCA pump usage more than twice per hour was considered in inadequate basal infusion and was increased by 20%. Following 24 hours of this dosing regimen, measures of respiratory function, arterial PCO_2 levels, and pain control were made. In all subjects, respiratory rates and blood oxygenation were normal. Arterial PCO_2 levels ranged from 40–47 mm Hg. PCA pump usage was within one to two doses per hour.

A computer simulation of a fentanyl challenge followed by the intraoperative and postoperative course is presented in Fig. 39–32. In this example, an 80-kg patient known to chronically consume opioids required 10 minutes to achieve the onset of respiratory depression. The corresponding fentanyl effect site concentration at this time

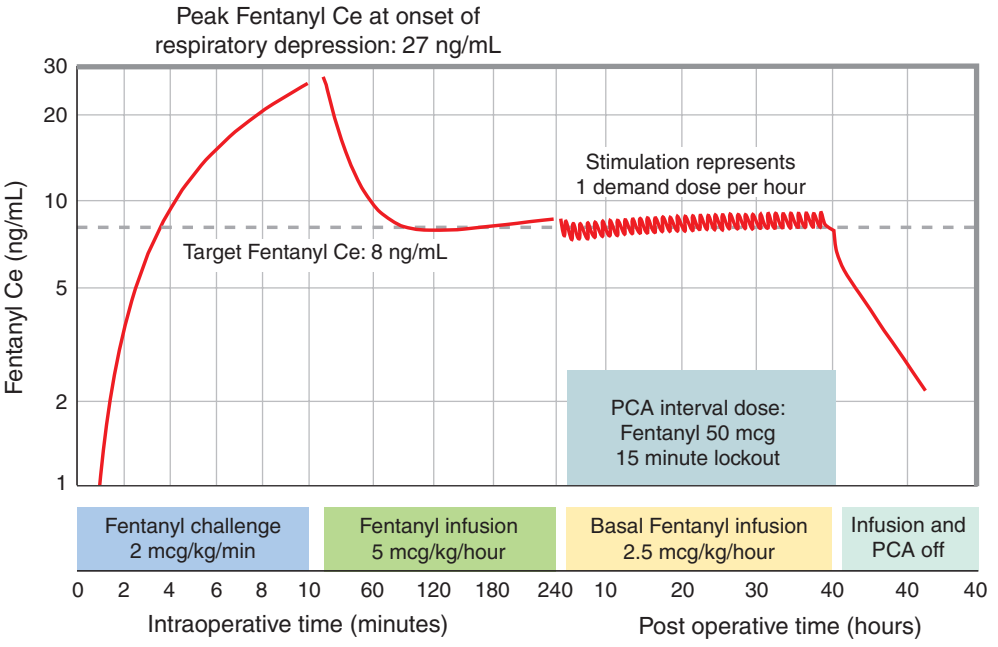

FIGURE 39–32. Computer simulation of the intraoperative and postoperative courses following a fentanyl challenge for an 80-kg, 180-cm patient. The fentanyl challenge (2 µg/kg/min) required 10 minutes to achieve respiratory depression (respiratory rate <6 breaths/min). The fentanyl effect site concentration at 10 minutes was 27 ng/mL. Subsequently, a fentanyl infusion was run at 5 µg/kg/h (8 mL/h) for 4 hours, with a target analgesic concentration of 8 ng/mL. Upon completion of the anesthetic, a basal infusion at 2.5 µg/kg/h (4 mL/h) and a patient-controlled analgesia (PCA) pump with a 50-mg bolus dose on a 15-minute lockout were started. The average PCA dose was one bolus per hour.

was 27 ng/mL. The target effect site concentration for analgesia was 30% of 27, or approximately 8 ng/mL. Subsequently, a basal infusion of fentanyl was administered at 5 µg/kg/h during the 4-hour intraoperative period as part of a combined technique with a potent inhaled agent. Upon completion of the intraoperative period, the patient was allowed to emerge from anesthesia. In the postoperative phase, a basal infusion was started at 2.5 µg/kg/h. In addition to the basal infusion, the PCA pump was set to deliver a demand dose of 50 µg every 15 minutes (2.5 µg/kg/h if using all four doses). The basal infusion and PCA pump were used for 36 hours following the anesthetic. Average PCA pump usage was one demand dose per hour. No adjustments were made in the PCA pump.

Several points of clinical interest are illustrated by this simulation. By starting the fentanyl infusion rate at 5 µg/kg/h immediately following the fentanyl challenge, the resultant effect site concentrations were well above the target concentration for nearly 90 minutes. This is an important feature to consider when delivering anesthetics of shorter duration. Also of interest, by the end of the 4-hour anesthetic, the effect site concentration was beginning to climb above 8 ng/mL. Should an anesthetic require more time, perhaps a more moderate infusion rate would be prudent (i.e., 4 µg/kg/h). In the postoperative phase, the simulation reveals that the basal infusion rate in combination with the PCA pump maintained the target concentration well. Once turned off, the fentanyl effect site concentrations drop fairly slowly. The time required for the fentanyl effect site levels to drop by half is >5 hours. This dissipation time may be important to consider when initiating oral analgesic therapy after terminating PCA pump use and basal infusion.

CHAPTER 40

Pharmacology of Intravenous Anesthetics

Mark Dershwitz, MD, PhD, and Carl E. Rosow, MD, PhD

HISTORY

For 90 years after the introduction of ether as a general anesthetic agent, almost all general anesthetics were administered via the inhalational route. That practice changed in 1935 following the description by Lundy[1] of the use of thiopental. It was soon recognized that intravenous anesthesia with thiopental required greater skill and was not as "forgiving" as general anesthesia with ether.[2] During World War II, both intravenous cannulation for the administration of blood products and crystalloid solutions, as well as physicians specializing in anesthesiology, became commonplace. Along with these changes in practice, thiopental was widely used during surgery for battlefield wounds. Over the next 3 decades, induction by inhalation became less and less common (with the exception of pediatric anesthesia) while additional intravenous agents were introduced to compete with thiopental.

Thiopental is an excellent intravenous anesthetic, and its introduction revolutionized the practice of anesthesiology. Newer agents such as propofol have improved upon thiopental and largely supplanted it in clinical practice. Nevertheless, thiopental and the other barbiturates are discussed first because they are the best characterized of all the intravenous anesthetics and the standard by which these newer drugs are judged. The characteristics of an "ideal" intravenous anesthetic agent are listed in Box 40–1. How each of the intravenous anesthetic agents available for use approaches this ideal is described in detail. Because not all clinical scenarios are identical, the unique characteristics of the individual agents must be considered when choosing the best drug for a particular patient.

KEY POINTS

1. Thiopental decreases cerebral metabolic rate for oxygen and cerebral blood flow. By causing vasoconstriction of CNS blood vessels, thiopental also significantly decreases intracranial pressure.
2. When thiopental is given in advance of a planned decrease or interruption in cerebral perfusion, the likelihood or severity of CNS damage appears to be reduced.
3. Thiopental produces a dose-dependent decrease in ventilatory drive. It causes a decreased tidal volume and minute ventilation and an increased $Paco_2$. The ventilatory depressant effect of thiopental is exaggerated in patients with underlying chronic obstructive pulmonary disease (COPD).
4. Thiopental has a direct effect on the heart by decreasing contractility, leading to a decrease in cardiac output. It also has a direct effect on both systemic arteries and veins causing vasodilatation.
5. Coexisting factors, such as previous premedication (e.g., benzodiazepines and/or opioids), advanced age, or presence of concurrent disease (e.g., cardiac dysfunction, COPD, hypovolemia) will decrease the required dose of thiopental to produce unconsciousness. Patients with acquired tolerance because of chronic use of barbiturates or cross-tolerance to benzodiazepines, anticonvulsants, or alcohol may require higher doses of thiopental to produce unconsciousness.
6. The CNS effects of propofol are similar to those of thiopental. Propofol causes a greater decrease in blood pressure than does thiopental because of a larger reduction in systemic venous and arteriolar vascular resistance, resulting in decreases in both preload and afterload. Propofol also blunts the barostatic reflex, resulting in a slower heart rate for a given decrease in blood pressure as compared with thiopental.
7. Propofol causes the least incidence of postoperative nausea and vomiting of any general anesthetic agent, injected or inhaled. Propofol also has intrinsic antiemetic activity and has been used successfully as an antiemetic.
8. Propofol often causes pain, sometimes severe, on injection. Injecting lidocaine with a proximal tourniquet provides the highest efficacy in preventing such pain.
9. Propofol is the shortest-acting intravenous anesthetic. It accumulates to the least degree, and because of its rapid recovery characteristics following infusion, even after long-duration infusion, it is an extremely useful drug for maintaining general anesthesia.
10. The CNS effects of etomidate are similar to those of thiopental and propofol.
11. Etomidate is notable for its lack of cardiovascular effects. It has little effect on systemic arterial or venous vascular tone or on cardiac contractility, and usually little change in blood pressure or heart rate occurs. Cardiovascular stability is generally preserved in persons with hypovolemia or cardiac dysfunction.
12. Etomidate inhibits the enzyme responsible for performing the 11β-hydroxylation reaction in cortisol synthesis. A single induction dose of 0.3 mg/kg inhibits cortisol synthesis and the normal response to adrenocorticotropic hormone for up to 12 hours. Infusions of several days' duration in ventilated ICU patients are associated with increased mortality.
13. Sedative doses of midazolam cause patients to become sleepy and calmer and to have anterograde amnesia. The amnestic effects of midazolam are variable but usually short-lived, and they should not be relied upon to prevent recall of intraoperative events.
14. Intramuscular administration of midazolam results in reliable absorption and little injection pain. Its oral bioavailability is only approximately 15%.
15. Midazolam is synergistic with opioids or alcohol in depressing ventilatory drive. Patients with COPD are more sensitive to its ventilatory depressant effects.

Continued

Key Points—continued

16. Flumazenil is a benzodiazepine antagonist. When given to healthy volunteers, mild anxiety and symptoms resembling those that occur during a panic attack may occur. When given to patients chronically taking benzodiazepines, acute withdrawal, including seizures, may occur.
17. Ketamine produces dissociative anesthesia. Under ketamine anesthesia, the patient may move, vocalize, have eyes open, and make ocular tracking movements. Depth of anesthesia is difficult to assess. It also produces profound analgesia and salivation.
18. Ketamine usually causes an increase in blood pressure, heart rate, cardiac contractility, cardiac output, and vascular resistance. It has little effect on ventilatory drive in normal patients or in patients with COPD, and it produces bronchodilation. Protective airway reflexes are less likely to be ablated.
19. Intramuscular administration of ketamine results in reliable absorption and little injection pain.
20. Droperidol produces a neuroleptic state in which behavior is diminished and responses to stimuli are fewer, slower, and smaller in magnitude. At high doses, it can produce catatonia, although consciousness and memory are preserved.
21. At subhypnotic doses, droperidol is an excellent antiemetic.
22. Dexmedetomidine is an α_2-adrenoceptor agonist that produces sedation without associated amnesia. Even at high doses, loss of consciousness does not occur.

BARBITURATES

Chemistry

A large number of barbiturates have been introduced into clinical medicine, but only two remain in use as intravenous anesthetics: thiopental (a thiobarbiturate) and methohexital (an oxybarbiturate; Fig. 40–1 and Table 40–1). Both of these medications are practically insoluble in water; however, they are weak acids, and their sodium salts are freely soluble in water.

The usual concentrations of the sodium salts used clinically are 2.5% thiopental and 1% methohexital. Thiopental is soluble at higher concentrations, but pain on injection is likely to occur. The 2.5% thiopental solution usually is painless when given intravenously. This solution is irritating to tissues if it extravasates because it has a pH between 10 and 11. If accidentally injected intraarterially, vasospasm and thrombosis may occur that can lead to limb loss if not treated rapidly by intraarterial injection of a vasodilator (e.g., papaverine or nitroglycerin) and an anticoagulant (e.g., heparin). The 1% methohexital solution is more likely to cause pain after intravenous injection; however, it is well tolerated after intramuscular injection and can be given via this route in a patient without intravenous access. Methohexital is hazardous if inadvertently injected intraarterially.

Both thiopental and methohexital are supplied in powdered form and usually are reconstituted with sterile, preservative-free water (although normal saline can be used). Neither reconstituted solution is stable in the long term, and the manufacturer's package inserts state that they are stable at room temperature for 24 hours. Despite this conservative recommendation, thiopental has been shown to be both chemically stable and bacteriologically sterile for at least 1 week following reconstitution when refrigerated.[3] Under refrigeration, methohexital remains chemically stable and microbiologically sterile for at least 6 weeks.[4]

Pharmacodynamics

Central Nervous System

Thiopental has its primary neuronal action at the γ-aminobutyric acid $(GABA)_A$ receptor, a ligand-gated ion channel. The $GABA_A$ receptor is coupled to a chloride channel; as the GABA effect increases, the postsynaptic membrane becomes hyperpolarized, and thus GABA acts as an inhibitory neurotransmitter. Thiopental binds to a unique binding site and increases chloride conductance in a concentration-dependent manner. Thus thiopental potentiates the inhibitory effects of GABA. Although barbiturates allosterically affect GABA binding (and vice versa), GABA is not necessary for barbiturate action on the channel.[5]

The barbiturates are classified as sedative–hypnotics; they produce dose-related depression of the central nervous system (CNS) ranging from mild sedation to unconsciousness. Thiopental or methohexital rapidly produce unconsciousness, and awakening will occur in minutes unless additional drugs are given. When administered in subhypnotic doses, barbiturates can sometimes produce disinhibition and "paradoxical" excitation. These drugs are not analgesics, and suppression of movement or hemodynamic responses to painful stimuli requires plasma concentrations in excess of those needed to cause unconsciousness.

In the CNS, neuronal activity is coupled to oxygen utilization and delivery as a result of autoregulation (Table 40–2). By decreasing neuronal activity, thiopental decreases both CNS

BOX 40–1.

The "Ideal" Intravenous Anesthetic Agent

- Stable in aqueous solution
- No pain on injection, venous irritation, or tissue damage from accidental perivenous administration
- Very low potential to release histamine or precipitate hypersensitivity reactions
- Rapidly metabolized to pharmacologically inactive substances, with minimal accumulation when administered by repeated bolus doses or continuous infusion
- Rapid and smooth onset of action, without excitatory phenomena such as muscle movements, hypertonus, or hiccoughing
- Produces a steep dose–response relationship so that changes in the rate of administration result in rapid changes in the depth of anesthesia when administered by continuous infusion
- Rapid and smooth return of consciousness, even after prolonged administration for maintenance of anesthesia or sedation
- Produces a decrease in cerebral metabolism proportional to the decrease in cerebral blood flow and does not increase intracranial pressure
- Minimal cardiovascular and ventilatory depressant effects with no adverse effects on other organ systems
- Allows rapid recovery without postoperative side effects, such as nausea and vomiting, psychomimetic symptoms, dizziness, headache, or prolonged sedation ("hangover")

Physicochemical Properties of Anesthetic Agents

Drug Group	Drug Name	Available Solutions (pH or pK_a)	Venous Irritation
Barbiturates			
Thiobarbiturate	Thiopental	pK_a = 7.5 Sodium salt, to be diluted in water or saline to create 2.5% solution, pH >10	+++
Oxybarbiturate	Methohexital	pK_a = 7.9 Sodium salt, to be diluted in water or saline to create 1% solution, pH >10	+++
Alkylphenol	Propofol	pK_a = 11 1% solution in aqueous emulsion containing 10% soybean oil, 2.25% glycerol, 1.2% lecithin	++
Imidazole	Etomidate	pK_a = 4.3 0.2% solution in 30% propylene glycol	+++
Benzodiazepines	Diazepam	0.5% solution in 40% propylene glycol, 10% ethanol	+
	Lorazepam	0.4% solution in 80% propylene glycol, 18% polyethylene glycol, 2% benzyl alcohol	+
	Midazolam	0.1% or 0.5% aqueous solutions, pH 3–4	–
Arylcyclohexylamine	Ketamine	pK_a = 7.5 1%, 5%, or 10% aqueous solutions, pH 3.3–5.5	–

oxygen utilization, as measured by the cerebral metabolic rate of oxygen consumption ($CMRO_2$), and cerebral blood flow (CBF). By causing vasoconstriction of CNS blood vessels, and therefore a reduction of cerebral blood volume, thiopental also significantly decreases intracranial pressure (ICP). In some instances thiopental may exert a "neuroprotective" effect (see two paragraphs later) in which decreased oxygen delivery to the CNS (e.g., during clamping of an intracranial artery) may be less likely to result in CNS damage because there has been a drug-induced decrease of oxygen utilization.

Because of its effects on $CMRO_2$, CBF, and ICP, intravenous thiopental injection may produce beneficial effects in patients with intracranial space-occupying lesions or cerebral edema associated with a brain tumor, intracranial hemorrhage, or head trauma (Table 40–2). Cerebral perfusion pressure (CPP) is estimated to be the difference between the mean arterial pressure (MAP) in the carotid arteries and the ICP or, if low, the venous pressure in the jugular veins (see Chap. 10). It is significantly affected by the position of the patient with respect to gravity. The effect of thiopental on CPP in the supine patient is unpredictable. Thiopental decreases mean arterial pressure in a dose-dependent manner (see Cardiovascular System); however, if CPP is low in a patient because of an elevated ICP, the overall effect of thiopental may be beneficial.[6]

The ability of thiopental to produce "neuroprotection" is both variable and controversial. When thiopental is given *in advance* of a planned reduction or interruption of cerebral perfusion, the likelihood or severity of subsequent CNS damage appears to be less.[7] In contrast, when thiopental is given *after* the onset of cerebral ischemia, such as following a cardiac arrest, no apparent beneficial effect is seen.[8] Protective efficacy appears to be superior when the size of the ischemic area is smaller and when the total duration of ischemia is shorter (see Chap. 88 for detailed considerations on this topic).

Thiopental produces a dose-dependent effect on the electroencephalograph (EEG; Fig. 40–2).[9] At sedative doses or at doses associated with excitation or disinhibition ("stage 2" anesthesia), median EEG frequency increases because alpha waves (7–13 Hz) typical of the awake state change to beta waves (13–30 Hz). As the depth of hypnosis increases, there is a decrease in fre-

quency and an increase in amplitude (power) of the EEG waves. Surgical anesthesia is associated with an EEG characterized by a predominance of delta waves (0.5–3.5 Hz). Increasing the dose of thiopental further leads to burst suppression (characterized by alternating periods of delta waves and electrical inactivity) and, finally, a completely isoelectric ("flat-line") EEG. An isoelectric or burst suppression EEG pattern is associated with a profound decrease in both $CMRO_2$ and CBF, and this end point has been used to titrate the dose of thiopental for brain protection studies. Some studies suggest that alternative mechanisms (e.g., decrease in amino acid–induced excitotoxicity) are more important than reducing cerebral metabolic rate.[10]

Thiopental is an excellent anticonvulsant. The typical intravenous anesthetic induction dose of 4–7 mg/kg usually is effective in rapidly terminating seizures. Refractory status epilepticus is often treated with repeated boluses or with continuous infusion of thiopental; such patients usually also require mechanical ventilatory support and may require infusion of vasopressors (see Cardiovascular System).

In contrast to thiopental, methohexital may cause abnormal spiking activity of the EEG and may elicit seizures in patients with a seizure disorder, especially in those with psychomotor epilepsy. For this reason, methohexital has long been used as the hypnotic agent to render patients unconscious for electroconvulsive therapy. Methohexital is also associated with abnormal motor activity during induction of general anesthesia, such as myoclonic jerks, muscle tremors, and hiccoughs.

Respiratory System

Thiopental produces a dose-dependent decrease in ventilatory drive, with a decreased tidal volume and minute ventilation and an increased $PaCO_2$ (Table 40–3). At the usual intravenous anesthetic induction dose of 4–7 mg/kg, most patients will become apneic for a few minutes. Accompanying this ventilatory depression is a decrease in protective airway reflexes, although overall responsiveness of the airway is increased. The incidence of coughing and laryngospasm during induction is higher with barbiturates than with most other sedative–hypnotics. The ventilatory depressant effect of thiopental is exaggerated in patients with underlying chronic obstructive pulmonary disease (COPD), and there is a synergistic effect between thiopental and opioids in decreasing ventilatory drive.

Thiopental produces an increase in the circulating concentration of histamine (see Hypersensitivity Reactions). The effect of histamine on the respiratory musculature is to cause constriction in the trachea and dilation in smaller airways. Typically no net alteration in bronchial resistance occurs.[11]

Cardiovascular System

Thiopental typically causes a transient, although significant, decrease in systemic blood pressure when it is administered to induce general anesthesia (Table 40–4).[12] This decrease in blood pressure is exaggerated in persons with preexisting cardiac dysfunction or hypovolemia, those given opioid or benzodiazepine premedication, or those receiving therapy with β-adrenergic blockers or vasodilators. Thiopental-induced hypotension is more pronounced in older patients and when the drug is administered rapidly. Thiopental has a direct effect on the heart, decreasing contractility and leading to a decrease in cardiac output. It also has a direct effect on both systemic arteries and veins, causing vasodilatation. This vasodilatation results in decreased systemic arterial pressure as well as decreased venous return to the heart, the latter effect compounding the decrease in cardiac output and blood pressure. An equipotent dose of methohexital causes slightly less hypotensive effect than does thiopental. Thiopental increases the pulmonary vascular resistance in rat lung,[13] although this effect may not be significant in humans.[14]

Adverse Effects

Hypersensitivity Reactions In an *anaphylactic* reaction, there is IgE-mediated release of vasoactive and immune mediators from mast cells and basophils. An *anaphylactoid* reaction results when a drug directly causes the release of some of these mediators from mast cells or basophils. Anaphylaxis and other true immunologic reactions to barbiturates are extremely rare. They occasionally produce an *anaphylactoid* reaction by displacing vasoactive mediators from tissue mast cells or basophils. Thiopental injection increases the circulating concentration of histamine 3.5-fold, with the histamine concentration returning to baseline within 10 minutes.[15] This effect contributes to the overall decrease in systemic vascular resistance produced by the drug. Anaphylactic or anaphylactoid reactions to thiopental are much less common than are perioperative reactions to latex exposure or injection of muscle relaxants and antibiotics.[16]

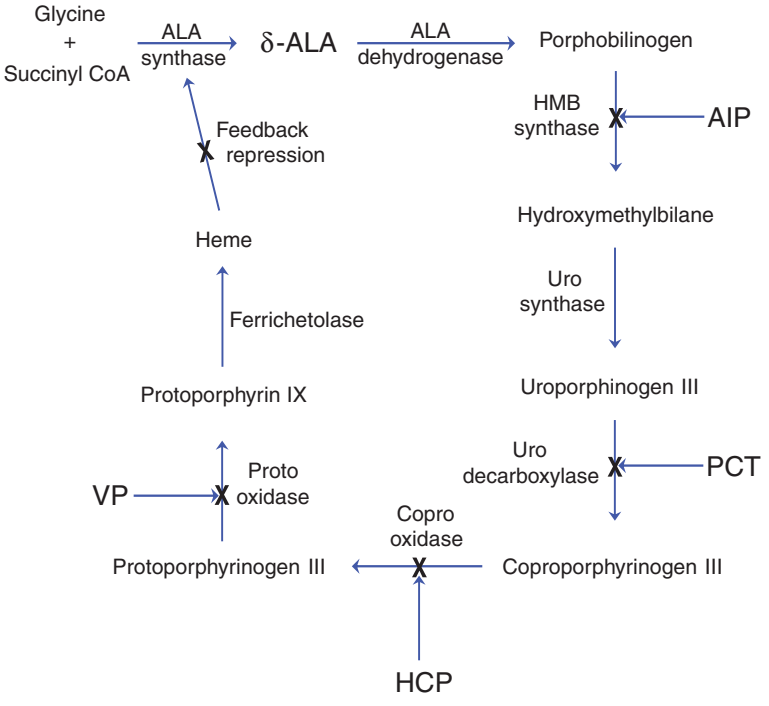

FIGURE 40–3. Heme biosynthesis pathway. The enzyme deficiencies that result in the various forms of porphyria are indicated with an "X." AIP, acute intermittent porphyria; ALA, aminolevulinic acid; HCP, hereditary coproporphyria; HMB, hydroxymethylbilane; PCT, porphyria cutanea tarda. (Redrawn from Desnick[17] with permission.)

Porphyria Barbiturates are the prototypical inducers of the hepatic microsomal enzyme system, including the cytochromes P450 and the glucuronyl transferases. The rate of metabolism of some medications may be increased in the postoperative period if a patient is given thiopental for anesthesia induction, although this effect is rarely of clinical consequence. Thiopental is also an inducer of the enzyme δ-aminolevulinic acid (ALA) synthase, an enzyme that catalyzes the initial step in the biosynthesis of heme. Thiopental is absolutely contraindicated in persons with certain porphyrias (Fig. 40–3). In three of the clinically important porphyrias, there is a deficiency in a heme biosynthetic enzyme that follows ALA synthase in the pathway, and ALA, which is neurotoxic, then accumulates. These three porphyrias are acute intermittent porphyria, hereditary coproporphyria, and variegate porphyria,[17] and the enzyme deficiencies responsible for them are shown in Fig. 40–3. Each of these is transmitted as an autosomal dominant trait, so affected individuals usually are heterozygotes with approximately half the normal amount of enzyme. Interestingly, a fourth variety, porphyria cutanea tarda, also due to a deficiency in a heme biosynthetic enzyme, is not a contraindication to use of a barbiturate.[17] Anesthetic medications generally considered safe or unsafe in persons with porphyria are listed in Box 40–2.

Renal Effects Thiopental decreases renal blood flow and increases the secretion of antidiuretic hormone. The actions act together to decrease urine output.

Other effects In comparison to propofol (see Propofol, Nausea and Vomiting), thiopental used for anesthesia induction results in a higher incidence of postoperative nausea and vomiting. In sedative (i.e., subhypnotic) doses, thiopental causes hyperalgesia (i.e., it decreases the threshold to pain).[18] This effect (and thiopental's tendency to accumulate) make it a poor choice for intraoperative sedation during regional anesthesia or monitored anesthesia care. Thiopental is safe to use in patients susceptible to malignant hyperthermia.

Pharmacokinetics

Lipid Solubility

Thiopental is administered as the alkaline (pH 10–11) solution of its sodium salt, but it is buffered to physiologic pH immediately upon contacting the circulation. Because its pK_a is 7.5, at physiologic pH slightly >50% of the thiopental molecules are uncharged and therefore lipid soluble. Its oil/water partition coefficient of approximately 500 is more than twice that of halothane, indicating that it is highly lipid soluble. This high lipid solubility, coupled with the large fraction of the cardiac output typically delivered to the brain, is responsible for the very rapid onset of effect, typically well under 1 minute, following intravenous administration.

BOX 40-2.

Safety of Anesthetic Medications in Porphyria[a]

Unsafe	Safe	Inadequate Data[b]
Alcohol	Acetaminophen	Atracurium
Barbiturates	Aspirin	Diazepam
Carbamazepine	Atropine	Halothane
Etomidate	Bupivacaine	Isoflurane
Pentazocine	Droperidol	Ketamine
Valproic acid	Nitrous oxide	Lidocaine
	Opioids	Midazolam
	Phenothiazines	Vecuronium
	Procaine	
	Propofol	
	Scopolamine	
	Succinylcholine	

These recommendations are based upon the authors' review of the available literature.
[a]Acute intermittent porphyria, hereditary coproporphyria, and variegate porphyria.
[b]These medications probably are safe in that there are no case reports that have linked them to exacerbations of porphyria; however, the number of reports suggesting that they are safe is inadequate to justify a generalized recommendation as safe.

TABLE 40–5.

Pharmacokinetic Parameters for Intravenous Anesthetic Agents

Drug Name	Redistribution Half-Life (min)	Terminal Half-Life (h)	Clearance (mL/min)	Volume of Distribution (L)	Protein Binding (%)
Thiopental	2–4	6–12	120–180	100–200	85
Methohexital	5–6	2–5	700–900	60–80	85
Propofol	1–2	4–6	1400–2800	200–500	98
Etomidate	2–4	2–5	800–1400	200–400	75
Diazepam	10–15	20–40	15–35	60–100	98
Lorazepam	3–10	10–20	50–70	50–90	98
Midazolam	7–15	2–4	300–550	70–130	94
Ketamine	11–17	2–3	1250–1400	200–250	12

Protein Binding

Thiopental is approximately 85% bound to plasma protein. Protein-bound thiopental is unable to diffuse across the blood–brain barrier and produce a pharmacologic effect. In addition, the extensive binding of thiopental limits overall hepatic clearance, as only free drug is taken up by the liver to be metabolized. In clinical situations where the plasma concentration of protein is decreased (e.g., hepatic disease or hemodilution due to fluid resuscitation), the free fraction of thiopental is elevated, and lower doses of thiopental may be needed.

Redistribution

The redistribution half-life of a drug, often abbreviated as $t_{1/2\alpha}$, is the time required for the central compartment concentration of the drug to decrease by 50% as the drug is distributed to peripheral compartment(s) (see Chap. 39). For thiopental, $t_{1/2\alpha}$ is approximately 2–4 minutes,[19] indicating that, following a typical bolus injection, the effect of the drug will be terminated within 3–4 half-lives or approximately 6–16 minutes (Table 40–5). Redistribution is the primary process by which the pharmacologic effects of thiopental are terminated. Unless the drug is given in very large doses (e.g., barbiturate coma), repeated doses, or by a long continuous infusion, metabolism and elimination are much less important in terminating its effect.

Metabolism and Elimination

The terminal half-life of a drug, often abbreviated as $t_{1/2\beta}$ for medications fitting a two-compartment model (see Chap. 39), is a function of the processes of both metabolism and elimination. For thiopental, $t_{1/2\beta}$ is approximately 6–12 hours.[19] Thiopental undergoes an interesting metabolic reaction catalyzed by cytochrome P450. The initial step is oxidation of the sulfur atom, forming a sulfoxide derivative that spontaneously rearranges leaving oxygen in place of the sulfur in the barbiturate ring. This metabolite is the active barbiturate pentobarbital. Because of slower redistribution, pentobarbital is a longer-acting drug than thiopental. Thus, when very large doses of thiopental are given, clinically significant concentrations of pentobarbital occur. Pentobarbital contributes to the overall effect and makes thiopental appear as a much longer-acting medication.[20] Other inactive hydroxylated metabolites of thiopental also are produced. Methohexital has a lower volume of distribution and a higher hepatic clearance than thiopental, and it is metabolized to inactive hydroxylated metabolites (Table 40–6).

Factors Affecting Pharmacodynamics and Pharmacokinetics

Many factors affect the pharmacodynamics and pharmacokinetics of thiopental. For example, elderly patients require lower doses of thiopental to produce unconsciousness. This altered response is due to the decreased rate of distribution from the central compartment to the rapidly equilibrating compartment.[21]

The pharmacokinetics of thiopental in persons with significant impairment of hepatic function is complex. The fraction of unbound thiopental is increased because of decreased plasma albumin concentrations, but hepatic clearance of unbound drug is decreased. Total clearance remains normal.[19] Persons with cardiac dysfunction typically have an exaggerated hypotensive response to thiopental. In hypovolemic shock, a lower thiopental dose is needed because a greater fraction of the cardiac output goes to the brain. The hypovolemic patient may tolerate thiopental-induced vasodilatation very poorly.

Clinical Use

Induction of Anesthesia

The characteristics of thiopental as an induction agent are listed in Table 40–7. An induction dose of 4–7 mg/kg is reasonable in the typical healthy patient undergoing elective surgery. Coexisting factors, such as previous premedication (e.g., with benzodiazepines and/or opioids), advanced age, or presence of concurrent disease (e.g., cardiac dysfunction, COPD, hypovolemia) will decrease the required dose of thiopental. Patients with acquired tolerance because of chronic use of barbiturates or cross-tolerance to benzodiazepines, anticonvulsants, or alcohol may require higher doses of thiopental to produce unconsciousness.

TABLE 40–6.

Relative Hepatic Extraction Ratios for Intravenous Anesthetic Agents

Low	Intermediate	High
Diazepam: 0.01–0.025	Midazolam: 0.2	Etomidate: 0.7
Thiopental: 0.1–0.2	Methohexital: 0.5–0.6	Ketamine: 0.8
		Propofol: >1

TABLE 40–7.

Induction Characteristics for Intravenous Anesthetic Agents

Drug Name	Induction Dose (mg/kg)	Onset (sec)	Duration (min)	Excitatory Activity	Injection Pain
Thiopental	4–7	<30	5–10	+	+
Methohexital	1–3	<30	5–10	++	++
Propofol	1–3	<30	3–8	+	+++
Etomidate	0.2–0.3	<30	5–10	+++	++
Diazepam	0.3–0.6	45–60	15–30	0	++
Lorazepam	0.03–0.06	60–120	60–120	0	++
Midazolam	0.2–0.4	30–60	15–30	0	0
Ketamine	1–2	45–60	10–20	++	0

If there is concern about a possibly exaggerated response to thiopental, a prudent practice would be to administer the induction dose slowly or in divided doses, using a small initial bolus as a "test dose" and waiting 1–2 minutes to evaluate the central nervous and hemodynamic responses.

After administration of the induction dose, consciousness typically is lost within 30 seconds, although this time may be longer in persons with a slow circulation time because of cardiac dysfunction. Recovery of consciousness usually occurs within 5–10 minutes; however, some degree of cognitive impairment (a "hangover") may persist for hours.

The induction dose of methohexital is 1–3 mg/kg. Onset and awakening are similar to those with thiopental; however, the duration of cognitive impairment will be somewhat shorter.

Maintenance of Anesthesia

General anesthesia can be maintained by either intermittent intravenous boluses or a continuous intravenous infusion of thiopental; however, a rapid recovery should not be anticipated. Giving any rapidly redistributed medication by intermittent bolus results in a series of peaks and troughs in both blood concentration and effect, typically causing alternating periods of overmedication and undermedication. A continuous infusion, typically following a loading dose, permits a more constant blood (and brain) concentration and effect (see Chap. 42).

The context-sensitive half-time (CSHT) describes the time required for the central compartment blood concentration to fall by half as a function of the duration of an infusion (of variable rate designed to maintain a constant blood concentration).[22] The CSHTs for thiopental following 1- and 2-hour infusions are approximately 80 and 100 minutes, respectively (Fig. 40–4). Thus thiopental is not a good choice for a maintenance infusion when rapid emergence and recovery are desired.

Methohexital has shorter CSHT values than does thiopental. The CSHTs for methohexital following 1- and 2-hour infusions are approximately 26 and 48 minutes, respectively (Fig. 40–4). Although shorter than for thiopental, emergence and recovery following an infusion of methohexital are still prolonged.

Sedation

Sedation during regional anesthesia or monitored anesthesia care can be achieved by the administration of intermittent boluses or a continuous infusion of a medication or medications. Frequently an opioid is given along with a sedative to relieve the discomfort that may accompany a noxious procedure as well as decrease the required dose of the sedative. Intermittent bolus administration has the additional risk of causing periods of unconsciousness that may be accompanied by diminished or absent airway reflexes.

Barbiturates are infrequently used for procedural sedation (except perhaps the use of methohexital during office-based oral surgical procedures). In subhypnotic doses, thiopental has only mild suppressant effects on memory[23] (usually considered a desirable effect), and there may be hyperalgesia to pain.

PROPOFOL

Chemistry

Propofol is 2,6-diisopropylphenol, a simple derivative of phenol (Fig. 40-1 and Table 40–1). Propofol is an oil at room temperature and is essentially insoluble in water. Its initial formulation used a detergent called Cremophor, but this solubilizer was found to produce anaphylactoid reactions. Propofol subsequently was prepared as a 1% emulsion in Intralipid, a commonly used source of nutritional fat in patients receiving total parenteral nutrition. Intralipid contains 10% soybean oil, 2.25% glycerol, and 1.2% egg lecithin. The propofol emulsion readily supports bacterial growth, and the original formulation was associated with numerous cases of iatrogenic sepsis. Currently, all propofol formulations have a bacteriostatic agent added in low concentration to slow, but not prevent, bacterial growth. Depending on the manufacturer, the bacteriostatic agent

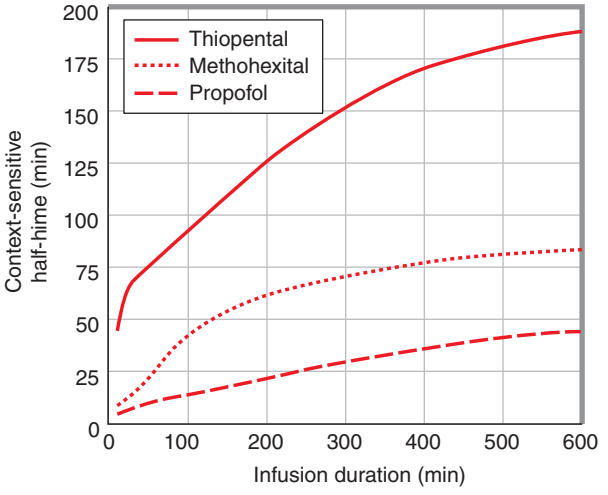

FIGURE 40–4. Context-sensitive half-times for thiopental, methohexital, and propofol as a function of the duration of infusion.

is 0.005% ethylenediaminetetraacetic acid (EDTA), 0.025% metabisulfite, or 0.1% benzyl alcohol. Propofol undergoes dimerization and oxidation to a quinone when exposed to oxygen. These chemical reactions occur at a more rapid rate in the preparation containing metabisulfite.[24] When the metabisulfite-containing propofol preparation is exposed to room air, it becomes visibly yellow after approximately 6 hours because of the presence of quinone. Whether this oxidation product affects safety or efficacy is unknown, but all opened vials and syringes containing propofol (irrespective of preservative) should routinely be discarded after 6 hours in order to reduce the risk of bacterial contamination.

Pharmacodynamics

Central Nervous System

The CNS effects of propofol are very similar to those of thiopental (Table 40–2). It is a rapid-acting hypnotic whose effects are terminated by rapid redistribution. Like thiopental, propofol exerts its CNS effects primarily via the $GABA_A$ receptor.[25] In vitro studies suggest that it also acts to inhibit glutamate action at *N*-methyl-D-aspartate (NMDA) receptors.[26] Propofol also decreases $CMRO_2$, CBF, and ICP. Although it has not been studied as well as thiopental for its neuroprotective activity, it appears to share that effect with thiopental.[27] It must be used cautiously in this setting because it causes more hypotension than thiopental (see Cardiovascular System) and therefore is more likely to reduce CPP and thus CBF.

Like thiopental, propofol is an anticonvulsant, and it has been used to terminate status epilepticus. It probably does not produce this effect in sedative doses.[28] Although propofol shortens the duration of "therapeutic" seizure during electroconvulsive therapy compared with methohexital, it still can be used in this setting.[29]

Propofol has pharmacodynamic effects that differ from those of thiopental in several ways. It does not produce hyperalgesia in sedative doses, and it is more likely to suppress movement responses to painful stimuli at concentrations achieved during routine administration. Unlike thiopental, sedative doses of propofol can produce significant amnesia.[23] At sedative and hypnotic concentrations, propofol is much more effective in reducing airway responsiveness, and the incidence of cough or laryngospasm is greatly reduced. On the other hand, induction of anesthesia with propofol often causes myoclonic movements, an effect that is much less common with thiopental. Finally, even subhypnotic concentrations of propofol have a direct antiemetic effect (see Nausea and Vomiting). In this respect it is unlike any other intravenous anesthetic agent.

Respiratory System

The effects of propofol on respiratory control are very similar to those of thiopental (Table 40–3). Like thiopental, propofol produces a dose-dependent decrease in ventilatory drive manifested as decreased tidal volume and minute ventilation and increased $Paco_2$. After injection of the usual anesthetic induction dose of 1–3 mg/kg, most patients will become apneic for a few minutes and have decreased airway reflexes. The ventilatory depressant effect of propofol is exaggerated in patients with underlying COPD, and there is a synergistic effect between propofol and opioids in decreasing ventilatory drive.

Unlike thiopental, propofol does not cause histamine release. Airway resistance following intubation is lower after induction with propofol than after thiopental.[30] Some persons with reactive airway disease become bronchospastic when exposed to sulfites in the environment, such as those found naturally in certain wines. Reports on the bronchospastic effects of the metabisulfite-containing propofol preparation are conflicting, but any such effects, if they exist, appear to be sporadic and minor.

Cardiovascular System

Propofol causes a greater decrease in systemic blood pressure than does thiopental (Table 40–4).[31] Although the two drugs have similar depressant effects on cardiac contractility, propofol causes a larger reduction in venous and arteriolar systemic vascular resistance resulting in decreases of both preload and afterload. Contributing to the hypotensive effect of propofol is its action in blunting the barostatic reflex, resulting in a slower heart rate for a given decrease in blood pressure compared with thiopental.[32] As is seen with thiopental, the decrease in blood pressure with propofol injection is exaggerated in older persons and those with preexisting cardiac dysfunction or hypovolemia, those given opioid or benzodiazepine premedication, or those receiving therapy with β-adrenergic blockers or vasodilators. Propofol does not alter the normal resting pulmonary vascular resistance in dogs; however, it potentiates the pulmonary vasoconstriction produced by phenylephrine.[33]

Nausea and Vomiting

Propofol causes the least incidence of postoperative nausea and vomiting of any general anesthetic agent, injected or inhaled.[34] The use of propofol as a maintenance anesthetic is associated with a very low incidence of postoperative nausea and vomiting, perhaps because residual subhypnotic concentrations are antiemetic.[35] In addition, propofol has intrinsic antiemetic activity and has been used successfully as an antiemetic.[36] The mechanism of this effect is unknown, although it does not involve dopamine D_2 receptors such as with droperidol or metoclopramide.[37]

Other Effects

Like thiopental, propofol decreases renal blood flow and causes increased secretion of antidiuretic hormone. Subhypnotic doses appear to be effective in reversing the itching produced by cholestasis or by epidural morphine.[38] Propofol is safe to give to patients with all types of porphyria and for those with malignant hyperthermia.

Adverse Effects

Pain on Injection Propofol often causes pain, sometimes severe, on injection. The importance of this problem to the anesthesia community is indicated by the fact that, in the 20 years since the introduction of propofol, more than 300 publications have addressed this adverse effect. What is apparent when considering the published studies is that no technique is universally reliable in preventing this adverse effect, nor is there general agreement on which technique is most recommended.

Mitigating the pain on injection of propofol has involved three general approaches: modifying the vehicle in which the propofol is contained, adding a drug to the propofol emulsion, or administering a drug prior to propofol injection.

There appears to be a correlation between the incidence and severity of pain and the free concentration of propofol in the aqueous phase of the emulsion. Modifications of the emulsion

that increase the free propofol concentration (i.e., decreasing the concentration of lecithin) are associated with increases in pain. Conversely, a modified emulsion product has been developed that uses a mixture of medium-chain and long-chain triglycerides instead of egg lecithin (Propofol Lipuro). It has a lower free concentration of propofol and causes less pain on injection.[39] Although not available in the United States (as of 2007), it is widely used in Europe and Japan.

Free propofol may exert its painful effect by stimulating the kallikrein-kinin system, resulting in the generation of bradykinin, which stimulates intravascular nociceptors. Administration of nafamostat, an inhibitor of kallikrein, prior to propofol injection has significantly decreased the incidence and severity of pain.[40]

Clinicians desiring a simple and practical method for alleviating pain on injection have studied numerous medications either given prior to propofol or mixed with the propofol emulsion. A review of the published studies suggested that injecting lidocaine with a proximal tourniquet provided the highest efficacy.[41] The authors recommended that "IV lidocaine (0.5 mg/kg) should be given with a rubber tourniquet on the forearm, 30 to 120 seconds before the injection of propofol." This method was superior to mixing lidocaine with propofol, which itself was superior to giving lidocaine without a tourniquet prior to injecting the propofol.

Hypersensitivity Reactions Propofol does not cause histamine release and is only very rarely associated with hypersensitivity reactions. Although components of the emulsion are derived from eggs and soybeans, the product contains no egg albumin or soy protein (the proteins to which hypersensitive persons are most likely to react). Persons allergic to egg albumin or soy protein have been given propofol safely.

Pharmacokinetics

Lipid Solubility

Propofol is one of the most lipid-soluble drugs used in medicine. Its oil/water partition coefficient of 4700 is almost 10-fold higher than that of thiopental. This high lipid solubility, coupled with the large fraction of cardiac output typically delivered to the brain, is responsible for the very rapid onset of effect, typically well under 1 minute, following intravenous administration (Table 40–7).

Protein Binding

Protein-bound propofol is unable to diffuse across the blood–brain barrier and produce a pharmacologic effect. Propofol is approximately 98% bound to plasma protein. In clinical situations where the plasma concentration of protein is decreased, as in hepatic disease or hemorrhage that has been treated only with crystalloid solutions and/or packed red blood cells, the free fraction of propofol will be elevated compared with normal, and lower doses of propofol may be needed. Despite being an extensively bound drug, propofol has a high hepatic extraction ratio (Table 40–6). The total clearance of propofol is greater than hepatic blood flow, indicating that there is significant extrahepatic metabolism (see Metabolism and Elimination).[42]

Redistribution

Propofol has a redistribution half-life $t_{1/2\alpha}$ of approximately 1–2 minutes, indicating that the effect of a typical bolus injection will be terminated within 3–4 half-lives or approximately 3–8 minutes (Table 40–5).[43] This process of redistribution is the primary process by which the pharmacologic effect of propofol is terminated. Unless very large doses are given or a long infusion is given, the processes of metabolism and elimination are much less important in terminating the drug's effect.

Metabolism and Elimination

Propofol has a terminal half-life $t_{1/2\beta}$ of approximately 4–6 hours, substantially less than the corresponding value for thiopental.[43] This difference, as well as propofol's very short redistribution half-life, helps explain why propofol, given as a continuous infusion, has a substantially shorter duration than thiopental after termination of the infusion (see Maintenance of Anesthesia).

Approximately 60% of administered propofol is hydroxylated at the carbon located *para* to the existing hydroxyl group and then conjugated with either glucuronide or sulfate. The remainder is conjugated to glucuronide via the existing hydroxyl group.[44] In persons with normal hepatic and renal function, approximately 60% of propofol metabolism occurs in the liver and approximately 40% occurs in the kidneys.[42] The overall clearance of propofol is not reduced in patients with end-stage renal disease[45] or with cirrhosis.[46] Significant propofol metabolism occurs in the lungs of some animals, but kidney rather than pulmonary metabolism of propofol may be more important in humans.[42]

Factors Affecting Pharmacodynamics and Pharmacokinetics

Many factors affect the pharmacodynamics and pharmacokinetics of propofol. Like thiopental, elderly patients require lower doses of propofol to produce unconsciousness. This altered response is due to increased sensitivity of the brain to the drug's effect (pharmacodynamic alteration)[47] and a decreased plasma protein concentration and decreased clearance rate (pharmacokinetic alterations).[48]

The pharmacokinetics of propofol in persons with significant impairment of hepatic function is complex. Despite a significant increase in volume of distribution, the total clearance rate is preserved.[46] Persons with cardiac dysfunction typically have an exaggerated hypotensive response to propofol, to a greater degree than with thiopental. In hypovolemic shock, a lower propofol dose is needed because a greater fraction of the cardiac output goes to the brain. The hypovolemic patient tolerates propofol-induced vasodilatation very poorly.

Clinical Use

Induction of Anesthesia

The characteristics of propofol as an induction agent are listed in Table 40–7. An induction dose of 1–3 mg/kg is often given to the typical healthy patient undergoing elective surgery, but there is enormous variability between patients in the amount actually required. Coexisting factors, such as previous premedication (e.g., with benzodiazepines and/or opioids), advanced age, or presence of concurrent disease (e.g., cardiac dysfunction, COPD, hypovolemia), will decrease the required dose of propofol. Conversely, patients with acquired tolerance because of chronic use of medications that exhibit cross-tolerance with propofol (e.g., benzodiazepines, barbiturates, anticonvulsants, or alcohol) may require higher doses of propofol to produce unconsciousness.

If there is concern about a possibly exaggerated response to propofol and a rapid sequence induction is not planned, it may be prudent to admin-

ister the induction dose slowly or in divided doses, treating the initial bolus as a "test dose" and waiting 1–2 minutes to evaluate the effects.

After administration of the induction dose, consciousness is typically lost within 30 seconds, although this time may be longer in persons with a slow circulation time because of cardiac dysfunction. Recovery of consciousness usually occurs within 3–8 minutes; however, some degree of cognitive impairment may persist for hours. The time to awakening from propofol is faster than with thiopental, and patients in ambulatory surgical settings are able to achieve recovery "milestones" more rapidly. A portion of the rapid recovery may be due to propofol's relative freedom from "hangover" and its tendency to cause an elevation in mood. Emergence from propofol is often accompanied by a sense of well-being,[49] and patients occasionally become euphoric. Occurrence of hallucinations and sexual fantasies during emergence also has been reported.

Maintenance of Anesthesia

General anesthesia can be maintained by either intermittent intravenous boluses or continuous intravenous infusion of propofol. Following an induction bolus, infusion rates of 100–200 μg/kg/min typically are used to maintain general anesthesia in healthy patients. If nitrous oxide and/or opioids are administered concurrently, a reduction in the required propofol infusion rate by one third to half may be anticipated. To maintain a nearly constant blood (and brain) concentration of propofol during an infusion requires that the infusion rate be decreased as the infusion continues (see Target-Controlled Infusion). Use of a monitor that measures the depth of the hypnotic effect, such as the bispectral index or patient state index, facilitates titrating the infusion rate. Elderly patients and those with coexisting cardiopulmonary disease typically will require reduced infusion rates.

Because of propofol's shorter kinetic parameters compared with thiopental, it accumulates to a much lesser degree, and its recovery characteristics following an infusion, even of very long duration, permit it to be an extremely useful drug for maintaining general anesthesia. The CSHTs for propofol following 1-, 2-, and 6-hour infusions are approximately 11, 16, and 34 minutes, respectively (Fig. 40–4). Thus, a "rule of thumb" for the CSHT for propofol would be to take the value of 11 minutes for a 1-hour infusion and add to that 4 minutes for each additional hour of infusion duration; this linear relationship remains valid for infusions up to approximately 10 hours in duration. Remember that CSHT is not the same as time to clinical recovery, which depends upon the actual concentrations achieved.

Sedation

Propofol is commonly used for procedural sedation as well as for longer-term sedation in the intensive care unit (ICU). If loss of consciousness is to be avoided (as is the goal for most cases of procedural sedation), a loading dose of 0.5–1 mg/kg is used, followed by an infusion of 25–75 μg/kg/min. Lower infusion rates will be required in persons given benzodiazepines and/or opioids, in elderly patients, and in those with coexisting cardiopulmonary disease.

Propofol is routinely used in the ICU for long-term (i.e., weeks) sedation of patients requiring mechanical ventilation. Even in this setting, its recovery characteristics permit rapid recovery. For example, a patient who is sedated (but not rendered unconscious) for 2 weeks will recover in approximately 3 hours.[50] Long-term infusion of propofol may give the patient a very large amount of lipid, which has been associated with hypertriglyceridemia and pancreatitis.[51] Logically, propofol should be administered cautiously in patients with preexisting pancreatitis or hyperlipidemia. Long-term administration (particularly in critically ill children) has also been linked to a rare and often fatal disorder termed *propofol infusion syndrome.* The pathophysiology has not been well characterized, but typical features include rhabdomyolysis, metabolic acidosis, and cardiac and renal failure.[52]

Target-Controlled Infusion

By using estimates of the pharmacokinetic parameters for propofol, it is possible to achieve and maintain a targeted blood (or brain) concentration utilizing a computer-controlled infusion pump (see Chap. 42). Such a target-controlled infusion (TCI) pump, with the pharmacokinetic constants for propofol built in, is marketed as the Diprifusor in many countries (but not in the United States). The patient's age, body weight, and desired blood concentration are entered, and the pump delivers a propofol bolus followed by a variable-rate infusion. The rate is automatically adjusted to match predicted losses from distribution and elimination, in order to maintain a constant propofol concentration. TCI pumps have been used successfully in closed-loop delivery systems with processed EEG signals as a control variable. For scientists interested in studying TCI, several public-domain computer programs are available that facilitate this process.[53] Most modern infusion pumps have the ability to be controlled by a computer, so by connecting the pump to a portable computer and using one of the available programs, a TCI can be delivered. Despite more than a decade of clinical use in other parts of the world, it must be emphasized that TCI is still considered an experimental treatment in the United States.

ETOMIDATE

Chemistry

Etomidate is an imidazole derivative whose structure is unlike that of any other anesthetic (Fig. 40–1 and Table 40–1). Its imidazole nucleus permits it to bind to, and inhibit, certain isozymes of cytochrome P450 (see Endocrine Effects). It contains an ester linkage that is rapidly hydrolyzed to produce an inactive metabolite. With a pK_a of 4.2, it is water soluble at acidic pH and lipid soluble at physiologic pH. It is supplied as a 0.2% solution in 35% propylene glycol.

Pharmacodynamics

Central Nervous System

Etomidate works via $GABA_A$ receptors to produce rapid onset of unconsciousness. It has a brief duration of effect, similar to that of thiopental and propofol. The drug has virtually no analgesic effects, so usually it must be combined with other drugs to suppress autonomic or somatic responses to painful surgical stimulation. Induction of anesthesia is frequently accompanied by myoclonic movements (Table 40–2).

Cardiovascular System

Etomidate is notable for its lack of cardiovascular effects, although the reasons for this remain obscure (Table 40–3).[54,55] At the typical induction dose of 0.3 mg/kg, it has little effect on arterial or venous vascular tone or on cardiac contractility. Following induc-

tion of general anesthesia with etomidate, usually little change in blood pressure or heart rate occurs. Cardiovascular stability usually is preserved in persons with hypovolemia or cardiac dysfunction. Etomidate does not release histamine. At the higher dose of 0.7 mg/kg needed to produce EEG burst suppression, hypotension due to vasodilatation has been reported.[56]

Respiratory System

Etomidate has less of a ventilatory depressant effect than does thiopental or propofol; however, an induction dose is still likely to result in transient apnea (Table 40–4). The ventilatory depressant effect is not exaggerated in persons with COPD.

Endocrine Effects

In 1984, Watt and Ledingham[57] reported a 2-fold increase in mortality among ventilated ICU patients who were given etomidate for 5 days or longer. This excess mortality subsequently was confirmed and attributed to the production of adrenal insufficiency. At clinically relevant concentrations, etomidate inhibits the mitochondrial P450 isozyme responsible for performing the 11β-hydroxylation reaction in cortisol synthesis. Etomidate is also able to inhibit the 17α-hydroxylase isozyme, although not at the plasma concentrations achieved during clinical infusions.[58] The clinical relevance of this effect for perioperative use of etomidate remains controversial 20 years after its description.

The duration of suppression of cortisol synthesis by etomidate is dependent upon the cumulative dose. A single induction dose of 0.3 mg/kg inhibits cortisol synthesis and the normal response to adrenocorticotropic hormone for up to 12 hours. However, the effects are not large, and there is no convincing evidence that this effect is deleterious in normal persons undergoing elective surgery. Even infusions of a few hours duration do not appear harmful in healthy patients. Nevertheless, fear of adrenal suppression has significantly limited the popularity of etomidate over the years (see Clinical Use).

Other Effects

Etomidate produces changes in $CMRO_2$, CBF, and ICP similar to those seen with thiopental and propofol. In contrast, etomidate will not likely lower, and may actually increase, CPP because it has minimal effect on blood pressure while decreasing ICP. Etomidate may be useful in the short-term management of the neurosurgical patient in whom cardiovascular stability is desired.

Etomidate is associated with the highest incidence of postoperative nausea and vomiting among the intravenous anesthetics (30–40%, by some estimates). The propylene glycol solvent can cause pain on injection and superficial phlebitis. Excitatory phenomena, such as hiccoughs and myoclonic movements, are common during induction. The safety of etomidate in patients with porphyria is questionable. Although a few case reports have described its safe use in patients known to have porphyria, etomidate induces the synthesis of ALA synthase in rats. Etomidate is safe to give patients with malignant hyperthermia.

Pharmacokinetics

Following an induction dose of 0.3 mg/kg, loss of consciousness and recovery will be similarly rapid as with thiopental and propofol. Because of the long duration of adrenal suppression associated with etomidate infusions, it has not been as extensively studied. Its redistribution half-life is similar to that of thiopental, whereas its terminal half-life is shorter than that of thiopental and similar to that of propofol (Table 40–5).

Etomidate is approximately 75% bound to plasma proteins, a fraction that is significant but not as high as for thiopental or propofol. Most of an administered dose of etomidate is metabolized via ester hydrolysis, yielding an inactive carboxylic acid that is excreted in the urine. Despite the presence of high concentrations of esterases throughout the body, hydrolysis of etomidate occurs primarily in the liver. It has a high extraction ratio of 0.7, so alterations in hepatic blood flow should affect clearance. Because the effects of a bolus are terminated by redistribution and repeated doses or infusions are unlikely to be given, hepatic clearance of etomidate is unlikely to play an important role in recovery (Table 40–6).

Clinical Use

Etomidate is a popular choice for induction of anesthesia in patients compromised by cardiac dysfunction or hypovolemia (Table 40–7). Hemodynamic stability following induction with etomidate is superior to that of any alternative method of induction. In theory, etomidate's pharmacokinetics should make it an excellent drug for use during short surgical procedures, but the high incidence of nausea and vomiting is a major disadvantage for patients undergoing same-day surgery. The occurrence of myoclonus and hiccoughs is annoying but similar in frequency to that seen with methohexital.

After more than 20 years of using etomidate, what can we conclude about the importance of adrenal suppression? When etomidate is used for induction and short-term maintenance, reduction in cortisol historically has not been a problem, although there is substantial conflict in the literature on this issue. For example, one review suggests that a single induction dose of etomidate may be hazardous in patients with established or evolving septic shock.[59] Another reports no harm from etomidate infusions during coronary surgery and concludes that the stress of a major operation overcomes the inhibition of cortisol synthesis.[60] Some investigators have proposed the concurrent administration of etomidate plus a glucocorticoid, but in the absence of a proven harmful effect, it is difficult to imagine any benefit.

Ultimately, the decision to use etomidate must rest on the proven benefits of this drug, that is, cardiovascular and respiratory stability. These benefits are most likely to be seen when higher doses are used during induction. In our opinion, there is little compelling reason to use etomidate for maintenance of anesthesia or for procedural sedation.

BENZODIAZEPINES

Chemistry

Three injectable benzodiazepines are used in the perioperative period: midazolam, diazepam, and lorazepam (Fig. 40–1 and Table 40–1). Diazepam and lorazepam are "classic" benzodiazepines that are lipid soluble and difficult to solubilize for injection. Diazepam injection is supplied as a 0.5% solution in 40% propylene glycol and 10% ethanol. Lorazepam is supplied as a 0.4% solution in 80% propylene glycol, 18% polyethylene glycol, and 2% benzyl alcohol. Midazolam has unique properties as a result of its substituted imidazole ring. The imidazole nitrogen has a pK_a of 6.2, so it becomes protonated and water soluble when buffered in a

solution of pH 3–4 (as supplied in the vial).[61] At physiologic pH, >90% of the midazolam molecules exist in the unprotonated lipid-soluble form. Hydroxylation of the methyl group on this imidazole ring decreases the pharmacologic activity of midazolam and increases its clearance, permitting this drug to be shorter acting than the other injectable benzodiazepines.

The water solubility of midazolam at low pH has erroneously been attributed to opening of one of the rings in the benzodiazepine nucleus. In fact, all benzodiazepines undergo ring opening at low pH. At pH 2, 75% of the midazolam molecules are in the open-ring configuration, whereas at pH 4 that percentage decreases to 9%.[61] Because midazolam is supplied at a pH of 3–4 in the vial, ring opening can account for only a small percentage of its water solubility at that pH.

Pharmacodynamics

Central Nervous System

Benzodiazepines bind to a specific site located at the interface between the α and γ subunits of the pentameric $GABA_A$ receptor. GABA itself appears to bind at a different site between the α and β subunits.[5] Binding by endogenous benzodiazepine ligands (endozepines) or by benzodiazepine agonists to this benzodiazepine receptor acts allosterically to increase the affinity of the GABA receptor for GABA. Thus benzodiazepines potentiate the inhibitory effects of GABA, thereby increasing chloride conductance and hyperpolarizing neuronal membranes. Unlike barbiturates, benzodiazepines cannot affect the chloride channel directly but must work via GABA. At higher doses, such as those necessary to produce hypnosis or anticonvulsant effects, benzodiazepines may be working by non-GABA mechanisms such as inhibition of adenosine reuptake[62] or inhibition of neuronal Ca^{2+} currents.[63] Benzodiazepines also have agonist activity at the glycine receptor, an important inhibitory neurotransmitter in the spinal cord. Some of the effects of benzodiazepines, such as muscle relaxation, likely are mediated by their actions in the spinal cord. Benzodiazepine receptors in the periphery appear to regulate the initial step in the synthesis of steroid hormones from cholesterol.[64] The physiologic significance of this action remains unclear.

Patients who are chronically taking benzodiazepines can become tolerant to some, but not all, of the effects. The initial drowsiness usually decreases, although some degree of psychomotor impairment seems to persist. Tolerance develops to the muscle relaxant and anticonvulsant effects, and the latter has limited the use of benzodiazepines in chronic seizure disorders. Alcohol, barbiturates, and benzodiazepines exhibit some cross-tolerance, so higher doses of these sedatives will be needed in patients with significant alcohol or barbiturate intake.

Benzodiazepines have effects on $CMRO_2$ and ICP qualitatively similar to the effects of thiopental; however, the magnitude of these effects is far less (Table 40–2). The effect of benzodiazepines on CBF and CPP is variable and is more of a function of their effects on blood pressure. Benzodiazepines are excellent anticonvulsants, although their primary use is limited to initial control of seizures and not prophylaxis. All of them raise the threshold for seizures induced by local anesthetics. Unlike thiopental and propofol, benzodiazepines, even in very high doses, do not cause burst suppression on the EEG or an isoelectric tracing, and they are not used for neuroprotection. Benzodiazepines given in subhypnotic doses produce amnesia for events following drug administration (anterograde amnesia).

Benzodiazepines are classified as "anxiolytics" because they are active in various animal models thought to represent anxiety. In patients who have chronic anxiety states, benzodiazepines can reduce anxiety at doses that are not highly sedating. Of note, the same effects may not occur in surgical patients. Many patients scheduled for surgery do not have high levels of self-rated anxiety, and the effect of midazolam is more likely to produce dizziness or sleepiness.[65] An occasional patient may find the feeling of drunkenness or dizziness to be unpleasant.

Other Effects

Benzodiazepines produce much smaller cardiovascular effects than do thiopental or propofol, even when used for general anesthesia induction (Table 40–4). Some dilation of capacitance vessels leads to a decrease in venous return; however, there is little or no effect on myocardial contractility. Thus, the overall effect on blood pressure and heart rate will depend on the volume status of the patient. Elevated blood pressure in the anxious patient is often lowered by low doses of benzodiazepines by virtue of their sedative properties (see later, Clinical Use).

Although benzodiazepines cause a dose-dependent decrease in hypoxic ventilatory drive, subhypnotic doses given alone rarely cause apnea. Doses of midazolam sufficient to induce unconsciousness produce apnea with a frequency similar to that of thiopental.[66] There is profound synergy in depressing ventilatory drive between benzodiazepines and opioids or ethanol. Patients with COPD are more sensitive to the ventilatory depressant effects of benzodiazepines (Table 40–3).

Benzodiazepines, given alone, have a very low risk for causing nausea and vomiting. They are safe in patients with malignant hyperthermia, but they should be used with caution in persons with acute intermittent porphyria, hereditary coproporphyria, and variegate porphyria because some benzodiazepines induce ALA synthase in rats. Hypersensitivity reactions to benzodiazepines are rare.

Pharmacokinetics

Following an induction dose of 0.3 mg/kg midazolam, loss of consciousness is rapid; however, awakening will be much slower and hangover more prolonged than after thiopental or propofol. Simultaneous pharmacokinetic–pharmacodynamic modeling using an EEG end point suggests that midazolam is slightly slower in onset than is diazepam. The half-time for steady state was over 4 minutes, compared to 90 seconds for diazepam.[67] The $t_{1/2\alpha}$ for midazolam is 7–15 minutes, much longer than the 2–4 minutes values for thiopental or propofol. The $t_{1/2\beta}$ for midazolam is 2–4 hours. When given by infusion, recovery following termination of the infusion will be longer than following propofol but shorter than following thiopental (Table 40–5).

Midazolam is metabolized primarily via hydroxylation of the *N*-methyl group on the imidazole ring (Table 40–6). Although this metabolite has some residual benzodiazepine activity, circulating concentrations are low because it is rapidly conjugated with glucuronic acid, yielding an inactive and rapidly excreted metabolite. Midazolam has high first-pass metabolism following oral administration, with an oral bioavailability of approximately 15%.[68]

Diazepam and lorazepam are metabolized and eliminated much more slow-

ly than midazolam because of a high degree of protein binding (98%) and a much lower hepatic clearance. Whereas lorazepam is metabolized to an inactive glucuronide, diazepam is metabolized to several active metabolites. The most important of these active metabolites is nordazepam, which has an extremely long terminal half-life (100 hours vs. 20 hours for diazepam). The processes of metabolism and elimination of these medications become important only when repeated doses or long infusions are given.

Clinical Use

Midazolam is the most commonly used preoperative sedative in anesthesia (Table 40–7). It replaced diazepam largely because it does not produce pain on injection. Given as a single intravenous bolus, the effects of diazepam and midazolam are quite similar and have about the same duration. Lorazepam is slower in onset and longer in duration, and its tendency to cause prolonged amnesia may be undesirable for patients undergoing short procedures. Following administration of 1–2 mg of midazolam, most patients become sleepy and calmer and have anterograde amnesia, effects that persist for 30–60 minutes. At these doses and in the absence of other medications, there are few significant effects on cardiorespiratory parameters. Sedation can be maintained by repeating intermittent boluses of 0.5–1 mg or by giving a continuous infusion. As with barbiturates, administration of benzodiazepines can sometimes produce paradoxical excitation.

The amnestic effects of benzodiazepines are dose related and often occur in patients who remain conscious and capable of normal conversation. The amnestic effects of midazolam (when given in usual doses for premedication) are variable but usually short lived, and they should not be relied upon to prevent recall of intraoperative events. Although lorazepam has a shorter plasma half-life than does diazepam, its amnestic effects are more prolonged. This may be a function of higher affinity for benzodiazepine receptors.

Midazolam is commonly given by mouth for preoperative sedation in pediatric patients. The usual dose is 0.5–0.75 mg/kg, and a significant effect is apparent within 15–30 minutes. However, the peak effect may occur up to 1 hour following oral administration, so there might be significant postoperative sedation following short procedures.[68] An official oral preparation of midazolam is unavailable in many countries. The intravenous solution can be mixed with fruit juice or flavored syrup; however, there is no completely effective way to mask the bitter taste.

Midazolam is one of only two induction agents (the other being ketamine) whose administration by the intramuscular route is well tolerated without pain and whose absorption is both reliable and predictable. Doses ranging from those that produce mild sedation up to those required to induce general anesthesia can be given intramuscularly. Doses in excess of a few milligrams should be given using the more concentrated 10 mg/mL preparation to minimize injected volume.

Diazepam is an excellent oral preoperative sedative and anxiolytic agent for patients undergoing inpatient surgery. A dose of 10–20 mg in an adult, or 0.2–0.4 mg/kg in a child, given by mouth an hour before transport to the operating room usually results in a drowsy and calm patient. Both diazepam and lorazepam are associated with significant pain when given intravenously, and the propylene glycol solvent can cause superficial phlebitis. Both medications are absorbed erratically when administered by intramuscular injection.

Midazolam can be used in higher intravenous doses (0.05–0.15 mg/kg) to induce anesthesia, or it can be given via continuous infusion during maintenance (see Chap. 42). The slower onset and offset of effect compared to propofol or thiopental are counterbalanced by midazolam's modest cardiovascular effects. The drug is not an analgesic, so it is usually administered with opioids. This significantly reduces the required dose of midazolam but usually causes a greater decrease in peripheral vascular resistance than seen with the individual drugs. This vasodilatation may be due to an increased effect on central sympathetic tone or possibly to a decrease in plasma catecholamines.[69,70]

The doses of midazolam and diazepam should be reduced in the elderly because of their increased sensitivity and reduced clearance. Hepatic disease or drugs that inhibit the oxidative metabolism of diazepam (e.g., cimetidine) can significantly increase the intensity and duration of sedation.[71] Because midazolam has a moderately high rate of hepatic clearance, it is less susceptible to enzyme induction or inhibition. Renal disease, on the other hand, can delay the excretion of hydroxymidazolam and cause an increase in effect. Lorazepam is glucuronidated and has no active metabolites, so its effects are not markedly altered by moderate hepatic or renal disease.

Flumazenil

Flumazenil (Fig. 40–1) is a benzodiazepine antagonist.[72] It has high affinity for the benzodiazepine binding site on the $GABA_A$ receptor, and flumazenil binding prevents the effects of benzodiazepines and endozepines. There is no evidence that flumazenil will reverse nonbenzodiazepine CNS depression. The usual initial dose in a patient who has been given a therapeutic dose of a benzodiazepine is 0.1–0.2 mg intravenously. The initial dose can be repeated every minute or two, up to a total dose of 1 mg to antagonize benzodiazepine-induced sedation. The various actions of benzodiazepines require different concentrations of agonist, and effects that require high doses (e.g., hypnosis) are most sensitive to flumazenil reversal. Some effects, such as depression of hypoxic ventilatory drive, appear to be incompletely antagonized (see following list on next page, second bullet).[73]

Reports of weak partial agonist or inverse agonist effects from flumazenil are inconsistent. Healthy volunteers given a relatively high dose (2 mg) of flumazenil alone experienced mild anxiety and symptoms resembling those that occur during a panic attack.[74] These symptoms are more likely to occur in patients with previously diagnosed panic attacks. These effects indicate tonic activity in some critical $GABA_A$ pathways, and flumazenil may be acting weakly as a so-called "inverse agonist" (i.e., producing an effect opposite to that of the benzodiazepine). This action likely is not clinically important in the typical anesthesia setting where flumazenil is used to reverse midazolam. Persons on chronic benzodiazepine therapy who are given flumazenil have been reported sporadically to have seizures,[75] sometimes progressing to status epilepticus.[76] This finding suggests that some patients develop physical dependence to the benzodiazepine, and flumazenil can precipitate withdrawal. A few cases of flumazenil-induced seizures in persons

not on chronic drug therapy have been reported.[75]

Flumazenil is rapidly cleared by hepatic metabolism, with a half-life of approximately 1 hour. Therefore, it has a shorter duration than the benzodiazepines it is used to antagonize, so repeated doses usually are necessary.

The appropriate clinical roles for flumazenil are relatively limited:

- If a patient who is receiving midazolam for sedation or monitored anesthesia care becomes disoriented or uncooperative, reversal may be helpful. In contrast, planned use of flumazenil, that is, giving excessive amounts of benzodiazepines for a procedure and then relying on reversal at the end, seems to be of little benefit. Such treatment risks ventilatory depression and loss of airway reflexes during the procedure and recurrence of depression when the effects of the short-acting antagonist decay.
- Remember that excessive sedation and ventilatory depression most often occur when benzodiazepines are combined with opioids. Flumazenil only partially reverses the depression of hypoxic ventilatory drive produced by midazolam, and it has no effect on ventilatory depression due to an opioid. In this setting, support of ventilation and administration of naloxone are more appropriate treatments.
- When flumazenil has been used empirically for treatment of suspected drug overdoses, deaths due to status epilepticus have occurred. Risk factors in such deaths include concurrent ingestion of tricyclic antidepressants and prior long-term therapy with benzodiazepines or anticonvulsants. Unless an overdose is known to be due to the acute ingestion of only a benzodiazepine, flumazenil treatment may be riskier than cardiorespiratory support of depression due to drugs.

KETAMINE

Chemistry

Ketamine is a derivative of aminocyclohexanone whose chemical structure is related to phencyclidine (Fig. 40–1 and Table 40–1). It is a weak base with a p*K* of 7.5 and is supplied in solution as the hydrochloride salt. The three concentrations available—10 mg/mL, 50 mg/mL, and 100 mg/mL—are typically used for monitored anesthesia care, intravenous anesthesia, and intramuscular injection, respectively. Ketamine is compatible in solution with atropine or glycopyrrolate, with which it is often mixed.

The commercial preparations of ketamine contain a racemic mixture of its two isomers. The *S*-isomer is a more potent anesthetic with fewer adverse effects[77] and is available in Europe, but this enantiomer is not commercially available in the United States.

Pharmacodynamics

Central Nervous System

Whereas all the previously discussed intravenous anesthetics potentiate the inhibitory effects of GABA, ketamine produces its inhibitory effects by blocking the NMDA receptor.[78] The NMDA receptor is, like $GABA_A$, a ligand-gated ion channel, but it is gated by the excitatory neurotransmitter glutamate. When open, it passes a current carried by calcium ions.

The anesthetic state induced by ketamine is called *dissociative anesthesia.* It does not resemble normal sleep; rather, patients appear to be dissociated from their environment. Under ketamine anesthesia, patients may move, vocalize, have their eyes open, and make ocular tracking movements. However, patients are anesthetized and do not respond to noxious stimuli or have any recall of events that occurred during the anesthetic. Ketamine causes profound analgesia that persists well into the postoperative period. Vivid dreams or hallucinations that may be perceived as unpleasant often accompany ketamine anesthesia, and hallucinations and/or dysphoria may occur in the postoperative period.

In contrast to the other intravenous anesthetics, ketamine produces increases in $CMRO_2$, CBF, and ICP. Thus, ketamine is relatively contraindicated in patients with an intracranial mass or increased ICP, or who have suffered recent head trauma (Table 40–2).

Ketamine produces dose-dependent changes in the EEG that are quite different from those resulting from thiopental or propofol (Fig. 40–5).[79] For this reason, EEG-based monitors of the depth of anesthesia (see Chap. 32) are not accurate when ketamine is the primary anesthetic. As seen with thiopental, light anesthesia with ketamine is associated with an increase in EEG frequency so that beta waves predominate. As the depth of anesthesia increases, high-amplitude theta waves, with intermittent delta waves, can occur. An isoelectric EEG does not occur with ketamine anesthesia.[80]

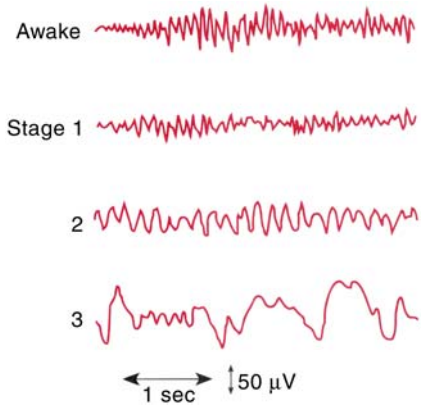

FIGURE 40–5. Progressive changes in the electroencephalogram produced by ketamine. Stages 1 to 3 are achieved with racemic ketamine and its *S*(+) isomer. With *R*(–) ketamine, stage 2 was the maximal electroencephalographic depression produced. (Redrawn from Schuttler et al.[79] with permission.)

Cardiovascular System

In contrast to the other intravenous anesthetics, ketamine usually causes an increase in blood pressure, heart rate, cardiac contractility, cardiac output, and systemic vascular resistance (Table 40–4). These are indirect effects by virtue of increased centrally mediated sympathetic tone and increased centrally mediated release of catecholamines from the adrenal medulla. In the critically ill or injured patient whose circulating catecholamine concentration has reached its maximum value, a decrease in blood pressure and cardiac output may occur when ketamine is injected because ketamine and its major metabolite have a direct negative inotropic effect. Ketamine may increase myocardial oxygen demand more than it increases oxygen delivery, and in some patients with coronary artery disease this effect may lead to ischemia.

Respiratory System

Ketamine differs from the other intravenous anesthetics in its respiratory effects (Table 40–3). Ketamine has little effect on ventilatory drive in normal patients or in those with COPD. It produces bronchodilation and has proved useful in patients with, or prone to, bronchospasm. Protective airway reflex-

es are less likely to be ablated by ketamine, even in the presence of surgical anesthesia, although aspiration remains a risk in a patient with ketamine-induced unconsciousness. Ketamine causes copious salivation, and its use is generally preceded by, or it is administered with, an anticholinergic drug such as glycopyrrolate.

Other Effects

Like etomidate, ketamine is associated with a high risk for postoperative nausea and vomiting. Ketamine is safe in patients with malignant hyperthermia and, based upon a number of case reports, probably is safe in patients with porphyria.

Pharmacokinetics

Following an intravenous induction dose of 1–2 mg/kg of ketamine, loss of consciousness is rapid; however, awakening will be much slower and the hangover more prolonged than after any other intravenous anesthetic. Ketamine has a redistribution half-life $t_{1/2\alpha}$ of 11–17 minutes, much longer than the values for either thiopental or propofol (Table 40–5).

Ketamine is extensively metabolized, primarily by *N*-demethylation. The resulting active metabolite, norketamine, is approximately one fourth as potent. Norketamine is further metabolized to an inactive glucuronide.

In contrast to the other intravenous anesthetics, only a small fraction of circulating ketamine is bound to plasma protein. Ketamine has a high hepatic extraction ratio, and other medications or coexisting diseases that decrease hepatic blood flow would be expected to prolong its duration of action (Table 40–6). Ketamine has high first-pass hepatic metabolism following oral administration, although it is sometimes administered by this route.

Clinical Use

Like etomidate, ketamine is most commonly used for induction of general anesthesia in patients compromised by concurrent cardiac dysfunction or hypovolemia (Table 40–7). It has been used extensively for acute and chronic treatment of burn victims. Infusions are used for analgesia and hypnosis as part of balanced anesthesia. Because increasing doses of ketamine do not produce consistent changes in hemodynamics, respiration, eye signs, or movement, the depth of anesthesia may be difficult to assess. Unless there is maximal sympathetic tone, ketamine usually causes an increase or no change in blood pressure. Ketamine is a good choice for patients with, or prone to, bronchospasm. A slow emergence, often accompanied by hallucinations and/or dysphoria, are common adverse effects that must be balanced against the desire for a lack of cardiovascular depression. The unpleasant psychological effects may be mitigated, but not eliminated, by concurrent administration of propofol or a benzodiazepine.

In subhypnotic doses (0.15–0.3 mg/kg), ketamine is commonly used for monitored anesthesia care. It produces profound analgesia without the concurrent ventilatory depression produced by opioids. In combination with a low dose of propofol or a benzodiazepine, the unpleasant psychological effects are minimal, and the ventilatory depressant effects are much less than the combination with an opioid.

Ketamine is commonly used, either alone or in combination with midazolam, as an oral medication in children, especially as the sole agents for conscious sedation for a short but noxious procedure (e.g., upper endoscopy). Typical doses of the combination are 3–6 mg/kg of ketamine plus 0.25–0.5 mg/kg of midazolam.

Ketamine is one of only two induction agents (the other being midazolam) that have reliable and predictable absorption with minimal pain following intramuscular injection. Doses ranging from those that produce mild sedation to those required to induce general anesthesia may be given intramuscularly. The preparation containing 100 mg/mL usually is given, especially in adults, to minimize the injected volume. A rapid onset after intramuscular injection makes ketamine a frequent choice for induction of anesthesia in children and adults with mental disabilities who will not tolerate a mask or the placement of an intravenous catheter. Following intramuscular administration of 2–4 mg/kg of ketamine, the patient will lose consciousness, thus allowing placement of an intravenous catheter within approximately 5 minutes.

ADJUNCTS

Butyrophenones

Droperidol and the closely related antipsychotic agent haloperidol exert their CNS effects via antagonism of the dopamine D_2 receptor. Unlike their predecessors, the phenothiazines, they have less affinity at other sites, such as α-adrenoceptors or muscarinic cholinergic receptors. They are classified as *neuroleptic* agents because of their distinct behavioral effects. When a neuroleptic agent is given to a "normal" individual, behavior is diminished and responses to stimuli are fewer, slower, and smaller in magnitude. In high doses, a catatonic state is induced, although consciousness and memory are preserved. These drugs should generally not be given by themselves. Patients treated this way usually appear sleepy and comfortable when drug concentrations are maximal, but they often describe an intensely dysphoric experience after the effects have worn off. This is in distinct contrast to the benzodiazepines, which often produce anterograde amnesia. When a neuroleptic agent is given to a psychotic patient, the thought disorder usually improves. In schizophrenia, the delusions and auditory or visual hallucinations become less pronounced or disappear, and thinking becomes more orderly. Even if some hallucinations remain, the patient is far more likely to recognize them as unreal.

Droperidol is a highly effective antiemetic at doses (0.625–1.25 mg) that do not cause sedation or dysphoria (see Chap. 73). In rare instances, it may be useful in higher doses for its neuroleptic effect. Droperidol is a very safe sedative, albeit one often associated with dysphoria. It causes no ventilatory depression and, in contrast to the benzodiazepines, does not potentiate the ventilatory depressant effects of opioids.[81] It has few cardiovascular side effects other than very mild vasodilatation due to its weak interaction with α-adrenoceptors. Butyrophenones can lower the seizure threshold and cause extrapyramidal symptoms (see next paragraph), so they are generally avoided in patients with seizure disorders or Parkinson disease. Many clinicians find droperidol useful for sedation during monitored anesthesia care or regional anesthesia in patients with dementia, psychosis, or mental retardation. In addition, droperidol may be useful to facilitate procedures such as line placement or awake intubation in uncooperative and/or intoxicated trauma patients. In such cases, its overall safety renders the possible later dysphoria a tolerable adverse effect.

Like all dopamine antagonists, droperidol has the potential to cause extrapyramidal reactions. These may include involuntary facial grimacing, neck stiffness, and limb movements such as akathisia ("restless legs"). These effects usually are not seen with antiemetic doses unless they are repeated, and they can be treated by administration of diphenhydramine or trihexyphenidyl, drugs with central anticholinergic effects.

An anesthetic technique rarely used today is neuroleptanesthesia, which involves the concurrent administration of droperidol (a butyrophenone with neuroleptic activity), fentanyl (an opioid), and nitrous oxide. Anesthesia induction is accomplished via administration of 10–15 mg of droperidol and 250–500 μg of fentanyl. Loss of consciousness and a lack of awareness are unlikely unless a high concentration of nitrous oxide is also given, and even then awareness still may occasionally occur. The neuroleptanesthetic state is accompanied by cardiovascular stability, and for this reason the technique gained some popularity before the use of invasive monitoring and Intensive Care Units. The technique is associated with prolonged emergence and frequent dysphoria.

Although droperidol has been used as a neuroleptic for more than 4 decades, its ability to cause cardiac dysrhythmias has only recently been appreciated. Droperidol causes a dose-dependent prolongation of the QTc interval, and, in a subset of the population (of unknown incidence), this may lead to polymorphic ventricular tachycardia (torsade de pointes). Antiemetic doses of droperidol almost certainly are safe, but there is the possibility that larger, sedating doses may be associated with this dysrhythmia.[82] In the United States, droperidol is labeled with a boxed warning that mandates continuous electrocardiographic monitoring for 2–3 hours following droperidol administration.

α_2-Adrenoceptor Agonists

Clonidine was the first centrally acting α_2-adrenergic agonist widely used in medicine. Introduced as an antihypertensive, a common adverse effect was sedation to which the patient became tolerant after 1–2 weeks of therapy. Because one person's adverse effect may be another person's therapeutic effect, clonidine was later investigated and used as a preoperative sedative (see Chap. 5). In some studies, such use was associated with diminished intraoperative requirements for hypnotic and analgesic medications and less intraoperative tachycardia and hypertension.

Dexmedetomidine is the first α_2-adrenoceptor agonist specifically marketed as a sedative. It is considerably more selective for α_2-receptors than clonidine. The primary site of its action as a sedative is in the locus ceruleus, where its effect is to mimic physiologic sleep.[83] Dexmedetomidine decreases inhibitory neuronal outflow from the locus ceruleus to the ventrolateral preoptic nucleus, resulting in increased GABA release from the latter. In rats, dexmedetomidine produces analgesia at the spinal cord level by activating descending inhibitory pathways originating in the midbrain, thereby reducing pain impulses that would otherwise ascend in the cord. Additionally it acts synergistically with nitrous oxide to potentiate the latter's analgesic activity in the spinal cord.[84]

Dexmedetomidine produces intense sedation, although it cannot reliably produce amnesia, hypnosis, or general anesthesia.[85] It does not have anticonvulsant properties. As would be expected, dexmedetomidine lowers blood pressure and heart rate, and dramatic decreases have occasionally occurred in patients without preexisting cardiovascular disease. Like clonidine, higher doses of dexmedetomidine can produce an initial increase in blood pressure that is believed to result from stimulation of α_{2B}-adrenoceptors. Sympathetic stimulation is also responsible for the common side effect of dry mouth. In animals and humans, dexmedetomidine can markedly reduce the requirement for volatile or intravenous anesthetics and opioids. Sedative doses have very little effect on ventilation and do not appear to increase the ventilatory depressant effects of opioids.[86]

Although dexmedetomidine has been studied in a number of environments, currently it is only approved for sedation of mechanically ventilated adult patients, and then only for up to 24 hours. The infusion typically is started near the end of an operative procedure before the patient is transported to the ICU or shortly after arrival. A bolus dose of 10 μg/kg is given over 10 minutes, followed by an infusion of 0.2–0.7 μg/kg/h. No ventilatory depression is associated with this sedation, and patients should require less opioid for management of postoperative pain. The heart rate usually is slow, although symptomatic bradycardia occasionally occurs, and dexmedetomidine should not be given to patients with preexisting heart block. Postoperative hypertension usually is well controlled; however, some patients experience hypotension and require pressor infusion, especially if they have preexisting ventricular dysfunction.

An intriguing possibility is that perioperative administration of an α_2-adrenoceptor agonist decreases cardiovascular mortality. A meta-analysis concluded that such use decreases mortality and myocardial infarction following vascular surgery.[87]

FUTURE HORIZONS: EXPERIMENTAL DRUGS

Fospropofol Disodium

Fospropofol (Fig. 40–6) is a water-soluble prodrug of propofol that results in incomplete (20–30%) liberation of propofol into the systemic circulation by alkaline phosphatase. It is believed that most (70–80%) of the propofol liberated is further metabolized prior to entering the systemic circulation. The peak hypnotic effect occurs approximately 10 minutes following a bolus injection. The kinetic disposition of liberated propofol differs from that of an injected propofol emulsion, with the former being slower for reasons that remain unexplained.[88,89]

Apparent advantages of an aqueous solution of fospropofol are a reduced risk of bacterial contamination compared with a propofol emulsion and the absence of an infused lipid load that has been associated with organ toxicity during long-term infusions of a propofol emulsion. Whether the new medication will cause less pain on injection remains to be determined. The relatively slow-onset kinetics of fospropofol probably would not make it useful for induction of general anesthesia. It may find utility for sedation in the ICU, procedural sedation outside of the operating room (where its safety needs to be demonstrated), and for sedation during monitored anesthesia care or regional anesthesia during which a rapid onset is less critical.

Propanidid Congener (TD-4756)

Propanidid was formerly used as an intravenous anesthetic in countries other than the United States. It is a

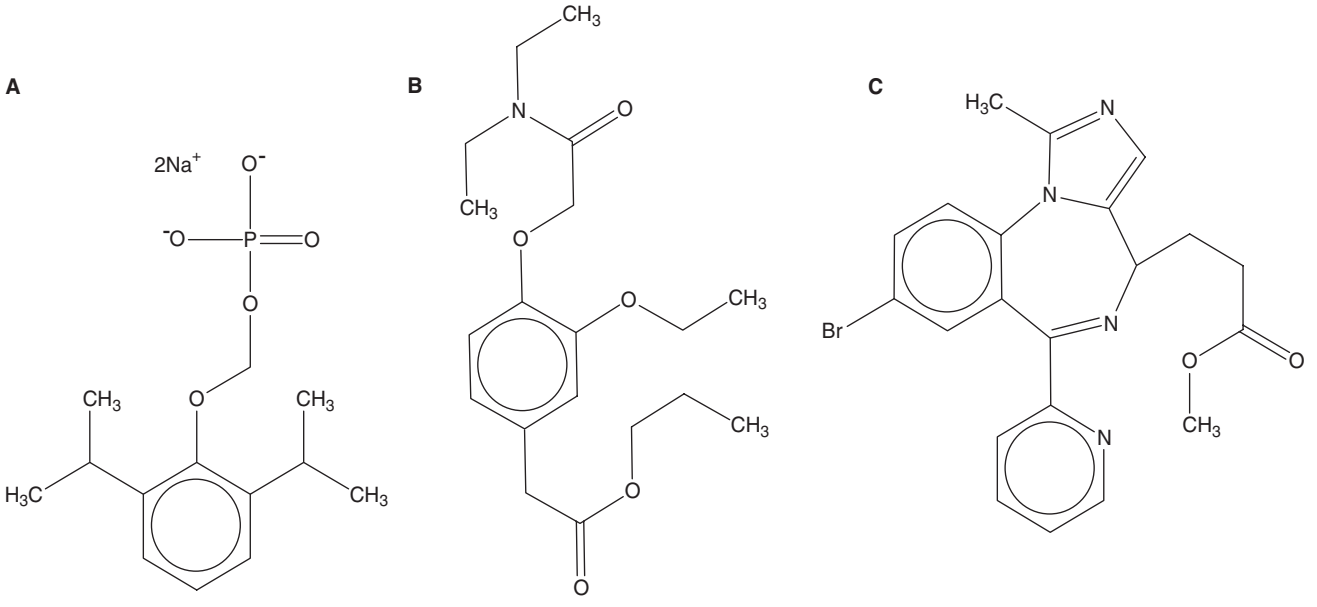

FIGURE 40–6. Structures of some investigational intravenous anesthetic agents: fospropofol (**A**), TD-4756 (**B**), and CNS 7056X **(C)**.

naturally occurring constituent of clove oil and is an ester whose rapid hydrolysis by plasma cholinesterase in the circulation gives it the shortest terminal half-life of any intravenous hypnotic (approximately 6 minutes). It is insoluble in water and was formulated in Cremophor when it was marketed. Because of the occurrence of anaphylactoid reactions to the vehicle, it was withdrawn from the market.

TD-4756 (formerly called THRX-918661, Fig. 40–6) is a propanidid congener with about twice its potency. TD-4756 contains an ethoxy group at the number 3 position on the benzene ring, whereas propanidid has a methoxy group. Although not yet studied in humans, TD-4756 is much shorter acting than propofol when infused in animals. Its duration of action is independent of the duration of infusion; thus, like remifentanil, its CSHT appears to be a constant regardless of infusion duration.[90] Reliance on plasma cholinesterase for metabolism likely will make the drug subject to genetic variability in clearance and possibly interactions with succinylcholine.

Esterase-Metabolized Benzodiazepine (CNS 7056X)

CNS 7056X (Fig. 40–6) is an esterase-metabolized benzodiazepine. It is metabolized by nonspecific tissue esterases, as is remifentanil (see Chap. 41). The carboxylic acid metabolite that results from its hydrolysis is approximately 400 times less potent than the parent medication. Although CNS 7056X has not yet been administered to human volunteers, its duration of action in animals is much less than that of midazolam following equisedating doses.[91]

CHAPTER 41

Pharmacology of Opioid Analgesics

Carl Rosow, MD, PhD, and
Mark Dershwitz, MD, PhD

KEY POINTS

1. An *opioid* is any natural or synthetic compound that has effects similar to those of morphine or that acts as an antagonist at the same receptors to which morphine binds.
2. Because opioid agonists relieve pain, they are classified as *analgesics*. In contrast to the local anesthetics (which interrupt the transmission of all nerve impulses, including pain), and the antiinflammatory analgesics such as aspirin (which decrease some of the pathologic processes leading to pain), the opioid analgesics act primarily to alter the *perception* of pain as a noxious entity.
3. The "classical" pharmacologic effects of morphine, like analgesia and ventilatory depression, are mediated by μ receptors. The κ receptor shares a number of effects with the μ receptor, including analgesia, sedation, and ventilatory depression. The δ receptor is responsible for mediating some of the analgesic effects of the endogenous opioid peptides, especially in the spinal cord.
4. All opioid receptors are G-protein-coupled receptors. The actions of both μ and δ agonists result in overall neuronal depression, and they share several signal transduction mechanisms, including inhibition of adenylyl cyclase, activation of K^+ currents, and suppression of Ca^{2+} currents.
5. Five families of endogenous opioid peptides bind to the various opioid receptors. Although some of these peptides undoubtedly function in nociceptive pathways, they also appear to play fundamental roles in processes like thermoregulation and hormone release, as well as gastrointestinal and cardiovascular control.
6. The most widely used opioid analgesics are the pure agonists, and all of these are relatively selective for μ-opioid receptors. Unlike the volatile anesthetics, opioid agonists produce a group of highly specific depressant and stimulant effects by acting at discrete sites within the central nervous system.
7. Opioid analgesic effects result from actions at several different levels of the neuraxis. Sufficient doses of opioids will relieve almost any pain, although some types of pain are typically more responsive than others. Prolonged, burning pain, for example, is more effectively blunted than the brief, sharp pain of an incision. Neuropathic pain (e.g., pain of nerve root compression) can be very resistant to opioid treatment. Intraoperatively the opioids can produce sufficient analgesia to reduce or abolish autonomic and somatic responses to surgical stimuli.
8. In usual analgesic doses, morphine-like drugs may produce drowsiness, feelings of heaviness, and difficulty concentrating. Unlike benzodiazepines, opioids do not usually produce amnesia in subhypnotic doses. Doses of opioids that are sufficient to produce apnea and profound analgesia do not always produce sleep in healthy individuals.
9. Seizures can be produced by meperidine because its major metabolite, normeperidine, is a potent convulsant. This is most likely to occur after large doses, or if the patient has renal failure and cannot excrete the metabolite.
10. Opioids produce a dose-related depression of the ventilatory response to CO_2 by a direct effect on ventilatory centers in the medulla. It is important to remember that a decrease in ventilatory rate is not a very sensitive indicator of opioid effect. A patient's drive to breathe may be abnormal despite an apparently normal ventilatory rate and state of consciousness. Sleep further depresses the response to CO_2 and potentiates the ventilatory depression caused by opioids.
11. Equianalgesic doses of all opioids produce equivalent amounts of ventilatory depression. There is no convincing evidence that any analgesic is more or less dangerous than morphine in this regard.
12. Tolerant individuals who require large amounts of opioid for relief of pain are not at a proportionately increased risk of ventilatory depression.
13. Ventilatory depression is difficult to reverse without reversing some analgesia.
14. Opioids suppress cough by depressing cough centers in the medulla. This effect apparently involves different receptor mechanisms than those mediating analgesia and ventilatory depression.
15. The pinpoint pupil is a pathognomonic sign of opioid overdose (unless hypoxia is severe enough to produce mydriasis).
16. Opioids produce complex effects on vomiting centers in the medulla. There is direct stimulation of the chemoreceptor trigger zone (CTZ) in the area postrema on the floor of the fourth ventricle. This, in turn, activates the vomiting center proper, which is a deeper structure. The emetic effects are markedly potentiated by stimulation of the vestibular apparatus, so ambulatory patients are much more likely to vomit than those patients who are lying quietly.

Continued

HISTORY AND CHEMISTRY

With perhaps the exception of ethanol, the opioids have enjoyed the longest history of use of any of the groups of medicinal agents. In 300 B.C., Theophrastus wrote of the medicinal effects of the juice extracted from the poppy. This elixir was known to the Arabs and Chinese of medieval times, and was described in the writings of Paracelsus in the 16th century. Morphine was isolated and purified from poppy extract in 1806 by Sertürner, and Wood's introduction of the hypodermic needle a half-century later enabled the parenteral administration of morphine. Based on his battlefield experiences, Beecher described, in 1946, the dramatically smaller morphine requirements in seriously wounded soldiers as compared with persons having elective surgery. His observations are now understood in terms of how stress and the humoral responses to stress modify intrinsic analgesic pathways.

Opioid analgesics are used in nearly every facet of modern anesthesia prac-

Key Points—continued

17. Generalized hypertonus of skeletal muscle can be produced by large intravenous doses of most opioid agonists. Although morphine can produce rigidity, the problem is most commonly associated with fentanyl, alfentanil, sufentanil, and remifentanil. In its most severe form, "lead pipe" muscle rigidity can totally prevent mechanical ventilation. The difficulty is caused, in part, by loss of chest wall compliance, as well as constriction of laryngeal and pharyngeal muscles.

18. At normal analgesic doses opioids produce minimal cardiovascular effects. Bradycardia and peripheral vasodilatation are seen at higher doses and when opioids are combined with other anesthetic drugs. The combination of slow heart rate, peripheral vasodilatation, minimal myocardial effects, and preservation of autonomic function makes opioid-based anesthesia particularly useful for critically ill patients with cardiac ischemia or failure.

19. Some opioids, particularly morphine and meperidine, produce a nonimmunologic release of histamine from tissue mast cells. This is most often seen as local itching, redness, or hives near the site of intravenous injection. Sometimes a patient will experience generalized flushing. If sufficient histamine is liberated, it may cause decreases in systemic vascular resistance, hypotension, and tachycardia. The potent opioids fentanyl, sufentanil, alfentanil, and remifentanil do not release histamine.

20. Opioids decrease the passage of fluids and solids at every level of the GI tract—so-called opioid bowel dysfunction (OBD). Opioids delay gastric emptying and increase antral tone, which may slow the absorption of oral medications that are administered concomitantly. Food might not pass into the proximal jejunum for many hours, so surgical patients given opioids preoperatively may remain at risk for aspiration despite nominal NPO status. Chronic administration of opioids usually necessitates the administration of laxatives and stool softeners to treat constipation.

21. Opioids cause contraction of smooth muscle in the gall bladder and spasm of the sphincter of Oddi. In some individuals this can precipitate biliary colic.

22. Opioids increase the contractions of the ureter although they relieve the pain caused by ureteral stones. They also decrease detrusor contraction in response to bladder distension (the voiding reflex) and increase the tone of the urinary sphincter by both central and peripheral mechanisms.

23. Although opioids have no specific teratogenic effects, chronic opioid use by the mother can lead to physical dependence by the fetus. Neonatal withdrawal may occur shortly following delivery, and in some instances, may be life-threatening.

24. When tolerance to an opioid occurs, there is simultaneous development of *cross-tolerance* to all other opioid agonists. In general, tolerance develops most rapidly to the effects we have described as depressant (analgesia, ventilatory depression, euphoria), but much less tolerance occurs to some of the stimulant effects, such as constipation or pupillary constriction.

25. Morphine is the least lipophilic of the opioids, which has two important implications for its pharmacokinetics: morphine penetrates biologic membranes more slowly than lipophilic opioids, and it is less likely to accumulate in lipid membranes or fatty tissues. The plasma pharmacokinetics of morphine does *not* parallel its clinical effects. In spite of morphine's rapid distribution and elimination from plasma, the changes in brain concentration are small and delayed. As a result, the onset and offset of analgesia are slow.

26. Morphine 6-glucuronide (M6G), which may constitute 15% of total morphine metabolites, possesses morphine-like analgesic and respiratory depressant activity, although higher doses are required.

27. Meperidine is significantly more lipid soluble than morphine, although its plasma pharmacokinetics is similar. The onset of analgesic effect is faster than morphine, and the duration is shorter (2–3 hours). Meperidine is rapidly *N*-demethylated to form normeperidine. Seizures have occurred in patients with renal failure (who could not excrete normeperidine) and in cancer patients who received high doses of meperidine over long periods of time.

28. Patients chronically taking nonselective monoamine oxidase inhibitors who are given meperidine may suffer a serotoninergic crisis manifested as clonus, agitation, hyperreflexia, and hyperthermia.

29. Hydromorphone is a hydrophilic drug with an octanol–water partition coefficient only slightly higher than morphine's. Its water solubility means that it can be prepared in concentrated solutions (up to 100 mg/mL) that are useful for highly tolerant patients or delivery with implanted infusion pumps. The low lipid solubility gives hydromorphone some of morphine's characteristics as a selective spinal analgesic.

30. Methadone is a long-lasting synthetic μ opioid approximately equipotent with morphine. Unlike most other opioids, methadone has very high oral bioavailability (approximately 80%). Repeated oral or parenteral doses may result in substantial accumulation; subsequent doses appear to last much longer than the initial dose.

31. Fentanyl is extremely fat soluble, which accounts for its rapid onset and relatively short duration. The effects of low doses (e.g., 100–200 μg) are brief because they are terminated by rapid redistribution. After much higher doses (e.g., >20 μg/kg) redistribution may be insufficient to bring plasma concentrations to subtherapeutic levels. In this circumstance, termination of effect depends on the much slower elimination process, and the drug appears long-acting

32. Alfentanil is a slightly less potent congener of fentanyl, and has an extremely rapid onset and short duration of effect. Peak analgesic and ventilatory depressant effects occur in less than 2 minutes, and the duration of the effects of small doses (10 μg/kg) may last only 15 minutes.

33. Sufentanil is a thienyl derivative of fentanyl that is more potent and even more fat soluble. Despite a

Continued

Key Points—continued

terminal half-life of approximately 10 hours, (longer than that of fentanyl and much longer than that of alfentanil), sufentanil has the shortest context-sensitive half-time when given by infusion for up to 10 hours.

34. Pharmacodynamically, remifentanil is similar to the other fentanyl derivatives, but it has an extremely short duration of action due to rapid metabolic inactivation. It is hydrolyzed by nonspecific esterases primarily in skeletal muscle. The context-sensitive half-life is less than 5 minutes, regardless of the duration of the infusion. There is essentially no accumulation of remifentanil after infusions or repeated boluses. The ultrashort duration of this analgesic can be a drawback: patients who are expected to have postoperative pain should receive a longer-acting opioid *prior* to stopping remifentanil.

35. Clinically available preparations of tramadol contain the racemic mixture of two isomers. (+)-Tramadol is a weak agonist at μ receptors and an inhibitor of serotonin reuptake. It is also demethylated to yield a metabolite with greater μ opioid efficacy. (–)-Tramadol more selectively inhibits norepinephrine reuptake. The effects on neurotransmitter reuptake enhance inhibitory effects on pain transmission in the spinal cord.

36. The first attempts at "balanced" anesthesia used curare together with thiopental and nitrous oxide, but these techniques usually failed to block autonomic responses to surgical stimuli. In 1947, Neff et al. introduced a more satisfactory anesthetic that included small doses of meperidine in combination with thiopental, curare, and nitrous oxide. Although the individual components have changed over the years, this technique is the basis for modern balanced anesthesia.

37. The administration of opioids potentiates the hypnotic effects of barbiturates, benzodiazepines and propofol. By reducing the amount of hypnotic administered, an opioid can sometimes produce more rapid emergence. The opioids also produce a dramatic, dose-related decrease in the need for volatile anesthetics, and they are frequently used for this specific purpose.

38. The amount of opioid analgesic required varies tremendously from patient to patient, so anesthetic "recipes" with a predetermined opioid dose are not advisable.

39. How does one titrate an opioid intraoperatively? Decreasing ventilatory rate or depth is usually a reliable sign of increasing opioid effect if the case permits spontaneous ventilation. More commonly, the rise in blood pressure and other autonomic responses to a "painful" stimulus are gauged. This requires good clinical judgment because autonomic responses are nonspecific and may be produced by many conditions that do not involve pain. Unlike the volatile anesthetics, the opioids do not produce graded cardiovascular depression as depth increases. Normal blood pressure does not necessarily mean that the anesthetic level is appropriate, because large overdoses of most opioids are well tolerated as long as ventilation is supported.

40. Naloxone acts as a competitive antagonist at all opioid receptors, but it has greatest affinity for μ receptors. Small doses of naloxone reliably reverse or prevent the effects of pure opioid agonists and most mixed agonist–antagonists. The block is reversible and competitive, so it can be overcome by additional agonist. The onset of antagonist effect is extremely rapid, but the duration of action is quite brief. An IV dose of 0.4 mg will usually antagonize morphine for less than 1 hour; increasing the dose does not increase the duration appreciably. With the exception of remifentanil, the duration of naloxone is shorter than the opioids it is used to antagonize.

41. The agonist–antagonist opioids are synthetic and semisynthetic analgesics that are structurally related to morphine. They have been used primarily for moderate to severe acute pain, although buprenorphine has now been approved for maintenance therapy in opioid addiction. All these compounds produce some degree of competitive antagonism to morphine and the other pure agonists.

42. Most of the clinically available agonist–antagonists bind to both μ and κ receptors, but they have different intrinsic activities at each site. Nalorphine, pentazocine, butorphanol, and nalbuphine produce analgesia and sedation by a partial agonist effect at κ receptors. All of them are competitive antagonists at μ receptors, and therefore reverse the effects of morphine. Buprenorphine binds to μ receptors with extremely high affinity but has limited efficacy. When given alone, its effects are similar to those of morphine. When given after morphine, it competes with the full agonist and causes a reduction in opioid effect.

43. The subjective effects of buprenorphine are similar to morphine throughout the dose range. The κ-type agonists have been described as producing "apathetic sedation." Patients given pentazocine, nalbuphine, or butorphanol may experience floating and dissociation, but usually do not experience mood elevation. After analgesic doses these patients often appear extremely sedated, yet remain capable of surprisingly lucid conversation. With pentazocine, patients are increasingly likely to experience "weird" feelings, dysphoria, or even hallucinations as the dose is raised. These unpleasant effects occur less frequently with butorphanol or nalbuphine. Lack of a morphine-like mood effect makes these analgesics much less desirable for opioid addicts, and it is thought to be a key factor in their low abuse liability.

44. Nalbuphine and buprenorphine are strong antagonists, and they have been used clinically for this purpose. Administration of an opioid antagonist to an opioid-dependent patient will precipitate withdrawal, and this has occurred after therapeutic doses of pentazocine, nalbuphine, and buprenorphine.

45. There has been renewed interest in chronic sublingual administration of buprenorphine since 2002 when the FDA approved it for maintenance therapy of opioid addicts. In the event that a patient taking buprenorphine presents for surgery, treatment of acute pain may present a significant problem. These patients are highly tolerant to opioids, and residual levels of the partial agonist may antagonize other opioids for a long time.

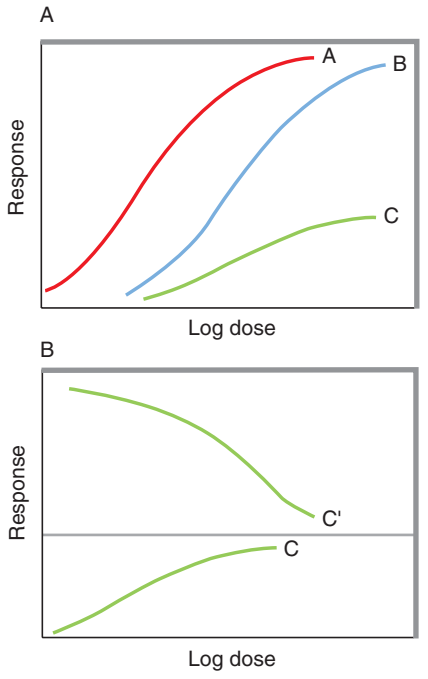

FIGURE 41–1. A. Idealized log dose–response curves for two agonists (*A* and *B*) and a partial agonist (*C*) with an intrinsic activity of approximately 0.4. **B.** Idealized log dose–response curve for the interaction of a partial agonist with a pure agonist. Curve (*C*), the partial agonist alone; curve (*C'*), increasing doses of the partial agonist in the presence of a high concentration of pure agonist. The final level of response is 0.4 × maximum. (Reproduced with permission from Rance MJ. Multiple opiate receptors—their occurrence and significance. Clin Anaesthesiol 1983;1:183.)

tice. They are used as premedicants or sedatives (Chap. 68), intravenous anesthetics (Chap. 42), postoperative analgesics (Chap. 74), intraspinal analgesics (Chap. 46), and in the management of chronic pain (Chaps. 92 and 94). Unfortunately, they are also abused by patients (Chap. 23) and physicians (Chap. 96).

The initial suggestion that more than a single mechanism may be operative in opioid-mediated analgesia came in 1954, when Beecher and Lasagna reported that nalorphine had the characteristics of both an agonist and an antagonist. In the succeeding decade, a number of agonists and antagonists were synthesized, permitting the description of three opioid receptor types by Martin in 1967. Goldstein hypothesized the existence of endogenous opioid compounds in 1970, and 3 years later, independent research teams led by Terenius, Snyder, and Simon identified stereospecific binding sites for opioids. Hughes, Kosterlitz, Goldstein, and their respective colleagues then isolated peptide molecules having morphine-like effects from brain and pituitary gland.

For the purposes of pharmacologic discussions, the term *narcotic* is avoided. Narcotic implies sleep (which opioids surely may produce), but does not connote analgesia. Furthermore, under United States law, a narcotic is any substance deemed likely to be abused, and the class includes such obviously "nonnarcotic" agents as amphetamine, cocaine, and marijuana. Morphine and codeine are opiate analgesics—naturally occurring alkaloids obtained from the juice of the poppy *Papaver somniferum*. An opioid is any natural or synthetic compound that has effects similar to those of morphine or that acts as an antagonist at the same receptors to which morphine binds.

An opioid agonist, like morphine or fentanyl, binds to one (or more) of the opioid receptors and elicits the typical response mediated by that receptor. The opioid antagonists, such as naloxone, are competitive, meaning they produce a block of opioid effect that is surmountable when a sufficient amount of agonist is present. Some clinically used opioids, such as buprenorphine, are partial agonists. Such drugs have lower efficacy than full agonists, even when given at extremely high doses. Their dose–response curves plateau at a lower maximal effect than do those of full agonists (Fig. 41–1A). In some circumstances a partial agonist may act like an antagonist: in the presence of a full dose of an agonist, the partial agonist may displace the agonist from its receptor binding sites and reduce the overall effect (Fig. 41–1B).

Because opioid agonists relieve pain, they are classified as analgesics. In contrast to the local anesthetics (which interrupt the transmission of all nerve impulses, including pain) and the antiinflammatory analgesics such as aspirin (which decrease some of the pathologic processes leading to pain), the opioid analgesics act primarily to alter the perception of pain as a noxious entity. A patient's overall response to pain is a function of many simultaneous processes. These include the magnitude of the noxious stimulus, the patient's individual threshold for experiencing suffering in response to pain, what the patient anticipates will be the result of the noxious stimulus, and the presence or absence of agents (such as opioids) capable of modulating the integration of these processes. As we shall see, the opioid analgesics are also used to decrease "pain" responses in individuals who are unconscious.

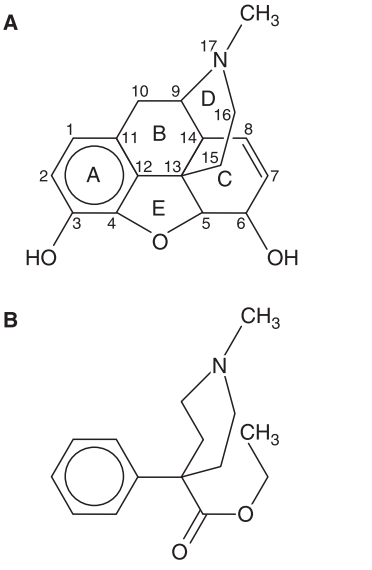

FIGURE 41–2. Structural formulas of morphine (**A**) and meperidine (**B**).

Figure 41–2A shows the structure of morphine. It is a 5-ring molecule, 3 rings of which lie in one plane, while the other 2 (labeled *C* and *D*) lie nearly perpendicularly, forming a T shape. There are two hydroxyl groups (one phenolic and one alcoholic), a quaternary carbon atom at position 13, and a piperidine ring with a methyl group on the nitrogen. Morphine is optically active, and only the levorotatory form is analgesically active. Codeine is morphine that has been *O*-methylated at position 3. The first semisynthetic opioids (heroin, hydromorphone) were made by simple substitution, but the morphine molecule may be much simplified while retaining opioid agonist activity. Meperidine (Fig. 41–2B) is a phenylpiperidine that contains only fragments of the original morphine structure. Fentanyl and its derivatives are anilidopiperidines, closely related to meperidine (Fig. 41–3). Note that when the piperidine ring is opened, the ensuing molecule is structurally analogous to tyrosine, the amino acid required to be in the terminal position for peptide opioid activity.

When the piperidine nitrogen has a bulkier chemical group (e.g., allyl, cyclopropyl, cyclobutyl), the compound often takes on opioid antagonist prop-

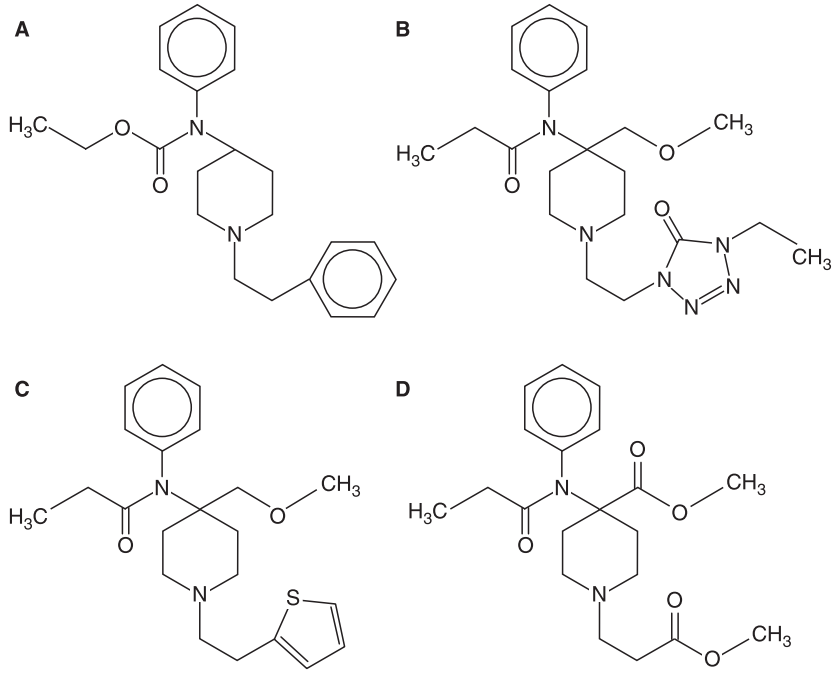

FIGURE 41–3. Structural formulas of fentanyl (**A**), alfentanil (**B**), sufentanil (**C**), and remifentanil (**D**).

erties. For example, the *N*-allyl derivatives of morphine and oxymorphone are the antagonists nalorphine and naloxone, respectively.

OPIOID RECEPTORS

Four broad classes of opioid receptors are currently accepted, each encoded by a different gene. Most of the clinically important pharmacologic effects of opioid alkaloids are mediated by μ or κ receptors. The international names for these receptors are MOP and KOP, but in this chapter we will use the Greek letter designations. Some opioid peptides are more selective for a third receptor, the δ receptor (DOP). A fourth receptor called the nociceptin-orphanin FQ receptor (NOP) may also be involved in pain processing (see Endogenous Opioids). Older literature describes a σ receptor, but this is no longer considered to be a true opioid receptor.

The "classical" pharmacologic effects of morphine, like analgesia and ventilatory depression, are mediated by μ receptors. Other μ effects include sedation, euphoria, tolerance and physical dependence, decreased gastrointestinal motility, biliary spasm, and miosis. Studies with selective agonists and antagonists support the concept that there are many subclasses of μ receptors, and specific functions have been ascribed to a few of these subclasses. For example, ventilatory depression and spinal opioid analgesia are mediated by μ_2 receptors, whereas supraspinal analgesia is a μ_1-opioid effect.[108] A μ_3 receptor is found in vascular tissue and in leukocytes,[20] and it may have roles in vascular control and immunomodulation. It is possible that a μ subtype-specific agonist might have greater efficacy or less toxicity than morphine, but no such agent has been developed for clinical use.

All μ receptors are encoded by a single gene, denoted OPRM1, found on chromosome 6q24-q25. Although genetic polymorphisms exist,[86] most receptor variants arise from posttranscriptional or posttranslational modifications.[82,108] The transcribed messenger ribonucleic acid (mRNA) may be modified by splicing or polyadenylation, whereas the receptor may be covalently modified by phosphorylation or conjugation to ubiquitin. There is now evidence for the existence of more than 20 μ-receptor variants. This heterogeneity may explain why opioids have variable efficacy and toxicity in different patients, and it may also account for the fact that patients who are tolerant to the effects of one μ agonist can sometimes get relief with another.

The κ receptor shares a number of effects with the μ receptor, including analgesia, sedation, and ventilatory depression. It now appears that the ability of some opioids to cause dysphoria is caused by action at κ receptors. All κ receptors are encoded by a single gene that may theoretically produce at least 6 mRNA variants.[82] The κ receptors have been subdivided into several subclasses, two of which (κ_1 and κ_3) are relevant to the effects of drugs used in anesthesia. The κ_1 receptor mediates spinal analgesia,[148] whereas activation of the κ_3 receptor results in supraspinal analgesia,[109] sedation, and ventilatory depression. The κ_3 receptor is the most prevalent opioid receptor in the brain.

The δ receptor is responsible for mediating some of the analgesic effects of the endogenous opioid peptides, especially in the spinal cord.[52,114] Few of the clinically used opioid alkaloids have significant affinity for δ receptors at usual analgesic doses. If a μ-selective opioid is administered in a sufficiently high dose (to treat a tolerant patient, for example), the drug may be less selective and produce significant δ effects.

All opioid receptors are G-protein coupled receptors. All have 7 transmembrane domains and significant structural homology. The actions of both μ and δ agonists result in overall neuronal depression, and they share several signal transduction mechanisms, including inhibition of adenylyl cyclase,[116,140] activation of K^+ currents, and suppression of Ca^{2+} currents. Opening of the inwardly rectifying K^+ channel serves to hyperpolarize neuronal membranes, and inhibition of inward calcium current limits the release of various neurotransmitters. Other mechanisms have been demonstrated, including stimulation of phospholipase C[140] and mitogen-activated protein kinase,[59] as well as blockade of L-type calcium channels.[112] The κ receptor elicits similar cellular responses,[59,61,141] and it may also block N-type calcium channels.[146]

ENDOGENOUS OPIOIDS

Five families of endogenous opioid peptides bind to the various opioid receptors. The peptides show some binding selectivity, but there is no consistent association between a peptide family and a particular receptor mechanism. Four of the families begin as large polypeptide molecules that are subsequently cleaved to yield sev-

eral opioid (and some nonopioid) peptides. Although some of these peptides undoubtedly function in nociceptive pathways, they also appear to play fundamental roles in processes like thermoregulation and hormone release, as well as gastrointestinal and cardiovascular control.

1. The *enkephalins* are pentapeptides derived from proenkephalin A. Each molecule of proenkephalin contains four sequences of met-enkephalin (Tyr-Gly-Gly-Phe-Met), one copy of leu-enkephalin (Tyr-Gly-Gly-Phe-Leu), and some slightly larger enkephalin-like peptides. The enkephalins are moderately selective for δ receptors and probably act as neurotransmitters released from short interneurons within the spinal cord and brainstem. They are found in the adrenal medulla and in nerve terminals that contain catecholamines. Enkephalins (and exogenous opioids) bind to presynaptic opioid receptors on nociceptive neurons containing neurotransmitters like substance P. Inhibition of substance P release is an important mechanism of opioid analgesia. The naturally occurring enkephalins are hydrolyzed extremely rapidly by peptidases in plasma. Stable analogues of the enkephalins have been synthesized, permitting in vivo experiments on their actions.
2. *Prodynorphin* (also called proenkephalin B) contains the sequences for dynorphin A and dynorphin B. The dynorphins are the endogenous ligands at the κ receptor, and their distribution is similar to that of the enkephalins. The 5 amino acids at the *N*-terminus of the dynorphins are identical in sequence to leu-enkephalin.
3. Proopiomelanocortin (POMC) contains a multitude of opioid and nonopioid peptides and is found in high concentrations in the anterior pituitary gland and the hypothalamus. The *N*-terminus of POMC is identical to met-enkephalin, although POMC is not cleaved to yield met-enkephalin. The final 31 amino acids form β-endorphin, the most important of the humoral endogenous opioids, and an important endogenous ligand at the μ receptor. In addition, selective cleavage of POMC yields many nonopioid hormones including adrenocorticotropic hormone (ACTH), several varieties of melanocyte-stimulating hormone (MSH), and the lipotropins.
4. *Proorphanin* is cleaved to orphanin FQ (also called nociceptin), a peptide containing 17 amino acids. Although proorphanin has significant sequence homology with the other 3 parent opioid peptides, orphanin FQ does not bind to μ, κ, or δ receptors. It binds to a G-protein coupled receptor (NOP) and causes cellular responses similar to other opioids, including inhibition of adenylyl cyclase, opening of the inwardly rectifying potassium channel, and blocking N-type calcium channels.[97] Orphanin FQ is found in unusual places like hippocampus and sensory cortex. It has a supraspinal antianalgesic effect while producing spinal analgesia. Its possible roles in pain modulation, learning, and drug reward are topics for much current research.
5. The *endomorphins* appear to be endogenous agonists that have high affinity and high selectivity for the μ receptor. A precursor molecule for the endomorphins has not yet been identified. The tetrapeptide Tyr-Pro-Trp-Phe-NH_2 is called endomorphin-1, and a related peptide, Tyr-Pro-Phe-Phe-NH_2, is called endomorphin-2.[171] In vivo studies suggest that endomorphin-1 acts via stimulation of μ_2 receptors. Endomorphin-2 is less specific, acting at both μ and κ receptors. These peptides have both in vitro and in vivo cardiovascular effects. They decrease spontaneous discharge in the rostral ventrolateral medulla (RVLM), an area important in the central control of blood pressure. Peripherally, they decrease norepinephrine release from vascular sympathetic neurons.

When nature creates an interesting and useful molecule, it is often found at work across wide expanses of the plant and/or animal kingdoms. Thyroid hormone is an excellent example of a simple, small molecule whose structure has been conserved for millions of years. Morphine, too, may be such an example. Although the poppy flower may possess the machinery to manufacture morphine in large quantities, mammalian systems may also synthesize morphine from tyrosine precursors, using apparently the same reaction scheme. The significance of endogenous morphine is unknown, but it is interesting that arthritic rats make more morphine than do healthy ones.[35,165]

OPIOID AGONISTS

General Properties

The most widely used opioid analgesics are the pure agonists, and all of these are relatively selective for μ-opioid receptors. Unlike the volatile anesthetics, opioid agonists produce a group of highly specific depressant and stimulant effects by acting at discrete sites within the central nervous system. For example, morphine stimulates the vagal nuclei in the medulla while depressing ventilatory centers only a few millimeters away. Box 41–1 lists the acute and chronic effects of opioids.

Given their common mechanism of action, it is easy to see why morphine, meperidine, fentanyl, and the fentanyl congeners have very similar pharmacodynamic effects. The few qualitative differences between them (e.g., histamine release) usually do not involve specific opioid receptor mechanisms. However, the various opioids differ greatly in their physicochemical properties, as well as in speed of onset and duration of action, so the clinical selection of an opioid is frequently based on pharmacokinetic considerations. Opioid pharmacokinetics are considered later in the discussion of specific agonist drugs.

CNS Effects

Analgesia and Mood Effects The opioids produce selective relief of pain at doses that do not produce sleep or impair sensation. Opioid analgesic effects result from actions at several different levels of the neuraxis. The processing of pain information is inhibited by a direct spinal effect at the dorsal horn; the rostrad transmission of pain signals is decreased by activation of descending inhibitory pathways in the brainstem[1]; finally, the emotional response to pain is altered by opioid actions on the limbic cortex. Opioids also act at receptors located peripherally on sensory and smooth muscle motor neurons.[146]

Opioids affect both the perception of pain and the response to pain, but it is difficult to make the distinction in most clinical circumstances. Patients given morphine will typically report that pain is still present, but the intensity is decreased and it no longer bothers them as much. The relief of pain and anxiety will often result in sleep, but sometimes mood elevation or frank euphoria can occur. The euphoriant effect or sense of well-being produced by opioid agonists is thought to be one of the most important reasons for their abuse.

Sufficient doses of opioids will relieve almost any pain, although some types of pain are typically more responsive than others. Prolonged, burning pain, for example, is more effectively blunted than the brief, sharp pain of an incision. Neuropathic pain (e.g., pain of nerve root compression) can be very resistant to opioid treatment.[33,37] Intraoperatively, the opioids can produce sufficient analgesia to reduce or abolish autonomic and somatic responses to surgical stimuli. In this circumstance, they are almost always combined with other central nervous system depressants (see discussion on Intraoperative Use of Opioids).

Table 41–1 lists some commonly used opioid agonists along with their recommended doses and durations of action. The relative potencies of most older opioids have been determined in postoperative pain models, whereas those for the fentanyl series are from intraoperative studies. The doses in the table are for comparison only, and the actual doses given during administration of anesthesia will vary greatly depending on the application. "Equianalgesic" doses can be very difficult to determine when bolus doses of opioids with very different analgesic time-effect curves are being compared (Fig. 41–4). Fentanyl is often stated to have 80–100 times the potency of morphine, a figure that takes into account both the intensity and duration of effect (i.e., the area under the curve is measured). If one considered only the peak intensity of effect, fentanyl might appear to be 200 times more potent than morphine. Because the anesthesiologist typically looks for peak analgesic and toxic effects following an intravenous bolus, the latter number might be more useful.

Sedation–Hypnosis In usual analgesic doses, morphine-like drugs may produce drowsiness, feelings of heaviness, and difficulty concentrating. Unlike benzodiazepines, opioids do not usually produce amnesia in subhypnotic doses. At higher doses sedation becomes more pronounced, and, eventually, hypnosis may occur. Doses of opioids that are sufficient to produce apnea and profound analgesia do not always produce sleep in healthy individuals.[9] The use of opioids alone to produce both hypnosis and analgesia has resulted in numerous cases of intraoperative awareness. Sleep is much more likely to occur in elderly or debilitated patients or in those given small doses of benzodiazepines.[138] High doses of morphine, fentanyl, or its congeners produce a cortical electroencephalogram (EEG) pattern that is superficially similar to deep sleep.[134] The average frequency decreases, and large-amplitude delta waves predominate. Unlike the intravenous or inhaled anesthetics, high doses of opioids will not produce EEG burst suppression.

CNS Toxicity Dysphoria and agitation occur infrequently after analgesic doses of most opioids, although their incidence is higher with meperidine and codeine. True seizures can be produced by meperidine because its major metabolite, normeperidine, is a potent convulsant. This is most likely to occur after large doses, or if the

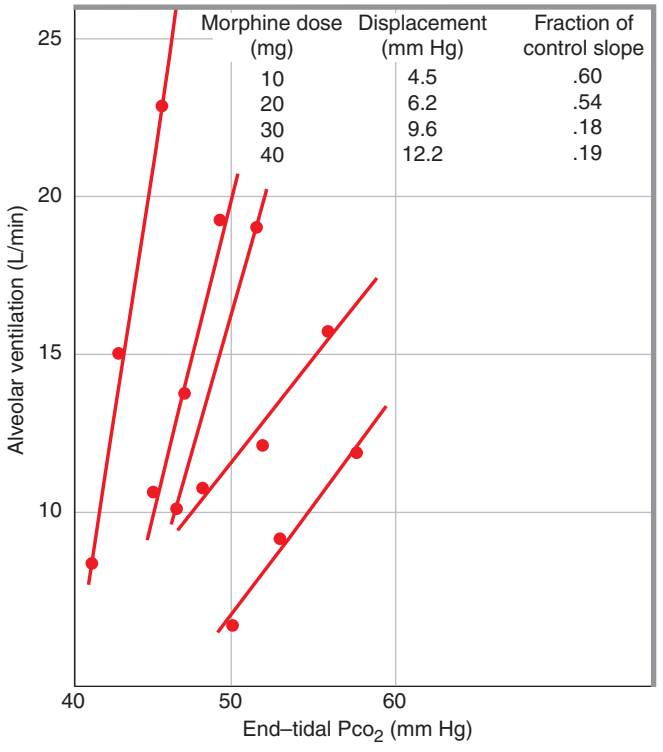

FIGURE 41–5. CO_2 response curves from one subject who received 4 doses of morphine 10 mg intravenously at 40-minute intervals. Reprinted, with permission, from the Annual Review of Pharmacology and Toxicology, Volume 41 © 1985 by Annual Reviews. www.annualreviews.org

patient has renal failure and cannot excrete the metabolite[26] (see Specific Drugs).

In laboratory animals, extremely high doses of morphine or fentanyl can produce seizure activity, but this does not occur at the concentrations achieved in clinical practice.[98] Opioid-induced hypertonus of skeletal muscle (see Muscle Rigidity) can sometimes lead to myoclonic movements that have been mistaken for seizures.

Administration of opioids can raise cerebrospinal fluid pressure if ventilation is not controlled, and $Paco_2$ is allowed to rise. Opioid premedication should generally be avoided when elevated intracranial pressure (ICP) is suspected; ICP may rise further, and the opioid effects may mask changing neurologic signs. These drugs are very useful, however, during induction of anesthesia in neurosurgical patients. When ventilation is controlled, fentanyl and sufentanil have little effect on cerebral metabolic rate and blood flow, and therefore do not increase ICP.[94,137]

Ventilatory Depression Opioids produce a dose-related depression of the ventilatory response to CO_2 by a direct effect on ventilatory centers in the medulla.[73] Morphine also blunts the response to hypoxia.[161] In awake subjects given an analgesic dose of morphine, the intercept of the CO_2 response curve is shifted to the right, and (depending on the measurement technique) there may also be a decrease in slope (Fig. 41–5).[32] Both the rate and the rhythm of breathing are affected: as the dose of opioid is increased, ventilatory rate will slow, but the effect of this may be partially offset by an increase in tidal volume. It is important to remember that a decrease in ventilatory rate is not a very sensitive indicator of opioid effect. A patient's drive to breathe may be abnormal despite an apparently normal ventilatory rate and state of consciousness. Sleep will further depress the response to CO_2 and potentiate the ventilatory depression caused by opioids.[42]

At usual analgesic doses the opioids rarely cause clinically significant ventilatory depression unless there is preexisting pathology (such as hypothyroidism or pulmonary or CNS disease) or previous drug administration (alcohol, general anesthetics, or benzodiazepines). Patients with obstructive sleep apnea are at increased risk for opioid-induced ventilatory depression, and postoperative use of opioid analgesics in such patients may warrant increased monitoring as compared to patients without sleep apnea.[14,26]

Very large doses of opioids will eventually result in inadequate ventilation. Breathing may become irregular or even take on a Cheyne-Stokes pattern. There may be complete inattention to breathing; otherwise responsive patients may hypoventilate to the point of cyanosis unless they are reminded to breathe. Ventilatory depression is, of course, the major toxicity of opioids and nearly always the cause of death from overdose.

Equianalgesic doses of all opioids produce equivalent amounts of ventilatory depression. There is no convincing evidence that any analgesic is more or less dangerous than morphine in this regard. Despite experimental evidence that analgesia and ventilatory depression may be mediated by different receptor subtypes (μ_1 and μ_2, respectively), no highly selective agonist or antagonist has been developed for clinical use.[108]

Both analgesia and ventilatory depression are reduced by administration of an opioid antagonist or by the development of tolerance. This has two important clinical implications:

1. Tolerant individuals who require large amounts of opioid for relief of pain are not at proportionately increased risk of ventilatory depression.
2. Ventilatory depression is difficult to reverse without reversing some analgesia (see Naloxone below).

A number of case reports have described "recurrent" or "delayed" ventilatory depression after administration of anesthetics with fentanyl or alfentanil. Becker et al.[11] showed that CO_2 sensitivity could recover after fentanyl-N_2O anesthesia, only to decline once again over the next hour (Fig. 41–6). It is likely that these events are actually caused by varying levels of stimulation: opioid-induced ventilatory depression is antagonized by pain and movement during emergence and transfer to the recovery area; it may reappear if the patient goes back to sleep.

Cough Suppression Opioids suppress cough by depressing cough centers in the medulla. This effect apparently involves different receptor mechanisms than those mediating an-

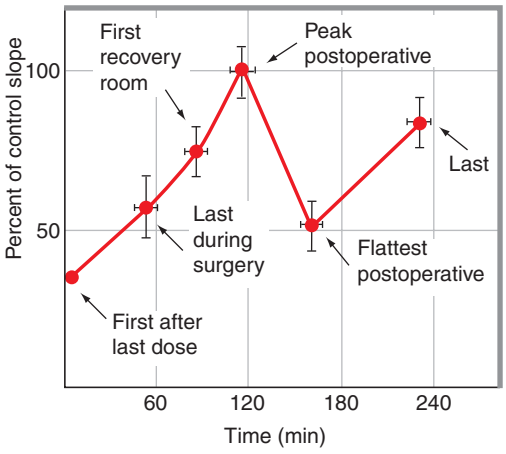

FIGURE 41–6. Recurrent ventilatory depression expressed as slope of CO_2 response curve (percentage of awake control) vs. time. First data point obtained after last intraoperative dose of fentanyl. Response recovered, then subsequently declined when patients were no longer stimulated (see text). (Reproduced with permission from Becker LD, Paulson BA, Miller RD, et al. Biphasic respiratory depression after fentanyl-droperidol or fentanyl alone used to supplement nitrous oxide anesthesia. Anesthesiology 1976;44:291.)

algesia or ventilatory depression. Some animal data suggest that peripheral opioid receptors may be involved as well. Cough is effectively suppressed by stereoisomers of opioids (e.g., dextromethorphan) that have no analgesic activity. The molecular modification that selectively increases antitussive potency is replacement of the 3-hydroxyl group on morphine with a bulkier group. Thus, cough suppression is strong with heroin (3-acetoxy-) and codeine (3-methoxy-), but weak with meperidine (no functional group).

Pupillary Constriction Opioids stimulate the Edinger-Westphal nucleus of the oculomotor nerve to produce miosis.[83] The pinpoint pupil is a pathognomonic sign of opioid overdose (unless hypoxia is severe enough to produce mydriasis). Miosis is rapidly reversed with naloxone. Miosis occurs after relatively small doses of opioids, and reaches a plateau after moderate doses, so it is not a very useful way to grade the intensity of opioid effect following larger doses.[32,75] Absence of miosis, however, suggests absence of opioid effect.

Nausea and Vomiting Opioids produce complex effects on vomiting centers in the medulla (Fig. 41–7). There is direct stimulation of the chemoreceptor trigger zone (CTZ) in the area postrema on the floor of the fourth ventricle. This, in turn, activates the vomiting center proper, which is a deeper structure.[157] The emetic effects are markedly potentiated by stimulation of the vestibular apparatus, so ambulatory patients are much more likely to vomit than those patients who are lying quietly. Postoperatively, patients frequently become nauseated when they have to move from stretcher to bed. Costello has shown that high doses of opioids can actually have antiemetic effects by depressing the vomiting center proper.[25] It is not clear at which dose a given opioid becomes antiemetic.

Tolerance can occur to the emetic effects of opioids, but treatment with antagonists may often make the symptoms worse. The emetic effects involve a complex interaction of dopaminergic, cholinergic, and serotonergic mechanisms, and opioid-induced nausea and vomiting may be treated successfully with a wide variety of antiemetic drugs that block these neurotransmitter systems.

Muscle Rigidity The opioids have no significant effects on nerve conduction, at the neuromuscular junction or at the skeletal muscle membrane. In animals they produce minimal depression of monosynaptic and polysynaptic spinal reflexes, but the clinical relevance of this is not known. A much more important effect is the generalized hypertonus of skeletal muscle, which can be produced by large intravenous doses of most opioid agonists. Although morphine can produce rigidity, the problem is most commonly associated with fentanyl, alfentanil, sufentanil, and remifentanil.

Opioid-induced rigidity was originally thought to be restricted to the abdominal and thoracic musculature, but it is now known that muscles of the neck and extremities are involved as well.[13] The incidence and severity of the problem are greatest when large amounts of opioids are infused rapidly, but rigidity can occur with doses of only 1–2 μg/kg of fentanyl. This effect is usually seen during induction of anesthesia, just at loss of consciousness. When very large amounts of opioid have been administered (e.g., for cardiac surgery), rigidity may occur upon emergence. Rigidity is more likely to occur in older patients and when nitrous oxide is administered along with the opioid.[128]

In its most severe form, "lead pipe" muscle rigidity can totally prevent mechanical ventilation. The difficulty is caused, in part, by loss of chest wall compliance, as well as by constriction of laryngeal and pharyngeal muscles. Some suggest that supraglottic obstruction is the more important problem.[128] Substantial amounts of positive pressure are sometimes needed for effective ventilation, which can lead to decreased venous return, gastric insufflation, and so forth. Such rigidity is substantially mitigated by pretreatment with midazolam or diazepam (and to a lesser degree with thiopental).[128]

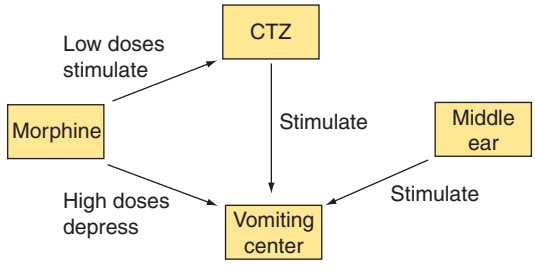

FIGURE 41–7. Mechanisms of opioid-induced nausea and vomiting (see text for details). (Reproduced with permission from Rosow CE. Newer synthetic opioid analgesics. In: Smith G, Covino BG, eds. Acute Pain. London: Butterworths, 1985 p.74.)

Opioids are believed to produce rigidity by actions at μ receptors in the striatum. Opioids increase the rate of striatal dopamine biosynthesis and inhibit the release of the inhibitory neurotransmitter γ-aminobutyric acid (GABA).[24] Antagonism of this effect on GABA may account for the beneficial effects of sedative–hypnotics. In the rat, microinjection of opioid antagonists at certain raphe nuclei will selectively block rigidity.[163]

Cardiovascular Effects

At normal analgesic doses opioids produce minimal cardiovascular effects. Bradycardia and peripheral vasodilatation are seen at higher doses and when opioids are combined with other anesthetic drugs.

Opioids produce bradycardia by a specific stimulant effect on the central nuclei of the vagus nerves. In animals, microinjection of naloxone at these sites antagonizes the bradycardia, but not the analgesia, produced by intravenous fentanyl.[81] The bradycardic effect is most likely to occur when large doses of opioids are administered rapidly. It may be prevented or reversed by atropine, pancuronium, and other vagolytic drugs. Opioid-induced bradycardia may be more frequent when a relaxant such as vecuronium is used because it lacks vagal blocking effects. Meperidine, which is weakly atropinic, does not usually cause bradycardia.

The opioid-induced increase in vagal tone leads to a prolongation of atrioventricular (AV) conduction. There is also evidence of a direct depressant effect on the sinoatrial (SA) node.[152] Morphine and fentanyl decrease central sympathetic tone, which raises the threshold for ventricular fibrillation in the dog.[126]

Opioids produce peripheral vasodilatation by depressing vasomotor centers in the medulla. Analgesic doses frequently cause orthostatic hypotension, and higher doses may significantly reduce venous return. The peripheral vascular effects involve both resistance and capacitance vessels.[60] Zelis showed that an analgesic dose of morphine increases blood flow through forearm skeletal muscle without altering systemic pressure.[171] This effect is thought to represent a centrally mediated lysis of sympathetic tone. Lowenstein et al. demonstrated that morphine's effect on skeletal muscle vascular resistance is neurally mediated and markedly increased under conditions of high sympathetic activity.[87] This is consistent with the clinical observations that opioids are more apt to cause hypotension in patients with conditions that elevate the baseline level of sympathetic tone (e.g., hypovolemia, coronary artery disease, congestive failure).

A number of studies have documented a direct effect of opioids on vascular smooth muscle, but its contribution to overall hemodynamic effects is unclear.[59] Morphine, but not enkephalin analogues, can bind to a μ_3 receptor on arterial endothelial cells and cause vasodilatation by releasing nitric oxide.[20] For morphine, some vasodilatation is caused by the release of histamine.

Venodilation may lead to significant pooling of blood, especially in the splanchnic vasculature.[83] There is evidence in the dog that morphine causes blood to be sequestered in hepatic sinusoids.[53] In both humans and animals, opioid-induced venodilation seems to occur later and last longer than the effect on arterioles.[60,64]

At clinically relevant concentrations the opioids do not produce significant myocardial depression. Unlike the volatile anesthetics, morphine does not block arteriolar constriction in response to sympathetic nerve stimulation or circulating catecholamines.[158] Unlike the volatile anesthetics, fentanyl (even when combined with a benzodiazepine) does not block high- or low-pressure baroreceptor responses.[36] The combination of slow heart rate, peripheral vasodilatation, minimal myocardial effects, and preservation of autonomic function makes opioid-based anesthesia particularly useful for critically ill patients with cardiac ischemia or failure. When hypotension does occur, it frequently responds to simple measures like administration of intravenous fluids.

Histamine Release

True allergic responses to opioids are very rare, although anaphylaxis to fentanyl and meperidine has been reported. Some opioids, particularly morphine and meperidine, produce a nonimmunologic release of histamine from circulating basophils and tissue mast cells. This is most often seen as local itching, redness, or hives near the site of intravenous injection. Sometimes a patient will experience generalized flushing. If sufficient histamine is liberated, it may cause decreased systemic vascular resistance, hypotension, and tachycardia.[123] The cardiovascular effects (but not the histamine release) may be prevented by pretreatment with H_1 and H_2 antagonists like chlorpheniramine and cimetidine.[110]

This is a nonspecific effect that depends upon competitive displacement of the amine by opioid molecules. Mast cell degranulation is more likely to occur in some sites (e.g., skin) than others (lung, GI tract).[151] Because the more potent opioids expose tissue mast cells to lower opioid concentrations, they are less likely to cause release. The potent opioids fentanyl, sufentanil, alfentanil, and remifentanil do not release histamine[41,124,138] (Fig. 41–8). Chemical structure also influences this process, because even equimolar concentrations of fentanyl and morphine do not cause equivalent histamine release.[62]

Histamine release does not usually cause bronchospasm, but opioids should still be used with great care on patients with asthma. These drugs may exacerbate preexisting bronchospasm by depressing cough and ventilatory drive, and by drying airway secretions.

Pruritus

Patients given opioids frequently complain of itching and warmth over the neck and face, especially over the malar area. Neuraxial administration of opioids (especially intrathecal) can often produce very troublesome generalized itching.[10] This effect is an opioid receptor-mediated dysesthesia, and it can be produced by opioids like fentanyl that do not release histamine. The itching is not antagonized by antihistamines, but it may be reversed with opioid antagonists.

Smooth Muscle Effects

Intestine and Stomach Opioids decrease the passage of fluids and solids at every level of the GI tract—so-called opioid bowel dysfunction (OBD). They delay gastric emptying and increase antral tone, and these effects may slow the absorption of oral medications that are administered concomitantly. Food may not pass into the proximal jejunum for many hours, so surgical patients given opioids preoperatively may remain at risk for aspiration despite nominal NPO status. Chronic administration of opioids usually necessitates the administration of laxatives and stool softeners to treat constipation. Meperidine and some of the agonist–antagonist opioids

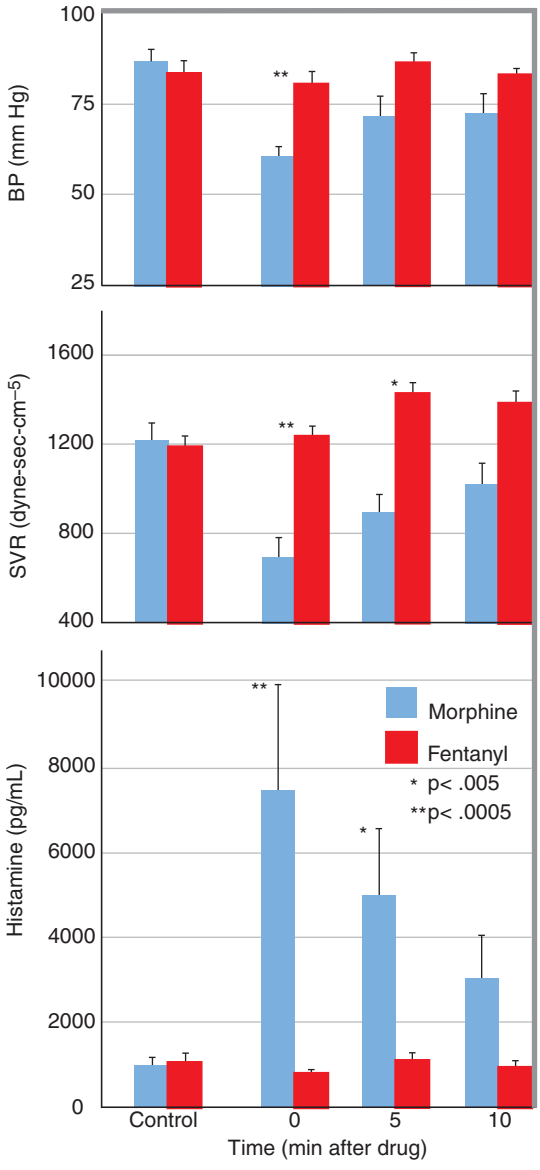

FIGURE 41–8. Plasma histamine increases while mean arterial pressure (*BP*) and systemic vascular resistance (*SVR*) decrease in cardiac surgical patients given morphine 1 mg/kg, IV. These effects do not occur after fentanyl 50 µg/kg, IV. (Reproduced with permission from Rosow CE, Moss J, Philbin DM, et al. Histamine release during morphine and fentanyl anesthesia. Anesthesiology 1982;56:93.)

are less likely to cause this effect. OBD can be reversed or prevented by the use of opioid antagonists that act peripherally (see Opioid Antagonists).

The constipating effect is caused by a combination of decreased intestinal fluid production and increased fluid absorption as the passage of intestinal contents is delayed. Opioids decrease GI secretory activity by direct effects on intestinal secretory cells and by modulation of sympathetic transmission in the enteric nervous system. The decrease in GI motility involves both CNS effects and peripheral actions on opioid receptors in the bowel.[78] In the small bowel, there is initial stimulation of activity followed by atony. The stimulation produces segmenting, nonpropulsive contractions that prolong intestinal transit time. Opioids increase GI sphincter tone and cause an increase in colonic tone. The increase in resting colonic tone is especially pronounced in patients with ulcerative colitis, and opioids may predispose these patients to the development of toxic megacolon.

Opioids may also be used therapeutically in the treatment of diarrheal syndromes. Treatment of diarrhea is usually accomplished with orally administered drugs like diphenoxylate and loperamide. Therapeutic doses of these drugs do not usually produce central effects because they are poorly absorbed, and loperamide is actively pumped from the CNS by a P-glycoprotein transporter.

Biliary System Opioids cause contraction of smooth muscle in the gall bladder and spasm of the sphincter of Oddi. In some individuals this can precipitate biliary colic. Intraoperatively, the same effect has been reported to cause false-positive cholangiograms and even to prevent instrumentation of the common duct. The biliary effects may be completely antagonized by naloxone and partially reversed by glucagon, nitroglycerin, or atropine.[5,119] The biliary effects of full agonists (including meperidine) appear to be similar when the medications are given at equianalgesic doses, while the agonist–antagonist opioids have much smaller smooth muscle effects[119] (Fig. 41–9).

Urinary Tract Opioids increase the contractions of the ureter although they relieve the pain caused by ureteral stones. They also decrease detrusor contraction in response to bladder distension (the voiding reflex) and increase the tone of the urinary sphincter by both central and peripheral mechanisms.[36] This may cause a sense of urinary urgency but an inability to void. Sufficient opioid may also eliminate urgency; that is, the patient may become inattentive to the stimulus of bladder distension. Urinary retention occurs much more commonly in men, and it is an especially frequent side effect when opioids are administered into the subarachnoid or lumbar epidural spaces.

Hormonal Effects

Morphine inhibits the release of gonadotropin-releasing hormone and corticotropin-releasing factor by acting on the hypothalamus.[155] The concentrations of testosterone and cortisol in plasma are decreased because the secretion of pituitary trophic hormones is inhibited.[21] Opioids also increase plasma levels of certain hormones such as growth hormone and prolactin. Over the short term, most of these hormonal changes are probably not clinically significant. Perhaps more importantly, surgery and pain can produce large increases in many hormones (the so-called stress response), and opioids are able to blunt or abolish these responses (see Intraoperative Use of Opioids below).

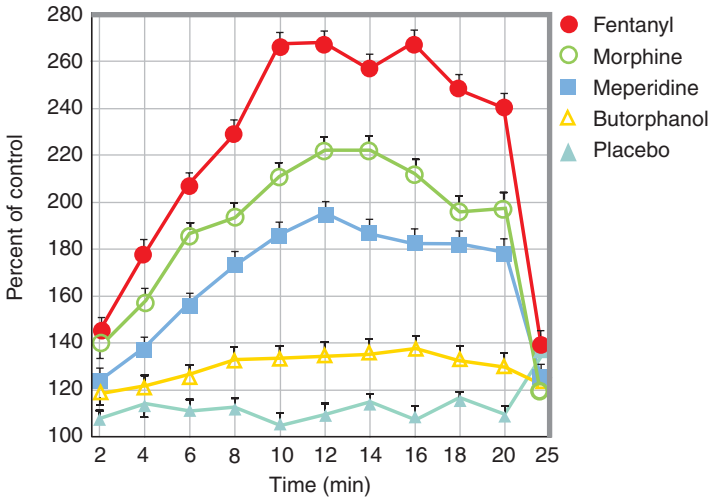

FIGURE 41–9. Percentage change in common bile duct pressure versus time following equianalgesic doses of several opioids. Patients were undergoing cholecystectomy with basal enflurane anesthesia. After 20 minutes, the effect was reversed by naloxone. (Reproduced with permission from Radnay PA, Duncalf D, Novakovic M, et al. Common bile duct pressure changes after fentanyl, morphine, meperidine, butorphanol and naloxone. Anesth Analg 1984;63:441.)

Immune Effects

For many years there have been reports about the immunosuppressive effects of opioids. In animal models, there is evidence that opioids suppress resistance to infection and may promote metastatic spread of tumors. Heroin addicts have increased incidences of many different infections, although multiple factors are undoubtedly involved in this setting. Opioid-induced immunosuppression is probably mediated by effects on both peripheral immune cells and the central nervous system. Opioids decrease natural killer cell activity, lymphocyte proliferation, antibody production, and nuclear factor kappa B (NF-κB) activation in neutrophils.[161] Many of these effects are blocked in μ-receptor knockout mice, and some are blocked by opioid antagonists.[49]

The clinical impact of all this is still unknown and it is likely to be complex. Opioid agonists do not all produce the same effects on immune cells, and untreated pain can also be immunosuppressive. This research may have important implications, particularly for patients with chronic pain, those in methadone programs, and hospitalized patients given very large doses of opioids.

Effects on Pregnancy and the Neonate

Opioids have no specific teratogenic effects, but chronic opioid use by the mother may lead to physical dependence in the fetus. Neonatal withdrawal may occur shortly following delivery, and, in some instances, may be life-threatening. Parenteral opioids are commonly used to treat labor pain. Because opioids cross the placenta readily, they can cause ventilatory depression in the neonate. Morphine produces more depression in the neonate than meperidine.[160] The newborn infant has an incompletely developed blood–brain barrier, so a dose of morphine that is appropriate for the mother may produce excessive effects in the baby. Meperidine is more lipophilic, and its effects in mother and infant are more comparable. Opioids take time to accumulate in the fetus, so the neonate may actually be less affected if the opioid is given very close to the time of delivery. Naloxone may be required to reverse the effects of meperidine given repeatedly during a long labor.

Opioid agonist–antagonist agents like nalbuphine and butorphanol are popular for use in laboring women. Because they produce less ventilatory depression at higher doses than full agonists (See Opioid Agonist-Antagonists), they are thought to be safer for mother and child; however, convincing controlled trials are lacking.

Tolerance

There appear to be two types of tolerance to opioid action. When a large dose is administered by bolus or rapid infusion, *acute tolerance* or *tachyphylaxis* may occur. Acute tolerance to a brief infusion of remifentanil was reported,[157] but this has been difficult to confirm.[58,131]

The more important problem of *chronic tolerance* occurs when opioids are administered frequently over longer periods of time. The first indication of tolerance is often a decrease in the duration of analgesia after each dose, but eventually the intensity of effect also declines. Tolerance may be overcome, in most cases, by an increase in the dose of the opioid. Cancer patients receiving very high doses or continuous neuraxial opioid administration can acquire profound tolerance, and huge doses may be needed to produce an adequate analgesic effect. Regional blocks and nonopioid analgesics may be necessary to produce adequate pain relief in these circumstances. In recent years, opioid tolerance has also become a common problem for mechanically ventilated ICU patients who receive fentanyl or morphine infusions for sedation.

When tolerance to an opioid occurs, there is simultaneous development of cross-tolerance to all other opioid agonists. In general, tolerance develops most rapidly to the effects we have described as depressant (analgesia, ventilatory depression, euphoria), but much less tolerance occurs to some of the stimulant effects like constipation or pupillary constriction. For example, a heroin addict who is placed on chronic methadone treatment becomes tolerant to the euphoriant effect but frequently continues to have miosis and constipation. Similarly, constipation is a common problem for the terminal cancer patient who requires large doses of morphine for relief of pain. As previously discussed, cross-tolerance among full agonists is often incomplete, perhaps because of the heterogeneity of μ-receptor subtypes. A patient who is tolerant to one opioid can often get additional relief by switching to another—a process known as *opioid rotation*.[39]

The precise mechanisms of both acute and chronic tolerance are still unclear. Some of the mechanisms are similar to desensitization of other G-protein coupled receptors: receptor phosphorylation and internalization can occur, as well as activation of mitogen-activated protein kinases, adenylyl cyclase, and phosphokinase C. Confusingly, the mechanisms are not consistent for the various opioid receptors, not even for different ligands of the

TABLE 41–2.

Physicochemical Properties of Some Opioid Agonists

Drug	pK_a	% Ionized at pH 7.4	Partition Coefficient[a]

same receptor. Activation of glutamate (*N*-methyl-D-aspartate [NMDA]) receptors may play a role, and inhibitors of NMDA may reduce tolerance development.[118] A growing literature now suggests that chronic administration of opioids can actually activate some pain pathways (possible via NMDA activation and consequent nitric oxide production). This means that a part of what we term opioid "tolerance" may be a result of a hyperalgesic effect.[76]

Physical Dependence

After sufficient doses have been administered for an adequate period of time, all opioids induce a state of physical dependence. Abruptly stopping the drug or administering an antagonist then causes a stereotypic withdrawal syndrome. The symptoms of withdrawal can be rapidly terminated with small doses of intravenous morphine.

Some authorities believe that medically induced physical dependence is common, and clinically imperceptible dependence may actually be present after only a few injections of a potent opioid. In most cases, "withdrawal" may occur without the patient or physician being aware of it. Physical dependence is not the same thing as *psychological dependence* or *addiction,* which includes the dimension of compulsive drug-seeking behavior. The data of Porter and Jick suggest that addiction resulting from appropriate medical treatment is a very unusual event.[114] Irrational fear of causing patients to become addicted has been cited as a frequent cause for the inadequate treatment of acute pain.

When a patient with known physical dependence is to be detoxified (withdrawn), the patient is commonly switched to methadone, and the dose is reduced slowly. This produces a mild, although protracted, withdrawal syndrome. However, a person addicted to heroin or methadone who presents emergently for medical treatment is generally not an appropriate candidate for detoxification (see Chap. 23).

Specific Drugs

As discussed previously, the onset or duration of effect is most often the basis for selection of a particular opioid. Chapter 39 discusses many of the pharmacokinetic properties of opioids. The clinically available opioid agonists vary greatly in their physicochemical properties and therefore in their absorption and distribution throughout the body. Table 41–2 lists important physicochemical properties of several opioids, and Table 41–3 lists pharmacokinetic parameters. It should be noted that there is tremendous variability in the published values for most of these pharmacokinetic parameters. Some of this variability reflects true differences between patient populations, whereas some is the result of sampling times and other technical aspects of measurement.

Morphine

Morphine is the least lipophilic of the opioids listed,[73,125] and this has two important implications for its pharmacokinetics: morphine penetrates biologic membranes more slowly than lipophilic opioids, and it is less likely to accumulate in lipid membranes or fatty tissues. The plasma pharmacokinetics of morphine is similar to that of a fat-soluble drug. It is rapidly absorbed after intramuscular, subcutaneous, or oral administration. After an intravenous bolus, plasma concentrations decline rapidly as the drug is distributed into well-perfused tissues. Only about 25–35% is bound to plasma proteins, primarily albumin. The steady-state volume of distribution is very large, and it is probably made up of nonfatty tissues.

Morphine is a substrate for P-glycoprotein, an energy-dependent transporter molecule responsible for the efflux of many cationic compounds out of cells. What used to be called the blood–brain barrier for morphine is actually a combination of slow CNS penetration and rapid efflux. Togeth-

[a]Data fitted to two-compartment model.

er, these effects account for the relatively slow onset and low concentrations of morphine found in the brain after analgesic doses.[85]

Morphine is eliminated primarily by hepatic biotransformation with approximately 5–15% excreted unchanged in the urine. The rate of hepatic clearance is very high, and accounts for the relatively short 3-hour terminal half-life. The hepatic extraction of morphine is approximately 0.7; that is, 70% is cleared in 1 pass through the liver. Morphine therefore undergoes flow-dependent elimination, so factors that decrease hepatic blood flow will prolong its elimination. High hepatic clearance also means that morphine is subject to a large first-pass effect, and larger doses are required when the drug is given orally.

More than 90% of a dose of morphine is metabolized and excreted within 24 hours. The primary route of metabolism is conjugation in the liver to produce morphine 3-glucuronide and morphine 6-glucuronide. A small amount of morphine is *N*-demethylated to form normorphine.[96] These polar metabolites are then excreted in the urine and bile. Morphine 6-glucuronide (M6G), which may constitute 15% of total morphine metabolites, possesses morphine-like analgesic and respiratory depressant activity, although higher doses are required.[121,122] M6G is a substrate for a transporter protein distinct from the P-glycoprotein,[140] and it does not appear to contribute to the overall analgesia produced by morphine after a single or a few doses.[139] M6G may contribute more to the overall analgesic effect of morphine administered long-term.

The plasma pharmacokinetics of morphine does not parallel its clinical effects. In spite of morphine's rapid distribution and elimination from plasma, the changes in brain concentration are small and delayed. As a result, the onset and offset of analgesia are slow. In a study in human volunteers, the peak pupillary effect occurred 86 minutes after intravenous injection, although 90% of that effect was achieved within 22 minutes.[32] Hug demonstrated in dogs that peak ventilatory depression did not occur for 30–60 minutes following an intravenous bolus of morphine[67] (Fig. 41–10). During the recovery period, Hug showed that concentrations of morphine in cerebrospinal fluid declined more slowly than those in plasma, and the decline in ventilatory depression was slower still.

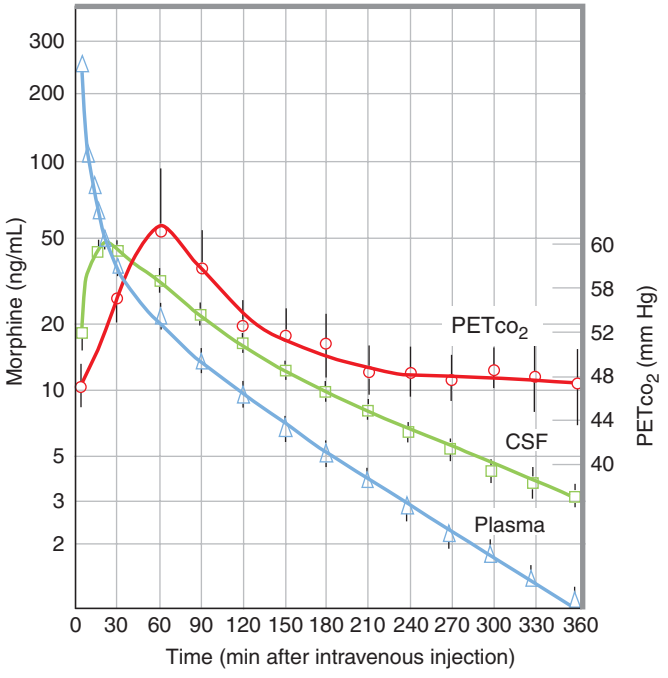

FIGURE 41–10. Concentration of morphine in plasma and cerebrospinal fluid (CSF), and end-tidal CO_2 ($PETCO_2$) versus time in 6 dogs given 0.3 mg/kg and allowed to breathe spontaneously (see text for details). Meperidine

This substituted phenylpiperidine is significantly more lipid soluble than morphine, although its plasma pharmacokinetics is similar. The onset of the analgesic effect is faster than morphine, and the duration is shorter (2–3 hours). Meperidine is rapidly distributed into a large apparent volume of distribution, and it has a very high rate of clearance by hepatic biotransformation.[91,156] The high hepatic extraction means that meperidine undergoes significant (48–56%) first-pass metabolism. The terminal half-life has been estimated as 3–7 hours—which is similar to or longer than that of morphine. Meperidine is more highly protein bound than morphine (65–80%), and it is bound mainly to α_1-acid glycoprotein.

Meperidine is rapidly *N*-demethylated to form normeperidine; the other major metabolites are meperidinic acid and normeperidinic acid. Less than 7% of a dose is excreted unchanged in the urine. The metabolism of meperidine plays a significant role in its pharmacodynamics. In the mouse, normeperidine is an analgesic with about half the potency of meperidine; unfortunately, in both mouse and man it is a potent convulsant. Normeperidine has a terminal half-life of 8–12 hours, so significant amounts of this toxic metabolite can accumulate. Seizures have occurred in patients with renal failure (who could not excrete normeperidine) and in cancer patients who received high doses of meperidine over long periods of time.[147]

A large amount of data has been obtained on the correlation between meperidine plasma concentration and its pharmacodynamic effects. For meperidine, the relationship between plasma level and analgesia is both predictable and useful. Austin et al. titrated meperidine to analgesic effect in postsurgical patients. For each individual, the change from no pain relief to excellent pain relief occurred over a very narrow range of plasma concentrations, and this level was fairly consistent over a 2-day period.[8] In contrast, there was a large variability (40%) in meperidine requirement between individuals. These data are remarkably similar to those describing the relationship of alfentanil concentration to intraoperative analgesic response[7] (see Intraoperative Use of Opioids). The data on meperidine have been used to demonstrate why our traditional fixed-dosage regimens for relief of acute

pain often result in inadequate or excessive plasma concentrations.

Meperidine (or one of its metabolites) appears to have serotonin reuptake inhibitory effects.[50] This effect may form the basis for the well-described and potentially fatal interaction between meperidine and monoamine oxidase inhibitors. Patients chronically taking nonselective monoamine oxidase inhibitors who are given meperidine may suffer a serotoninergic crisis manifested as clonus, agitation, hyperreflexia, and hyperthermia.

Hydromorphone

Hydromorphone is an older, semisynthetic μ agonist that has gained increasing popularity for a number of acute and chronic indications as an alternative to morphine. It is approximately 5–7 times more potent than morphine (although some data suggest as much as 10 times more potent), and it has a slightly shorter duration of action. It is cleared by hepatic glucuronidation with an approximate 62% first-pass metabolism. There is no active 6-glucuronide, but the 3-glucuronide can accumulate to produce neuroexcitation.

Hydromorphone is a hydrophilic drug with an octanol–water partition coefficient only slightly higher than that of morphine.[125] This probably explains the 10–20-minute delay in peak analgesic effect after an IV bolus dose, as well as the relatively poor correlation between plasma concentration and effect.[23] Its water solubility means that it can be prepared in concentrated solutions (up to 100 mg/mL), that are useful for highly tolerant patients or delivery with implanted infusion pumps. The low lipid solubility gives hydromorphone some of morphine's characteristics as a selective spinal analgesic. The epidural-to-parenteral equianalgesic ratio is 1:2, and the duration of a single epidural dose is estimated as being between 7.7 and 19.3 hours.[102] A few papers suggest that hydromorphone may produce fewer side effects (nausea, pruritus) than morphine, but the evidence for this is weak.

Methadone

Methadone is a long-lasting synthetic μ opioid approximately equipotent with morphine. Unlike most other opioids, methadone has very high oral bioavailability (approximately 80%). Compared to morphine, methadone is more lipid soluble and has higher tissue and plasma protein binding (to α_1-acid glycoprotein). Methadone has a very large volume of distribution and its clearance (by hepatic biotransformation) is low.[68] The redistribution kinetics of methadone is similar to that of morphine, so the drugs may have similar durations after single bolus doses. The terminal half-life of methadone is approximately 35 hours, and repeated oral or parenteral doses can result in substantial accumulation; subsequent doses appear to last much longer than the initial dose.

There is renewed interest in methadone for the therapy of chronic pain. The drug is available as a racemic mixture, and the *d*-isomer was long thought to have no activity. Recently *d*-methadone was demonstrated to be a noncompetitive glutamate (NMDA) antagonist in concentrations similar to those achieved with analgesic concentrations of the racemate. In animal models, *d*-methadone attenuates the development of opioid tolerance and blocks NMDA-induced hyperalgesia.[69] It is not known whether these benefits can be achieved in humans.

Fentanyl

This potent synthetic opioid is extremely fat soluble, which accounts for its rapid onset and relatively short duration. After intravenous administration fentanyl is rapidly distributed to the brain, heart, and other highly perfused tissues,[66] and its peak effect occurs in only 3–5 minutes. Within a short time, the drug is distributed extensively throughout the body (steady-state volume of distribution is more than 4 L/kg), so plasma levels drop precipitously. Termination of effect occurs when fentanyl redistributes away from the central nervous system.

Plasma concentrations fall much more slowly during the elimination phase. Fentanyl is biotransformed in the liver to inactive metabolites, primarily norfentanyl and several hydroxylation products. Only 6–8% is excreted unchanged in the urine. The hepatic clearance of fentanyl is very high, and more than 60% is cleared in 1 pass. The large distribution volume, however, means that most of the drug remains extravascular and unavailable for biotransformation. The long terminal half-life of fentanyl (approximately 8 hours) is a function of the slow rate at which it reenters the central compartment.[93]

Fentanyl concentration in the plasma correlates well with cerebrospinal fluid (CSF) concentration and pharmacodynamic effect.[65] Fentanyl plasma pharmacokinetics therefore predicts some of its more important pharmacodynamic properties:

- The effects of low doses (e.g., 100–200 μg) are brief because they are terminated by rapid redistribution. After much higher doses (e.g., >20 μg/kg) redistribution may be insufficient to bring plasma concentrations to subtherapeutic levels. In this circumstance, termination of effect depends on the much slower elimination process, and the drug appears long-acting[101] (Fig. 41–11). The distribution and terminal half-lives do not change with dosage (fentanyl obeys first-order kinetics throughout the clinical dose range).
- A long terminal half-life means that repeated intravenous boluses of fentanyl are very likely to produce cumulative effects.
- A high hepatic extraction ratio (0.6) means the clearance of fentanyl is limited by hepatic blood flow. Factors that lower hepatic blood flow (e.g., intraabdominal surgery, cardiopulmonary bypass) can decrease elimination of fentanyl.
- Fentanyl undergoes substantial first-pass metabolism, so the oral route is inefficient. The drug is well absorbed when given transdermally, intranasally, or via the oral mucosa. These routes bypass the portal circulation and result in high blood levels of fentanyl.

Alfentanil

Alfentanil is a slightly less potent congener of fentanyl, and has an extremely rapid onset and short duration of effect. Peak analgesic and ventilatory depressant effects occur in less than 2 minutes, and the duration of the effects of small doses (10 μg/kg) may last only 15 minutes. The pharmacokinetics of alfentanil is unusually well studied; Table 41–3 lists some of its more important pharmacokinetic parameters.

The pharmacokinetic behavior of fentanyl and alfentanil is qualitatively similar. A single bolus of alfentanil undergoes rapid redistribution followed by slower elimination. Termination of alfentanil effects after small doses still depends on redistribution, and the effects of larger doses (100–200 μg/kg) may be prolonged. Alfentanil is less lipophilic than fentanyl, and

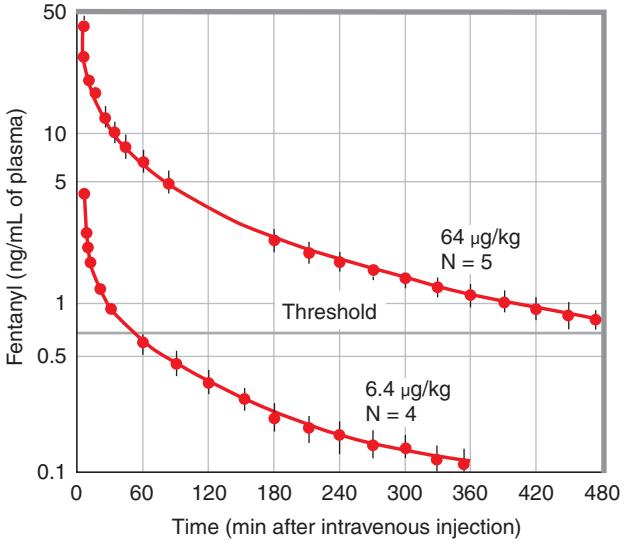

FIGURE 41–11. Plasma concentration of fentanyl versus time in dogs given either 6.4 or 64 µg/kg intravenously. Threshold represents the concentration above which depression of ventilation occurs (see text for details). Effects of the lower dose are terminated by redistribution; those of the higher dose are terminated by elimination. it has much less tendency to bind nonspecifically in muscle and fat. This is reflected in smaller initial and steady-state volumes of distribution.[18]

Alfentanil is rapidly metabolized by *N*-dealkylation and *O*-demethylation, and very little of the drug is excreted unchanged in the urine.[18] The relatively small steady-state volume of distribution is less than one fourth that of fentanyl, so the terminal half-life of alfentanil is only 1.5–2 hours in most healthy patients. Alfentanil is less likely than fentanyl to produce cumulative effects after repeated doses, and it is a better choice for administration by continuous infusion.[7,135] For infusions of 2 hours or less, its context-sensitive half-time (see Chap. 39) is about half the infusion duration. For infusions longer than 2 hours, its context-sensitive half-time remains at approximately 1 hour.

Alfentanil was one of the very first drugs characterized by simultaneous pharmacokinetic–pharmacodynamic modeling. Scott et al. gave volunteers a brief infusion of either fentanyl or alfentanil at a sufficient rate to produce slowing of the EEG[132] (Fig. 41–12). Both opioids produced a decrease in the average EEG frequency as the plasma level increased; when the infusions were terminated, the EEG reverted to normal fast frequencies. In the fentanyl group, there was a delay of 2–3 minutes before measurable slowing occurred, and the effects persisted for 20–30 minutes after the infusion was discontinued. In the alfentanil group, the onset and offset of effect were much more closely correlated to the rise and fall in plasma levels. The reasons for this remain speculative: Diffusion of alfentanil into the CNS may be faster because more of the drug is in a diffusible, nonionized form at body pH (see Table 41–2). It is also 22 times less soluble than fentanyl in rat brain.[16] This property may allow it to achieve more rapid effect-site equilibrium (see Chap. 39) because it undergoes less nonspecific binding in brain tissue.

Sufentanil

This thienyl derivative of fentanyl is more potent and even more fat soluble. The drug is rapidly and extensively distributed, and the effects of small doses are terminated by redistribution. Despite a terminal half-life of approximately 10 hours (longer than that of fentanyl and much longer than that of alfentanil), sufentanil has the shortest context-sensitive half-time when given by infusion for up to 10 hours. For example, after a 2-hour infusion, the context-sensitive half-time of sufentanil is approximately 20 minutes, about a third the value for alfentanil. Hepatic clearance is greater than that of

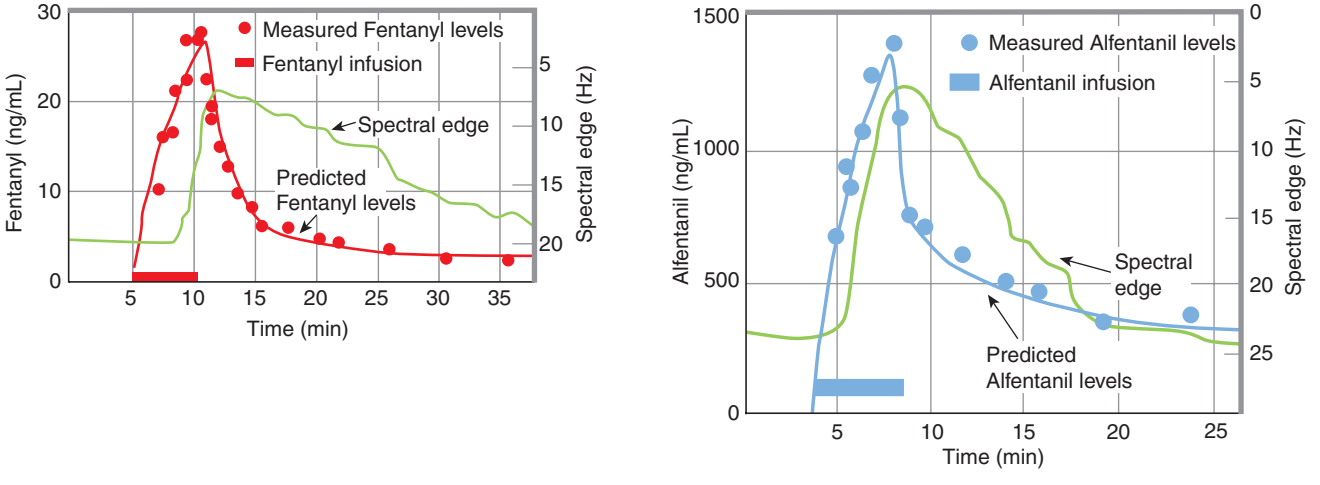

FIGURE 41–12. Plasma concentration of fentanyl or alfentanil versus time with simultaneous measurement of EEG spectral edge. Volunteers were given fentanyl 150 µg/min or alfentanil 1500 µg/min. Increasing opioid effect is depicted as a decrease in average EEG frequency and spectral edge. Changes in spectral edge follow plasma concentrations more closely for alfentanil (see text for details). (Reproduced with permission from Scott JC, Ponganis KV, Stanski DR. EEG quantitation of narcotic effect: the comparative pharmacodynamics of fentanyl and alfentanil. Anesthesiology 1985;62:234.)

fentanyl (extraction ratio = 0.7). Sufentanil is metabolized by *N*-dealkylation and *O*-demethylation.

Sufentanil has had extensive use in cardiac surgery, where it has been given in very large doses (up to 30 μg/kg). At these doses, profound analgesia and ventilatory depression last for many hours, although extubation is usually possible earlier than with comparable doses of fentanyl. The distribution of the opioid is dramatically affected by cardiopulmonary bypass: plasma concentrations of sufentanil drop with hemodilution, but the huge amounts sequestered in lung and muscle cause a secondary increase when the bypass is discontinued.[106] Large amounts of sufentanil can also be bound to oxygenators and tubing in the bypass circuit.

The fat solubility of sufentanil allows it to be absorbed rapidly through intact skin and mucous membranes. Although it has been used epidurally, its rapid absorption by spinal cord and vertebral plexus gives it a very short duration.

Remifentanil

Remifentanil is the newest opioid to be introduced into clinical use. Pharmacodynamically, it is similar to the other fentanyl derivatives, but it has an extremely short duration of action because of rapid metabolic inactivation. It is hydrolyzed by nonspecific esterases, primarily in skeletal muscle, and the resulting metabolite is several thousand-fold less potent as a μ-opioid agonist. Remifentanil is not a substrate for pseudocholinesterase, and the dose does not need to be changed for patients with pseudocholinesterase deficiency. Its redistribution half-life is similar to those of other fentanyl derivatives, but metabolism is always the predominant mechanism for clearance. The context-sensitive half-life is less than 5 minutes, regardless of the duration of the infusion.[164] There is essentially no accumulation of remifentanil after infusions or repeated boluses.

Remifentanil is more potent than alfentanil and less potent than sufentanil. In the presence of 70% nitrous oxide, infusion rates between 0.05 and 0.3 μg/kg/min will provide adequate analgesia for most surgical procedures. Higher doses have been approved, but they are usually not needed; additionally, they may produce bradycardia and hypotension. Emergence from anesthesia is essentially independent of the infusion rate or cumulative dose given (Fig. 41–13), and will occur within a few minutes of discontinuing the infusion.[30] The ultrashort duration of this analgesic can be a drawback: patients who are expected to have postoperative pain should receive a longer-acting opioid prior to stopping remifentanil.

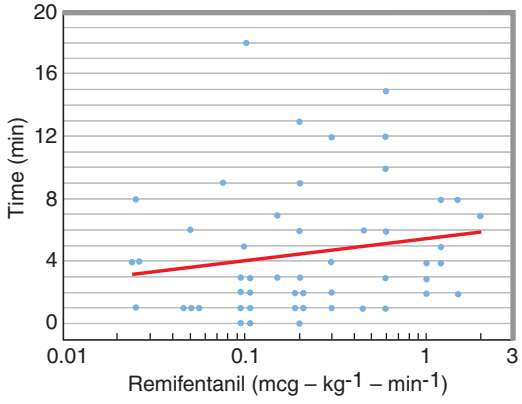

FIGURE 41–13. The time to spontaneous ventilation after discontinuing an infusion of remifentanil expressed as a function of the infusion rate. (Reprinted from Dershwitz M, Rosow CE. Remifentanil: a truly-short-acting opioid. Semin Anesth 1996;15:88, with permission from Elsevier.)

Patients with hepatic or renal failure do not experience a prolongation in effect, and the dose of remifentanil does not need to be adjusted in such patients.[31,33] In fact, the dose of remifentanil does not need to be adjusted for age or weight except at the extremes of these parameters.

Tramadol

Tramadol is considered here with other opioid agonists, but it has multiple and unique mechanisms of action as an analgesic. Clinically available preparations of tramadol contain the racemic mixture of two isomers. (+)-Tramadol is a weak agonist at μ receptors and an inhibitor of serotonin reuptake. It is also demethylated to yield a metabolite with greater μ opioid efficacy. (–)-Tramadol more selectively inhibits norepinephrine reuptake. The effects on neurotransmitter reuptake enhance inhibitory effects on pain transmission in the spinal cord.[55] Tramadol is partially reversed by naloxone and exhibits incomplete cross-tolerance to opioid agonists. It does not have opioid antagonist properties and does not precipitate withdrawal when given to opioid-dependent addicts.

In the United States, tramadol is only available for oral administration, whereas a parenteral preparation is available in many other countries. Given orally, tramadol is effective in both acute postoperative pain and neuropathic pain. Given parenterally, it has been used epidurally, as part of a balanced anesthetic, and for patient-controlled analgesia.[56] The drug undergoes oxidative hepatic metabolism then renal excretion of a glucuronidated metabolite. The active *O*-demethylated metabolite is formed by CYP2D6, and there is some evidence that genetic polymorphisms will influence the drug effect. Common side effects are sedation and nausea. Because it inhibits serotonin reuptake, tramadol (like meperidine) can cause a serotonergic crisis in a patient taking a monoamine oxidase inhibitor or another reuptake inhibitor like fluoxetine or paroxetine.[50] Its effects on ventilatory drive and its potential to be abused appear to be less than those of the typical μ-opioid agonists.

INTRAOPERATIVE USE OF OPIOIDS

Although opium extracts were used hundreds of years ago in "soporific sponges," the modern concept of an opioid-based general anesthetic did not evolve until quite recently. Gray and Rees defined general anesthesia as a "triad" consisting of narcosis (i.e., hypnosis), analgesia, and muscle relaxation.[53] The opioids by themselves do not produce muscle relaxation, and even high doses sometimes fail to produce sleep. In the days before muscle relaxants, endotracheal tubes, and controlled ventilation, high doses of morphine were tried alone as total anesthetics and found to be both dangerous and only marginally effective.

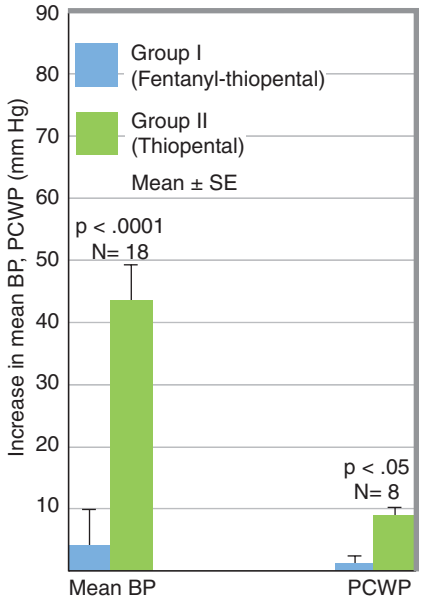

FIGURE 41–14. Fentanyl 8 µg/kg, administered intravenously, prevents the increase in mean systemic and wedge pressure following laryngoscopy and intubation. All patients were given thiopental and pancuronium. (Reproduced with permission from Martin DE, Rosenberg H, Aukburg SJ, et al. Low-dose fentanyl blunts circulatory responses to tracheal intubation. Anesth Analg 1982;61:680.)

Balanced Anesthesia

In 1942, Griffiths introduced curare, which made it possible for muscle relaxation to be achieved during relatively light levels of anesthesia.[55] The first attempts at "balanced" anesthesia used curare together with thiopental and nitrous oxide, but these techniques usually failed to block autonomic responses to surgical stimuli. In 1947, Neff et al. introduced a more satisfactory anesthetic that included small doses of meperidine in combination with thiopental, curare, and nitrous oxide.[104] Although the individual components have changed over the years, this technique is the basis for modern balanced anesthesia.

In the 1950s the major tranquilizers (phenothiazines and butyrophenones) were introduced into clinical practice. DeCastro and Mundeleer described a technique called *neuroleptanalgesia* in which a butyrophenone (droperidol) was combined with fentanyl.[27] This combination did not necessarily cause sleep or amnesia, but it produced analgesia, apparent indifference to stimuli, immobility, and autonomic stability. When nitrous oxide was added to produce sleep, the resulting state was called *neuroleptanesthesia*. This anesthetic technique is infrequently used today.

In modern practice, nearly all anesthesia is "balanced." The term is no longer restricted to nitrous oxide-opioid anesthesia, but includes mixtures of opioids with volatile agents or infusions of intravenous hypnotics.

Intraoperative Analgesia

Analgesia is sometimes difficult to assess—or even to define—in a patient who is not awake. In general, we consider intraoperative analgesia to be a reduction in autonomic and somatic responses to noxious surgical stimuli. The cardiovascular responses to incision, laryngoscopy, and other painful events are blunted much more effectively by opioids than by most other intravenous agents[90] (Fig. 41–14).

Analgesia can also be measured by the decreasing requirement for other anesthetic agents. The administration of opioids potentiates the hypnotic effects of barbiturates, benzodiazepines and propofol[13,77] (Fig. 41–15). By reducing the amount of hypnotic administered, an opioid can sometimes produce more rapid emergence. The opioids also produce a dramatic, dose-related decrease in the need for volatile anesthetics, and they are frequently used for this specific purpose. The minimum alveolar concentration (MAC) of isoflurane, for example, is decreased as the blood concentration of remifentanil is increased[79] (Fig. 41–16). The maximal effect of full opioid agonists seems to be approximately a 70% reduction in MAC whereas the mixed agonist–antagonists have lower efficacy.[100]

The amount of opioid analgesic required varies tremendously from patient to patient, so anesthetic "recipes" with a predetermined opioid dose are inadvisable. Shafer et al. found that administration of alfentanil at a fixed infusion rate resulted in inadequate anesthesia in some patients and postoperative ventilatory depression in others.[135] This variability is a result of both pharmacokinetic[89] and pharmacodynamic[7] factors. The requirement for opioid also depends on the nature of the surgical stimulus.

Ausems et al. demonstrated the nature of this variability in patients receiving nitrous oxide and a continuous infusion of alfentanil.[7] The infusion was titrated to suppress various clinical responses, and plasma concentrations were measured simultaneously. The Cp50 (plasma concentration necessary to prevent a response in 50% of patients) was calculated for each stimulus. The study showed, for example, that the Cp50 for tracheal intubation was 475 ng/mL of alfentanil, but skin closure required only 150 ng/mL (Fig. 41–17). These investigators also found a 2-fold to 3-fold difference in opioid sensitivity between individuals, but for each patient, the change between adequate and inadequate analgesia occurred over a very small range of plasma concentrations. The challenge for the anesthesiologist is to find the clinical end point that establishes this narrow range for the individual patient.

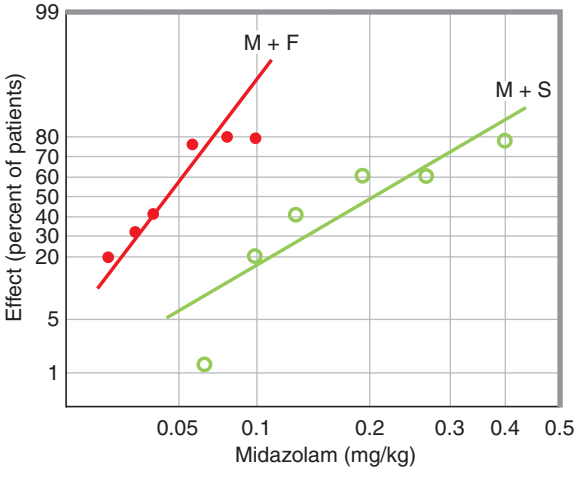

FIGURE 41–15. Percentage of patients asleep versus dose of midazolam on a log-probit plot. Curve is shifted to the left in the presence of fentanyl 1.9 µg/kg (*M + F*) compared to midazolam plus saline (*M + S*). (Ben-Schlomo I, abd-el-Khalim H, Ezry J, et al. Midazolam acts synergistically with fentanyl for induction of anesthesia. Br J Anaesth 1990;64:45. By permission of Oxford University Press.)

Decrease in minimum alveolar concentration (MAC) for isoflurane versus blood concentration of remifentanil in humans. *F* represents a patient who moved, and *S* a patient who did not move. (Reproduced with permission from Lang E, Kapila A, Shlugman D, et al. Reduction of isoflurane minimal alveolar concentration by remifentanil. Anesthesiology 1996;85:721–728.)

How is an opioid titrated intraoperatively? Decreasing ventilatory rate or depth is usually a reliable sign of increasing opioid effect if the case permits spontaneous ventilation. More commonly, the rise in blood pressure and other autonomic responses to a "painful" stimulus are gauged. This requires good clinical judgment because autonomic responses are nonspecific and may be produced by many conditions that do not involve pain. Unlike the volatile anesthetics, the opioids do not produce graded cardiovascular depression as depth increases. Normal blood pressure does not necessarily mean that the anesthetic level is appropriate, because large overdoses of most opioids are well tolerated as long as ventilation is supported. Thus far, neurophysiologic measurements such as cortical EEG, EMG, cortical-evoked potentials, and evoked spinal reflexes have not been demonstrated to be useful indices of opioid analgesia.

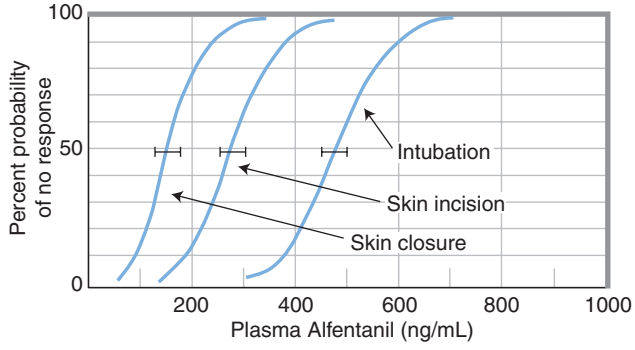

FIGURE 41–17. Percentage probability of no response to various stimuli versus plasma concentration of alfentanil. Patients received 66% nitrous oxide and muscle relaxants. During balanced anesthesia, much lower concentrations of alfentanil are required for skin incision and closure than for intubation. (Reproduced with permission from Ausems ME, Hug CC Jr, Stanski DR, et al. Plasma concentrations of alfentanil required to supplement nitrous oxide anesthesia for general surgery. Anesthesiology 1986;65:362.)

The dose of opioid may need to be modified according to the patient's age and physical condition. On average, opioid sensitivity is increased in patients who are elderly,[133] hypovolemic, or debilitated. Reduced doses are usually given to patients with significant CNS disease and those who have received other CNS depressants. The clearance of morphine, meperidine, fentanyl, and alfentanil is decreased in the elderly and the neonate; however, pharmacokinetic differences due to age are frequently smaller than those attributable to the variability between individuals. This means that some elderly patients may require higher doses than some young patients. A frail older patient probably requires cautious opioid titration, but arbitrarily reducing the dose can cause unnecessary suffering.[6]

A number of animal studies and a few clinical studies have examined the influence of gender on the response to opioids. Morphine appears to produce a greater analgesic and respiratory depressant effect in males, although the variation among subjects is larger than that attributable to gender.[129] Thus far, the data do not indicate any consistent pattern among the opioid agonists.

Hepatic dysfunction must usually be severe before it produces a substantial change in opioid pharmacokinetics. The clearances of morphine and alfentanil are reduced in cirrhosis, but fentanyl and sufentanil are not greatly affected.[148] Interestingly, renal failure can cause an increase in the effect of morphine, and there have been several cases of ventilatory depression reported in such patients. The mechanism may be delayed renal excretion of morphine's active metabolite.[27] As stated above, remifentanil clearance is unaffected by hepatic or renal dysfunction.

High-Dose Opioid Anesthesia

Some aspects of high-dose opioid anesthesia are discussed in greater depth in Chap. 51. In 1969, Lowenstein et al. showed that high doses of morphine (>1 mg/kg) with only oxygen, and a muscle relaxant could be used during cardiac surgery to produce profound analgesia and sleep.[87] In patients with left ventricular dysfunction as a consequence of valvular disease, hemodynamics frequently improved because preload and afterload were reduced. This anesthetic technique rapidly became popular for cardiac surgery.

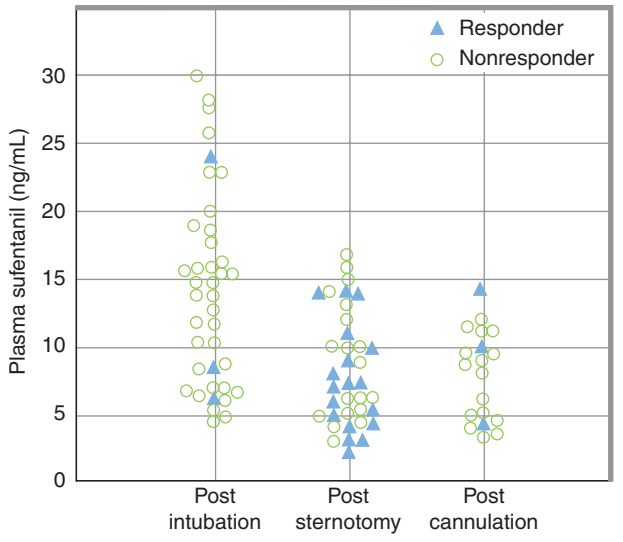

FIGURE 41–18. Presence or absence of hemodynamic response versus plasma concentration of sufentanil at three points during cardiac surgery. Patients undergoing coronary revascularization received only sufentanil, 100% oxygen, and muscle relaxant. Response was defined as a blood pressure increase of 15% or more over control value while awake. Given alone, even extremely high concentrations of sufentanil did not block all responses. (Reproduced with permission from Philbin DM, Rosow CE, Schneider RC, et al. Fentanyl and sufentanil anesthesia revisited: how much is enough? Anesthesiology 1990;73:5.)

Unfortunately, it had a number of drawbacks, including hypotension, histamine release, occasional intraoperative awareness, and prolonged ventilatory depression. Even these large doses of morphine did not block cardiovascular responses to some stimuli (e.g., sternotomy), but increasing the dose to nearly 10 mg/kg created unacceptable hypotension and fluid shifts.

Stanley evaluated fentanyl-oxygen "anesthesia" in a variety of cardiac surgical populations[144] and found that 50–100 μg/kg of fentanyl produced only modest decreases in systemic pressure and total peripheral resistance. Unlike morphine, high doses of fentanyl did not release histamine.[122] Within a few years, fentanyl had replaced morphine for this indication. Sufentanil was introduced a few years later, and in doses as high as 30 μg/kg, it shared fentanyl's hemodynamic advantages as an opioid anesthetic.[124]

Why give such huge doses of these opioids? If no other sedative-hypnotic agents are administered, very large doses are *required* to produce sleep.[9,138] Large doses of opioids have some advantages in the cardiac surgical population: induction is usually smooth and well tolerated, even by patients with limited myocardial reserve; most hemodynamic responses to surgery are suppressed, and there are no dangerous interactions with most vasoactive medications. This type of anesthesia can also block the release of many "stress" hormones (catecholamines, insulin, growth hormone, antidiuretic hormone, cortisol, renin, etc.) during major surgery.[17] The long duration of the opioid effect also allows for a smooth transition to mechanical ventilation in the immediate postoperative period.

Fentanyl and sufentanil have fewer limitations than morphine, but they should not be considered complete anesthetics: intraoperative awareness is less common, but still a possibility. Recall has been reported after fentanyl doses as high as 90 μg/kg.[98] Even very high plasma concentrations of fentanyl or sufentanil will not block all hemodynamic and hormonal responses to surgery[112] (Fig. 41–18). Certain reflex cardiovascular responses seem particularly opioid resistant; for example, the reflex hypertension and tachycardia that is elicited by manipulation of the heart and great vessels. The stress hormonal responses that occur during cardiopulmonary bypass are not completely eliminated by opioids.[17]

In clinical practice, "pure" opioid-oxygen anesthesia (without adjuvant anesthetic drugs) is rarely performed. The desire of most clinicians to be flexible and "fast-track" some of their patients makes such a long-lasting anesthetic less desirable. Most patients receive premedication and moderate doses of opioids; inhalation or intravenous agents are added to control hemodynamics and to ensure unconsciousness during surgery. The addition of hypnotic agents creates a more complete anesthetic, although cardiovascular depression is more likely. High-dose fentanyl, for example, produces a much larger fall in peripheral resistance when the patient has received intravenous diazepam.[153]

Paradoxically, anesthesiologists rely on opioids during surgery both for suppression and preservation of autonomic function. Opioids suppress autonomic responses to pain, but they are often part of anesthesia for critically ill patients because they preserve myocardial function and many essential hemodynamic reflexes. In an otherwise fit hypertensive patient, the *lack* of cardiovascular depression can sometimes make it difficult to control intraoperative hemodynamics. Opioids are not substitutes for β-blockers, intravenous vasodilators, or the controlled vasodilatation produced by inhalation anesthesia. This was elegantly demonstrated by Wynands et al., who compared high-dose fentanyl anesthesia in patients with good or poor left ventricular function.[167] Plasma concentrations of fentanyl were high in all patients, but hypertensive episodes occurred almost exclusively in those with good left ventricular function. In this study, hypertension was not a sign of insufficient analgesia, it was an indicator of adequate myocardial function! These patients tolerated—and required—supplemental intravenously administered or inhaled anesthetic agents.

OPIOID ANTAGONISTS

Naloxone

Naloxone, the *N*-allyl derivative of oxymorphone, was the first pure opioid antagonist to become available for parenteral use (Fig. 41–19A). Naloxone acts as a competitive antagonist at all opioid receptors, but it has greatest affinity for μ receptors. Small doses of naloxone reliably reverse or prevent the effects of pure opioid agonists and most mixed agonist–antagonists. The block is reversible and competitive, so it can be overcome by additional agonist. Naloxone probably has no effect

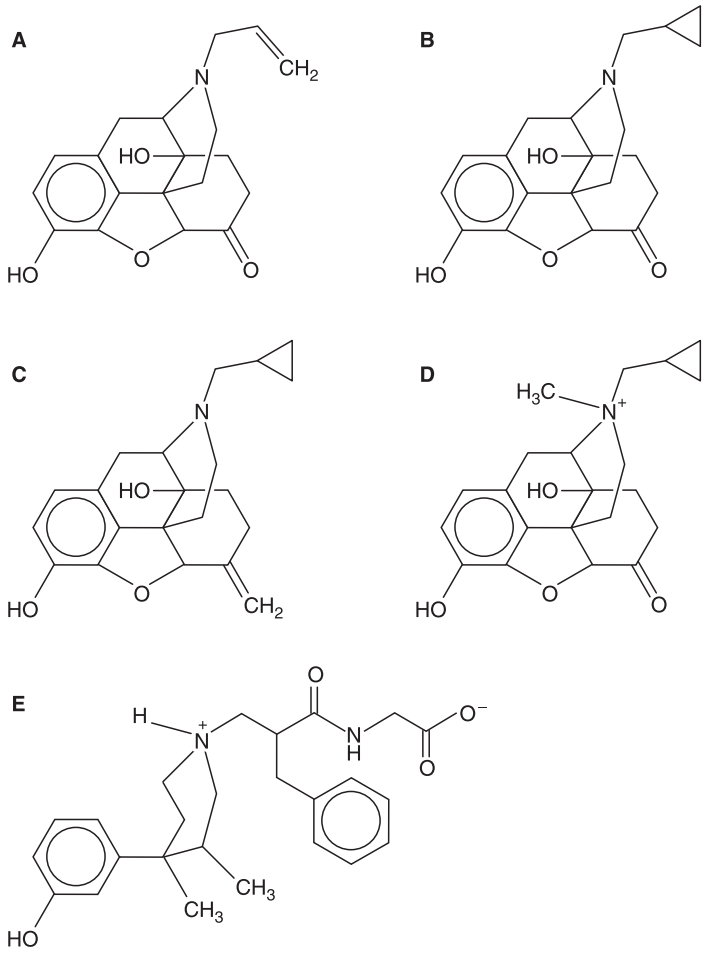

FIGURE 41–19. Structural formulas of naloxone (**A**), naltrexone (**B**), nalmefene (**C**), methylnaltrexone (**D**), and alvimopan (**E**).

on nonopioid anesthetics, although this remains somewhat controversial.[40]

Given alone, naloxone is nearly devoid of clinically demonstrable effects. In humans, extremely large doses (4 mg/kg) cause a mild increase in heart rate and systolic blood pressure, as well as slowing of EEG alpha-wave activity. Animal studies also show that naloxone can reduce food intake, alter sleep patterns, and improve spatial learning. In some disease states, such as septic shock, large doses can have a pressor effect. This may be the result of antagonism of elevated endogenous opioid peptides.[15]

Naloxone is widely distributed and rapidly achieves effective concentrations in the CNS. Plasma and brain levels fall precipitously because of rapid redistribution. The drug is rapidly cleared by hepatic biotransformation, mainly to the 3-glucuronide.[96] The clearance is very high (approximately 30 mL/kg/min), which suggests that extrahepatic elimination may be occurring. The terminal half-life is 1–2 hours. The onset of antagonist effect is extremely rapid, but the duration of action is quite brief. An IV dose of 0.4 mg will usually antagonize morphine for less than 1 hour; increasing the dose does not increase the duration appreciably. With the exception of remifentanil, the duration of naloxone is shorter than the opioids it is used to antagonize.

The presence of excessive opioid effects is a common problem in the postoperative setting. Small doses of naloxone (0.04 mg in an adult, repeated every 3 minutes) can be given intravenously, usually with dramatic improvement. In many cases there also is partial reversal of analgesia, but this can be minimized by careful dosing. Patients who receive naloxone need continued observation, and possibly repeated doses. Postoperative ventilatory compromise is frequently caused by a combination of factors, and therapy with naloxone does not eliminate the need to search for and treat conditions like residual paralysis, bronchospasm, and airway edema.

Naloxone is used to reverse opioids in several other clinical settings:

- In the delivery suite, naloxone can be used in depressed neonates whose mothers received opioids during labor. Clark showed that 0.01 mg/kg via an umbilical vein catheter was usually sufficient.[22] Acidotic infants were slower to reverse and sometimes required a second dose.
- In the emergency department, 0.4–0.8 mg of naloxone is usually administered in cases of suspected heroin overdose. Naloxone is also useful as an aid in the differential diagnosis of coma; if a patient fails to respond to naloxone, nonopioid causes should be considered.
- Patients who receive epidural or intrathecal opioids are frequently troubled by side effects like pruritus and urinary retention (see Chap. 46). An IV infusion of naloxone prevents or reverses these side effects, but may also produce an unacceptable reduction in analgesia.[57]

Opioid reversal can sometimes have important hemodynamic consequences. Increases in systemic pressure, heart rate, and plasma levels of catecholamines can occur. This may be because of the sudden onset of pain, but these effects have been reproduced experimentally in the absence of painful stimuli.[95] There are several case reports of fulminant pulmonary edema, dysrhythmias, and even death in young, previously healthy individuals given naloxone.[4] In one case, the dose of naloxone was only 0.1 mg.[107] The etiology of this rare, catastrophic response is unknown.

Naltrexone

Naltrexone is the *N*-cyclopropylmethyl derivative of oxymorphone (Fig. 41–19B). Like naloxone, it is a relatively pure antagonist. The main clinical use of naltrexone is in the treatment of previously detoxified heroin addicts. When high doses are taken chronically, naltrexone will block the euphoriant effects of injected heroin and thus help to prevent relapse. It also decreases drug craving in former addicts. Interestingly, naltrexone recently has been used to maintain sobriety in alcoholics, although the mechanism in this

indication is less clear.[142] It is available orally and in a depot formulation for intramuscular injection.

Naltrexone is rapidly absorbed and undergoes 95% first-pass metabolism to 6-β-naltrexol. This is an active metabolite that probably accounts for most of naltrexone's activity. The metabolite accumulates during chronic treatment; it has a terminal half-life of 12.9 hours, so significant antagonist effects may persist for 2–3 days after naltrexone is stopped.

In the event that a patient on naltrexone requires emergency surgery or treatment for acute pain, the patient should be managed (if possible) with regional anesthesia, nonopioid analgesics, and other nonopioid methods. If opioids are necessary, naltrexone antagonism is competitive and may be overcome with high doses of morphine or fentanyl.

Nalmefene

Nalmefene is a potent, extremely long-lasting pure antagonist. It is the 6-methylene derivative of naltrexone (Fig. 41–19C). Gal and DiFazio showed that 2 mg of nalmefene can block the effects of repeated fentanyl injections for more than 8 hours.[47] The long duration of nalmefene is probably because of its extensive distribution and long terminal half-life (9 hours).

Reversal with nalmefene can probably cause some of the undesirable autonomic activation seen with naloxone. A single dose of nalmefene should certainly prevent recrudescence of ventilatory depression in most cases, and infusions are unlikely to be necessary. Nalmefene should be titrated carefully, because it can potentially eliminate opioid analgesia for a very long period of time.

N-Methylnaltrexone

N-methylnaltrexone (MNTX) is a quaternary analogue of naltrexone that does not achieve significant concentrations in the CNS (Fig. 41–19D). It is being investigated in both parenteral and oral forms as a treatment for OBD.[19] In healthy volunteers who were given morphine, intravenous MNTX reversed depression of gastric emptying and intestinal motility, but it did not interfere with analgesia against experimental pain.[168] It rapidly relieves constipation in subjects on methadone maintenance and in hospice patients who are taking opioids chronically. Efficacy of the oral formulation suggests that this action is likely achieved via an intraluminal effect.[169] MNTX, like naloxone, has minimal effects on opioid-naïve persons.

Alvimopan

Alvimopan is another permanently charged, peripheral opioid receptor antagonist (Fig. 41–19E).[43] It is poorly absorbed after oral administration, does not cross the blood–brain barrier, and does not reverse opioid analgesia. Alvimopan has been studied exclusively in an oral formulation for the treatment of OBD and also for the more general problem of postoperative ileus. Its efficacy in postoperative ileus may be because surgical insult releases endogenous opioid peptides in the bowel wall, which accounts for some of the decrease in intestinal motility. In both OBD and postoperative ileus, alvimopan significantly improves various indices of motility. The improvement in postoperative ileus decreases the time to hospital discharge.[166] At this writing, FDA approval for the oral use of alvimopan in postoperative ileus is pending.

OPIOID AGONIST–ANTAGONISTS

General Properties

The agonist–antagonist opioids are synthetic and semisynthetic analgesics that are structurally related to morphine (Fig. 41–20). They have been used primarily for moderate to severe acute pain, although buprenorphine has now been approved for maintenance therapy in opioid addiction. All these compounds produce some degree of competitive antagonism to morphine and the other pure agonists.

Nalorphine, the original agonist–antagonist, is no longer used clinically,

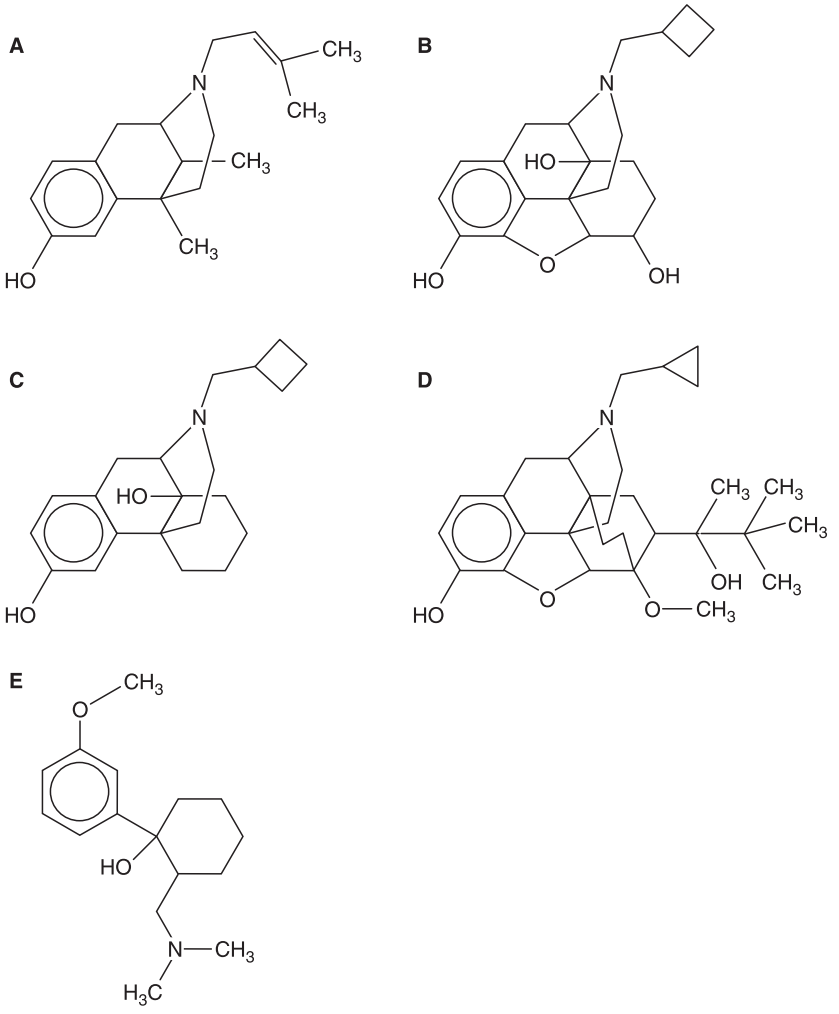

FIGURE 41–20. Structural formulas of pentazocine (**A**), nalbuphine (**B**), butorphanol (**C**), buprenorphine (**D**), and tramadol (**E**).

but it has pharmacologic properties that illustrate the most important features of the class:

- A strong analgesic effect, sufficient for moderate to severe postoperative pain.
- A morphine antagonist effect that depends on the ratio of morphine to nalorphine. At very high doses of nalorphine, the agonist effects predominate.
- A very low potential for diversion or abuse. Administration to subjects who are physically dependent on opioids produces a violent "precipitated withdrawal" syndrome. Former heroin addicts given nalorphine do not experience euphoria or perceive the drug as being similar to morphine.
- A combination of typical and atypical opioid side effects. Nalorphine produces limited ventilatory depression and GI effects, but analgesic doses can cause severe psychotomimetic reactions.

The unusual mental effects—distressing hallucinations and dysphoria—made nalorphine clinically unacceptable as an analgesic, although it was used for many years as an opioid antagonist. Nalorphine was an important milestone in opioid pharmacology because it demonstrated, for the first time, that addiction liability and potent analgesia might be separated. All the more modern agonist–antagonist opioids are products of an intense search for strong analgesics that are less likely to be abused.

All of the agonist–antagonists behave as partial agonists; these drugs tend to have shallower dose–response curves and produce lower maximal effects than fentanyl or morphine[119] (Fig. 41–1A). This means there is a "ceiling" to the analgesic effects, but the toxic effects also are limited. Most of the clinically available agonist–antagonists bind to both μ and κ receptors, but they have different intrinsic activities at each site:

- κ Partial agonists: Pentazocine, butorphanol, and nalbuphine (and nalorphine) produce analgesia and sedation by a partial agonist effect at κ receptors. All of them are competitive antagonists at μ receptors, and therefore reverse the effects of morphine.
- μ Partial agonists: Buprenorphine binds to μ receptors with extremely high affinity but has limited efficacy. When given alone, its effects are similar to those of morphine. When given after morphine, it competes with the full agonist and causes a reduction in opioid effect[119] (Fig. 41–1B). Buprenorphine is also an antagonist at κ opioid receptors.

TABLE 41–4.

Agonist vs. Antagonist Potential of Opioid Mixed Agonist–Antagonists

Drug	Analgesic Potency (Morphine = 1)	Morphine Antagonist Potency (Nalorphine = 1)
Pentazocine	0.2	0.02
Nalbuphine	1	0.25
Butorphanol	5	—[a]
Buprenorphine	25	10

[a]Weak antagonist; see text.

These drugs vary widely in their potencies, both as analgesics and antagonists (Table 41–4). Neither agonist versus antagonist potency nor μ versus κ interaction has proved to be a predictor of clinical usefulness or patient acceptance.

Acute Effects

Analgesia

The agonist–antagonists are effective in a variety of acute and chronic pain states. They can be given intramuscularly, orally, sublingually, intranasally, intravenously by bolus or continuous infusion, and in patient-controlled analgesia systems. Table 41–1 lists the agents and their recommended intravenous doses. None of these drugs is currently approved for epidural or intrathecal use, although they have all been reported to be effective by this route.

The agonist–antagonist opioids have been used during balanced anesthesia, but their partial agonist properties are not a particular advantage in this setting. Even extremely large doses of nalbuphine or butorphanol will not produce the intensity of analgesia one expects from fentanyl or its derivatives.[143] Compared with morphine or fentanyl, the agonist–antagonists produce more limited decreases in the requirements for potent volatile anesthetics.[99]

Sedation and Mood Effects

The subjective effects of buprenorphine are similar to morphine throughout the dose range. The κ-type agonists have been described as producing "apathetic sedation"; this may reflect the localization of κ receptors in deeper layers of the cerebral cortex.[50] Patients given pentazocine, nalbuphine, or butorphanol may experience floating and dissociation, but usually do not experience mood elevation like that seen with morphine. After analgesic doses these patients often appear extremely sedated, yet remain capable of surprisingly lucid conversation. With pentazocine, patients are increasingly likely to experience "weird" feelings, dysphoria, or even hallucinations as the dose is raised. As stated previously, these unpleasant effects may also be mediated by κ receptors. They occur less frequently with butorphanol or nalbuphine.

Most physicians are familiar with the pleasant mental detachment produced by morphine and use it as a sign that the drug is working. Because mood elevation and euphoria do not usually occur with the κ-type agonist–antagonists,[71] patient and physician acceptance of these drugs has been somewhat limited. Ironically, lack of a morphine-like mood effect makes these analgesics much less desirable for opioid addicts, and it is thought to be a key factor in their low abuse liability.

The sedative effects of some agonist–antagonists may be used to advantage. Butorphanol was evaluated as a premedicant in elective surgical patients, and it produced useful sedation in doses lower than those routinely used for analgesia.[28] Its effects on body perception, anxiety, and psychomotor testing were similar to those of midazolam. Unlike the benzodiazepine, it produced very little anterograde amnesia. In this patient population, there was no evidence of dysphoria or hallucinations.

Ventilatory Depression

As stated previously, these opioids are all partial agonists, and their toxic effects are limited in intensity. Ventilatory depression reaches a maximum after about 30 mg of nalbuphine[47] or

2–4 mg of butorphanol,[103] and even larger doses are well tolerated by most patients. Severe depression is still possible in sensitive individuals, those with concomitant CNS or pulmonary disease, and those receiving other depressant drugs. Ventilatory depression may be reversed with naloxone but *not* with another agonist–antagonist.

A ceiling effect on ventilation has also been demonstrated with the use of buprenorphine. This is important because buprenorphine has very high affinity for μ receptors and is not reliably antagonized by naloxone.[46]

Smooth Muscle Effects

Nalbuphine, butorphanol, and pentazocine do not cause significant elevation of intrabiliary pressure in animals or humans.[5,92,119] These agents may be particularly useful for patients who experience biliary colic after morphine. Buprenorphine is believed to cause biliary effects that are slightly more pronounced.[152] The agonist–antagonists appear to have small effects on smooth muscle in the intestine and bladder, and they cause less constipation than do drugs that are similar to morphine.

Cardiovascular Effects

The cardiovascular effects of buprenorphine and nalbuphine are similar to those of morphine. Pentazocine produces unusual cardiovascular effects, both in normal individuals and in those with ischemic heart disease.[2] Unlike morphine, pentazocine may increase heart rate, systemic and pulmonary artery pressure, and left ventricle end-diastolic pressure. These effects may be secondary to elevations in plasma catecholamines. Because these changes are likely to elevate myocardial oxygen consumption, pentazocine may be a poor choice for patients with ischemia or infarction.

Butorphanol (2 mg) can also increase pulmonary artery pressure, but heart rate and systemic pressure usually decrease slightly.[113] The rise in pulmonary artery pressure apparently does not increase as the dose is raised: In one study, doses of butorphanol greater than 25 mg were used safely during coronary artery bypass surgery.[3]

Antagonist Effects

Table 41–4 lists the approximate agonist versus antagonist potencies of these drugs. Nalbuphine and buprenorphine are strong antagonists, and have been used clinically for this purpose. The available evidence does not suggest that reversal with an agonist–antagonist is safer or more reliable than reversal with naloxone.[70]

Administration of an opioid antagonist to an opioid-dependent patient will precipitate withdrawal; this has occurred after therapeutic doses of pentazocine, nalbuphine, and buprenorphine. Butorphanol is a very weak antagonist, and it produces only mild withdrawal in addicts who are maintained on 30 mg/d of methadone.[116] A low level of physical dependence may occur in patients who receive opioid agonists over long periods, and this subclinical state may be unmasked by administration of an antagonist. During routine perioperative care, it seems prudent to avoid agonist–antagonists in patients who have had significant prior treatment with morphine, meperidine, oxycodone, and other such drugs.

Chronic Administration

In the United States, pentazocine is the only agonist–antagonist available in a typical oral tablet; butorphanol is available as a nasal spray; and buprenorphine is available as a sublingual tablet. It is possible to give these drugs parenterally for long periods of time, but there are few clinical data on such use.

Long-term studies on ex-heroin addicts showed that tolerance and physical dependence do occur after repeated administration of agonist–antagonist opioids. Withdrawal is usually qualitatively different from that of morphine and not usually accompanied by intense drug-seeking behavior. There has been renewed interest in chronic sublingual administration of buprenorphine since 2002 when the FDA approved it for maintenance therapy of opioid addicts (see Chap. 23). Chronic administration of buprenorphine in relatively high doses prevents withdrawal and reduces drug seeking.[43] Unlike methadone maintenance, buprenorphine treatment of addicts does not have to occur in a specially licensed clinic, although physicians who use it this way must have additional qualifications. The heroin addict is usually switched under supervision to sublingual buprenorphine (the partial agonist properties may sometimes elicit withdrawal symptoms). Chronic dosing is then done by the addict without direct supervision. To reduce the possibility that buprenorphine will be diverted or abused during chronic maintenance, it is dispensed in a formulation that combines buprenorphine and naloxone (Suboxone). Sublingual administration of the combination produces similar effects to buprenorphine alone, because sublingual naloxone does not achieve high concentrations in blood. If the tablet were inappropriately dissolved and injected intravenously, however, the naloxone would antagonize the euphoriant effect and possibly cause precipitated withdrawal.

In the event that a patient taking buprenorphine/naloxone presents for surgery, treatment of acute pain may present a significant problem. These patients are highly tolerant to opioids, and residual levels of the partial agonist may antagonize other opioids for a long time. Regional anesthesia and nonopioid techniques should be used, whenever possible. If opioid treatment is required, large doses of potent opioid agonists may be needed, and advice should be sought from a specialist in addiction medicine.

CHAPTER 42

Total Intravenous Anesthesia

John Sear, MA, PhD, MBBS, FFARCS, FANZCA

In 2006, we are still without any one drug that can provide all the requirements of anesthesia (i.e., unconsciousness, analgesia, amnesia, and muscle relaxation). Consequently, administration of several different agents is needed to produce the desired end result. The use of intravenous agents to achieve these goals began with the introduction of the rapidly acting barbiturates in 1934. Despite the disastrous consequences following the use of thiopental at Pearl Harbor in 1941, intravenous anesthesia is now well established as an alternative, and in some circumstances more appropriate, technique than the traditional approaches of volatile anesthetics alone, or balanced anesthesia where volatile and intravenous agents are combined together.

The kinetics of the early barbiturates did not render the drugs ideal for the *maintenance* of anesthesia; the provision of analgesia could not be achieved by the barbiturates alone; and the addition of either meperidine or morphine (both drugs having slow blood–brain equilibration) led to overdosing and hence to poor clinical conditions, especially in the spontaneously breathing patient. The introduction of modern *volatile* agents, starting with halothane in 1956, with their easy titratability, encouraged the anesthetist to turn away from the intravenous agents for the maintenance of anesthesia.

The development of and present interest in total intravenous anesthesia (TIVA) owes much to a number of important studies. From the standpoint of hypnosis, a key contribution was that of Savege et al., in 1975, who used the steroid agent Althesin (alphaxalone and alphadolone acetate) with meperidine to supplement oxygen-enriched air in the spontaneously breathing patient.[97] Subsequent drug developments included the use of infusions of thiopental, methohexital, carboxylated imidazole etomidate, propofol, and ketamine. However, with the exception of ketamine, none of these agents probably provided analgesia (although analgesic effects of alphadolone have been described by Goodchild et al.[36]).

The use of morphine to provide anesthesia *as a sole agent* in patients undergoing cardiac surgery was first described by Lowenstein et al. in 1969, where the hypnotic side effects of large doses of morphine were used to provide sedation.[61] However, this method of anesthesia (more popular in the United States and Europe than in the United Kingdom) was not reliably effective. It was associated with a high incidence of episodes of awareness during anesthesia, as well as intraoperative episodes of hypotension caused by histamine release, resulting in increased intraoperative and postoperative fluid and blood requirements.

The selective and highly potent μ-receptor opiates (fentanyl, alfentanil, sufentanil, and more recently, remifentanil) have the advantage of less cardiovascular depression, as well as the ability to obtund the hemodynamic responses to laryngoscopy and intubation. However this apparent stability is less evident during major cardiovascu-

KEY POINTS

1. The appearance of new drugs with short blood–brain equilibration times (especially those with an ester linkage) enables the clinician to use anesthetics and analgesics where titratability will be easy and recovery rapid.
2. Total intravenous anesthesia (TIVA) offers some important advantages over inhalation anesthetics, including rapid recovery with minimal hangover and a low incidence of nausea and vomiting. TIVA may be the technique of choice for some operations.
3. Effective delivery of TIVA requires the clinician to have a good knowledge and understanding of pharmacokinetics, pharmacodynamics, and pharmacokinetic–pharmacodynamic (PK-PD) modeling.
4. Important drug characteristics include induction dose, rate of administration and k_{eo} (rate constant for the elimination of drug from the effect compartment) (drugs with small k_{eo} values take longer to equilibrate between the blood and the effect compartment or biophase). Thus for a rapid sequence induction, drugs with a large k_{eo} are preferable (viz., propofol, thiopental, remifentanil, and alfentanil compared with midazolam, ketamine, and fentanyl)
5. Drug interactions are important in TIVA. Excepting ketamine, opiates and hypnotics potentiate each other and can result in synergistic cardiovascular and respiratory depression. This means the doses of each can be reduced. There is a ceiling to the potentiating effect of the opiates, beyond which there is an increased incidence of adverse side effects and often delayed onset of spontaneous ventilation at the end of surgery.
6. Ketamine is the only hypnotic drug with analgesic properties; there are few data suggesting that the S (+) isomer has major advantages.
7. If the patient shows signs of response during TIVA, there is need for additional IV supplementation by bolus doses or by increasing the targeted concentration if using target-controlled infusion (TCI).
8. The elimination half-life and systemic clearance are not useful in TIVA for determining the offset of IV drugs. The context-sensitive half-time (CSHT) is more relevant, and modeled data and dynamic measurements correlate well.
9. Context-sensitive decrement times are useful indices of recovery from anesthesia. Recovery is influenced by other factors apart from the CSHT, including patient characteristics such as age, gender, body habitus, and disease states.
10. A knowledge of the context-sensitive decrement times for opiates and hypnotics allows appropriate choice of drugs for the maintenance of anesthesia. CSHT also helps determine which infusions should be terminated at the end of anesthesia, and which some time beforehand.

TABLE 42–1.

Adverse Properties of Volatile Agents

1. Organ toxicity is associated with the use of most of our present volatile agents, such as dose-related cardiovascular and respiratory depression; dose-related increases in cerebral blood flow and intracranial pressure; hepatic and renal toxicity; coronary blood-flow steal phenomena; and immunodepression.
2. Environmental issues related to trace concentrations of volatile agents and nitrous oxide as well as the effects of these trace concentrations on the health and work performance of anesthesiologists, surgeons, operating room and recovery area personnel.

lar surgery, particularly during the period of sternotomy and aortic root dissection in patients undergoing cardiopulmonary bypass, where there are frequent episodes of significant hypertension and tachycardia that are not always remediable by increased doses of the opiates. Thus it became clear that use of high doses of opiates *alone* was inappropriate to provide anesthesia. Hence attempts to control the hemodynamic effects of surgical stimulation and to reduce the incidence of awareness have used either low inspired concentrations of volatile agents or infusions of a sedative-hypnotic agent as supplements to opiates.

Use of TIVA techniques are not without difficulties in these patients as some combinations of opiates, such as fentanyl and diazepam, can result in significant reductions in both cardiac output and systemic vascular resistance. However, the effectiveness of the benzodiazepines in reducing the circulating levels of catecholamines may be important, and greater hemodynamic stability has been found in cardiac surgical patients where the combination of sufentanil with ketamine or midazolam has been employed. In noncardiac surgery, opiates remain popular as the basis of most neurosurgical anesthetic techniques, as they do not alter the carbon dioxide reactivity of the cerebral blood vessels. The kinetics and dynamics of remifentanil (and to a less extent alfentanil) allow the anesthesiologist to titrate dose requirements more closely for a given surgical procedure during abdominal and other major body surface surgical procedures.

Over the past two decades, increased interest in intravenous anesthesia has been prompted both by the availability of newer and more appropriate rapid-onset and short-acting IV sedative-hypnotics (e.g., midazolam, propofol, etomidate), analgesics (alfentanil, sufentanil, remifentanil), and muscle relaxants (atracurium, vecuronium, mivacurium, and rocuronium). All these factors have refocused the anesthetist's attention on the *total* provision of anesthesia by the intravenous route. Furthermore, there are also a number of clinical situations where intravenous anesthesia techniques are advantageous, including:

- To provide sedation to supplement local or regional anesthetic techniques.
- To provide general anesthesia with accompanying minimal cardiovascular depression.
- For office or ambulatory surgery, where the speed and completeness of recovery are important.
- For situations where volatile-based anesthetics may be difficult to administer because of the unavailability of resources, such as nitrous oxide; at sites of military or nonmilitary trauma; and for anesthesia at increased ambient pressure.
- In circumstances where nitrous oxide may either be undesirable (e.g., because of the need for high inspired oxygen concentrations) or contraindicated (e.g., for one-lung anesthesia; for middle ear surgery, some neurosurgical operations, and prolonged abdominal surgery where nitrous oxide can cause closed-space effects as a result of increased volume and pressure; for relief of cardiac tamponade; for airway endoscopies [bronchoscopy and laryngoscopy]; and for bronchotracheal surgery), or where volatile agents may best be avoided (Table 42–1).
- To prevent awareness during cardiopulmonary bypass, and to offer cerebral protection to patients at risk of episodes of brain ischemia.
- In malignant hyperpyrexia-susceptible patients.

However, the general application of TIVA techniques is not without important considerations and questions. These include the possibility and detection of awareness; the possibility of postoperative respiratory depression because of the persistent effects of concurrently administered analgesic agents; the requirement of a separate dedicated IV access site; appropriate infusion pumps; and the observation that some researchers consider depth of anesthesia as uncontrollable as with the volatile agents.

TABLE 42–2.

Ideal Properties of a Hypnotic Drug for Use during Total Intravenous Anesthesia

1. Soluble in aqueous such that use of a solvent is avoided.
2. Stable in solution and on exposure to light for prolonged periods of time.
3. No absorption onto plastic tubing or giving sets.
4. No venous damage (pain on injection, venous phlebitis, or thrombosis) or tissue damage when administered either extravascularly or intraarterially.
5. Sleep in one arm–brain circulation time.
6. Short duration of action, and inactivation by metabolism in either the liver, blood, or other organs of the vessel-rich group of tissues.
7. Inactive, nontoxic, water-soluble metabolites.
8. Minimal cardiovascular and respiratory side effects.

What Are the Ideal Drug Properties for and Advantages of TIVA?

Table 42–2 lists the ideal properties of a hypnotic drug for continuous infusion anesthesia. Although *none* of the present hypnotic or analgesic agents fulfills all of these criteria, some are more suitable than others under differing circumstances. Table 42–3 lists the pharmacologic advantages of TIVA over inhalational agents.

Dosing Strategies for TIVA

The administration of hypnotic, analgesic, and neuromuscular blocking components of TIVA can be provided in a number of different ways:

- Intermittent bolus doses of the drugs;
- Continuous infusions using syringe infusion pumps or similar delivery systems;

TABLE 42–3.

Advantages of TIVA

1. Smooth induction of anesthesia without coughing or hiccupping.
2. Easy control of depth of anesthesia when using drugs with short blood–brain equilibration times.
3. With most of the agents there is rapid and predictable emergence with minimal hangover.
4. Low incidence of postoperative nausea and vomiting.
5. Ideal operating conditions for neurologic surgery with reduced cerebral brain flow and cerebral metabolic rate for oxygen.
6. Minimal organ toxicity, although infusions of etomidate cause depression of adrenosteroidogenesis and red cell hemolysis. Infusions of propofol can lead to a metabolic syndrome.

- Through the introduction (in most parts of the world, although not presently in the United States) of target-controlled infusion systems (TCI).

When given by intermittent bolus doses, there will be fluctuating drug concentrations that are associated with accompanying changes in the depth of anesthesia. Continuous infusions of IV hypnotics, opiates, and muscle relaxants can reduce these swings in drug concentrations, as well as minimize any relative under- or overdosing during drug administration. This offers a number of advantageous features to the anesthetized patient, including greater hemodynamic stability; fewer episodes of hemodynamic breakthrough and other signs of patient responsiveness; reduced need for supplemental anesthetics or vasoactive drugs; more rapid awakening and decreased incidence of requirements for naloxone or need for postoperative ventilatory support; decreased incidence of side effects; and a 25–30% lower total drug dose compared with bolus dosing.[4,5,92,139,140] Use of continuous drug infusions may also lead to decreased drug costs.

However, because modern IV agents exert profound pharmacologic effects and have short durations of action, frequent adjustments to drug dosage are necessary in order to match anesthetic effect to the varying noxious stimuli being perceived at different times during surgery, as well as the different noxious intensities of different surgical operations. This requires either frequent additional bolus dosing, or the calculation of new infusion rates to achieve different drug targets.

Early studies using IV infusion anesthesia focused on providing fixed rate infusions that were adequate for 50% or more of a given population.[5,89] With the passage of time, these have been viewed as being less appropriate and flexible in output because they failed to allow easy titration of the achieved drug concentration to clinical effect in accordance with an individual patient's requirements. Indeed there is the probability that many patients received an overdosage because of the desire to design regimens that were "all-embracing" to all people! Nevertheless, the work of Prys-Roberts et al. confirmed the usefulness of this approach to the provision of anesthesia with minimal cardiorespiratory depression, and no reported cases of awareness.[88,109,110]

With the hypnotic drugs currently available for continuous infusion, several manual schema for anesthesia delivery have been developed. For example, there is the regimen for propofol described by Roberts et al. based on an infusion protocol to maintain a plasma propofol concentration of around 3 μg/mL.[93] This was achieved by an initial 1 mg/kg induction dose, then 10 mg/kg/h for 10 minutes, 8 mg/kg/h for 10 minutes, and maintained at 6 mg/kg/h. As this scheme is designed to achieve a fixed plasma propofol concentration, there is often a need for supplementation with additional propofol boluses and/or opiates during abdominal or other major operations. Manual regimens have similarly been described for midazolam by infusion. Persson et al. used an induction dose of 0.25 mg/kg, followed by a fast infusion of 0.65 mg/kg/h for 15 minutes and maintained with 0.13 mg/kg/h. This provided a hypnotic plasma concentration of between 300 and 400 ng/mL.[84,86] In a separate study, Thiel et al. described an infusion of midazolam (0.1–0.15 mg/kg then 0.02 mg/kg/h) supplemented with an opiate infusion of sufentanil for cardiac surgery.[126]

Pharmacokinetic Principles of TIVA

Simplistically, the design of infusion schema for TIVA is based on two important equations which define the loading dose and the maintenance infusion rate.

$$\text{Loading dose} = V_d \times Cp$$

$$\text{Maintenance infusion rate} = Cp \times Cl$$

where V_d = initial apparent volume of distribution; Cp = the desired plasma drug concentration; and Cl the systemic clearance of the drug.

However, these calculations of drug requirements to reach a given target concentration are flawed for several reasons. First, the plasma is not the site of action of IV drugs; the site where the drugs produce their effects is in the brain, and is termed the *biophase*. To reach the biophase, drug redistributes from the blood to the brain. At the same time, drug is also being redistributed to other tissues of the body. Hence the loading dose necessary to produce a desired pharmacologic effect cannot usually be calculated based on the initial volume of drug distribution (which is primarily the blood volume), but should use the apparent volume of distribution into which the drug has distributed once it has equilibrated with the biophase (i.e., this will, of necessity, be a larger volume).

When a drug is given by rapid infusion, there may be a simultaneous pharmacologic effect; however, the measure of drug effect (be it electroencephalogram [EEG] spectral edge frequency, minute ventilation volume, or change in blood pressure or heart rate) does not always parallel the rapid increase and decrease in the plasma drug concentration. This implies "hysteresis" in the relationship between drug concentration and effect. From studies that provide continuous measurement of plasma drug concentration and effect, it is possible to relate the plasma drug concentration to the effect produced in the biophase,[108] and, in turn, to calculate the volume of distribution of this effect compartment. Furthermore, by complex mathematical manipulation, the hysteresis loop can be "collapsed" to derive a linear relationship between concentration and effect. The value that causes the hysteresis loop to collapse represents the rate of equilibration of the drug concentration between the plasma and the biophase. This is termed k_{e0} or the blood–brain equilibration rate constant. Table 42–4 shows the values of k_{e0}, $t_{1/2}k_{e0}$, time to peak effect, and the apparent volume of the effect compartment.

TABLE 42–4.

Typical Values for the k_{eo}, $t_{1/2}k_{eo}$, Time-to-Peak Effect following a Bolus Dose and the Apparent Volume of Distribution Incorporating the Effect Compartment

	k_{eo} (min − 1)	$t_{1/2}k_{eo}$ (min)	Time-to-Peak Effect (min)	V_{de}
PROP	0.291	2.4	2.2	37
THIOP	0.46	1.5	1.4	
ETOM	0.48	1.5	2.0	
KET				
MIDAZ	0.124	5.6	3.0	
REMI	0.46	1.5	1.5	
ALF	0.77	0.9	1.4	5.9
FENT	0.147	4.7	3.6	75
SUF	0.227	3.0	5.6	89

ALF, alfentanil; ETOM, etomidate; FENT, fentanyl; KET, racemic ketamine; MIDAZ, midazolam; PROP, propofol; REMI, remifentanil; SUF, sufentanil; $t_{1/2}k_{eo}$, half-time for blood–brain equilibration; THIOP, thiopental; V_{de}, volume of distribution incorporating the effect compartment.

Although the $t_{1/2}k_{e0}$ is the time for blood–brain equilibration, it also relates closely to the "time to peak drug effect." For optimal dosing strategies, clinicians need to know the time to peak effect when giving IV drugs during both the induction and maintenance phases of anesthesia (Fig. 42–1).

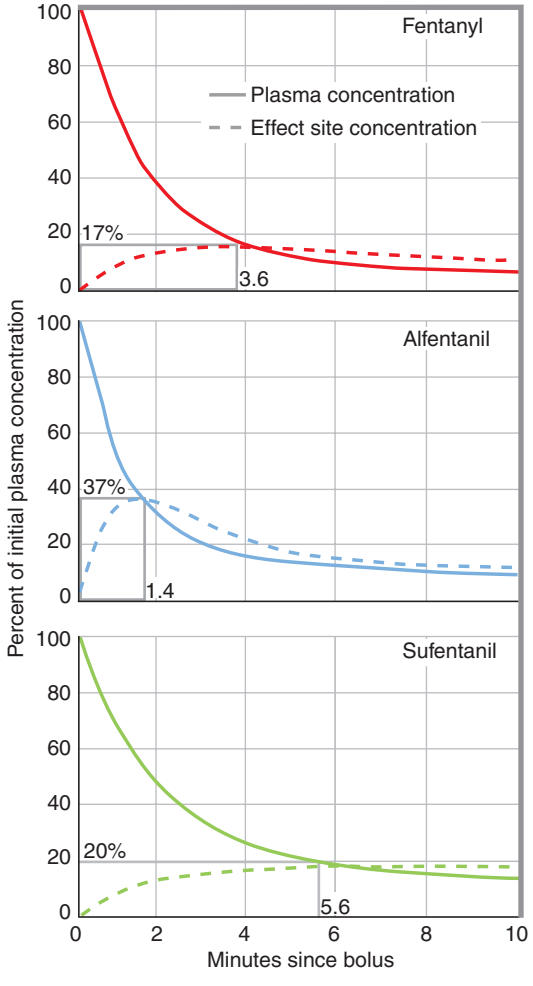

FIGURE 42–1. Computer-simulated plasma and effect-site concentrations for fentanyl, alfentanil, and sufentanil for the first 10 minutes after a bolus injection, as a percent of initial plasma concentration. (Adapted with permission from Shafer SL, Varvel JR. Pharmacokinetics, pharmacodynamics and rational opioid selection. Anesthesiology 1990;74:53–63.)

For example, during a rapid sequence induction, the anesthesiologist should use drugs with short times to peak effect. The combination of thiopental or etomidate and alfentanil or remifentanil is probably more appropriate than a combination of propofol and fentanyl. With the latter combination, the effect of the fentanyl (if given immediately before the hypnotic agent) would not be maximal by the time of intubation, leading to an initial hypertensive response to the noxious stimulus of laryngoscopy. This might then be followed by a hypotensive response when the peak effect of the fentanyl is achieved and airway stimulation is minimal. In addition, when giving drugs by bolus dosing, the interval between doses needs to be of a sufficient duration to allow the peak effect of one bolus to be observed before the next dose of the drug is administered.

For most of the drugs used as the hypnotic and analgesic components of TIVA, plasma (blood) concentration–effect relationships have now been determined. From these, and using appropriate kinetic datasets, the clinician can derive manually controlled dosing schedules (Tables 42–5 and 42–6). However, these schema do not really take account of time delays in the concentration–effect relationship. Hence, many anesthesiologists view TIVA using manually controlled infusion systems and devices as a more complex strategy for maintaining anesthesia than using a vaporizer in the case of volatile agents!

Computerized Drug Administration: Target-Controlled Infusions

One of the most significant and recent advances in the delivery of infusion anesthesia over the last decade is the introduction of TCI systems that allow the anesthesiologist to set the target concentration of anesthetic. This target can be defined as either the blood or the effect-site (i.e., brain) concentration. In many respects, these systems function in a similar manner to the setting of the inspired concentration of the volatile agents using a vaporizer.

A number of publications describe a theoretical approach to attaining and maintaining steady-state drug concentrations,[55,106,130,131] with different algorithms employed for targeting blood concentrations,[4,22,44,125] and incorporating effect-site concentrations into

TABLE 42–5.

Plasma Drug Concentrations of Hypnotics and Analgesics Needed for Provision of Adequate Anesthesia for Different Noxious Stimuli during Surgery in Patients Receiving TIVA

	Incision	Major Surgery[a]	Minor Surgery[b]
Hypnotics (μg/mL)			
Propofol	5–6	2.5–7.5	2–6
Methohexital	5–10	5–15	5–10
Thiopental	35–45	10–20	10–20
Etomidate	0.4–0.6	0.5–1.0	0.3–0.6
Midazolam	—	0.05–0.20	0.02–0.25
Ketamine (racemic)	—	—	1–2
Opiates (ng/mL)[c]			
Alfentanil	200–300	250–450	100–300
Fentanyl	3–6	4–8	2–5
Sufentanil	1–3	2–5	1–3
Remifentanil	2–6	4–8	2–4

[a]Major surgery includes abdominal and vascular surgery, thoracic surgery, major orthopaedic surgery, and neurosurgery.
[b]Minor surgery is body surface surgery.
[c]In the case of the opiates, adequate spontaneous ventilation will occur at concentrations ≤200–250, ≤1–2, ≤0.2, and ≤1–3 ng/mL, respectively.

model-driven automated delivery systems.[48,114] Several different systems for computerized drug delivery have been described. For example, Schwilden et al. formulated a system to maintain anesthesia using the hypnotic agent etomidate.[107] Other systems include the CACI (computer-assisted continuous infusion) system for fentanyl[4]; the TIAC (target-controlled infusion-based anesthesia) system also for fentanyl[5]; and the various systems for propofol.[19]

A TCI system consists of an infusion pump linked to a microprocessor containing the disposition pharmacokinetic parameters for the drug in question. The equations describing disposition are based on the BET (bolus-elimination-transfer) scheme of Schuttler et al.[105] TCI combines sequential BET schemes for maintaining or increasing the target concentration, and periods of discontinuation of the infusion when the target concentration has to decrease. Infusion halts are mandatory if a new lower drug concentration is to be achieved as fast as possible. The first commercially available TCI system is the Diprifusor,[35] which was introduced in 1996 and uses prefilled glass syringes of propofol tagged with a unique metallic strip. More recently "open TCI systems" that allow use of the various available generic formulations of propofol have been developed. Such systems include the Alaris Asena PK system and the Base Primea system of Fresenius.

At present, no drugs apart from propofol are licensed for use for TCI; in addition, approval for TCI is still awaited in the United States. However, research or developmental computer-driven delivery systems have been described for both sufentanil and remifentanil.[7,10,42,81,100,116] Sufentanil has been administered by TCI in combination with isoflurane, propofol, and midazolam, with targeted concentrations, in most studies, of sufentanil between 0.2 and 1.5 ng/mL for noncardiac surgery and 3–10 ng/mL for cardiac surgery. Most studies report good quality anesthesia with hemodynamic stability and satisfactory times to return of spontaneous ventilation and extubation. Remifentanil by TCI has been assessed in combination with both IV hypnotics and volatile agents,[32,41,57,65] the most appropriate kinetic model for drug delivery being that of Minto et al.[68] For analgesia, concentrations between 1 and 1.5 ng/mL are needed. In combination with propofol for noncardiac surgery, remifentanil concentrations in the range of 4–8 ng/mL are appropriate. However, these data need confirmation in larger clinical trials.

Any TCI drug delivery system has 4 key components:

1. A calculator (computer or microprocessor) and a software program, either separate with cables linking to a syringe pump, or an "all-in-one" system (as is the case with the Diprifusor);
2. Datasets of pharmacokinetic parameters for each drug to be infused;
3. An infusion device; and
4. A user interface.

For TCI delivery, the anesthesiologist needs to enter the patient's age and weight into the device, and then select the desired target drug concentration. On pressing "start," the TCI system delivers precisely the amount of drug to achieve the target drug concentration and then continues to infuse drug at an appropriate rate to maintain that concentration. Unlike using a manual fixed-infusion system, the anesthesiologist can easily either

TABLE 42–6.

Dosing Strategies (μg/kg or μg/kg/min) of Hypnotics and Analgesics When Given by Manual Infusion Regimens to Achieve the Concentrations (μg/mL) Needed for Major Surgery as Identified in Table 42–5

	Induction or Loading Dose	Maintenance Infusions Rate
Hypnotics		
Propofol	1000–2000	50–150
Methohexital	1500–2500	50–150
Midazolam	50–150	0.25–1.5
Ketamine (racemic)	1500–2500	25–75
Opiates[a]		
Alfentanil	50–150	0.5–3.0
Fentanyl	5–15	0.03–0.10
Sufentanil	1–5	0.01–0.05
Remifentanil	0.5–1.0	0.1–0.4

[a]For the opiates, the induction of loading dose is best given over 2 minutes to avoid marked cardiorespiratory depression.

increase or decrease the target drug concentration at any time, thereby facilitating the titration of the drug concentration according to the patient's response to differing noxious stimuli.

One fundamental principle underlies the TCI pump—namely, the relationship between the infusion rate and achieved drug concentration:

$$\text{Drug concentration} = \frac{\text{Infusion rate}}{\text{Drug clearance}}$$

If a higher target concentration is selected, the system automatically delivers a further small bolus of drug and then infuses at a faster rate to achieve and maintain the higher drug concentration. When a lower target is chosen, the device discontinues the infusion of drug until the system predicts that the patient's drug concentration has decreased to the new value (by a combination of drug redistribution and clearance). The system then restarts the infusion at the appropriate rate for the new target concentration. With a TCI system, the anesthesiologist does not control the device's infusion rates and the size of bolus doses; rather, the anesthesiologist titrates the depth of anesthesia by selecting target drug concentrations appropriate to the patient's needs. A number of different algorithms are used in the different systems to calculate the required infusion rate.[44,45,55,114]

Kinetic Model Selection

TCI systems tend to incorporate population-averaged pharmacokinetic parameters to drive the infusion pump. This can lead to considerable variability in the observed drug concentration compared with the targeted concentration. The mean variation between these two concentrations (targeted and observed) is usually of the order of 20–30% with a maximum of 50–60% considered clinically acceptable. It seems likely that greater accuracy is not going to be achievable. The sources of this variability include the differences in the parameter estimates of the polyexponential equation that is used to describe the concentration–time relationship. At the present time, there are several different commercial systems on the market for the delivery of propofol and the opiates sufentanil and remifentanil. Two types of systems can be identified—those incorporating the Diprifusor module, using tagged Diprivan prefilled syringes with the finger-grip tag and the original Diprifusor kinetics, and "open" systems that do not require the tagged syringes and use different pharmacokinetic datasets for the delivery of propofol, remifentanil, and sufentanil (Table 42–7).

Effect-Site Targeting

Initial drug-targeting technology was based on the plasma concentration; but as this is not the site of anesthetic action, it is more logical to target the effect-site or biophase. This has been described by several authors, and reviewed by Jacobs and Williams.[48] Effect-site control should allow for a faster induction time; and during maintenance a more rapid increase in the depth of anesthesia. However, there are some limitations to effect-site compartment targeting, including that of overshoot of the arterial drug concentration with associated adverse consequences. Effect site TCI has been described by a number of different research groups.[48,123,138] Wakeling et al. have compared the efficacy of plasma and effect-site targeting.[137] Twenty ASA (American Society of Anesthesiologists) classification PS-I or PS-II patients were randomized to receive TCI propofol targeted at one or the other site. In this study, the delivery system was modeled according to the kinetic dataset of Gepts and Camu[34] and a k_{e0} value of 0.63 min^{-1}. At a target concentration of 5.4 μg/mL (the predicted effect-site concentration associated with loss of consciousness in 95% of subjects),[117,134] Wakeling found a median time to loss of consciousness of 3.02 minutes in the plasma-targeted group, but only 1.23 minutes in the effect-site targeted group. However, loss of consciousness occurred at the same predicted effect-site concentration in both groups. Other studies of effect-site drug control have found similar results.[82,123,138]

Although an advantage of these systems is that drug delivery is optimized to a given effect-site concentration, the speed of achieving this concentration varies with the k_{e0} value incorporated into the different delivery systems. At present, several different models with different k_{e0} values are in use for the delivery of propofol. If the Diprifusor is used with the Marsh model kinetics, the blood–brain equilibration half-life ($t_{1/2}\ k_{e0}$) is 2.6 minutes (k_{e0} 0.26 min^{-1}).[62] However modifications of the Diprifusor algorithm in the two new "open-TCI" systems (the Base Primea and Asena PK systems) with a longer k_{e0} of 1.2 min^{-1} gives a $t_{1/2}\ k_{e0}$ of 34 seconds. When the slower k_{e0} is used, any increase in the target effect-site concentration requires higher blood drug concentrations to generate a bigger gradient to drive drug to the effect-site.

A second effect-site model, based on the kinetics of Schnider et al., incorporates additional details into the algorithms (including patient age, height, weight, and calculated lean body mass). In this system, the k_{e0} varies with the

TABLE 42–7.

TCI Systems Currently Available for the Delivery of Propofol, Remifentanil, and Sufentanil in the United Kingdom and Other Parts of the World[a]

"Diprifusor" TCI systems incorporate use of tagged prefilled syringes:

1. Graseby 3500 system (Graseby Medical, Watford, UK)
2. Vial Medical Master TCI (Fresenius Vial, Brezins, France)
3. Alaris IVAC TIVA TCI (ALARIS Medical Systems, Basingstoke, UK)
4. Terumo TERUFUSION TE-372 TCI TIVA (Terumo Corporation, Tokyo, Japan)

Open TCI systems have the advantages of being able to use "generic" formulations of propofol:

1. **Alaris Asena PK Syringe Pump.** This has the same pharmacokinetic model as in the Diprifusor, with a k_{eo} of 0.26 min^{-1}. It also incorporates modeling for effect-site control.
2. **Base Primea** (Fresenius Vial, France). This includes 2 kinetic sets for propofol delivery. There is the kinetic model included in the Diprifusor but with a modified value for k_{eo} of 1.21 min^{-1}. The second model system is based on the kinetics of Schnider et al.[99] where the kinetics are corrected for patient age and weight. The k_{eo} is also different (0.456 min^{-1}), which leads to a faster rise in brain propofol concentration.
3. B Braun (FM System—**"Space Station"**) incorporating the "ProTiva" pump system. This was introduced in Europe in 2006.

[a]At the time of writing (March 2007), none of these delivery systems are licensed for use in the United States.

age of the patient.[98] Although most studies suggest that effect-site targeting provides faster control, it is only true if there is an accurate value for k_{e0}! The recent studies of Kazama et al. show that k_{e0} values have a wide interindividual variability with regard to age, and end point assessed.[52] This may be a result of a number of factors, including poor delineation of early distribution kinetics and failure to accurately define the EEG hysteresis effect; this will clearly limit the accuracy of any effect-site TCI delivery system in a given individual. Use of effect-site TCI will, of necessity, lead to an overshoot of the plasma drug concentration, which can result in hemodynamic depression. Although this overshoot has little effect in patients younger than age 60,[123] further study is needed in the elderly.

As a further development in effect-site targeting, Van Poucke et al. have described modified delivery algorithms that target the effect-site but limit the peak plasma concentration.[129] This should have the advantage of reducing the acute hemodynamic effect of intravenous anesthetic drugs on the heart and circulation. Simulations suggest that this approach will reduce the plasma overshoot by approximately 60%, with an accompanying 20% delay in the time to peak effect and hence the onset of drug effect. In vivo studies are clearly needed to confirm the efficacy of this method of TCI delivery.

INDUCTION OF ANESTHESIA WITH TIVA

Several factors affect the speed of induction by TIVA, including the size of the induction dose and important drug interactions.

Factors Determining the Induction Dose of Hypnotic Agents

The onset of anesthesia requires the brain drug concentration to reach a given level; this can be achieved either slowly or rapidly. Rapid achievement is usually accompanied by significant adverse effects such as hypotension, bradycardia, and respiratory depression. The greater the concentration gradient between the blood and the effect-site, the greater the time needed to induce anesthesia. Conversely, any marked overshoot in the effect-site concentration leads to a greater incidence and severity of the adverse effects. The transfer of drug from the blood to the effect site is governed by simple diffusion. The time needed to achieve this transfer varies with the concentration gradient and the k_{e0}.

The rate of infusion of the induction dose is another determinant governing the size of the induction dose; an infusion rate designed to only just achieve a desired effect-site concentration causes a loss of consciousness but at the cost of a slow onset. The loss of consciousness is only transient, and is maintained only for the duration that the targeted effect-site concentration is maintained. A faster rate of infusion provides a more rapid onset of anesthesia and a longer duration of loss of consciousness, but again involves administration of a larger induction dose and hence a greater likelihood of adverse effects.

Variations in induction dose requirements also occur because of interindividual pharmacokinetic differences, and because of pharmacodynamic differences that are the result of age, gender, cardiac output, smoking, concomitant medications, and the presence of coexisting disease states.[46]

Drug Interactions

Because no single IV drug (with the possible exception of ketamine) can provide hypnosis, amnesia, and analgesia, total intravenous anesthesia will be, by definition, provided by a combination of drugs. However, in contrast to the simply additive effects of the different gaseous and volatile anesthetics, IV anesthetics may interact in either additive or synergistic manners (see Chaps. 40 and 41). In the case of most IV agents, this interaction is synergistic. One example used to good effect is the combination of a hypnotic and benzodiazepine or other sedative drug (such as an α_2-agonist) for induction of anesthesia (the technique of *coinduction*). One major advantage of this technique is to provide an adequate depth of anesthesia for a noxious stimuli such as laryngoscopy and intubation *without any associated significant cardiovascular depression*.

Also clinically useful is pretreatment with an opiate (fentanyl, sufentanil, alfentanil, or remifentanil), which will reduce the amount of hypnotic agent needed for loss of consciousness and provide analgesia to reduce the adrenergic stimulus caused by the instrumentation of the airway (whether by laryngoscopy and intubation, or insertion of the laryngeal mask airway). However, the combination of an opiate with an IV hypnotic agent can cause both positive and negative side effects (namely, cardiovascular stability *or* profound cardiovascular and respiratory depression). Respiratory depression is of little importance in the mechanically ventilated patient, but is a significant and unwanted effect in the spontaneously breathing individual.

Although the combination of benzodiazepines with nitrous oxide produces minimal cardiovascular effects for induction of anesthesia, the combination of benzodiazepines with opiates results in a synergistic depression of most hemodynamic parameters. Because opiates *alone* are not complete anesthetics, they cannot be used reliably to induce anesthesia and amnesia in the absence of supplements. In clinical practice, a second anesthetic drug (such as an IV hypnotic) should always be given to ensure loss of consciousness. Thus the main functions of opiates are to provide analgesia *and potentiate* the effects of IV anesthetic agents, both at induction and during the maintenance phase.

Termination of IV Anesthetic Action

The duration of drug effect of a bolus dose of IV drugs is terminated predominantly by redistribution of drug from the blood and brain to the lean tissues. This redistribution occurs by a series of different intercompartmental clearances, and to a lesser extent, metabolic clearance, the sum of these being dependent on cardiac output in the case of lipid-soluble hypnotic agents. However, if the dose of the induction agent causes a significant reduction in cardiac output, the offset of the drug effect is delayed.

DRUGS FOR INDUCTION OF ANESTHESIA

Thiopental

This thiobarbiturate continues to be the most popular of all IV anesthetic induction agents, even though propofol may be more appropriate in circumstances where rapid recovery from anesthesia is a prerequisite (e.g.,

in ambulatory surgical practice). Thiopental, however, has a number of drawbacks as it is highly alkaline in solution, and therefore extremely irritating if injected extravascularly or intraarterially, and has a low therapeutic index of about 4. When given IV, the barbiturates achieve onset of hypnosis within one arm–brain circulation time. Because of their high lipid solubility and low percentage of ionization at physiologic pH, there is rapid uptake into the brain. The maximum effect of thiopental is seen within about 1 minute of a single induction dose of 3–6 mg/kg. There then follows a similarly rapid decline in the brain concentration as a consequence of redistribution into the "lean" body tissues, making the duration of effect of an induction dose about 5–10 minutes. However, at the time of awakening, only 18% of the injected thiopental dose will have undergone metabolism (compared with approximately 38% of a dose of methohexital and nearly 70% of propofol).

Several different factors influence thiopental elimination. Stanski and Maitre showed that, although age influenced the kinetics of thiopental, it had no effect on brain responsiveness or dynamics when the spectral edge frequency was used as the measure of drug effect.[119] The induction dose requirements for thiopental anesthesia vary with patient age and weight, and, most importantly, cardiac output. Lower doses are indicated in the premedicated patient; in patients with severe anemia or burns; in malnourished patients; in patients with uremia or liver failure; and in the hypovolemic individual regardless of cause. Both circulatory failure and hypothermia slow the circulation time, prolonging the induction period for thiopental. Moreover, the total dose needed in such patients is also reduced.

The blood–brain equilibration rate constant for thiopental is rapid (0.46–0.58 min^{-1}). The effect-compartment concentration associated with dropping a loaded syringe is about 17 μg/mL, and the duration of effect of an induction dose of 320 mg is about 4 minutes. Induction with thiopental causes a decrease in cardiac output, and a compensatory 10–15% increase in heart rate. Thiopental also causes venodilation, but has no effect on systemic vascular resistance.[96] Another feature of thiopental induction is the decrease in respiratory responsiveness to hypoxia and hypercapnia. Opiates potentiate these effects. When anesthesia is induced with the combination of thiopental and midazolam, the two hypnotics act synergistically; when thiopental is given with an opiate such as alfentanil, there is greater potentiation of the antinociceptive response than hypnosis.[64]

Thiamylal

Thiamylal (another thiobarbiturate used mainly in the United States and Japan) has pharmacologic characteristics similar to thiopental with regard to potency, incidence of laryngospasm and respiratory depression, cardiac toxicity, and recovery time. It is formulated as a racemic mixture. The potency of the S enantiomer is about twice that of the R+ form, and there are also kinetic differences. The plasma protein binding of the R+ isomer is 82.5%, and of the S– isomer 88.3%. The elimination half-life of the R+ enantiomer is 20.2 hours; the apparent volume of distribution is 3.66 L/kg; and clearance is 0.27 L/kg/h. The corresponding values for the S– compound are 24.1 hours, 2.60 L/kg, and 0.15 L/kg/h, respectively.

Methohexital

This is an oxybarbiturate with a faster recovery profile than thiopental because of a greater systemic clearance and a shorter elimination half-life. Compared with thiopental, methohexital has a more appropriate kinetic profile for both induction and maintenance of IV anesthesia (elimination half-life of 420–460 minutes, clearance of 700–800 mL/min). Because its main metabolite, 4-OH methohexital, has no pharmacologic activity (unlike thiopental's major metabolite, pentobarbital), methohexital may be usefully given by continuous infusion for maintaining anesthesia or sedation (see Drugs for Maintenance of TIVA).

Induction of anesthesia with methohexital requires doses of 1–2 mg/kg, giving it a potency of 2.7 times that of thiopental. The side-effect profile of methohexital is more significant than that following thiopental, and includes increased incidences of pain on injection, a tendency to venous thrombophlebitis, and exaggerated involuntary movements, especially in the unpremedicated patient. Inadequate induction doses can also cause excitatory phenomena because the inhibitory areas of the brain are thought to be depressed at lower drug concentrations.

Etomidate

Etomidate is a carboxylated imidazole compound formulated as the R+ enantiomer. The approximate potency ratio of the enantiomers is R+:S– = 1:10.[127] As an induction agent, etomidate has important advantages over the barbiturates, showing many ideal properties for an IV agent (cardiostability; reduction of cerebral blood flow, cerebral metabolic rate, and intracranial pressure; no release of histamine and low rate of allergic reactions; only transient and minimal respiratory depression and no inhibition of the hypoxic pulmonary vasoconstrictor reflex), and offers hemodynamic advantages during induction of anesthesia in patients with poor cardiac reserve, and hypovolemia. The drug also has a wider margin of safety in animals, with a high therapeutic index of 26.4.

Because it is unstable in water, etomidate is presently solubilized either in 33% propylene glycol or as an emulsion. The drug has a pH of 8.1 and pK_a of 4.2. It is a base and approximately 99% of the drug is unionized. Plasma protein binding is approximately 75% (mainly to albumen). Metabolism occurs predominantly in the liver and plasma by esterase hydrolysis, and hence etomidate shows the expected high systemic clearance.

Induction doses of 0.2–0.4 mg/kg provide hypnosis for between 5 and 15 minutes, with only minor alterations in cardiovascular parameters in healthy patients and in those with valvular or ischemic heart disease. Little is known about the interaction of etomidate and opiates or other hypnotics for loss of consciousness. Etomidate alone does not obtund the sympathetic responses to laryngoscopy and intubation;[39] and for a smooth hemodynamic profile, etomidate is best combined with an opiate or benzodiazepine.

However, its use as an induction agent is also associated with a number of minor disadvantages, with significant incidences of pain on injection, thrombophlebitis, myoclonia, and a high incidence of postoperative nausea and vomiting. When given either as a single induction dose or by infusion, etomidate suppresses adrenal steroidogenesis,[69] and low plasma cortisol levels are found following use of the agent. Does this matter? In pa-

tients receiving etomidate by infusion for intensive therapy unit sedation, Ledingham et al. found that its use was associated with increased mortality.[58] However these findings were *not* based on a double-blind, randomized, controlled trial. There are no data to support this association when etomidate was administered by continuous infusion to anesthetized surgical patients. As a result of the cortisol suppression, etomidate by infusion is contraindicated in many countries, and any continued use in that way must be considered as off-label.

The role of etomidate is further confused by a recent unreasoned and unsupported editorial in *Anaesthesia* expressing the view that the drug has no place in current anesthetic practice.[70] This view is *not* shared by the present author in the absence of properly conducted clinical outcome trials.

Alternate Formulations of Etomidate

Attempts at improving the side-effect profile of etomidate have focused primarily on the solvent. Development of an emulsion formulation does not change the drug's dynamic properties, but is associated with lower incidences of pain on injection, myoclonus, and local thrombophlebitis.[56,128] Another advantage of the emulsion formulation is its lower osmolality and higher pH (400 mOsm/kg and pH 7.6 compared with 4965 mOsm/kg and pH 5.1 for the propylene glycol formation), which means less red cell hemolysis.[29,74] A second reformulation of etomidate has used 2-hydroxypropyl-β-cyclodextrin as the solvent.[30] Again, there was a lower incidence of myoclonia (17% vs. 92%) and pain (8% vs. 58%), and thrombophlebitis (0% vs. 42%), and no hemolysis. None of these formulations appears to show alterations in the kinetics or dynamics of etomidate.

Although it is widely believed that use of etomidate is associated with an increased incidence of postoperative nausea and vomiting, this has not been supported by a recent comparison where etomidate-lipuro and propofol were used for induction of anesthesia to supplement isoflurane/fentanyl in air in patients undergoing orthopedic procedures.[122] There were no differences in rates of nausea, vomiting, or the intensity of any nausea during the early postoperative period to 24 hours. However the rates of vomiting after etomidate were higher (27% vs. 10%).

Midazolam

Midazolam is the only currently available benzodiazepine that is suitable for induction of anesthesia. It has a faster onset and lower incidence of venous complications than either diazepam or lorazepam, but a slower onset than the other IV hypnotic agents (30–60 seconds for loss of consciousness). Induction of anesthesia (as is the case with the barbiturates) coincides with loss of the eyelash reflex. Induction occurs with doses of 0.1–0.2 mg/kg midazolam given over 20–30 seconds; smaller doses are sufficient in premedicated patients, in the elderly, and in patients of ASA groups PS-III to PS-IV. However, emergence from midazolam-induced anesthesia may be prolonged.[79]

Midazolam has some advantages over thiopental, including improved perioperative amnesia and hemodynamic stability. However, the combination of midazolam and an opiate can result in significant cardiovascular depression. Although a single induction dose of midazolam does not suppress the adrenal steroidogenesis,[27] data from Crozier et al. and Desborough et al. suggest that high doses of midazolam given by infusion prevent the increase in plasma cortisol concentrations in response to surgical stress.[24,28] As with etomidate, the significance of this finding during TIVA is uncertain in the absence of appropriate outcome data.

Another advantage of midazolam over other hypnotic agents is the availability of a specific antagonist, flumazenil, which is devoid of any intrinsic effects on the respiratory or cardiovascular systems. However, it has a short duration of action, with peak effect occurring 1–3 minutes following IV injection. Because of its shorter elimination half-life (40–70 minutes) and faster clearance rate than midazolam, flumazenil may produce an initial arousal from sedation or anesthesia, followed by resedation.[77] Thus, if larger doses of midazolam are used for induction and/or maintenance of anesthesia, flumazenil preferably should be given as the combination of a loading dose and continuous infusion to maintain a plasma drug concentration in excess of 20–40 ng/mL.

Propofol

This sterically hindered alkyl phenol was originally formulated as an emulsion containing soybean oil and egg phosphatide (Diprivan). A number of other formulations are either available or undergoing clinical evaluation (Table 42–8). However, the efficacy of these newer formulations in large outcome studies is awaited, but there appears to be little difference in their kinetic and dynamic properties.

Propofol (as Diprivan) has a neutral pH of 7.4, and pK_a of 11.0; this means that the drug is 99.7% nonionized and highly lipid soluble at pH 7.0. It is rapidly broken down to inactive me-

TABLE 42–8.

Different Formulations of Propofol (di-Isopropyphenol) Presently in Preclinical Trials, Current Clinical Practice, or Under Development[a]

1. Original preclinical formulation: 2% propofol in 16% Cremophor EL and 8% ethanol
2. 1% Propofol in 16% Cremophor EL (preclinical)
3. 1% Propofol in lipid emulsion (containing 10% soybean) [= Diprivan]; emulsion preservatives include ethylenediaminetetraacetic acid (EDTA) and sulfite
4. Ampofol (Amphaster Pharmaceuticals Inc, Rancho Cucamonga, CA) formulated in 1% propofol in 5% soybean [AQ: Please verify this entry. Product not listed at company's website.]
5. Modified lipid emulsions containing medium-chain triglycerides (MCTs) and 1% propofol: IDD-D propofol (Skye Pharma Inc., New York, NY) and Propofol-lipuro (B Braun, Meslungen, Germany)
6. 6% propofol in MCTs-LCT (long-chain triglycerides) (Lipofundin, B Braun)
7. AM 149 (Amrad Operations Pty Lyd, Richmond, Victoria, Australia): 1% propofol in MCT alone
8. Albumin-containing emulsions (under development)
9. Nonemulsion formulations (under development)
   β-Cyclodextrin
   Micelle formulations
   Polysorbate formulation
10. Propofol prodrugs formulated as the hemisuccinate, hemigluratate, hemiadipate, monophosphate, diphosphate

[a]Data so far suggest little difference between formulations with regard to pharmacokinetics and pharmacodynamics.

tabolites (the glucuronide and the corresponding quinol glucuronide and sulphate) in the liver, and possibly in other organs, such as the lungs.[26,40] Other minor metabolites detected in the urine include 2-(ω-propanol)-6-isopropylphenol and 2-(ω-propanol)-6-isopropyl-1,4-quinol. It is not known whether any of these have anesthetic potencies. The hydroxylation of propofol by hepatic cytochrome P450 (CYP) involves the isoform 2B6, which shows wide individual variability.[21] Another isoform that shows high binding for propofol is CYP 2C9.[80]

Despite its rapid and complete offset of effect, propofol has a long elimination half-life (of up to 45 or more hours), an apparent volume of distribution of between 1000 and 3940 L, and a systemic clearance between 1.0 and 1.8 L/min. Because of its high extraction ratio, propofol shows flow-dependent clearance, and its own clearance is reduced secondary to its action on myocardial contractility and cardiac output. Population kinetic analyses by Schuttler and Ihmsen indicate weight to be a significant covariate for the elimination clearance, the 2 intercompartmental clearances of a 3-compartment model, and the apparent volumes of the central and 2 peripheral compartments, whereas in older patients (age >60 years), both elimination clearance and the central volume compartment decrease linearly with age.[102]

Induction of anesthesia with propofol is smooth and associated with a low incidence of excitatory side effects. Doses of 1–2.5 mg/kg (depending on patient age, physical status, and use of premedicant drugs) induce anesthesia in approximately 30 seconds; however, lower induction doses should be used in patients with cardiovascular disease. Loss of consciousness occurs at propofol concentrations between 2.5 and 5.5 μg/mL, with the concentration for loss of response to verbal command being between 2.5 and 3.5 μg/mL. The speed of onset and the dose of propofol needed for induction are dependent on the administration rate. Stokes et al. compared induction times when propofol was infused at 50, 100, and 200 mg/min and as a 2 mg/kg bolus. Times to loss of consciousness were 124, 92, 62, and 32 seconds, respectively, with the corresponding total induction doses being 1.4, 1.96, 2.61, and 2.15 mg/kg.[120]

The size of the induction dose depends on many physiologic factors. Kazama et al. determined 4 factors to be independent variables influencing the size of the induction dose (namely age, lean body mass, central blood volume, and liver blood flow).[53] When the dynamics of propofol are related to age, 3 functions correlate in a linear manner: the blood–brain equilibration rate constant and time to peak effect; the steepness of the concentration–response relationships for EEG activation and depression; and the effect-site concentration associated with 50% of peak EEG activation.[99]

The hemodynamic effects following induction doses of propofol are similar to those of the thiobarbiturates, although propofol additionally decreases systemic vascular resistance. In contrast to the barbiturates, propofol has little effect on heart rate. In contrast to the barbituates, propofol has little effect on heart rate; the combination of the drug's vagotonic effect and the fall in vascular resistance predisposing to significant falls in blood pressure when used in the hypovolemic patient or in patients receiving other vagotonic drugs (e.g., opiates).[15] The ventilatory effects of propofol are comparable to those of other hypnotic agents. Induction doses cause significant decreases in tidal and minute volumes, coupled with episodes of apnea often greater than 30 seconds, in 25–30% of patients. Comparative studies indicate the duration of apnea following propofol is longer than with thiopental.[118] All induction agents decrease the rib cage and abdominal components of ventilation to a similar amount. The ventilatory depressive effects of propofol are synergistic with those of midazolam and fentanyl, and with the combination alfentanil-midazolam.

One advantage of propofol as an induction agent is the greater depression of pharyngeal and laryngeal reactivity than is seen with thiopental, methohexital, or etomidate. This can be of benefit during upper airway instrumentation and insertion of the laryngeal mask airway.

Pain on injection is commonly observed during induction of anesthesia with propofol, with incidences of up to 50% when administered into the small veins on the dorsum of the hand. The incidence may be reduced by use of large veins, by mixing with lignocaine (10–20 mg), and by pretreatment with drugs such as fentanyl and alfentanil. Other side effects of induction include excitatory myoclonic phenomena and occasional epileptiform fits reported during recovery. Like etomidate, propofol appears to have in vitro potential for inhibition of adrenal steroidogenesis, but this is not relevant in clinical anesthetic practice.

Ketamine (2-*O*-Chlorophenyl-2-Methylaminocyclohexanone HCl)

This phencyclidine derivative is formulated as a racemic mixture. It is unique among the induction agents in that it produces both dose-related unconsciousness and analgesia. Following induction with ketamine, patients have little recall of surgery or anesthesia.

The two stereoisomers, R(–) and S(+), show differing anesthetic potencies (1:3–4), but have similar kinetics. The pH of ketamine is 3.5–5.5, and the pK_a is 7.5. At physiologic pH, ketamine is highly lipid soluble, with 12–35% being plasma protein bound, and 44% nonionized. Recovery from ketamine anesthesia occurs as a result of both distribution and degradation by demethylation and hydroxylation by hepatic cytochrome P450. The metabolic breakdown of ketamine is complex, but one metabolite (norketamine; metabolite I) is pharmacologically active with a potency of approximately 30% that of the parent drug, and a longer elimination half-life. The main excretory metabolites are ketamine and metabolite I and II glucuronides. The efficacy of ketamine is enhanced in patients with renal impairment with an accompanying delayed recovery. Most of the ketamine is excreted in the urine as the glucuronides; only 2.5% is unchanged.

Ketamine causes rapid induction of anesthesia by the IV route. However, its cardiovascular effects differ from other hypnotic agents; ketamine causes increases in heart rate, blood pressure, and cardiac output. These inotropic and chronotropic effects are seen in both healthy patients and in those with heart disease, and are mediated via central mechanisms. Ketamine blocks the reuptake of noradrenaline by both the uptake 1 (extraneuronal) and uptake 2 (intraneuronal) mechanisms, as well as causes the release of noradrenaline from the sympathetic ganglia. The in vivo effects are obtunded in patients receiving adrenergic antagonists (both α and β) and vasodilators, as well as by pretreatment with benzodiazepines.

Ketamine has advantages over propofol and etomidate because it is water

soluble. However, although it lacks the cardiorespiratory depressive properties of other IV agents, its usefulness is limited by high incidences of disturbing emergence reactions (up to 30% of patients). Ketamine also causes increases in intracranial pressure and salivation. The psychomimetic effects of ketamine may be attenuated by benzodiazepine premedication, although these drugs appear to prolong the elimination half-life of ketamine and increase its recovery time.

Stereoisomers of Ketamine

The potency ratio for anesthesia is approximately 4:2:1 for S(+) ketamine, ketamine racemate, and R(–) ketamine enantiomers. Some data suggest administration of S(+) ketamine is accompanied by a lower median EEG power spectrum, a greater rise in blood pressure and heart rate, decreased locomotor activity, shortened recovery times, and equipotent analgesia compared with the racemate at similar doses.[87,102,104,142]

Opiates

As already detailed in the section on induction of anesthesia with TIVA, these are not complete IV hypnotics and do not produce anesthesia in the absence of other supplements. However all opiates potentiate the effects of hypnotics when used for induction of anesthesia (this is seen less with thiopental, but is most important with midazolam).

DRUGS FOR MAINTENANCE OF TIVA

In modern anesthesia, the dosing of both hypnotics and analgesics is by titration to clinical effect, measured either by effects on the cardiovascular system or the EEG (or one of its surrogates). The changes in heart rate and blood pressure tend to be "agent specific" (for *most* IV agents, increasing depth of anesthesia causes a reduction in heart rate and blood pressure, although with ketamine, the heart rate may increase with increasing plasma drug concentrations). However, of all the markers of inadequate anesthesia, patient movement remains the most reliable.

Despite the availability of pharmacokinetic-based infusion regimens, it is the dynamic responses of the individual patient to any given surgery that governs the rate of drug infusion. No single plasma drug concentration results in satisfactory anesthetic and surgical conditions for all patients and all operations.

Titration of the infusion rate should reflect the anticipated intensity of the applied stimulus and likely observed patient responses. In general, drug requirements are greatest during endotracheal intubation, and decrease during surgical preparation and draping. The infusion rates will need to be increased prior to skin incision, whereas during anesthesia, drug dosing should be titrated according to signs of patient movement, hemodynamics, and autonomic responses. In the absence of any response over a given period of time, the anesthesiologist may consider reducing the infusion rate by 15–20%.

Table 42–9 shows typical infusion regimens used to achieve the steady drug concentrations required to provide analgesia using IV analgesic drugs given by infusion. If the dose of drug administered is clearly too high in the presence of continuing signs of inadequate anesthesia, then the anesthesiologist should examine for a disconnection of the delivery system, or delivery to a subcutaneous rather than vascular site. Other causes could include incorrect programming of pumps, or mechanical errors of the delivery systems.

During TIVA, use of combinations of drugs poses questions over which one to increase or decrease and for what reasons. In general, the dosing of opiates should be aimed at achieving analgesic drug concentrations at the effect site, whereas the hypnotic infusion should be titrated to individual patient requirements and to the intensity of the surgical stimulation. At the end of surgery, the anesthesiologist should reduce the infusion rates of the hypnotic and analgesic during skin closure to allow restoration of spontaneous respiration by the end of surgery.

Thiopental and Thiamylal

Early recovery from thiopental occurs because of a decline in the blood (and brain) concentrations as a result of drug redistribution. Following bolus doses and after short or low-dose infusion regimens, thiopental is eliminated by first-order kinetics and the patient promptly awakens. However, at rates in excess of 300 μg/kg/min, thiopental concentrations increase nonlinearly because of the peripheral tissue stores becoming saturated. Maintaining anesthesia with infusions of thiopental requires rates of 150–300 μg/kg/min in combination with an opiate. This will achieve thiopental concentrations of between 15 and 25 μg/mL.[22] In the absence of an analgesic supplement, thiopental concentrations of the order

TABLE 42–9.

Typical Drug Concentrations and Manual Infusion Regimens to Provide Adequate Analgesia for Major Noncardiac Surgery Under TIVA and Other Target Analgesic Concentrations

	Cp50 (ng/mL) for Surgery	Cp50 (ng/mL) for Adequate Spontaneous Respiration
Alfentanil	200–300	10–30
Fentanyl	4–6	0.5–1.0
Remifentanil	4–6	0.5–1.0
Sufentanil	0.3–0.4	0.025–0.05

Dosing strategies

	Target Concentration (ng/mL)	Loading Dose (mg/kg)	Maintenance Infusion (mg/kg/min)
Alfentanil	40	20	0.25
	160	80	1.0
	320	160	2.0
Fentanyl	1	3	0.02
	4	10	0.07
Remifentanil	6	1	0.02
	12–20	1–2	0.04–1.0
Sufentanil	0.15	0.15	0.003
	0.5	0.5	0.01

of 40–50 μg/mL will abolish the response to squeezing the trapezius muscle (which has been equated with the initial surgical incision). Besides the changes in pharmacokinetics, high doses of thiopental also lead to the formation of significant blood concentrations of its active metabolite, pentobarbital. Other inactive metabolites occur following C_5 side-chain oxidation. Renal excretion of thiopental is very low (approximately 0.3%).

Possible advantages to the use of thiopental infusions include minimal cardiovascular depression and cerebral protection during ischemic episodes, with blood thiopental concentrations on the order of 70 μg/mL resulting in EEG burst suppression.[20]

There are no published reports in the English-language literature of thiamylal being used as part of infusion anesthesia.

Methohexital

Plasma methohexital concentrations of between 3 and 4 μg/mL result in hypnosis, and concentrations between 10 and 12 μg/mL cause EEG burst suppression. Based on dose–response data from Sear and Prys-Roberts,[90,112,113] infusion rates of 50–65 μg/kg/min supplemented by opiates or of 100 μg/kg/min methohexital alone are required for anesthesia. Methohexital infusions depress both blood pressure and cardiac output; they also decrease baroreceptor reflex sensitivity with a resetting of the response to allow a more rapid heart rate at lower arterial pressures than when awake.[16] Side effects include excitatory movements, pain on injection, and predisposition to convulsions. Epileptiform activity has been recorded by EEG, but clinical fitting is rare. Methohexital also causes pain if accidentally injected into arteries, but unlike thiopental, this does not normally lead to thrombosis.

The combination of methohexital and opiates can cause significant respiratory depression. No untoward effects of methohexital infusions on liver, renal or adrenal function have been described.

Midazolam

Continuous infusions of midazolam have been used to provide both sedation and maintenance of anesthesia. When used as the hypnotic component to supplement alfentanil in a TIVA technique, and compared with propofol, Vuyk et al. observed similar hemodynamic effects but slower recovery.[135] For the maintenance of anesthesia, infusions on the order of 10 mg/h (resulting in plasma drug concentrations of 200–350 ng/mL) are needed to supplement opiate infusions.[24,79,85,86,92] Several of these studies showed that infusions of midazolam and opiates together may cause myocardial depression; this does not appear to be dose dependent and there is an apparent ceiling effect at midazolam concentrations greater than 100 ng/mL. Clinically relevant rates of infusion of midazolam in combination with alfentanil have no significant effect on the plasma cortisol response during lower abdominal surgery.[78] A major disadvantage of midazolam for TIVA is the slow recovery. Awakening occurs at drug concentrations around 50–80 ng/mL. Nilsson et al. showed that recovery can be improved by reversal with bolus doses of flumazenil; but resedation may subsequently occur as a consequence of the faster elimination of the antagonist and rebinding of the agonist.[77]

Ketamine

Although widely used throughout the world for the maintenance of anesthesia, there are few concentration-effect data for continuous infusions of ketamine. Most studies suggest hypnotic and analgesic thresholds are about 1.5–2.5 μg/mL and 150–200 ng/mL, respectively. Awakening from anesthesia occurs in the concentration range 600–1100 ng/mL. As sole agent, infusion rates of 60–80 μg/kg/min will provide clinical anesthesia.

The use of TCI ketamine for sedation and maintenance of anesthesia was described by Bowdle et al. and Gray et al.[14,37] For examination of the psychomimetic effects of ketamine, Bowdle et al. designed a BET delivery scheme based on the kinetic parameters of Domino et al.[31] to achieve a stepwise series of plasma target concentrations between 0 and 200 ng/mL. Bowdle et al. showed a good correlation and relationship between the targeted and observed drug concentrations. Increasing ketamine concentrations were associated with greater psychedelic effects for a variety of symptoms. Interestingly, there was no apparent threshold concentration, and no concentration at which these effects plateaued.

In the second study, Gray et al. developed a TCI scheme for ketamine to provide the analgesic component of a TIVA technique with propofol in spontaneously breathing patients undergoing body-surface surgery, using the kinetic parameters of Wieber et al.[143] The target concentration of ketamine was 300 ng/mL, with propofol delivered according to the manual BET scheme of Roberts et al.[93] Clinically this combination provided good cardiovascular control throughout the surgery, with an average end-tidal carbon dioxide of 5.8 kPa (kilopascals). There were episodes of involuntary movements (although these did not interfere with the surgery being undertaken), and no episodes of recall. However, recovery to giving date of birth was prolonged in some patients. There were no reports of unpleasant dreams or other psychomimetic side effects.

Schuttler et al. described a similar technique in patients undergoing lower abdominal surgery under propofol-ketamine anesthesia.[103] They describe satisfactory anesthesia without any significant psychic disturbances or cardiovascular stimulation. Recovery was not significantly delayed.

A major development in the use of ketamine as part of TIVA has been the separation of the hypnotically active S(+) ketamine enantiomer from the racemic mixture. In a crossover volunteer study, White et al. examined the pharmacologic effects of infusions of racemic, S(+), and R(−) ketamine, with measurement of cardiovascular parameters, the raw EEG, and a battery of psychometric tests.[142] S(+) ketamine was approximately 2 times more potent in terms of anesthesia, and was associated with faster recovery compared to both the racemic mixture and the R(−) isomer. This is in agreement with subsequent kinetic studies showing inhibition of metabolism of S(+) ketamine by its R(−) isomer.[54] Ketamine enantiomer concentrations at time of regaining consciousness and orientation are consistent with an S-to-R potency ratio of 4:1, while for impairment of psychomotor function, the ratio was between 3:1 and 5:1. When administered at equipotent doses, S(+) ketamine produces longer hypnosis than the R(−) isomer, with the racemate being intermediate. Improved recovery was seen after S(+) ketamine by infusion, compared with the racemate. However, cardiovascular stimulation and psychotomimetic effects are seen with both stereoisomers.

When given alone as part of an anesthetic technique to surgical patients, ketamine can cause considerable side effects. Emergence reactions are commoner after infusions of the R(−) enantiomer than after the racemate and S(+) isomer. However the incidences of dreaming with all three treatment groups were comparable.[141] There are no apparent differences between the enantiomers and racemate in their hemodynamic effects, but recovery is faster after the S(+) isomer. The EEG effects of both racemic ketamine and the S(+) isomer are similar; both cause increased fast activity (21–30 Hz) with an accompanying reduction in Δ power. The IC_{50} (concentration that inhibits 50%; in this instance, the plasma ketamine concentration necessary to achieve a 50% depression of the maximal EEG median frequency reduction) was 0.8 μg/mL for S(+) ketamine, compared with 1.8 and 2.0 μg/mL, respectively, for the R(−) and the racemic preparations.[104] The concentration–effect relationships show the curve for S(+) ketamine to lie to the left of the racemate, and to be steeper.

Propofol

Propofol is probably the most used hypnotic for the maintenance of TIVA. Infusion rates of 2–10 mg/kg/h are needed when administered with bolus doses or an opiate infusion, whereas drug concentrations >8 μg/mL will be necessary if propofol is used as a sole anesthetic agent. Recovery occurs rapidly after cessation of an infusion at blood concentrations of approximately 1.0 μg/mL.[15] Because of the wide variability in the therapeutic drug concentration window (related to both age and type of surgery) and intersubject drug kinetics, propofol dosing must be titrated to effect. This is easily achievable as it has a short blood–brain equilibration time ($t_{1/2}\ k_{e0}$).

When used to maintain anesthesia, infusions of propofol cause dose-related decreases in blood pressure, cardiac output, and systemic vascular resistance.[15] One important difference when compared with methohexital is that infusions of propofol do not show the normal baroreflex increase in heart rate to a decreased blood pressure. Propofol causes a resetting of the baroreceptor reflex such that slower heart rates are seen for a given arterial blood when compared with awake values.[25] As well as these central hemodynamic effects of propofol by infusion, other cardiac effects, including severe bradycardia, sinus arrest, heart block, and asystole, have been reported, which usually occur when propofol is coadministered with vagotonic drugs.[15] During TIVA, propofol affects ventilatory control, causing a reduction in the ventilatory response to carbon dioxide, and in the acute ventilatory response to isocapnic hypoxia.[73,76]

Although bolus doses of propofol have no effect on renal or portal venous blood flows, dose-related changes in liver blood flow have been reported in dogs during graded infusions to concentrations greater than those needed clinically in people.[111] However, in patients, clinically relevant infusion rates of propofol appear to cause no significant changes of liver blood flow.[72]

As well as being an anesthetic agent, propofol has a number of important and advantageous nonhypnotic effects.

1. *Mood-altering effects:* Subhypnotic doses of propofol administered by a patient-controlled analgesia (PCA) system (10 mg with a 1–5-minute lockout) exerts sedative and anxiolytic effects in anxious patients presenting for ambulatory surgery, and thus can be useful as premedication in ambulatory patients.[94]
2. *Antiemetic effects:* Although several authors have suggested an antiemetic effect of propofol (in both hypnotic and subhypnotic doses), the site of this action of the drug remains uncertain.[11] It is probable that propofol does not act at dopaminergic receptors. Subhypnotic infusions of the hypnotic are also effective in the prevention of nausea and emesis following cisplatin chemotherapy.[11]
3. *Antipruritic effects:* Again subhypnotic doses (10–20 mg IV) of propofol are equally as effective as naloxone in relieving pruritus caused by both epidural and spinally administered opiates.[12,95]
4. Effects on the central nervous system: Although in vitro studies demonstrate a vasodilating effect of propofol, in vivo measurement shows that infusions of propofol act to decrease cerebral blood flow and intracranial pressure (ICP), and decrease the cerebral metabolic rate. Infusions of propofol have no effect on cerebrovascular autoregulation to carbon dioxide, although the slope of the curve is decreased. There is some evidence for a cerebral protective effect of propofol, and high doses of propofol have been used to afford protection during cerebral aneurysm surgery in patients requiring cardiopulmonary bypass and deep hypothermic arrest, as well as in patients undergoing nonpulsatile bypass for cardiac surgery.[75,121]

Propofol–Drug Interactions during TIVA

Because TIVA normally depends on the coadministration of more than one IV drug, there is always the opportunity for drug–drug interactions, which may result in changes to drug distribution, metabolism and elimination, or drug dynamics. In vitro, propofol inhibits drug metabolism at clinical concentrations.[8,18,49] The magnitude of this inhibition varies from 30–71, with the greatest effect on biotransformations mediated by hepatic isocytochrome P450 2B1. Other cytochromes (P450 1A1 and 2A1) are also inhibited, and Chen et al. showed that clinical concentrations of propofol inhibit renal monooxygenase and defluorinase activities.[17]

As infusions of propofol decrease liver blood flow,[111] they also decrease clearance of flow-dependent drugs. Capacity-limited drug clearance is also decreased by action of propofol on the hepatic extraction ratio.[19] These findings are relevant during TIVA, because propofol may decrease the systemic clearance of other coadministered drugs through changes in effective liver blood flow or in the hepatic extraction ratio. However, simulation studies by Schnider et al. suggest that significant changes will not be associated with propofol infusion rates used in clinical practice, as the kinetics of propofol appear linear with regard to infusion rate at those concentrations.[98] Schnider's simulations are in general agreement with the data of Sear and colleagues in an open-chested dog model.[111]

What happens in vivo? There are data indicating significant interactions between propofol and alfentanil that lead to alterations in drug clearance.[67] In male volunteers, the addition of a propofol infusion (at a steady-state concentration ranging between 0.85 and 1.75 μg/mL) to alfentanil infused at 25 μg/kg/h resulted in a decrease in mean arterial pressure. In turn, this influenced the disposition of the alfentanil,

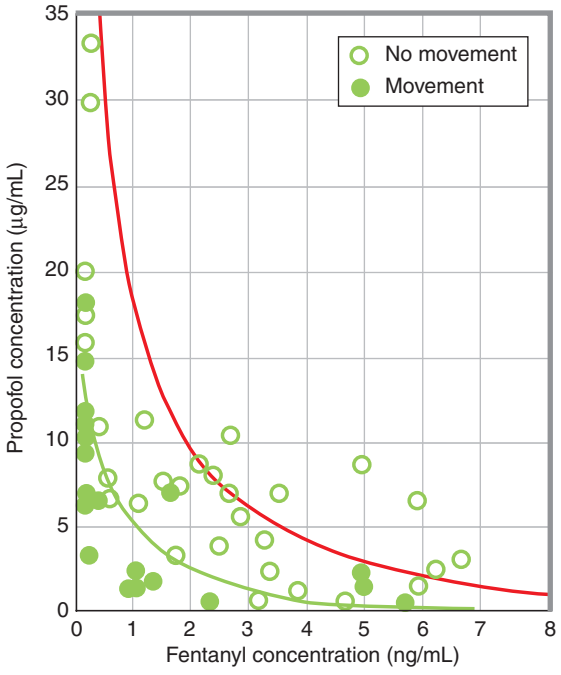

FIGURE 42–2. Increasing concentrations of fentanyl reduces the propofol concentration at which 505 (95%) of patients did not move at skin incision (Cp50i and Cp95i, respectively). *Solid lines*, logistic regression solution. (Adapted with permission from Smith C, McEwan AL, Jhaveri R, et al. The interaction of fentanyl on the Cp50 of propofol for loss of consciousness and skin incision. Anesthesiology 1994;81:820–828.)

resulting in a 15% decreased systemic clearance, a 68% reduction in the rapid distribution clearance, and a 51% reduction in slow distribution clearance. A similar interaction is seen with the combination propofol-remifentanil, where there is a significant reduction in the initial volume of distribution of the opiate and reductions in both systemic clearance and the intercompartmental distributional clearance. Because this effect is not concentration dependent, it does affect the dosing strategy when using this opiate.[13]

Of greater importance, however, are the dynamic interactions between the hypnotics and opiates during the maintenance phase of anesthesia. One of the earliest studies examining the hypnotic–opiate interaction was by Smith et al. (Fig. 42–2).[117] Other clinical studies and computer simulations by Vuyk et al. from Leiden confirm a synergism between these groups of drugs. They also indicate that regardless of an opiate's relative potency, the optimal effect-site concentration should be one that (a) prevents responses to noxious stimulation and (b) allows the rapid recovery of spontaneous ventilation at the end of anesthesia and surgery. Although the original interaction studies focused mainly on the combination propofol-alfentanil,[67,133–136] more recent studies confirm similar interactions for propofol with remifentanil and sufentanil.[59,66] A further dynamic interaction is seen between the two groups of drugs, with the frequent need for vasoconstrictor drugs to correct hypotension following the induction of anesthesia.

Adverse Effects of Propofol during TIVA

Although widely used as the main hypnotic component of TIVA, propofol exhibits a number of significant adverse effects, including pain on injection (especially when given into small veins and to children), hypotension and bradycardia (which are exaggerated in the presence of other vagotonic drugs such as opioids and hypovolemia), apnea in up to 40% of patients after induction, and reports of epileptiform movements and true convulsions.

α_2-Agonists and Other Sedative Drugs

α_2-Agonist drugs are widely used as part of TIVA techniques in veterinary practice; however, none of these agents are presently licensed for clinical use for sedation or hypnosis in people. Dexmedetomidine (DMD) is presently undergoing evaluation for both its sedative and hypnotic properties. It can also be seen to have analgesic properties in animals.

In humans, DMD interacts with both opiates and hypnotics to reduce drug requirements needed to maintain sedation or anesthesia. Peden et al. examined the combination DMD and propofol.[83] They found that an infusion of 3 ng/kg/min of DMD reduced the median effective (ED_{50}) infusion rate of propofol for loss of consciousness from 5.79 to 3.45 mg/kg/h, and the resulting plasma median effective concentration (EC_{50}) from 2.3 to 1.69 µg/mL. however, at these infusion rates, DMD caused significant side effects (with 2 cases of sinus arrest, and 1 of severe postural hypotension persisting for 24 hours postanesthesia). Sinus arrest has also been observed in other studies. Consequently, it is appropriate to pretreat patients (especially those younger than age 40 years) with an anticholinergic agent. At an infusion rate of 3 ng/kg/min, DMD blunted the hemodynamic responses to intubation and surgical incision, with the blood pressure and heart rate remaining stable throughout surgery and into the recovery period.

In a separate study, Dutta et al. determined the EC_{50} of propofol for loss of motor response to an electrical stimulus to be 6.63 µg/mL; when DMD was infused to a steady plasma concentration of 0.66 ng/mL, the EC_{50} of propofol was reduced by 41% to 3.89 µg/mL.[33]

A number of other clinical studies describe the use of DMD as part of TIVA techniques. Ramsey and Luterman used variable rate DMD infusions to provide hypnosis for surgery in patients with upper airway pathology.[91] When infused at rates up to 10 µg/kg/h, DMD caused no respiratory depression, none of the patients experienced severe hypotension or bradycardia, and recovery was not excessively prolonged (although the patients, who were ages 50–66 years, required 2–3 hours for complete recovery).

Clomethiazole (a derivative of the thiazole part of vitamin B_1) has been used as a continuous IV anesthetic to supplement both regional and spinal anesthesia. It permits ease of titration of the depth of sedation and anesthesia, with minimal cardiovascular effects. However, widespread use is limited because of the large fluid loads that

occur when administered as a 0.8% infusion in 4% glucose; increased red cell fragility when given as infusions of >5%; a high incidence of peripheral thrombophlebitis, necessitating central venous administration; and minor side effects of nasal irritation and stuffiness. Following prolonged infusions, recovery may be delayed.[63]

Opiates

Chapter 41 describes the use of infusions of opiates as part of balanced techniques. When used in TIVA, the opiates act synergistically with most hypnotic agents. Studies by Vuyk et al.,[65,66,133–136] Glass et al.,[117] and Lentschener et al.[59] show that even very small doses of opiates can markedly reduce the requirements of the hypnotic component. These studies also demonstrate a significant "ceiling effect"—such that above a given opiate dose or plasma concentration, little further reduction in hypnotic requirement can be achieved. During TIVA, the ability to prevent autonomic responses appears to be largely dependent on increasing the amount of the opiate drug. Examples of "useful" interactions between the hypnotic and analgesic components of TIVA can be found in the work of Vuyk et al. and Mertens et al.[66,133,134,136] Table 42–9 shows the typical plasma opiate concentrations needed to obtund responses to noxious stimuli during TIVA (and the associated opiate concentrations needed for adequate spontaneous ventilation in the recovery room), together with the regimens needed to achieve other drug concentrations.

RECOVERY FROM TIVA

The rapidity of recovery after TIVA depends on how well the clinician is able to keep the effect-site drug concentrations near to those concentrations found in the awake or spontaneously breathing subject. If intraoperative concentrations are kept at approximately 20% above those associated with wakefulness, rapid recovery will occur.

Context-Sensitive Half-Time

In 1992, Hughes et al. offered a different approach to the anesthesiologist's understanding of the recovery profile following infusions of intravenous anesthetic agents. Rather than relating recovery to elimination half-life or systemic clearance, they defined a new term: *context-sensitive half-time* (CSHT).[43] Compared to the various half-lives of a kinetic model, the CSHT describes what is happening to the plasma drug concentration.

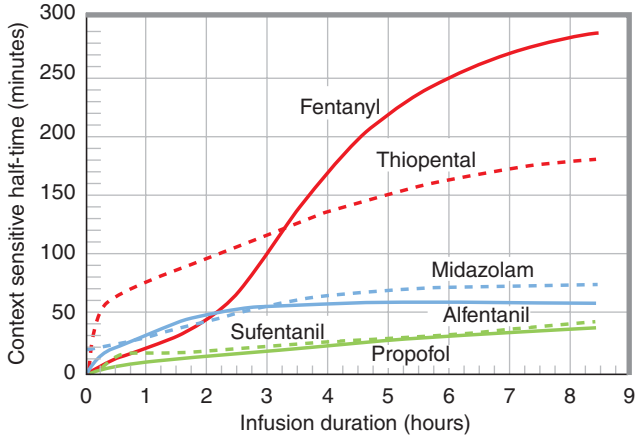

FIGURE 42–3. Context-sensitive half-times as a function of infusion duration from computer simulations of pharmacokinetic models. *Solid* and *dashed* lines are used only to permit overlapping lines to be distinguished. (Adapted with permission from Hughes MA, Glass PSA, Jacobs JR. Context-sensitive half-time in multicompartment pharmacokinetic models for intravenous drugs. Anesthesiology 1992;76:334–341.)

Termination of drug effect is dependent on two separate kinetic processes: drug distribution and drug elimination. An IV drug with a short elimination half-life is not necessarily a short-acting drug, as drug redistribution can affect the dynamic profile of the agent. The CSHT is dependent on the 3 rate constants—kel, k12, and k21—of a 2-compartment mamillary model in which drug elimination occurs only from the central kinetic compartment. The CSHT is a "half-time" rather than "half-life," as the time needed for plasma or effect-site drug concentration to decrease by 40% will not be twice that required to decrease by 20%! The term "context" refers to the duration of the drug administration, with the half-time measured from the moment of cessation of the infusion (Fig. 42–3). One limitation of the CSHT is that it describes the time to a 50% decrease in the plasma or central compartment drug concentration. This may not be the required decrement in the drug concentration needed to achieve recovery, although the studies of Prysi-Roberts and Sear suggest that it may certainly be appropriate when predicting the behavior of hypnotic agents given by infusion.[89]

The study of Kapila et al.,[51] comparing the modeled CSHT for both alfentanil and remifentanil with values determined from volunteers where the effect measured was that of depression of minute ventilation, validated the predictive accuracy of the CSHT. The modeled values of the CSHT following a 3-hour infusion were 2.0 and 51.9 minutes, respectively, for remifentanil and alfentanil, compared with measured values of 3.2 and 47.3 minutes, respectively.

Youngs and Shafer further elaborated on the concept of CSHT.[144] They produced simulations of the time courses not just for a 50% decline in the plasma drug concentration, but also for the 20% and 80% declines after varying-length infusions of 3 opiates (alfentanil, fentanyl, and sufentanil), giving rise to the "20%, 50%, and 80% decrement times." Examination of the relationship between 6 derived components of a 3-compartment mamillary model (namely V1, V2, V3, Cl10, Cl12, and Cl13) on these decrement times show that increases in the initial volume of drug distribution (V1) lead to longer decrement times. The reverse is true after increases in the clearance constant Cl10. Similarly, increases in the peripheral volumes of distribution (V2 and V3) and the intercompartmental clearances Cl12 and Cl13 lead to shorter decrement times when the infusion is of limited duration, but longer times after prolonged infusions.

For rapid recovery from TIVA, drugs with a small initial volume of distribution (V1) and high clearance (Cl10) are the most suitable. After prolonged anesthesia, the fastest recovery times are seen after infusion of drugs with small apparent peripheral volumes of distribution and small intercompartmental

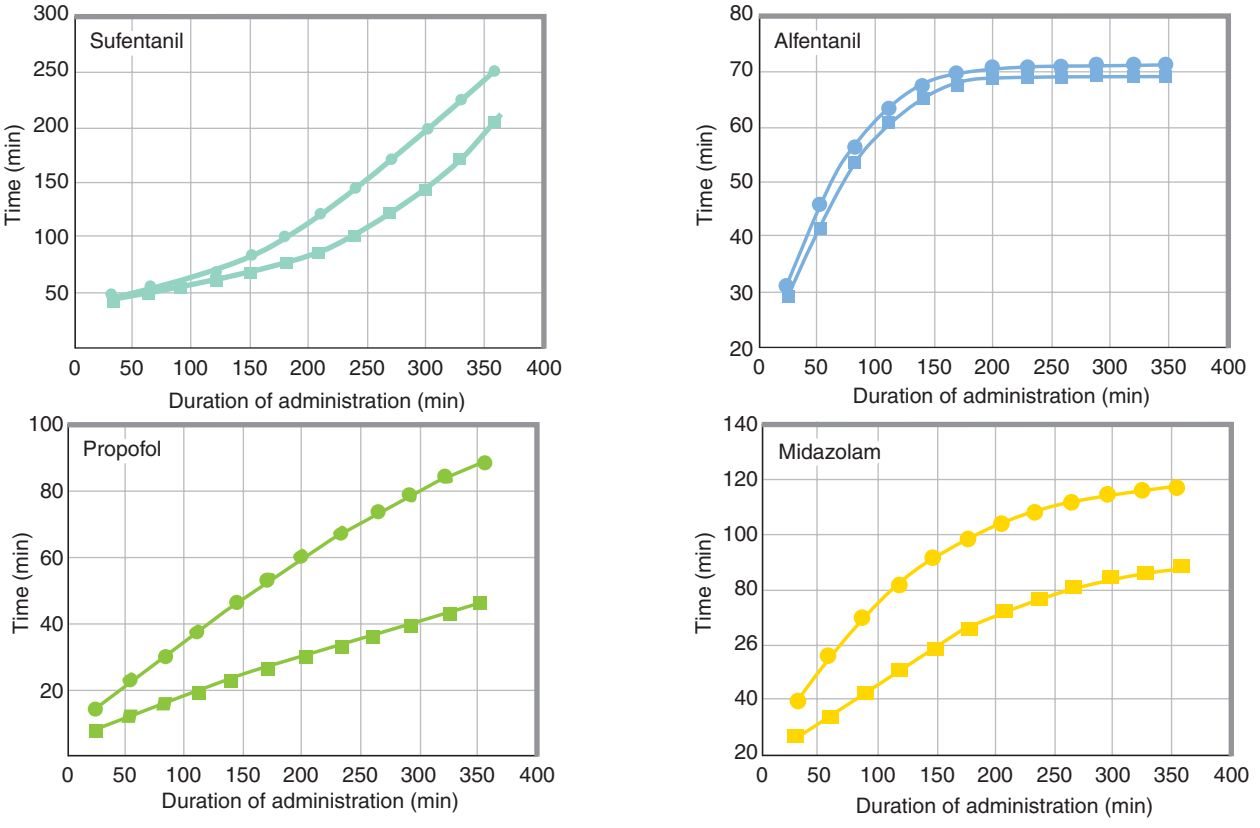

FIGURE 42–4. Comparison of mean effect time (MET) (●) and 50% decrement times (■) as a function of length of administration of sufentanil, alfentanil, propofol, and midazolam when maintained as an infusion maintaining a constant plasma concentration equal to the Cp90 for surgery. (Adapted with permission from Bailey JM: Technique for quantifying the duration of intravenous anesthetic effect. Anesthesiology 1995;83:1095–1103.)

clearances. As the "biophase" concentration is always related to the plasma drug concentration, the "decrement times" are also a good descriptor of drug effect *except* after bolus doses or very short infusions.

Bailey described another descriptor of recovery following intravenous infusions: the "mean effect time."[6] The mean effect time is based on whether or not a patient responds to a given parameter or end point. For a given plasma drug concentration, the "probability (p)" of a given drug effect is described by a logistic regression equation of the type:

$$p = C^g / C^g_{50} + C^g$$

where C = drug concentration; C_{50} = drug concentration at which there is a 50% probability of a given effect; and g = a parameter estimate describing the steepness of the concentration–probability relationship. From this equation, Bailey calculates the mean effect time as the integral of p against time.

Whereas the 50% decrement time of Youngs and Shafer will be, by definition, the median recovery value for a given population of patients after a given dosing regimen, it will also be the *mean* recovery index based on the probability of that event occurring. A large steepness coefficient g indicates a steep drug concentration–response relationship. Under such circumstances, the difference between the mean effect time and the 50% decrement times will be insignificant. However, if the concentration–response relationship is flatter, recovery times will tend to be right-skewed, and the mean effect time will be significantly greater than the 50% decrement time.

Although determination of decrement times is straightforward, the calculation of the 50% value for the intraoperative maintenance drug concentration, or determination of the mean effect time requires the anesthetist to have a clear understanding of the nature of the concentration–response relationship (and hence be able to determine g). For low values of g, the anesthetist needs to "overdose" the patient to make sure that *all* patients are adequately asleep or pain free. This necessitates a greater decline in the maintenance drug concentration in order to achieve concentrations where there is a 50% probability of recovery occurring. Alfentanil is an example of a drug with a high g value (9.2), whereas sufentanil, propofol, and midazolam have flatter dose–response curves (g values of 5.99, 3.27, and 3.05, respectively). Thus the mean effect time and the 50% decrement times for alfentanil are similar, whereas those for propofol, midazolam, and sufentanil differ, depending on the duration of drug administration, with the mean effect time being increasingly greater as the dosing time increases[6] (Fig. 42–4).

How Do All These Simulation Data Compare with In Vivo Observations for Different IV Agents?

Hypnotics

Propofol has a CSHT of < 25 minutes for infusions lasting up to 3 hours duration (Fig. 42–3) and hence recovery will be prompt; in contrast, thiopental has a longer CSHT, and after infusions to achieve plasma concentrations of 10–20 μg/mL, recovery takes 40–300 minutes.[23]

Methohexital has a CSHT similar to that for propofol, and its recovery profile is similar to that of propofol after

short duration procedures. On the other hand, as the studies of Vuyk et al.[135] demonstrate, midazolam has a CSHT about twice that of propofol. The computed CSHT for ketamine appears to be similar to that for propofol, although its rate of elimination is slower.[47] This is because ketamine equilibrates faster with the peripheral compartments. The modeled CSHT of ketamine after a BET infusion for 8 hours is approximately 50 minutes. However, its recovery profile is influenced by the high incidence of psychological reactions (seen in between 5% and 30% of patients).

Etomidate has a CSHT of approximately 50% that seen with propofol. This should lead to fast recovery after TIVA, but, again, there are associated high incidences of adverse recovery sequelae, including nausea and vomiting (15–20% of patients), twitching and restlessness, and venous sequelae such as thrombophlebitis. The occurrence of these postoperative side effects will slow the completeness of recovery following etomidate.

Opiates

The rational use of opiates in TIVA has been well discussed by Shafer and Varvel.[115] If a dosing strategy of providing analgesic concentrations is adopted, then a 20–30% decrease in the opiate concentration will allow adequate postoperative ventilation. Fentanyl concentrations show a rapid initial decline followed by a slower decrease, permitting spontaneous ventilation at the end of the procedure while maintaining analgesia for a considerable time thereafter. When a rapid and maximal decline in opiate concentration is desirable (as in ambulatory and day surgery), remifentanil, alfentanil, and sufentanil are more suitable (Fig. 42–5).

With infusions of less than 8 hours' duration, the decline in the sufentanil concentration is more rapid than that of alfentanil, although alfentanil has the shorter CSHT for infusions lasting 6–8 hours or longer. For infusions of less than 1 hour duration, fentanyl and sufentanil have CSHTs that are both shorter than alfentanil. However, for infusions of variable duration, the CSHT of remifentanil is virtually independent of its duration, with no adjustment apparently required for weight, age, or gender. Its high systemic clearance is because of its rapid metabolism by plasma esterases. The short

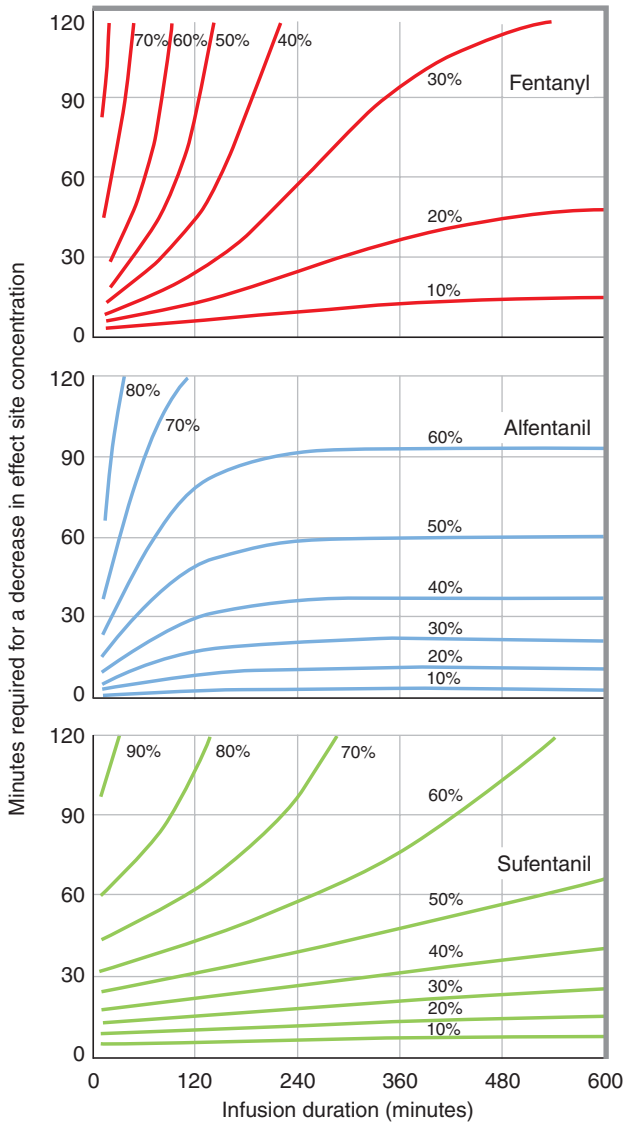

FIGURE 42–5. Recovery curves for fentanyl, alfentanil, and sufentanil showing the time required for decreases of a given percentage (labeled for each curve) from the maintained effect-site concentration after termination of the infusion. (Adapted with permission from Shafer SL, Varvel JR. Pharmacokinetics, pharmacodynamics and rational opioid selection. Anesthesiology 1990;74:53–63.)

CSHT means that most patients will achieve spontaneous ventilation within 3–5 minutes of stopping the infusion. However, there remains the *major* postoperative problem of how to provide adequate analgesia after the offset of action of the remifentanil. Although a number of strategies to overcome this have been suggested, several cases of abreaction-type responses to remifentanil have been described in the literature.[38,50]

Future trends in total intravenous anesthesia will probably be focused in several distinct areas. Firstly, there is need to develop kinetic models for patient populations other than the healthy adult (namely, the young, the elderly and those patients with comorbidities). One example is the Paedfusor for propofol administered to children.[1] An alternative will be further development of existing models to allow these covariates to be taken into account (as is presently the case when they are incorporated into TCI systems that use the Schnider kinetic model for propofol delivery).[98] Another major problem is obese patients as weight alone is a poor covariate against which to determine infusion rates or target drug concentrations.

New IV drug developments will include compounds with short context-sensitive half-times, and that are not significantly affected by any of the major comorbidities of renal or hepatic impairment, heart failure, or diabetes

mellitus. Other emphases will be on the development of hypnotic drugs with minimal cardiovascular and respiratory depression, no pain on injection, and, ideally, water soluble. New analgesics should not cause nausea and vomiting, or prolonged or delayed respiratory depression. Drugs fulfilling these desired kinetic and dynamic properties will probably be esterase-metabolized compounds similar to remifentanil; possible examples under development may include the hypnotic agent THRX-918661 (or TD 4756) and the benzodiazepine-like sedative drugs presently under development by CeNeS.

Patient-controlled TCI systems for sedation and analgesia have the potential to improve patient safety and satisfaction. The use of TCI remifentanil will probably become more widespread in the next few years.

Another development may be the further development of closed-loop control systems of anesthesia using biomarkers such as auditory-evoked potentials and the bispectral index to provide better control of the depth of sedation and anesthesia.[2,3,60,71,124] Indicators of the depth of analgesia may also be developed.

It is obvious that the development of TIVA has become a major technique in anesthetic practice only because of the availability of drugs with potent hypnotic or analgesic effects, minimal side effects, and kinetic profiles that allow easy and rapid titration to different noxious stimuli. There are still advances to be made, including the best and most accurate method of monitoring depth of anesthesia. Consequently, further developments should include focusing on monitoring for awareness in patients receiving TIVA for sedation or hypnosis.

CHAPTER 43

Cardiovascular Drugs

Alina Nicoara, MD, Mark Abel, MD, David Bronheim, MD, and Daniel Thys, MD

Cardiovascular disease is common in the general population, affecting the majority of adults past the age of 60 years; persons older than 65 years of age comprise the fastest growing segment of the population. For example, in 1994 there were 33.2 million persons age 65 years or older in the United States, nearly 500,000 (1.5%) of whom suffered a myocardial infarction. By the year 2030, there are expected to be more than 70 million persons in this age group, accounting for more than 1 million infarctions.[1]

No other life-threatening disease is as prevalent or expensive to society, and persons with cardiovascular pathology are likely to die from their disease. As advanced age and concurrent chronic diseases, including cardiovascular diseases, are no longer considered major restrictions to complex surgical procedures, we find ourselves taking care, as anesthesiologists, of sicker and older patients every year. These patients are frequently treated with several chronic medications, making optimal anesthetic management depend on an intimate

KEY POINTS

1. Patients with preoperative blood pressure elevation have exaggerated perioperative blood pressure fluctuations, which may be associated with electrocardiogram (ECG) evidence of myocardial ischemia. The American College of Cardiology/American Heart Association (ACC/AHA) Guidelines for Perioperative Cardiovascular Evaluation for Noncardiac Surgery recommend that antihypertensive medication be continued during the perioperative period. Particular care should be taken to avoid withdrawal of β-blockers and clonidine because of the potential for catastrophic withdrawal syndromes.
2. Recommendations for patients taking diuretics, call for withholding diuretics on the day of surgery unless evidence suggests volume overload or signs and symptoms of overt congestive heart failure (CHF). In stable patients with chronic mild-to-moderate hypokalemia without signs or symptoms of hypokalemia (e.g., muscle weakness, ileus, and nephropathy) and in the absence of dysrhythmias or digitalis use, anesthesia and surgery can proceed.
3. α_2-Agonists have many desirable effects such as minimum alveolar concentration (MAC) reduction, analgesia, anxiolysis, sedation, and sympatholysis. Recent studies evaluating the perioperative effect of α_2-agonists during noncardiac surgery show less perioperative myocardial ischemia. The ACC/AHA guidelines introduced the use of α_2-agonists as a class IIb recommendation for perioperative control of hypertension or risk reduction in patients with known coronary artery disease (CAD) or major risk factors for CAD.
4. During the perioperative period, patients maintained on angiotensin-converting enzyme (ACE) inhibitors and angiotensin II receptor blockers through the morning of the surgery have an increased number of hypotensive episodes requiring treatment with vasopressors.
5. Perioperatively, IV nitroglycerin may be used for treatment of myocardial ischemia, CHF, acute volume overload, systemic and pulmonary hypertension, and coronary artery spasm. It enhances blood flow to the subendocardium and areas of ischemia by both decreasing preload and left ventricular end-diastolic pressure and volume.
6. The recent focus on perioperative β-blockade has led to mounting evidence that their *prophylactic* use will reduce cardiac mortality and morbidity. β-Blockers reduce ischemia by decreasing myocardial oxygen demand caused by increased stress and catecholamine release in the perioperative period. The ACC/AHA guidelines state that whenever possible β-blockers should be started days or weeks before elective surgery in patients at risk for or with evidence of ischemia. The dose should be titrated to achieve a resting heart rate between 50 and 60 beats/min.
7. The calcium channel blockers represent a diverse group of compounds with dissimilar structures and pharmacologic effects. Unlike β-blockers, which all depend on blockade of receptors for their activity, the sites and mechanisms of action of the individual calcium channel blockers vary, as do their individual actions on different tissues.
8. Over the past decade, the use of most antidysrhythmic drugs has been reassessed and dramatically limited as a result of increased awareness of their proarrhythmic potential and advances in ablation techniques. Moreover, recent clinical trials have demonstrated negative effects on survival in many situations when these drugs may have been administered in the past. Finally, implantable cardiodefibrillators have largely replaced antidysrhythmic medications in the management of ventricular dysrhythmias.
9. Amiodarone is considered by some the most efficacious antidysrhythmic agent available; unfortunately, however, it is associated with a high incidence of side effects. In the intraoperative and postoperative settings, IV amiodarone may be used to treat a variety of ventricular and supraventricular arrhythmias. It may be used to convert new onset atrial fibrillation into sinus rhythm. In addition, its use is now advanced cardiac life support (ACLS) recommended for the treatment of pulseless ventricular tachycardia and ventricular fibrillation refractory to defibrillation, stable ventricular tachycardia, wide-complex supraventricular tachycardia, and atrial fibrillation.
10. Several studies have analyzed the effect of statin agents on perioperative cardiovascular mortality and morbidity in patients undergoing noncardiac surgery. Results of these studies, most of them retrospective, showed a reduction in perioperative cardiovascular events or mortality.

knowledge of the pharmacology and interaction of the cardioactive drugs with our anesthetic.

This chapter reviews frequently used cardiovascular medications and the anesthetic considerations associated with their use.

ANTIHYPERTENSIVES

Analysis of National Health and Nutrition Examination Survey data from 1999–2000 and United States Census bureau information revealed that there are 58–65 million hypertensives in the adult population in the United States.[2] Furthermore, as the population ages and the incidence of obesity increases, this number will continue to grow.

As many antihypertensive agents are currently available for treatment of essential hypertension, selection of one over another depends on the effectiveness of certain drugs within a given population, side effects, and concurrent diseases. For example, patients with hypertension and angina are frequently treated with regimens that include β-adrenergic blocking agents and calcium channel blockers. Hypertensive individuals with chronic obstructive pulmonary disease are managed with drugs that do not increase bronchial tone. Patients with hypertension and heart failure or renal insufficiency will usually be treated with angiotensin-converting enzyme inhibitors or angiotensin II receptor blockers. Certain medications are most useful in combination with a diuretic, whereas diuretics may exacerbate certain diseases (e.g., gout). In addition, patients often tolerate combinations of drugs in low doses better than single medications at higher doses.

Patients with preoperative blood pressure elevation have exaggerated perioperative blood pressure fluctuations, which may be associated with electrocardiogram (ECG) evidence of myocardial ischemia.[3] As perioperative myocardial ischemia has been linked to subsequent increased cardiac morbidity and mortality,[4] anesthesiologists have viewed preoperative control of blood pressure as optimal practice for over a generation. The American College of Cardiology/American Heart Association (ACC/AHA) Guidelines for Perioperative Cardiovascular Evaluation for Noncardiac Surgery guidelines for medical therapy recommend that antihypertensive medication be continued during the perioperative period. In addition, particular care should be taken to avoid withdrawal of β-blockers and clonidine because of the potential for catastrophic withdrawal syndromes.[5]

Diuretics

Patients with evidence of cardiovascular disease frequently are treated with a regimen that includes a diuretic for control of hypertension, for treatment of congestive heart failure (CHF) and fluid overload states, and for related diseases. Diuretics are among the most commonly used drugs. Table 43–1 lists dosage schedules and side effects for the more commonly prescribed diuretics.

Thiazides

Thiazide-type diuretics are the most frequently prescribed antihypertensive medications, because they reduce cardiovascular morbidity and mortality to a greater extent than other classes of medications. They are used as initial therapy for most patients with hypertension, either alone or in combination with one of the other classes (angiotensin-converting enzyme [ACE] inhibitors, angiotensin receptor blockers [ARBs], β-blockers, calcium channel blockers).[6] Thiazides act directly on the distal and connecting tubules to decrease sodium, chloride and water reabsorption.[7] This, however, is not the direct mechanism by which thiazides treat hypertension; chronically administered thiazides inhibit a maximal reabsorption of 3–5% of the filtered sodium, have little effect on cardiac output, and decrease plasma volume by only 5%. Blood pressure is directly lowered by arteriolar dilation that accompanies diuretic-induced sodium excretion. These drugs may be used in treatment of CHF, edema secondary to liver disease, diabetes insipidus, and urinary calculi in patients with hypercalciuria. Side effects may include hypokalemia, hypomagnesemia, hyperuricemia, hypocalcemia, hyperglycemia, metabolic alkalosis, hyponatremia, orthostatic hypotension, dysrhythmias, and gout.[8] Recently, studies suggest that lower-than-conventional doses of a thiazide diuretic might be effective, while producing no or only minor metabolic changes.[9]

Loop Diuretics

Furosemide, bumetanide, ethacrynic acid, and torsemide are unrelated chemically but act on the kidney at the level of the medullary and cortical aspects of the thick ascending limb of the Henle loop to prevent reabsorption of sodium, chloride, and water. This may not be the loop diuretics' sole effect. When given parenterally, furosemide causes systemic vasodilatation and reduction of left ventricular filling pressure before a diuretic effect is apparent. Loop diuretics are substantially more potent diuretics than thiazides and are indicated in treatment of acute and chronic CHF, as well as in treatment of edema of hepatic or renal origin. Loop diuretics are less effective than thiazides in treatment of hypertension, except when the hypertension is associated with chronic renal insufficiency. In this setting, fluid retention frequently plays a major role in the elevation in blood pressure and thiazides become less effective when the glomerular filtration rate (GFR) falls below 20 mL/min. Side effects include ototoxicity, hypokalemia, hypomagnesemia, hyperuricemia, metabolic alkalosis, dehydration, and hyponatremia. Treatment with loop diuretics may lower serum calcium levels. In combination with hydration, they are used in the acute therapy of hypercalcemia. Finally, loop diuretics have been used to decrease intracranial pressure and to convert acute oliguric renal failure to nonoliguric renal failure.[10]

Potassium-Sparing Agents

Spironolactone and eplerenone competitively inhibit the mineralocorticoid receptor. By inhibiting the effects of aldosterone on the nephron's distal convoluted tubule and collecting system, they decrease renal sodium absorption and potassium excretion. The potassium-sparing agents have relatively weak natriuretic activity, leading to the maximum excretion of only 1–2% of the filtered sodium.[11] Consequently, they are commonly used in combination with a loop or thiazide diuretic, either to diminish the degree of potassium loss or to increase the net diuresis in patients with refractory edema.[11] Spironolactone is particularly effective in patients with cirrhosis and ascites and improves survival in patients with heart failure when coadministered with conventional therapy.[12]

Triamterene and amiloride are also potassium-sparing diuretics. They are not aldosterone inhibitors but work

TABLE 43–1.

Diuretics

Agent	Usual Daily Dose (mg)	Precautions and Special Considerations	Side Effects
Thiazides and related sulfonamide diuretics			
Bendroflumethiazide	2.5–5	May be ineffective in renal failure except for indapamide and metolazone; hypokalemia increases digitalis toxicity; may cause an increase in blood levels of lithium; decrease urinary excretion of calcium; may precipitate acute gout	Hypokalemia, hypomagnesemia, hyperuricemia, glucose intolerance, insulin, hypercholesterolemia, increased low-density lipoprotein cholesterol, hypertriglyceridemia, hypercalcemia, sexual dysfunction, weakness, photosensitivity (except for ethacrynic acid), leucopenia, allergic skin rash
Benzthiazide (Exna)	12.5–50		
Chlorothiazide (Diuril)	125–500		
Chlorthalidone (Hygroton)	12.5–50		
Hydrochlorothiazide (HydroDIURIL, Esidrix)	12.5–100		
Hydroflumethiazide (Saluron, Dixardin)	12.5–50		
Indapamide (Lozol)	2.5–5		
Methychlothiazide	2.5–5		
Metolazone (Zaroxolyn)	2.5–5		
Polythiazide (Renese)	1–4		
Quinethazone (Hydromox)	25–100		
Trichlormethiazide	1–4		
Loop diuretics			
Bumetanide (Bumex)	0.5–5	Effective in chronic renal failure; increase urinary calcium excretion	As noted above, except for hypercalcemia
Ethacrynic acid (Edecrin)	25–100		
Furosemide (Latex)	20–320		
Torsemide (Demadex)	2.5–50		
Potassium-sparing agents			
Amiloride (Midamor)	5–10	Danger of hyperkalemia in patients receiving a potassium supplement, a potassium-containing salt substitute, or an angiotensin-converting enzyme inhibitor, and in patients with renal failure; can cause renal failure in patients treated with a nonsteroidal anti-inflammatory drug (indomethacin and triamterene) may increase blood levels of lithium; spironolactone interferes with digoxin immunoassay; danger of renal calculi (triamterene)	Hyperkalemia for all three agents; for spironolactone only: gynecomastia, mastodynia, gastrointestinal irritation, drowsiness, lethargy, irregular menses or postmenopausal bleeding, hirsutism
Spironolactone (Aldactone)	25–100		
Triamterene (Dyrenium)	50–200		
Eplerenone (Inspra)	50–100		

Modified with permission from Gifford RW. Treatment of patients with systemic arterial hypertension. In: Schlant RG, Alexander RW, eds. Hurst's The Heart. New York: McGraw-Hill, 1994:1430.

directly on distal convoluted tubules to prevent sodium–potassium exchange. As with spironolactone, triamterene and amiloride are used in combination with thiazides to treat hypertension and to reverse or prevent hypokalemia.[13] All these drugs may cause hyperkalemia.

Anesthetic Considerations

The major anesthetic considerations with diuretics pertain to their effects on fluid balance and electrolytes. Recommendations for patients taking diuretics, call for withholding diuretics on the day of surgery unless evidence suggests volume overload or signs and symptoms of overt CHF. Because intravascular volume may be decreased after diuretic administration, physical examination should include careful evaluation of vital signs, with particular attention to orthostatic blood pressures and other signs or symptoms of dehydration. If hypovolemia goes unrecognized, anesthetic induction may result in significant hypotension and tachycardia.

Diuretics can cause profound electrolyte disturbances, and serum electrolyte levels must be verified preoperatively. Patients receiving chronic therapy with loop diuretics or thiazides may have decreased total body potassium and evidence of low serum potassium levels. Chronic use of potassium-wasting diuretics, especially in patients with hypokalemia, is associated with increased incidence of dysrhythmias.[14] Rapid correction of mild-to-moderate hypokalemia before surgery in asymptomatic patients is not indicated for the following reasons:

1. Acute replacement may itself be dangerous and cause life-threatening hyperkalemia.
2. Little can be done to rapidly correct total body potassium. (The differ-

TABLE 43–2.

Centrally Acting α_2-Adrenoreceptors Agonists

Agent	Dosage (mg)	Duration of Action (hours)	Elimination
Clonidine	0.1–1.0 BID	6–12	Hepatic/renal
Clonidine TTS (patch)	3.5, 7.0, 10.5 cm² weekly	7 days	Hepatic/renal
Dexmedetomidine	IV: 1 μg/kg loading dose over 10 min; maintenance 0.2–0.7 μg/kg/h		Hepatic
Guanabenz	4–64 BID	6–12	Hepatic
Guanfacine	1–3 daily	12–24	Renal
α-Methyldopa	250–1000 BID	6–12	Renal/hepatic

ence between a serum potassium level of 2.5 mEq/L and 3.5 mEq/L may be 200–400 mEq in a 70-kg individual.)

3. Some studies suggest that chronic hypokalemia does not increase the incidence of intraoperative dysrhythmias.[15]
4. In stable patients with chronic mild to moderate hypokalemia without signs or symptoms of hypokalemia (e.g., muscle weakness, ileus, and nephropathy), and in the absence of dysrhythmias or digitalis use, anesthesia and surgery can proceed.

Diuretics enhance the effects of neuromuscular blocking agents.[16]

Centrally Acting α_2 Agonists

Table 43–2 lists the centrally acting α_2 agonists.

Clonidine

Clonidine is an antihypertensive agent with a complex mode of action. Its major effect is to activate central α_2 receptors and reduce norepinephrine (NE) release by peripheral sympathetic nerve terminals. This leads to a 60–80% reduction of sympathetic outflow and catecholamine levels. Part of the antihypertensive effect of clonidine is a result of its action as an agonist of the imidazoline-1 receptors located in the rostral ventrolateral medulla, a vasopressor area of the descending reticular formation.[17] Clonidine decreases heart rate, systemic vascular resistance, plasma renin activity, and epinephrine and norepinephrine levels. Side effects include orthostatic hypotension, sedation, dry mouth, and dizziness. Clonidine is notable in that sudden discontinuation may result in a severe withdrawal syndrome, which includes rebound hypertension or hypertensive crisis. Restlessness, insomnia, agitation, nausea, and sweating may also occur. These disturbances usually occur 18–36 hours after the last dose. The transdermal clonidine patch allows continued administration in those unable to take oral medication, thereby avoiding withdrawal. Administered orally, clonidine reaches peak plasma concentrations in approximately 90 minutes, whereas when administered topically, it takes approximately 2–3 days to reach therapeutic levels. The clonidine patch is available in 3.5, 7.0, and 10.5 cm sizes, equivalent to oral doses of 0.1, 0.2, and 0.3 mg/d, respectively. Clonidine may also be administered via the intrathecal or epidural route to enhance the efficacy of regional anesthesia.

α_2-Agonists have many desirable effects, such as minimum alveolar concentration (MAC) reduction, analgesia, anxiolysis, sedation, and sympatholysis.[18,19] In this vein, clonidine decreases the intraoperative requirements for isoflurane[20] and narcotics, and improves hemodynamic stability.[21] In addition, clonidine attenuates sympathetic outpouring during drug addiction withdrawal, although there are insufficient data to support their clinical use.[22] Several recent studies evaluating the perioperative effect of clonidine during noncardiac surgery showed less perioperative myocardial ischemia.[23,24] Although evidence supporting the routine use of α_2-agonists is not as compelling as that for perioperative β-blockade, the ACC/AHA guidelines introduced the use of α_2-agonists as a class IIb recommendation for perioperative control of hypertension or risk reduction in patients with known coronary artery disease (CAD) or major risk factors for CAD.[5] Unfortunately, the effects of clonidine are long acting and are not quickly reversed if severe hypotension or bradycardia develops. Recently, there has been resurgence in interest in clonidine because of its analgesic properties, both alone and in combination with other agents.

Dexmedetomidine

Dexmedetomidine is a highly selective α_2-adrenergic receptor agonist (an α_2-to-α_1 selectivity ratio of 1600:1) with pharmacologic properties similar to clonidine. It decreases sympathetic tone with associated decreases in heart rate and blood pressure. Like clonidine, it produces anxiolysis, and sedation with minimal respiratory depression.[25] Dexmedetomidine and other α_2-agonists are known to interrupt nociceptive processing in the periphery, in the spinal cord, and in supraspinal sites, thereby explaining its analgesic properties.[26]

Dexmedetomidine is administered as a continuous intravenous infusion and its dosage should be individualized and titrated to the desired clinical effect. In adult patients, treatment is generally initiated with a loading infusion of 1 μg/kg over 10 minutes, followed by a maintenance infusion of 0.2–0.7 μg/kg/h. The rate of the maintenance infusion is adjusted to achieve the desired level of sedation. It is not indicated for infusions lasting longer than 24 hours. When dexmedetomidine is administered chronically and discontinued abruptly, withdrawal symptoms similar to those reported for clonidine (e.g., nervousness, agitation, headache, rapid rise in blood pressure) may result.[27] Transient hypertension has occurred during the administration of the loading dose in association with the initial peripheral vasoconstrictive effects of higher concentrations of dexmedetomidine because of activation of α_2-adrenoceptor located on smooth muscle cells in the resistance vessels.[28] Treatment of this hypertension is not usually necessary, although reduction of the loading infusion rate may be beneficial. Dexmedetomidine may result in hypotension and bradycardia consistent with its mechanism. Like clonidine, dexmedetomidine may decrease MAC by up to 50%, thus reducing anesthetic requirements.[29] Because of its sedative–analgesic properties, it has found

TABLE 43–3.

α-Adrenergic Blocking Agents

Agent	Dosage (mg)	Duration of Action
Prazosin	1–10 BID	4–8 h
Terazosin	1–20 daily	12–24 h
Doxazosin	1–16 daily	24 h
Phenoxybenzamine	10–40 BID or TID	3–4 days
Phentolamine	IV: bolus 30–70 μg/kg, maintenance 1–20 μg/kg/min	10–15 min

application in managing the difficult airway,[30] in providing anesthesia for awake procedures,[31,32] and for sedation and ventilator weaning in ICUs.

Mivazerol

Mivazerol, another intravenous α_2-agonist that is administered by continuous infusion (α_2-to-α_1 receptor selectivity of 119:1), also has been studied for perioperative myocardial protection.[33,34]

α-Methyldopa

α-Methyldopa is an antihypertensive agent that was widely used in the past. Its major pharmacologically active metabolite, α-methylnorepinephrine, is a potent α_2-agonist that stimulates brainstem postsynaptic α_2 receptors. This decreases sympathetic tone and systemic vascular resistance.[35] As with clonidine, α-methyldopa should be used with diuretics to prevent tolerance secondary to volume expansion. Common side effects include orthostatic hypotension, dizziness, sedation, dry mouth, nasal congestion, headache, and impotence. Less common, but more serious, side effects include leukopenia, hepatitis, thrombocytopenia, and a lupus-like syndrome. Rebound syndromes may occur following discontinuation of α-methyldopa, but much less frequently than with clonidine. Patients unable to take oral medications postoperatively may receive α-methyldopa intravenously.

Guanabenz and Guanfacine

Guanabenz and guanfacine are centrally acting agonists with modes of action and anesthetic considerations similar to those of clonidine, including similar withdrawal syndromes.[36]

Peripherally Acting Sympatholytic Agents

α-Adrenergic Blockers

Table 43–3 lists α-adrenergic blocking agents.

Prazosin, terazosin, and doxazosin competitively block postsynaptic α_1-adrenergic receptors in vascular smooth muscle, their main cardiovascular action being arterial and venous dilation. They reduce blood pressure with little effect on cerebral and renal vascular blood flow or heart rate. Virtual absence of tachycardia makes them more useful than the nonselective α-blockers such as phentolamine. Prazosin, terazosin, and doxazosin have been used for treatment of hypertension and for afterload reduction in patients with CHF. Today, these drugs are most commonly and successfully used for the treatment of benign prostatic hypertrophy.[37] Side effects include orthostatic hypotension, dizziness, and even frank syncope after the initial dose, especially in patients already receiving other antihypertensive medications. Side effects may be significantly reduced by the administration of small initial doses. Subsequent dosages are generally well tolerated.[38] Other, less-common side effects include palpitations, headaches, sedation, dry mouth, gastrointestinal symptoms, tachycardia, and edema. As with clonidine and minoxidil, a diuretic must be added to prevent fluid retention when these drugs are used as antihypertensive agents.

Phenoxybenzamine and phentolamine are noncompetitive, nonselective antagonists. Whereas phenoxybenzamine has a half-life of 24 hours, phentolamine has duration of action of 10–15 minutes, making it suitable for continuous intravenous infusion. Phenoxybenzamine is predominantly used for long-term control of hypertension associated with pheochromocytomas. Phentolamine is used intravenously for perioperative management of hypertension associated with pheochromocytomas[39] and for reversal of deleterious effects secondary to drug extravasation (i.e., norepinephrine, dopamine).[40] Common side effects of these drugs include hypotension and tachycardia. Tachycardia occurs secondary to baroreceptor reflex activation and blockade of the presynaptic α_2-receptors interfering with the normal feedback inhibition of norepinephrine release. This tachycardia responds to β-blockers.

Adrenergic Neuronal Blocking Agents

Guanethidine and guanadrel are antihypertensive agents more often used in the past. They have limited current use because of availability of drugs with fewer side effects. They are selective inhibitors of postganglionic adrenergic neurons; however, their exact mechanism of action is incompletely understood. Guanethidine must be actively transported into the neuron, where it accumulates in neuronal storage vesicles and causes norepinephrine storage depletion. Although norepinephrine stores are depleted, guanethidine's antihypertensive effect does not actually depend on this depletion. Its major mode of action may be to inhibit nerve pulse transmission at the outer neuronal or vesicular membrane. With chronic administration, peripheral vascular resistance decreases.

Side effects include expansion of intravascular volume, necessitating its use with a diuretic, as well as orthostatic and exercise-induced hypotension, diarrhea, and sexual dysfunction. Tricyclic antidepressants, amphetamines, chlorpromazine, and ephedrine may interfere with its effectiveness by their effects on guanethidine's uptake mechanism. Guanethidine is contraindicated in patients with pheochromocytomas and should not be given to those receiving monoamine oxidase (MAO) inhibitors.

The anesthetic implications of guanethidine involve the decrease in norepinephrine concentration, which may cause the pharmacologic equivalent of denervation hypersensitivity. Therefore, direct-acting sympathomimetics may cause exaggerated hemodynamic responses. Decreased norepinephrine neuronal tissue stores render indirect-acting agents (e.g., ephedrine) less effective.[41]

Reserpine is a *Rauwolfia* alkaloid, which was the first effective antihypertensive agent. It exerts its antihypertensive effect at the postganglionic neuron. It is thought that reserpine's mode of action is related to inhibition of norepi-

TABLE 43–4.

Direct Acting Vasodilators

Agent	Dosage	Duration of Action
Minoxidil	PO: 10–40 mg daily	8–12 h
Hydralazine (PO)	PO: 40–300 mg daily	6–12 h
Hydralazine (parenteral)	IV: 2.5–10 mg q 20–30 min, max 30–40 mg IM: 10–20 mg q 4–6 h	4–8 h

nephrine and dopamine uptake into terminal vesicles, resulting in increased norepinephrine degradation and decreased conversion of dopamine to norepinephrine. Reserpine crosses the blood–brain barrier and decreases central nervous system (CNS) serotonin and dopamine. Although this effect is thought to be unrelated to its antihypertensive effect, it may be the mechanism by which reserpine causes depression, nightmares, and sedation. Because of vasodilatation, this drug may increase intravascular volume; consequently, diuretic use is mandatory. As with guanethidine, reserpine-induced depletion of norepinephrine stores renders ephedrine and indirect-acting agents less effective, whereas effects of direct-acting agonists may be accentuated.[41]

Vasodilators

Table 43–4 lists direct-acting vasodilators.

Hydralazine

Hydralazine is one of the oldest antihypertensives still in use. It is a direct arteriolar vasodilator with little or no effect on the venous circulation. Although ACE inhibitors and angiotensin receptor (ATR) blockers have largely usurped its use, hydralazine is still used in patients who cannot tolerate these other agents, during pregnancy, and intravenously. Several mechanisms of action have been proposed for its direct action on arteriolar smooth muscle, including preventing the accumulation of intracellular free Ca^{2+},[42] promoting influx of potassium,[43] and increasing nitric oxide (NO) production.[44]

In response to arteriolar vasodilatation, a baroreceptor-mediated increase in plasma volume, heart rate, cardiac output, and stroke volume often occurs accompanied sometimes by vasodilatory edema. As a result, β-blockers and/or diuretics are given concurrently to minimize reflex sympathetic stimulation and fluid retention. The addition of an ACE inhibitor or ARB could be more beneficial than a diuretic in controlling the vasodilatory edema if the individual patient[11,45] tolerates these agents. Additional side effects include palpitations, headaches, flushing, and nasal congestion, and in patients with coronary artery disease, worsening angina. Because hydralazine is metabolized by acetylation in the liver, in higher dosages, especially in slow acetylators, it may cause a lupus-like syndrome, which is completely reversible on discontinuation. It may be given by oral, IV, or intramuscular (IM) routes, and may be used in the treatment of hypertension, CHF, and preeclampsia.[46] Perioperatively, hydralazine is titrated intravenously for control of hypertension. Because it may take up to 30 minutes for an intravenous dose of hydralazine to exert its full effect, it should be administered in doses divided by appropriate time intervals.

Minoxidil

Minoxidil, like hydralazine, is a direct arterial vasodilator that has no effect on the venous circulation. It acts by opening adenosine triphosphate-sensitive potassium channels in vascular smooth muscle cells.[47] It is used to control hypertension resistant to multidrug regimens.[48] Like hydralazine, minoxidil may increase heart rate and cause fluid retention. To minimize these effects, it is generally administered with a diuretic and a β-blocker. Other side effects include facial hirsutism, hypertrichosis, and, infrequently, pericardial effusion.[49]

Sodium Nitroprusside

Sodium nitroprusside (SNP) dilates both arterioles and veins, and is one of the most effective parenteral drugs for treatment of hypertensive emergencies and acute congestive heart failure. In contrast to the organic nitrates, which require the presence of highly specific thiol-containing compounds to generate NO, SNP spontaneously generates this product.[50] In vascular smooth muscle, NO activates the enzyme guanylate cyclase resulting in increased intracellular cyclic guanosine monophosphate (cGMP), which inhibits calcium entry into the smooth muscle cell and may increase calcium uptake by the endoplasmic reticulum producing vasodilatation.[51]

While dissociating to produce NO, SNP interacts with oxyhemoglobin to produce cyanmethemoglobin and cyanide ions.[52] The cyanide ions are converted to thiocyanate via transsulfuration within the liver by the enzyme rhodanese, which uses thiosulfate ions as sulfur donors. In the face of SNP infusion rates exceeding 2 μg/kg/min, sulfur donors and methemoglobin are exhausted and cyanide radicals may accumulate, producing clinical cyanide toxicity by binding and inactivating tissue cytochrome oxidase. This prevents oxidative phosphorylation, thus producing tissue hypoxia and cell death despite adequate available oxygen. Because availability of thiosulfate is the rate-limiting step in cyanide metabolism, a concomitant infusion of sodium thiosulfate is advocated to prevent toxicity.[53] Thiocyanate itself can cause toxicity in patients with impaired renal function, but only at concentrations that are seldom reached. Other agents used in the treatment of cyanide toxicity are sodium nitrite, which converts hemoglobin in methemoglobin and hydroxocobalamin. Both methemoglobin and hydroxocobalamin bind cyanide radicals, forming cyanmethemoglobin and cyanocobalamin, respectively.

SNP produces direct venous and arterial vasodilatation with a dose-dependent decrease in blood pressure and a marked decrease in systemic vascular resistance (SVR). It produces pulmonary vasodilatation, decreases pulmonary vascular resistance (PVR), and directly inhibits hypoxic pulmonary vasoconstriction (HPV). The effect on cardiac output is dependent on end diastolic volume. With increased end diastolic volumes, such as one may see in patients with CHF, cardiac output may increase, whereas with normal volumes, cardiac output may be unchanged. SNP can produce "coronary steal" with shunting of blood

away from areas of ischemia.[54] In addition, although SNP appears to impair platelet aggregation via NO[55] in a dose-related manner, the duration of the effect is apparently limited to 5–25 minutes. The clinical importance of this effect has been questioned, as studies have not shown an increase in blood loss or blood transfusions with the use of SNP.[56]

SNP has an immediate onset and a very short duration of action (1–2 minutes), permitting very precise titratability and reliability.

SNP is a popular agent for induced intraoperative hypotension. Concern regarding its toxicity has prompted many anesthesiologists to supplement SNP with β-adrenergic blockers, calcium channel blockers, nitroglycerin, or volatile agents so as to maintain a rate of SNP infusion of less than 2 μg/kg/min. SNP has also found use in hypertensive emergencies, management of acute and congestive heart failure, pheochromocytomas, and blood pressure control during cardiac and aortic surgery.[52]

Other Vasodilators

Fenoldopam Fenoldopam, the first selective dopamine type 1 (DA1) receptor agonist, is approved for short-term (up to 48 hours) intravenous management of severe hypertension in hospitalized patients. It is a slightly more potent agonist than dopamine at the DA1 receptors, but does not act as an agonist at dopamine type 2 (DA2) receptors or at α and β receptors.[57]

Fenoldopam decreases blood pressure without increasing heart rate and cardiac contractility. It dilates a variety of arteries, including coronary arteries, afferent and efferent arterioles of the kidney, and mesenteric arteries.[57] Consequently, it increases renal blood flow,[58] creatinine clearance, urinary flow, and sodium excretion.[59] Fenoldopam can be safely used in hypertensive emergencies, and may be particularly beneficial in patients with renal insufficiency. The infusion is initiated at 0.1 μg/kg/min and the dose titrated at 15-minute intervals, depending on the blood pressure response. Although fenoldopam may be considered for control of perioperative blood pressure, agents such as nitroprusside are more titratable and may confer better minute-to-minute blood pressure control during the perioperative period.

Fenoldopam should be given cautiously to patients with glaucoma or high intraocular pressure as it may increase intraocular pressure.[57] Side effects are related to the vasodilator effect, mainly headache, dizziness, tachycardia, or bradycardia.[57]

Because of its renoprotective properties, numerous studies have investigated the usefulness of fenoldopam as prophylaxis for acute renal failure in cardiac surgery with cardiopulmonary bypass or liver transplantation. Results have been controversial: while some studies suggested that renal function was preserved in patients at increased risk for renal dysfunction after cardiac surgery or liver transplantation when low-dose fenoldopam was used in the perioperative period,[60–62] others have shown no difference in the clinical outcome compared with dopamine.[63]

Eicosanoids Prostaglandin E_1 (PGE_1) and prostacyclin (PGI_2) are direct vasodilators acting on specific prostanoid receptors on vascular smooth muscle. Although they produce reductions in the systemic vascular resistance, their most common clinical use in adults is for their effects on the pulmonary vasculature. PGE_1 is used in neonates and infants to selectively dilate and maintain the patency of the ductus arteriosus. PGI_2 is used for the long-term treatment of primary pulmonary hypertension.[64]

Angiotensin-Converting Enzyme Inhibitors

Table 43–5 lists ACE inhibitors.

ACE inhibitors have been successfully used in the management of hypertension, renal insufficiency, and congestive heart failure. They are generally well tolerated, producing few idiosyncratic side effects. They competitively inhibit the enzyme that converts angiotensin I to the potent vasoconstrictor, angiotensin II (Fig. 43–1). This decrease in plasma angiotensin II causes vasodilatation of both venous capacitance and arteriolar resistance vessels without reflex increases in heart rate.

ACE inhibitors also decrease aldosterone levels, potentiate the vasodilating kallikrein–kinin system and may affect prostaglandin levels. Side effects include hypotension, acute renal failure, and hyperkalemia.[65] Other complications, including cough, bronchospasm, angioneurotic edema, and anaphylactoid reactions, are believed to be related to increased kinin levels because ACE is also kininase. Precipitous reductions in blood pressure may occur following initiation of therapy, particularly in hypovolemic patients.

In those with normal renal function ACE inhibitors generally raise plasma potassium concentrations by less than 0.5 mEq/L. More prominent hyperkalemia may be seen in patients with renal insufficiency, concurrent use of a potassium-sparing diuretic or a nonsteroidal antiinflammatory drug, and in the elderly.[66] Declines in renal function occur in patients with bilateral renal artery stenosis, hypertensive nephrosclerosis, congestive heart failure, polycystic kidney disease, or chronic renal insufficiency. Nevertheless, as a result of the favorable effects on the progression of diabetic[67] and nondiabetic renal disease, an increase in serum creatinine of as much as 35% above baseline is acceptable, unless hyperkalemia develops.[68]

TABLE 43–5.

Angiotensin-Converting Enzyme Inhibitors

Agent	Dosage	Duration of Action (hours)	Elimination
Captopril	12.5–50 mg BID-TID	4–8	Renal
Enalapril	5–20 mg BID	12–24	Renal
Enalaprilat	1.25 mg IV QID	6	Renal
Lisinopril	10–40 mg daily	24	Renal
Benazepril	10–40 mg daily BID	24	Renal/hepatic
Fosinopril	10–40 mg daily BID	24	Renal/hepatic
Quinapril	5–80 mg daily BID	24	Renal/hepatic
Ramipril	1.25–20 mg daily BID	24	Renal/hepatic
Moexipril	7.5–30 mg daily BID	>24	GI tract/hepatic
Perindopril	4–8 mg daily BID		Renal/hepatic
Trandolapril	2–4 mg daily	72	Renal

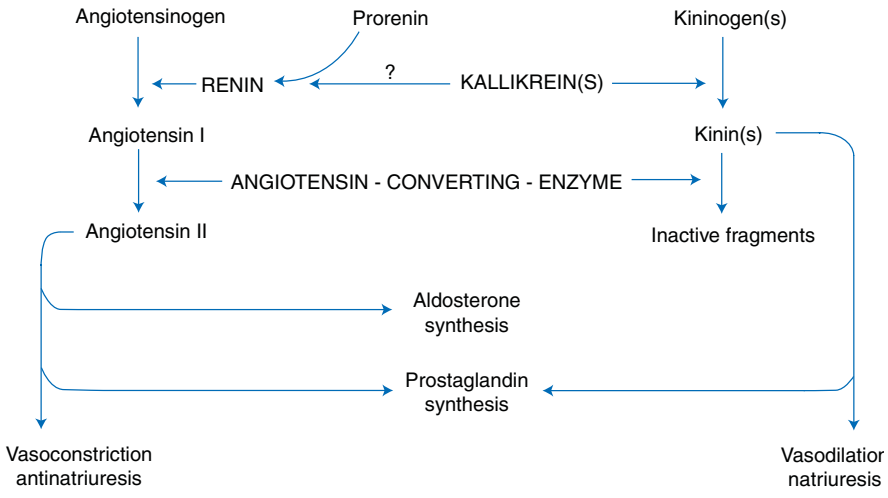

FIGURE 43–1. Schematization of the renin–angiotensin–aldosterone system and the kallikrein–kinin system and their interaction with the angiotensin-converting enzyme. (Reproduced with permission from Borek M, Charlap S, Frishman WH. Enalapril. Pharmacotherapy 1987;7:135.)

In addition to lowering blood pressure, ACE inhibitors decrease progression of cardiac dysfunction in heart failure, decrease the progression of chronic renal disease,[69] improve survival after myocardial infarction with reduced systolic function, and induce regression of left ventricular hypertrophy.[70] Consequently, they are frequently the antihypertensive of choice.[6] It has also been shown that increased kinin levels may increase insulin sensitivity, which can lower the blood glucose in patients with type 2 diabetes.[71]

During the perioperative period, patients maintained on ACE inhibitors through the morning of the surgery have increased numbers of hypotensive episodes that require treatment with vasopressors.[72]

Angiotensin II Receptor Blockers

Table 43–6 lists the angiotensin II receptor blockers.

There are two well-described subtypes of angiotensin II receptors, designated AT1 and AT2, both of which have a high affinity for angiotensin II.[73] The AT1 subtype mediates the vasoconstrictor effect of angiotensin II and may mediate angiotensin II-induced growth in the left ventricle and the arterial wall. The AT2 receptor has a less-well-understood role.

ARBs are selective blockers of AT1 receptors on the cell membrane.[74]

The ARBs have been primarily evaluated for the treatment of hypertension, where they appear to have an effect similar to monotherapy with other antihypertensive drugs, including ACE inhibitors. In fact, ARBs are more effective than β-blockers in reducing the long-term risk of cardiovascular morbidity and mortality.[75] ARBs prolong survival in heart failure[76–78] in patients with systolic heart failure who cannot tolerate ACE inhibitors,[76] and in those treated with both ARBs and ACE inhibitors.[77,78] Two major trials demonstrated a clear benefit in renal protection with ARBs in patients with nephropathy caused by type 2 diabetes, although these trials did not compare ARBs with ACE inhibitors.[79,80]

The angiotensin II receptor blockers are generally well tolerated. They exhibit side effects similar to ACE inhibitors, with the exception of those mediated by kinins, particularly cough, which is the most common reason that patients discontinue ACE inhibitors. Unlike ACE inhibitors, they are effective and safe in the treatment of hypertensives with symptomatic asthma.[81] It should be recognized, however, that multiple cases of angioedema have been described in patients taking losartan, typically characterized by swelling of the mouth, tongue, pharynx, and eyelids, and occasional laryngeal obstruction.[82] Consequently, physicians should proceed with caution when choosing an antihypertensive for patients who have discontinued ACE inhibitors because of angioedema.

As with ACE inhibitors, patients taking ARBs might be more prone to developing intraoperative hypotension.[83] A study in vascular surgery patients found a statistically significant increase in the number of hypotensive episodes in patients who were treated with ARBs prior to surgery compared with those patients who were treated with β-blockers or calcium channel blockers.[84]

DIGITALIS

More than 200 years after William Withering published "An account of the foxglove and some of its medical uses," digoxin remains a mainstay of cardiac therapeutics.

The mechanism of action of the cardiac glycosides is unique. They bind to and directly inhibit the membrane-bound sodium-potassium adenosine triphosphatase (ATPase) pump of the myocardial cell, causing increased intracellular sodium and decreased intracellular potassium. The increase in intracellular sodium changes the sodium concentration gradient and produces decreased exchange of extracellular sodium for intracellular calcium. This leads to net increased inward calcium current and intracellular calcium concentration, resulting in enhanced isolated myocyte contractile performance (increased shortening velocity) and left ventricular (LV) systolic function. Digitalis remains the most prominent

TABLE 43–6.

Angiotensin II Receptor Blockers

Agent	Dosage	Half-Life (hours)
Losartan	50–100 mg daily BID	6–9
Valsartan	80–320 mg daily BID	9
Irbesartan	150–300 mg daily BID	11–15
Telmisartan	40–80 mg daily BID	24
Candesartan	16–32 mg daily BID	3–11
Eprosartan	400–800 mg daily	5–7

inotrope available for chronic oral use and has been shown clinically to decrease symptoms of CHF as well as the number of hospitalizations.[85,86] Unlike all other inotropes, digitalis use is not associated with increased mortality.[87]

Cardiac glycosides have substantial electrophysiologic effects. Digitalis substantially enhances parasympathetic tone while causing some decrease in cardiac sympathetic activity. These effects are why digitalis is efficacious in treatment of supraventricular dysrhythmias.[88] By affecting the sodium-potassium ATPase pump, digitalis may also have effects on conduction that are independent of vagal tone. In normal subjects, digoxin has only a small effect on the sinoatrial (SA) node. It may be safely used in patients with sinus bradycardias without decreasing heart rates. However, patients with evidence of sick sinus syndrome given digitalis may have lengthened SA node conduction and recovery times.[89]

The major effects of digitalis on atrial and atrioventricular (AV) node tissue are also vagally mediated. In humans, therapeutic dosages decrease conduction velocity and either have no effect or increase effective atrial refractory period. Digitalis causes prolongation of both conduction time and the AV node's effective refractory period. In the accessory pathway of patients with Wolff-Parkinson-White (WPW) syndrome, digitalis may shorten the refractory period of the antegrade pathway[90] without affecting the retrograde pathway. Consequently, it should not be used in patients with WPW syndrome. In the ventricle, digitalis shortens the effective refractory period while having little indirect effect.

Digitalis possesses a very low therapeutic index. At toxic levels, in addition to causing anorexia, nausea, fatigue, visual disturbances, and confusion, digitalis may cause severe conduction disturbances. The ECG manifestations may include sinus bradycardia or SA node exit block, AV block, premature atrial contractions, junctional tachycardias, premature ventricular contractions, ventricular tachycardia, and fibrillation.

Certain factors, such as renal insufficiency, electrolyte abnormalities (hypokalemia, hypomagnesemia and hypercalcemia), hypothyroidism, pulmonary disease, and pharmacokinetic interactions with other drugs that can affect digoxin metabolism (quinidine, cyclosporine, verapamil, rifampin), can increase the risk of digitalis intoxication.

Treatment of digitalis toxicity can include several measures, ranging from simply stopping further dosages to aggressively treating hypokalemia and hypomagnesemia, oral therapy with activated charcoal, or placement of a transvenous pacemaker in patients with symptomatic bradycardia or AV dissociation. It has been suggested, however, that transvenous cardiac pacing might precipitate cardiac dysrhythmias and deterioration, and should, if possible, be avoided.[91] Atrial, junctional, and ventricular ectopy are amenable to therapy with phenytoin or procainamide. Ventricular ectopy is usually treated successfully with lidocaine. Anecdotal data suggest that magnesium, bretylium, and amiodarone may suppress severe life-threatening dysrhythmias although amiodarone itself may increase digoxin levels by 100%. In general, drugs that increase serum digitalis levels (e.g., quinidine, propafenone, verapamil) and administration of calcium salts should be avoided.

The availability of digoxin-specific Fab fragments has dramatically changed therapy for severe toxicity. The Fab fragments bind to digoxin intravascularly and in the tissues. The digoxin-Fab fragments complexes are small, so can be rapidly excreted by glomerular filtration in patients with normal renal function. Multiple studies show favorable response to digoxin-specific antibody fragments.[92]

The therapeutic indication for digitalis use is to control heart rate in atrial fibrillation or flutter, and symptomatic management of congestive heart failure.

The usual dose of digoxin is about 0.25 mg/d, with half that dose prescribed for the elderly (age > 65) and patients with renal insufficiency. When acute therapy is necessary, a loading dose of 1–1.5 mg is given over 24 hours. Digoxin-induced arrhythmias and other toxic manifestations occur at progressively increasing frequency as the plasma digoxin concentration rises above 2.0 ng/mL, the upper limit of normal.

Dysrhythmias occur often during the perioperative period. In patients receiving digitalis therapy, the possibility of digitalis toxicity as the dysrhythmia source must always be considered. This could delay introduction of drugs (e.g., verapamil) that substantially increase serum digitalis levels or delay use of cardioversion, which may precipitate ventricular fibrillation in the presence of digitalis toxicity. These considerations become even more significant when one realizes that powerful inotropes and antidysrhythmics with shorter half-lives than digitalis are available for acute administration if necessary.[93]

Some data suggest that halothane, enflurane, ether, methoxyflurane, ketamine, droperidol, and curare may reduce the likelihood of digitalis-induced ventricular dysrhythmias. Thiopental and fentanyl have no effect, whereas succinylcholine, neostigmine, and diazepam may induce dysrhythmias in patients taking digitalis. No reports are available regarding the interaction of digoxin with sevoflurane or desflurane to our knowledge. More important to any discussion of digitalis-associated dysrhythmias and toxicity is prevention of hypokalemia, acid–base imbalance, hypoxia, hypercalcemia, and catecholamine excess states, and avoidance of medications that acutely increase digitalis serum levels.[94]

ANTIANGINALS

Three groups of drugs—nitrates, β-adrenergic blocking agents, and calcium channel blockers—alone or in combination, are effective and are commonly used to manage angina. Choosing a class of drugs, or a particular drug within each class, depends primarily on patient tolerance of side effects, ventricular function, presence or absence of conduction disease, and relative indications or contraindications caused by additional illnesses.

Nitrates

Nitrates in many forms have been used in treatment and prevention of angina for more than 100 years. Nitrates are potent dilators of the vascular smooth muscle that affect venous capacitance more than arterial resistance.[95]

Other hemodynamic effects include decreases in left ventricular end-diastolic pressure, pulmonary artery pressure, pulmonary vascular resistance, and right ventricular end-diastolic pressure. Decreases in mean arterial pressure are usually slight and smaller than the other hemodynamic parameters. Low doses have little effect on cardiac output and heart rate in

patients with normal or increased intravascular volume. Rapid administration or high doses of nitrates, especially in patients with volume-contracted states, may decrease left ventricular end-diastolic pressure, stroke volume, cardiac output, and mean arterial pressure, and cause reflexive increases in heart rate and sympathetic tone.[95] Nitroglycerin inhibits hypoxic pulmonary vasoconstriction, but to a lesser extent than nitroprusside.

The antianginal use of nitroglycerin stems from its effect on the relationship between myocardial oxygen supply and demand. By increasing venous capacitance, and thus decreasing left ventricular end-diastolic pressure and volume, nitroglycerin decreases systolic ventricular wall tension, which is the major determinant of myocardial energy consumption.

An additional benefit of nitrates is improved flow to areas of ischemia. This effect is related to higher myocardial perfusion pressure, resulting from lower left ventricular diastolic pressure and redistribution of coronary blood flow to subendocardial tissue. This results in an increased endocardial-to-epicardial flow ratio, and probably in a decreased resistance to collateral blood flow.

Nitroglycerin is a direct coronary arterial vasodilator; especially of large epicardial vessels.[96] Dilation of large coronary arteries explains the beneficial effects of nitrates in patients with angina caused by coronary vasospasm. In patients with classic angina caused by coronary insufficiency, net coronary blood flow does not increase following administration of nitroglycerin. It has been postulated that dilation of large epicardial vessels or improvement of cardiac perfusion pressures causes an autoregulated increase in coronary vascular resistance in well-perfused arteriolar resistance vessels distal to large coronary arteries. This increased resistance shunts coronary flow to areas of ischemia where the arterioles are already maximally dilated. Effects of nitrates on coronary blood flow distribution are different (indeed opposite) from those of sodium nitroprusside and dipyridamole. The latter drugs dilate arteriolar resistance vessels and can lead to myocardial steal phenomena.

Nitroglycerin's effects on both systemic and coronary circulations are important. For example, intracoronary

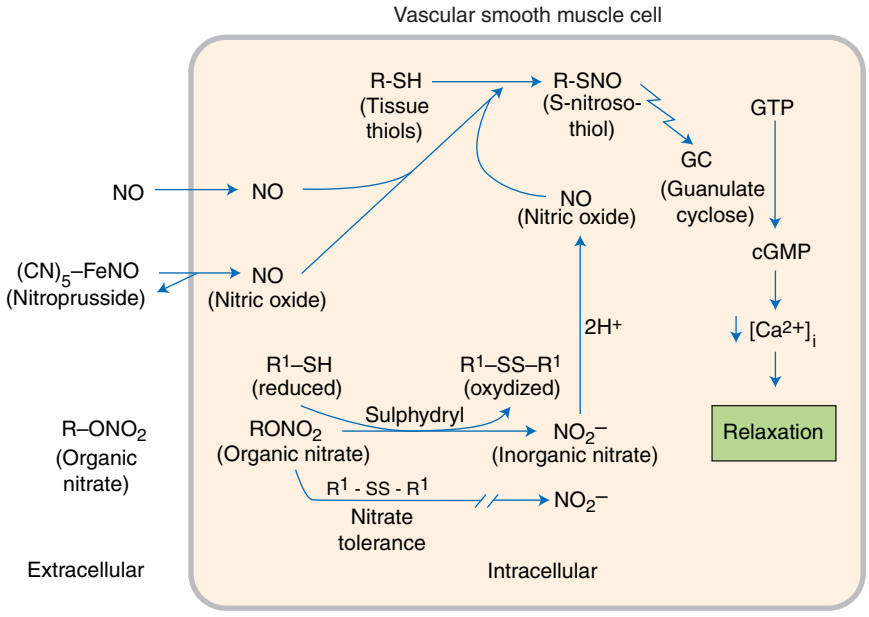

FIGURE 43–2. Cellular mechanism of action of nitroglycerin and nitroprusside. (Reproduced with permission from Ignarro LJ, Lippton H, Edwards JC, et al. Mechanism of vascular smooth muscle relaxation by nitrates, nitroprusside and nitric oxide. J Pharmacol Exp Ther 1981;218:739.)

injections of nitroglycerin are not as effective as IV nitroglycerin in treatment of pacer-induced ischemia. Beneficial systemic effect is suggested by the observation that intracoronary injection is less effective despite increased coronary blood flow. Conversely, intracoronary nitroglycerin in doses without systemic effect decreases ST segment elevations, improves systolic and diastolic function, and enhances flow to ischemic tissue.[97]

Nitrates produce these effects by entering vascular smooth muscle cells, where they are metabolized to 1,2-glyceryl dinitrate and nitrite via mitochondrial aldehyde dehydrogenase, whose sulfhydryl group is required for activity.[98] Nitrite is then oxidized to form nitric oxide. Nitric oxide in combination with tissue thiols forms *s*-nitroso-thiol, an activator of guanylate cyclase, the enzyme that catalyzes the formation of cGMP (Fig. 43–2).[99] As a second messenger, cGMP mediates many of the biologic effects of nitric oxide, including the control of vascular tone. Dephosphorylation of light-chain myosin occurs through a cGMP-mediated protein kinase, causing smooth muscle relaxation. Higher intracellular levels of cGMP also mediate bronchial, biliary, gastrointestinal, ureteral, and uterine smooth muscle relaxation. Nitrates also have beneficial antiplatelet and antithrombotic properties. The recently recognized role that platelet-dependent thrombotic processes play in acute coronary syndromes suggests that the inhibition of platelets by nitrates may offer an additional mechanism by which these compounds improve perfusion to ischemic myocardium. This effect is a result of stimulation of platelet guanylate cyclase by nitrates preventing fibrinogen binding to platelet IIb/IIIa receptors, which is essential for platelet aggregation.[100]

Clinically, nitrates can be used transdermally or orally for chronic therapy, on an intermittent basis via the sublingual route, or intravenously for acute therapy (Table 43–7). Clinical indications include classic exertional, Prinzmetal , and unstable angina; acute myocardial infarction (MI), and coronary artery spasm. Nitrates can be also useful in patients with congestive heart failure, particularly at night in those with significant orthopnea or paroxysmal nocturnal dyspnea. Tolerance has been a major problem with the use of nitrates as chronic antianginal therapy. How tolerance occurs is incompletely understood, but it is probably a result of attenuation of the vascular effect of nitrates and not of altered pharmacokinetics.[101] Common adverse effects in patients taking nitrate therapy are headache, flushing, and hypotension. Nitrates must be used cautiously in patients with severe aortic stenosis and volume depletion.

TABLE 43–7.

Nitrate Preparations

Nitroglycerin	
Sublingual tablets—Nitrostat	0.3–0.6 mg PRN (up to 3 tablets)
Translingual spray—Nitrolingual	0.4 mg/spray (up to 3 sprays)
Transmucosal tablets—Nitrogard (Forest)	1–3 mg q5h TID
Oral extended-release	2.5–6.5 BID to QID
Ointment—2%	1" to 2" q4h for 12–14 h/d
Transdermal patches	1 patch 12–14 h/d
Isosorbide Dinitrate	
Sublingual tablets—immediate release	2.5–10 mg q2–3h
Oral tablets	30 mg BID or 20 mg TID in morning and afternoon
Extended-release tablets and capsules	40–80 mg once daily to TID
Isosorbide-5-Mononitrate	
Immediate release	20 mg in morning and afternoon, 7 hours apart
Extended-release	60–120 mg once daily
Pentaerythroid tetranitrate	
Sublingual	10 mg PRN
Erythritol tetranitrate	
Sublingual	5–10 mg PRN
Oral	10–30 mg TID

Patients taking nitrates who are to have surgery should continue to receive therapy until and possibly throughout surgery. If a substantial perioperative or postoperative lapse is expected, nitrate ointments or IV nitroglycerin may be used.

Perioperatively, IV nitroglycerin may be used for treatment of myocardial ischemia, CHF, acute volume overload, systemic and pulmonary hypertension, and coronary artery spasm. In patients who are undergoing cardiac surgery, nitroglycerin is also used to facilitate infusion of oxygenator reservoir volume by venodilation and transfusion of blood to increase O_2-carrying capacity. Patients receiving acute nitroglycerin therapy may exhibit exaggerated hemodynamic responses to anesthetics, possibly related to its effects on preload. Prolonged use or excessive doses of nitroglycerin rarely may cause methemoglobinemia,[102] but to a much lesser extent than sodium nitroprusside.

β-Adrenergic Blocking Agents

β-Adrenergic blocking agents are among the most widely prescribed cardiac medications and have a wide spectrum of therapeutic uses beyond treatment of hypertension, angina, and dysrhythmias.

There are at least three distinct types of β-receptors:

- Activation of β_1 receptors, found primarily in the heart muscle, increases heart rate, contractility, and AV conduction, and decreases AV node refractoriness.
- Activation of β_2 receptors, present in cardiac muscle but more prominently found in bronchial and peripheral vascular smooth muscle, result in bronchodilatation and vasodilatation.
- Activation of β_3 receptors, found in adipose tissue and the heart, may induce thermogenesis[103] and may have cardiodepressant effects.[104]

The major therapeutic effects of β-adrenergic blockers are on the cardiovascular system.

Variations among β-adrenergic blocking agents result from their differing pharmacologic properties in regard to β_1 selectivity, α-adrenergic blocking activity, presence of intrinsic sympathomimetic activity (ISA) or membrane-stabilizing activity (MSA), potency, lipid solubility, first-pass effect, half-life, and mode of metabolism and excretion. All β-adrenergic blocking agents competitively block effects of catecholamines on receptors in the heart, lung, vasculature, kidney, brain, and eye, and their therapeutic value stems from these effects.

β-Adrenergic blockers lower blood pressure in patients with hypertension, although the mechanism is still debated. β-Blockers decrease myocardial contractility and heart rate, and thus cardiac output, but even at dosages lower than necessary to cause substantial decreases in cardiac output, they can be effective antihypertensives. β-Blockers with ISA such as pindolol, decrease cardiac output less, yet are similarly effective antihypertensives. β-Blockers decrease the release of renin from the juxtaglomerular apparatus. This action contributes to the antihypertensive effect. However, even though hypertensive patients with high plasma renin activity (PRA) respond well to propranolol, which decreases PRA, β-blockers that do not decrease PRA (e.g., pindolol) are also effective.

Evidence suggests that β-blockers cross the blood–brain barrier, and a CNS mechanism involving reduction of receptor-mediated sympathetic outflow has been proposed. On the other hand, lipophilic drugs such as propranolol and metoprolol are no more effective than hydrophilic compounds such as atenolol. Other proposed mechanisms of action include resetting of baroreceptors, attenuation of pressor responses to stress and exercise, and blockade of prejunctional receptors that normally facilitate norepinephrine release.[105,106] Despite unclear mechanisms, β-blockers are among the most useful and commonly prescribed cardiovascular medications.

With the recent introduction of the so-called third-generation β-blockers, other additional antihypertensive mechanisms have been proposed, such as release of nitric oxide, antioxidant action, Ca entry blockade, opening of K channels.[107]

In angina pectoris, β-adrenergic blocking agents decrease heart rate, blood pressure, and contractility, and therefore reduce myocardial O_2 consumption. They may improve perfusion by increasing diastolic coronary filling time. Although β-blockers have little effect on the factors influencing plaque vulnerability, they may decrease the incidence of plaque rupture by reducing mechanical stress.[108] Other mechanisms have been suggested (Box 43–1). Not all the actions of β-blockers are beneficial in all patients.

BOX 43–1.

Possible Mechanisms by Which β-Blockers Protect the Ischemic Myocardium

- Reduction in myocardial oxygen consumption, heart rate, blood pressure, and myocardial contractility
- Augmentation of coronary blood flow
- Increase in diastolic perfusion time by reducing heart rate
- Augmentation of collateral blood flow
- Redistribution of blood flow to ischemic areas
- Alterations in myocardial substrate utilization
- Decrease in microvascular damage
- Stabilization of cell and lysosomal membranes
- Shift to oxyhemoglobin dissociation curve to the right
- Inhibition of platelet aggregation

Reproduced with permission from Frishman WH. Clinical Pharmacology of the β-Adrenoceptor Blocking Drug. 2d ed. Norwalk, CT: Appleton-Century-Crofts, 1984:306.

In patients with very poor ventricular function, worsening failure may negate other gains. Similarly, in Prinzmetal angina, β-blockade is ineffective and may even be harmful because of unopposed α-tone in the large coronary arteries.[109] Treatment of angina pectoris with β-blockers, in combination with nitrates, aspirin, and/or calcium channel blockers, represents the current standard of care, if no contraindications exist.

Competitive β-receptor inhibition has useful antidysrhythmic effects. β-Blockers decrease the phase IV depolarization slope of the action potential and thus decrease automaticity. They slow the rate of discharge of the sinus and ectopic pacemakers and increase the effective refractory period of the AV node. The membrane-stabilizing effect of β-blockers does not appear to be relevant in the management of arrhythmias as it is manifested at concentrations well above therapeutic levels. β-Blockers are particularly effective in dysrhythmias caused by increased circulating catecholamines such as pheochromocytomas, anxiety, exercise, myocardial ischemia, and heart failure caused by cardiomyopathy; in those caused by increased cardiac sensitivity to catecholamines such as thyrotoxicosis; and in the dysrhythmias of mitral valve prolapse. They control heart rate in atrial fibrillation, flutter, and paroxysmal atrial tachycardia.[110,111] β-Blockers reduce sudden death, especially in patients with prior myocardial infarction or heart failure.[112] Survivors of myocardial infarctions have decreased morbidity, less sudden death, and fewer recurrent infarctions when treated with β-blockers. Although the reasons for this are not completely clear, a combination of the antiischemic and antidysrhythmic effects seems to play a key role.[113]

Other cardiovascular syndromes in which β-blocker therapy has proved useful include mitral valve prolapse, preexcitation syndromes, hypertrophic cardiomyopathy,[114] tetralogy of Fallot, aortic aneurysm, prolonged QT interval syndromes, and advanced cardiomyopathies. Noncardiac uses have included prevention of bleeding in patients with portal hypertension and treatment of glaucoma, thyrotoxicosis, migraines, essential tremors, delirium tremens, and anxiety.

These important drugs are not without significant side effects. β-Blockers may precipitate congestive heart failure in patients with preexisting ventricular dysfunction. Patients with sinus node dysfunction or AV block may develop symptomatic bradycardias; consequently, β-blockers are relatively contraindicated in patients with sick sinus syndrome. Stimulation of β_2 receptors in lungs causes bronchodilation; conversely, treatment with β-blockers may induce bronchospasm. Even β-blockers with relative β_1 selectivity (e.g., metoprolol, atenolol, betaxolol, esmolol, acebutolol, bisoprolol) occasionally induce bronchoconstriction in therapeutic doses. Nevertheless, they are preferred in patients with chronic lung disease.[115] β-Blockade may decrease cardiac output and block β_2-mediated coronary or peripheral arterial dilation, allowing unopposed constriction (e.g., spasm). Symptoms of peripheral vascular disease may worsen after β-blocker therapy, although this concern might be overstated in patients with mild to moderate peripheral vascular disease.[116] Additional concerns include impotence, and decreased sympathetic manifestations of hypoglycemia in patients taking insulin or hypoglycemic agents. CNS effects such as depression, psychosis, and obtundation may occur. Depression, fatigue, and sexual dysfunction are common causes of β-blocker discontinuation.

Multiple interactions between β-adrenergic blocking agents and other drugs have been described, particularly ones that depress myocardial function and automaticity, such as calcium channel blockers and antiarrhythmic drugs.

Abrupt discontinuation of β-blockers can result in a withdrawal syndrome caused by upregulation of β-receptors. This increased sensitivity to endogenous catecholamines can result in hypertension, tachycardia, or exacerbation of anginal syndromes, even MI or death.

The β-adrenergic blocking agents most frequently used in the United States today are described in the following sections (Table 43–8).

Propranolol

Propranolol is the prototype against which all other β-adrenergic blocking agents are measured. It is noncardioselective and has no ISA. Although propranolol possesses MSA, this occurs only at doses far beyond therapeutic and is not clinically relevant except following massive overdoses. Propranolol is almost completely absorbed after oral administration, but undergoes extensive first-pass hepatic metabolism. Thus, the usual oral dosage of propranolol is 40–320 mg/d, whereas the IV dosage is only 0.025–0.15 mg/kg. Cimetidine decreases hepatic metabolism and blood flow and may decrease propranolol's therapeutic dose. Propranolol is highly lipophilic and crosses the blood–brain barrier, which may explain its many CNS effects. Its usual oral half-life is approximately 4 hours. Propranolol is available as a long-acting preparation, a marked advantage for treatment of patients with angina pectoris.[117] Propranolol may be slowly administered intravenously to patients under anesthesia in incremental doses of 1 mg with frequent monitoring of blood pressure.

Metoprolol

Metoprolol is a β_1 selective blocker with no ISA or MSA. It is primarily hepatically metabolized, with a half-life of 3–7 hours. When used in low doses, metoprolol may be preferable to propranolol for smokers and other patients who may have bronchospastic diseases but who require therapy with β-blockers. Although relatively cardi-

TABLE 43–8.

Pharmacologic Properties of β Blockers

Agent	Relative β_1 Selectivity	ISA	MSA	α Activity	Elimination Half-Life Charts (hours)	Predominant Mode of Elimination	Oral Dosage (mg)	IV Dosage
Acebutolol	+	+	+	–	3–4	Renal/hepatic	200–600 BID	
Atenolol	++	–	–	–	6–7	Renal	50–200 daily	5–10 titrated at 1 mg/min
Betaxolol	++	–	+	–	16–22	Hepatic/renal	10–40 mg daily	
Bisoprolol	++	–	–	–	9–13	Renal/hepatic	10–20 mg daily	
Carteolol	–	+	–	–	5–6	Renal	2.5–10 daily	
Carvedilol	–	–	+	+	7–10	Hepatic	3.125–25 mg BID	
Esmolol	++	–			9 min	Red blood cell esterases	–	0.5–1 mg/kg bolus, then 100–300μg/kg/min
Labetalol	–	–	–	+	6–8	Hepatic	200–1200 BID	5–20 mg initially, then 40 mg q10min up to 300 mg as boluses or 2 mg/min as infusion
Metoprolol	+	–	–	–	3–7	Hepatic	50–200 BID	0.1–0.15 mg/kg titrated slowly to effect
Metoprolol extended release	++	–	–	–	?	Hepatic	50–400 daily	
Nadolol	–	–	–	–	20–24	Renal	40–240 daily	
Oxprenolol	–	+	+		4–6	Hepatic	40–80 TID	
Penbutolol	–	+	–	–	5	Renal	20 daily	
Pindolol	–	++	+	–	3–4	Renal/hepatic	5–30 BID	
Propranolol	–	–	++	–	4	Hepatic	40–320 daily, 0.1–0.15 mg/kg BID or QID titrated slowly to effect	
Propanolol extended release	–	–	++	–	10	Hepatic	80–320 daily, BID	
Timolol	–	–	–	–	4–5	Renal	10–30 BID	

oselective, metoprolol still may precipitate bronchospasm. It is less likely than propranolol to mask symptoms of hypoglycemia. Its usual oral dosage is 50–200 mg twice daily, although an extended-release formulation is also available and widely prescribed. Like propranolol, metoprolol is available in IV form, with usual dosage of 0.025–0.15 mg/kg. Metoprolol is used in the treatment of hypertension, stable angina, acute myocardial infarction, and chronic heart failure. The efficacy of metoprolol in heart failure management was studied in several randomized clinical trials, which showed an improved survival, reduced need for hospitalizations as a consequence of worsening heart failure, improved New York Heart Association (NYHA) functional class and beneficial effects on patient well-being.[118,119]

Atenolol

Atenolol is a long-acting, cardioselective β-blocker with no ISA or MSA. It is eliminated by renal excretion, and has a half-life of 6–7 hours. Its usual dosage is 50–200 mg daily. It is available in an IV form, with a recommended dosage of 5–10 mg given slowly. Besides being cardioselective and requiring only a single daily intake, other possible advantages include relative hydrophilia and minimal blood–brain barrier crossing. Unfortunately, in clinical trials with atenolol, this has not been reflected by a lower incidence of CNS side effects.[120]

Bisoprolol

Bisoprolol is a highly selective, long-acting, cardioselective β-blocker, without any ISA or MSA. It is well-absorbed following oral administration and is

eliminated by renal excretion, with 50% unchanged in the urine and the remaining 50% eliminated as inactive metabolites.[121] Its half-life of 9–13 hours makes it suitable for once-a-day administration. Recent randomized clinical trials show that bisoprolol prevents major cardiovascular events in patients with CHF.[122]

Betaxolol

Betaxolol is an oral, long-acting, cardioselective β-blocker with no ISA or MSA. Undergoing mainly hepatic metabolism, its half-life of 16–22 hours makes it suitable for once-a-day administration. As with timolol, betaxolol is available for topical ophthalmic use and may be better tolerated by patients with bronchospastic disease because of its β_1 selectivity.

Nadolol

Nadolol is a long-acting, noncardioselective β-blocker with no ISA or MSA. Unlike propranolol, it is renally excreted, with a half-life of 20–24 hours, allowing for once-a-day administration. The usual dosage is 40–240 mg/d; dosage should be reduced in patients with renal failure.

Timolol

Timolol is a noncardioselective β-blocker with no MSA or ISA. Its usual dosage is 10–30 mg twice a day, with a half-life of 4–5 hours. It undergoes both hepatic and renal excretion. Otherwise, it is similar to propranolol. Timolol is frequently used as an eyedrop therapy for open-angle glaucoma. In this form, it is often systemically absorbed and produces effects similar to those after oral ingestion.

Acebutolol, Carteolol, Penbutolol, Pindolol

Acebutolol, carteolol, penbutolol, and pindolol are nonselective β-blockers with ISA and partial agonist effects. With the patient at rest, these drugs may decrease heart rate to a lesser extent than other β-blockers. They are efficacious in blunting exercise-induced hemodynamic response. These drugs are thought to produce fewer lipid abnormalities and peripheral vascular complications, with less myocardial depression and bronchospasm. Specifically, pindolol produces less depression of heart rate and fewer nocturnal pauses in patients with sick sinus syndrome compared with agents lacking agonist effects.[123,124] Another possible advantage may be the absence of rebound following discontinuation; however, no large-scale trials are available to support these claims. No data are available to support the use of these drugs after MI. Table 43–9 lists the dosages for these drugs.

Labetalol

Labetalol is a nonselective β-blocker unique among β-blockers for its β-adrenergic blocking properties in a ratio of about 7:1(β:α). In addition, labetalol has partial agonist activity at β_2 receptors.[125] This blocking can be used to decrease arterial pressure with somewhat better maintenance of cardiac output. Labetalol is available in both IV and oral forms and its use is well established in acute therapy of severe hypertension in the emergency room, operating room, and recovery suite, but it is seldom employed as a long-term medication.

Esmolol

Esmolol is a highly cardioselective adrenergic blocker with little ISA and no MSA. It has a distribution half-life of 2 minutes and an elimination half-life of 9 minutes, as a result of rapid hydrolysis by red blood cell (RBC) esterases. Its short duration of action makes it particularly valuable in management of perioperative patients. Esmolol is typically used as a bolus, with or without an infusion. Steady-state plasma levels are obtained within 5 minutes. Usual bolus dosages are 0.5–1 mg/kg. Infusion rates of 50–300 μg/kg/min are titrated to clinical effect. On discontinuation of an esmolol infusion, significant recovery occurs within 10–20 minutes, and blood concentrations are undetectable within 30 minutes. Because esmolol is metabolized by red blood cell esterase, *plasma* cholinesterase inhibitors do not affect metabolism and elimination. Esmolol has been used intraoperatively to attenuate response to intubation, prevent and/or treat tachycardia and ischemia, and produce deliberate hypotension. The time course for attainment of heart rate decreases is faster than for changes in blood pressure.[126] It has been used to attenuate the increased heart rate and mean arterial pressure associated with rapidly increased desflurane concentrations.[127] Postoperatively, it has been used in treatment of hypertension, myocardial ischemia, and supraventricular dysrhythmias.

Celiprolol

Celiprolol is a third-generation cardioselective β-blocker without MSA but with evidence of ISA at the β_2 receptor.[107] It is an effective drug in the treatment of hypertension and angina.[128] It is a weak bronchodilator and vasodilator as a result of its β_2 receptor effect. It may prove superior to other β-blockers for asthmatic patients.[129]

Carvedilol

Carvedilol is a nonselective β-blocker that also blocks α_1 receptors in a manner similar to labetalol. It has MSA but no ISA. Carvedilol is also a potent antioxidant and antiproliferative, which inhibits vascular smooth muscle proliferation.[130] This property makes it useful in the treatment of chronic congestive heart failure. In numerous clinical trials, carvedilol significantly reduced morbidity and mortality in patients with heart failure.[131] Favorable effects on the remodeling process in heart failure were seen, with a decrease in left ventricular size and improvement in ejection fraction.[132] A recent clinical trial comparing metoprolol and carvedilol in patients with chronic heart failure showed that carvedilol extends survival.[133]

Bucindolol

Bucindolol is a third-generation nonselective β-blocker with α_1 blocking and β_2-agonist capabilities. In contrast to other β-blockers studied, bucindolol failed to show any significant overall survival benefit in patients with advanced cardiac failure.[134]

Nebivolol

Nebivolol is a highly selective β_1 receptor blocker, which can be distinguished from other β-blockers by its hemodynamic profile. It combines β-blocking activity with a vasodilating effect, which is mediated at least in part by endothelial NO. The blood-pressure-lowering effect of nebivolol is linked to a reduction in peripheral resistance and an increase in stroke volume with preservation of cardiac output.[135] Recent clinical trials show that it is an effective and well-tolerated treatment for heart failure in the elderly (age > 65).[136]

Anesthetic Considerations

Anesthetic considerations regarding β-blocker therapy are numerous. Initially, β-blockers and antihypertensives were discontinued before anesthesia

and surgery because of concerns that their effects would be additive with those of general anesthetic agents. Unfortunately, this sudden withdrawal tended to result in rebound effects with worsening of both angina and hypertension.[137] The 2002 ACC/AHA Guidelines for Perioperative Cardiovascular Evaluation for Noncardiac Surgery recommend that patients previously on β-blockers should continue these agents perioperatively.[5]

The recent focus on perioperative β-blockade has led to mounting evidence that the *prophylactic* use of β-blockers will reduce cardiac mortality and morbidity. β-Blockers reduce ischemia by decreasing myocardial oxygen demand caused by increased stress and catecholamine release in the perioperative period. It has been shown that in high-risk patients who have to undergo noncardiac surgery, perioperative β-blockade can reduce mortality and cardiovascular complications.[138,139] The ACC/AHA guidelines state that whenever possible β-blocker should be started days or weeks before elective surgery in patients at risk for or with evidence of ischemia. The dose should be titrated to achieve a resting heart rate between 50 and 60 beats/min.[5] Nevertheless, according to recent studies β-blockers are underused in the perioperative period.[140,141] More recent data show that low-risk patients do not benefit, indeed may suffer harm, from perioperative β-blockade. Conversely, high-risk patients may have a greater than 40% reduction in mortality.[142] Furthermore, β-blockers lower the incidence of atrial fibrillation after cardiothoracic surgery.[143]

Because of their pharmacologic effects, β-blockers interact with many anesthetic agents. β-Blockers have additive negative inotropic effects with potent inhalation agents. In dogs at 1.0 MAC of enflurane, propranolol causes mild decreases in myocardial contractility, heart rate, and cardiac output. These changes are more pronounced at deeper anesthetic concentrations. Circulatory depression, although present, is less when halothane or isoflurane are combined with propranolol compared with enflurane. In dogs anesthetized with halothane, isoflurane, or enflurane, propranolol produces additive slowing of heart rate and AV node conduction.[144]

Patients maintained on β-blockers, particularly when combined with calcium channel blockers, are at risk for

severe bradyarrhythmias when anesthesia is induced with high-dose fentanyl or sufentanil. These bradyarrhythmias especially occur when muscle relaxants lacking vagolytic effects are used. When high-dose narcotics are given to patients who take β-blockers, with or without calcium channel blockers, it is recommended that vagolytic muscle relaxants (e.g., pancuronium) be used.[145] β-Blockers are also associated with bradycardia during neuraxial anesthesia.[146]

The currently available IV β blockers—propranolol, metoprolol, atenolol, labetalol, and esmolol—may be administered perioperatively to attenuate hemodynamic responses to intubation or surgical stress, treat hypertension and ischemia, slow heart rates, or treat dysrhythmias, in addition to the prophylactic uses described above.

Calcium Channel Blockers

The calcium channel blockers represent a diverse group of compounds with dissimilar structures and pharmacologic effects (Table 43–9). They inhibit voltage-sensitive calcium channel function (L-type or slow channels), which mediate the entry of extracellular calcium into smooth muscle (Fig. 43–3), cardiac myocytes, and SA and AV nodal cells in response to electrical depolarization. They therefore have vasodilatory properties, especially in arterial beds, and have negative chronotropic and inotropic effects to varying degrees.[147,148] Unlike β-blockers, which all depend on blockade of receptors for their activity, the sites and mechanisms of action of the individual calcium channel blockers vary, as do their individual actions on different tissues. They are not nearly as interchangeable as β-blockers.

Used predominantly in antianginal and antihypertensive therapy (Fig. 43–4), calcium channel blockers are also used in treatment of syndromes as diverse as paroxysmal supraventricular tachycardia, hypertrophic obstructive cardiomyopathy, Raynaud phenomenon, preterm labor, and migraine headache prophylaxis.[114,149,150] The currently available calcium channel blockers can be categorized into 4 groups based on different chemical structures: dihydropyridines (which include nifedipine, nisoldipine, nicardipine, nimodipine, amlodipine, isradipine, felodipine, nitrendipine), verapamil (a phenylalkylamine), diltiazem (a benzothiazepine), and bepridil (a diarylaminopropylamine).

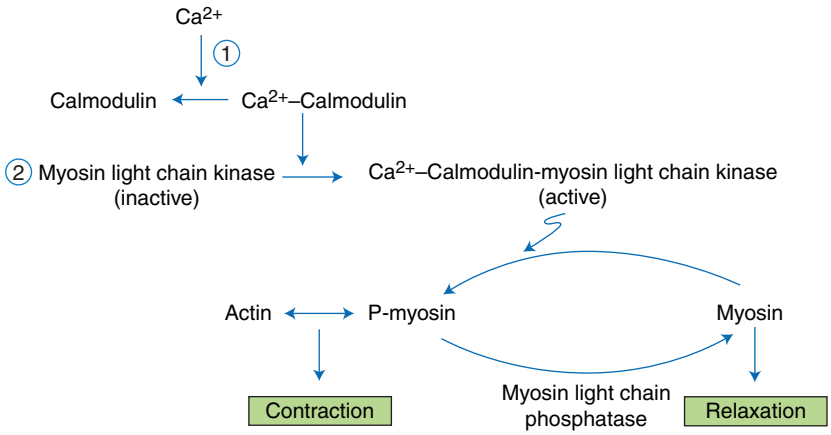

FIGURE 43–3. Activation sequence of mechanical contraction in vascular smooth muscle. The calcium ($Ca^{2|m+}$) calmodulin complex (*1*) activates myosin light-chain kinase (*2*), which catalyzes the phosphorylation of myosin (*P-myosin*). Cross-bridge formation between P-myosin and actin produces mechanical contraction. (Reproduced with permission from Anderson KE, Hogestatt ED. On the mechanism of action of calcium antagonists. Acta Med Scand 1984;681(Suppl):11.)

Verapamil

Verapamil, which is structurally similar to papaverine, has a complex mode of action. It is a racemic mixture with L-verapamil being a more potent calcium channel blocker than D-verapamil.[151] The net effect is depression of both slow channel activation and recovery from inactivation. Via its effects on the calcium channels, verapamil decreases myocardial contractility and dilates coronary and peripheral vascular beds, increasing coronary blood flow and decreasing systemic vascular resistance. Reflex tachycardia, secondary to decreased systemic vascular resistance, does not occur as a result of its negative chronotropic effect. Like other calcium channel blockers, verapamil has little effect on venous capacitance vessels in clinical doses. By decreasing heart rate, contractility, and peripheral resistance, verapamil decreases myocardial O_2 consumption. By increasing diastolic filling time and coronary blood flow while decreasing coronary

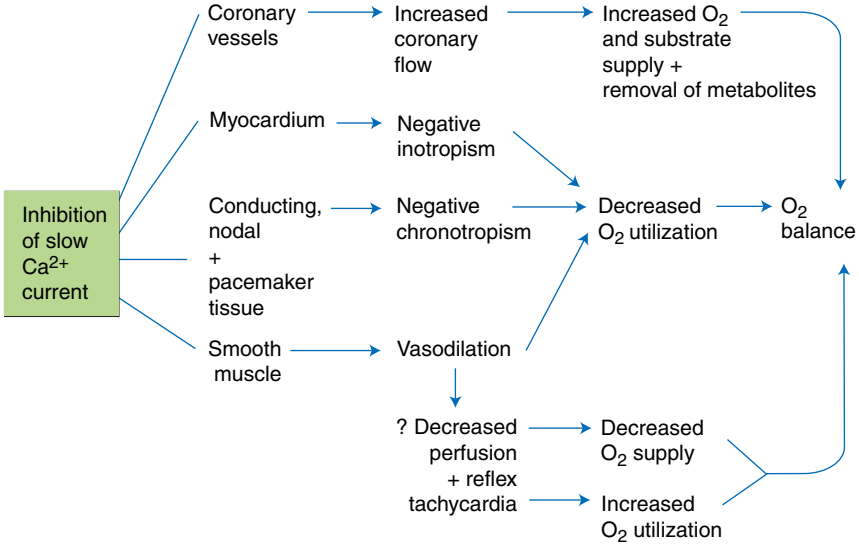

FIGURE 43–4. Consequences of calcium channel blockers on myocardial O_2 balance. Because of reflex responses, negative chronotropism and inotropism may not be important. (Reproduced with permission from Nayler WG, Dillon JS, Daly MF. Cellular sites of action of calcium antagonists and β-adrenoceptor blockers. In: Opie LH, ed. Perspectives in Cardiovascular Research. Vol 9. Calcium Antagonists and Cardiovascular Disease. New York: Raven Press, 1984:188.)

vascular resistance, it increases myocardial O_2 delivery. *In patients with congestive heart failure, intravenous verapamil can cause a marked decrease in contractility and left ventricular function*. By directly antagonizing coronary vascular spasm, verapamil is useful in treatment of classic and Prinzmetal angina. Verapamil is useful in managing patients after myocardial infarction without congestive heart failure, and its use may decrease long-term mortality.[152]

The electrophysiologic effects of verapamil are substantial. It slows spontaneous rates of firing and increases SA node recovery time, thereby decreasing heart rate. The velocity of AV node conduction decreases as a consequence of both decreased conduction and increased refractoriness. Because of this effect on the AV node conduction, verapamil can terminate paroxysmal supraventricular tachycardia, slow the ventricular response in atrial flutter, fibrillation, and multifocal atrial tachycardia. It can successfully convert paroxysmal supraventricular tachycardias (PSVTs) to sinus rhythm with an effectiveness of greater than 90%. It is also of prophylactic value in preventing recurrences of PSVT and controlling the ventricular response in atrial flutter and fibrillation during long-term oral therapy.[153] It should be noted that in patients with Wolff-Parkinson-White syndrome, verapamil might increase heart rate by preferential AV slowing, which may increase conduction through accessory pathways in patients who develop atrial fibrillation.

The net effect of verapamil in lowering both systolic and diastolic blood pressure with few side effects makes it efficacious for treatment of hypertension, although calcium channel blockers are currently not recommended as first-line therapy for hypertension. Possibly as a result of its improvement in diastolic function, verapamil improves exercise tolerance and decreases the severity of symptoms in patients with hypertrophic obstructive cardiomyopathy (HOCM). It is mainly used in HOCM patients who cannot tolerate β-blockers.[114]

In acute IV therapy, the recommended dose of verapamil is 0.075–0.15 mg/kg titrated to effect. Peak vasodilatory effect occurs at approximately 5 minutes and may persist for 30 minutes, although the antidysrhythmic effect may persist substantially longer. IV distribution half-life is 3.5 minutes and elimination half-life 110 minutes. Anesthetics or other drugs that decrease liver blood flow will increase the half-life of verapamil.

The side effects of verapamil are related to its pharmacologic and therapeutic actions. Verapamil may exacerbate SA and AV node dysfunction, especially in patients with underlying disease or those treated with digitalis or β-blockers. Verapamil may worsen symptoms of CHF, especially if used in combination with β-blockers.[147] Digitalis levels increase by an average of 70% after initiation of therapy with verapamil.

Diltiazem

Diltiazem, a benzothiazepine, is a calcium channel blocker with a spectrum of pharmacologic effects between verapamil and the dihydropyridines. Diltiazem, like all calcium channel blockers, is an effective coronary artery dilator, but has less effect on peripheral vessels than the dihydropyridines. It is a mild negative inotrope, but less so than verapamil.[147,154] Reflex tachycardia is also blunted because diltiazem decreases sinus node automaticity and AV nodal conduction, albeit to a lesser extant than verapamil. Although diltiazem can be used in combination with β-blockers, the effects may be additive, causing SA and AV node dysfunction in patients with underlying conduction disease.

Diltiazem is approved for rapid conversion of paroxysmal supraventricular tachycardia to sinus rhythm and for temporary control of rapid ventricular rate in atrial flutter or fibrillation. The usual dose of IV diltiazem is 0.25 mg/kg as a slow loading dose, followed by an infusion of 0.15 mg/kg. An additional bolus of 0.35 mg/kg may be given if needed. Oral diltiazem can be used for the chronic management of these problems.

The Dihydropyridines

Nifedipine

In vitro, nifedipine has significant effects on both smooth muscle and myocardium. In vivo, however, it is an effective coronary and systemic arterial dilator at doses that have little effect on myocardial contractility or conduction tissue. The vasodilatation and increase in coronary artery blood flow result from the blockade of calcium influx, as well as an increase in the levels of nitric oxide and bradykinin.[155] Because of its afterload reduction, nifedipine may cause reflex sympathetic increases in heart rate and cardiac output.[156] This sympathetic stimulation is more evident with short-acting preparations than it is with sustained-release nifedipine.[157]

Clinically, with the exception of short-acting formulations, which may occasionally worsen angina, nifedipine effectively improves exercise tolerance, prolongs the time to the onset of angina in exercise and decreases the frequency of episodes of angina.[147] Concurrent therapy with nifedipine and a β-blocker is more effective than either agent given alone. Indeed, β-blockers eliminate nifedipine's potentially detrimental reflex increases in heart rate.[158] Although it is an effective antihypertensive, nifedipine, and generally all calcium channel blockers are not currently recommended as first-line therapy, unless there are contraindications to other antihypertensives.[6] Even though nifedipine has fewer negative chronotropic or inotropic effects than verapamil or diltiazem, in long-term studies hemodynamic deterioration occurred in some patients with congestive heart failure who were treated with dihydropyridines.[159]

Because it is light sensitive, IV nifedipine is not commercially available in the United States. Nifedipine's side effects include headaches, pedal edema, hypotension, and exacerbation of angina. Like verapamil, nifedipine increases serum digitalis levels. Because a higher rate of cardiac events was reported among patients who were treated with short-acting nifedipine after myocardial infarction, this preparation is no longer recommended in patients with angina.[160]

Nicardipine

Nicardipine has structural and pharmacologic properties similar to those of nifedipine. Like nifedipine, nicardipine is a potent coronary and systemic vasodilator with little effect on contractility. It is available as an IV agent for treatment of hypertension in acute care settings, including the perioperative period and neurologic emergencies.[161–163] An initial intravenous bolus of 2 mg is followed by an initial infusion rate of 5 mg/h, which may be increased in 2.5-mg increments every 15 minutes, up to a maximum infusion rate of 15 mg/h. Nicardipine administered intraarterially

reverses vasospasm in subarachnoid hemorrhage and interventional coronary procedures.[164,165]

Nimodipine

Nimodipine, a nifedipine analogue, is a calcium channel blocker with high lipid solubility and apparent preference for cerebrovascular smooth muscle. It is useful in inhibiting cerebral vasospasm and improving outcome in patients with neurologic defects associated with cerebral vasospasm after subarachnoid hemorrhage.[166] Its usefulness in patients with acute ischemic stroke has not been proven.[167]

Amlodipine, Isradipine, Felodipine, Nisoldipine, and Nitrendipine

Amlodipine, isradipine, felodipine, nisoldipine, and nitrendipine are structurally and pharmacologically similar to nifedipine, the dihydropyridine prototype. They dilate coronary and peripheral arteries with minimal effect on cardiac conduction and contractility. Like nifedipine, these drugs are used to treat hypertension and angina, and may be safely used in patients with CHF.[168]

The individual agents are distinct from each other in many ways. Because isradipine has an inhibitory effect on the SA node but not on the cardiac myocytes, it produces little or no reflex tachycardia. Felodipine and nisoldipine have a higher degree of vascular specificity than the rest of the dihydropyridines. Several trials have shown that amlodipine increases exercise duration, decreases the number of anginal attacks, and reduces the consumption of nitroglycerin.[169] The Systolic Hypertension in Europe (Syst-Eur) Trial reported that antihypertensive therapy initiated with the nitrendipine reduced the risk of fatal and nonfatal stroke, as well as all cardiovascular events combined, in older patients (age > 65) with isolated systolic hypertension.[170]

Mibefradil

Mibefradil is an antagonist of T-type calcium channels. This arterial dilator has negative chronotropic effects but minimal inotropic effects. Mibefradil is an effective antianginal whose vasodilatory effects are associated with a reduction in heart rate.[171,172] There are case reports of QT interval prolongation and ventricular dysrhythmias during treatment with mibefradil.[173]

Monatepil

Monatepil is a calcium channel blocker similar to nifedipine, which also has α_1-adrenoreceptor blocking properties. It decreases systolic and diastolic pressure without changes in heart rate. Furthermore, it significantly decreases levels of low-density lipoprotein (LDL) cholesterol, apolipoprotein B, and glycosylated hemoglobin ($HgbA_{1c}$).[174]

Bepridil

Bepridil is structurally unrelated to other calcium channel blockers. It blocks slow calcium channels in both cardiac and vascular smooth muscles as well as fast sodium channels in cardiac muscle. It has negative chronotropic and dromotropic and mild negative inotropic effects.[175] Bepridil reduces blood pressure and heart rate, improves left ventricular performance in patients with angina, and decreases the frequency of exercise-induced angina attacks. Bepridil can prolong QT interval, especially in the setting of hypokalemia or bradycardia, and can precipitate polymorphic ventricular tachycardia.[175] Bepridil is also associated with agranulocytosis and pancytopenia. Because of these serious side effects, it should be used only in cases of angina refractory to other therapies.

Anesthetic Considerations

There are limited data regarding the risks and benefits of calcium channel blockers in the perioperative setting. Although a classic withdrawal syndrome has not been described, there are case reports of severe coronary vasospasm following abrupt discontinuation of the calcium channel blockers.[176] Overall, the continuation of calcium channel blockers in patients already taking them preoperatively is recommended, despite the paucity of information in relation to their interaction with the process of anesthesia and surgery.

There is considerable potential for drug interaction between anesthetic drugs and calcium channel blockers. When used in combination with high-dose narcotics in patients with normal conduction systems and ventricular function, IV verapamil decreases systemic vascular resistance and mean arterial pressure with no change in cardiac output or pulmonary capillary wedge pressure. Although lengthening of the PR interval has been observed, neither first-degree nor more advanced AV block has occurred.

In combination with inhalation agents, verapamil may produce varying degrees of AV block and must be given carefully in patients anesthetized with enflurane, halothane, and, to a lesser degree, isoflurane in patients with AV nodal block or in patients chronically taking β-blockers.[177]

Verapamil has many perioperative uses. It has been used for intraoperative control of paroxysmal supraventricular tachycardia. During cardiopulmonary bypass, verapamil terminates refractory ventricular fibrillation following aortic cross-clamp removal. Verapamil successfully treats intraoperative myocardial ischemia refractory to IV nitroglycerin.[178]

In vitro, diltiazem may depress left ventricular function in the presence of enflurane or desflurane, while the incidence of bradyarrhythmias is higher with enflurane than with equivalent levels of desflurane.[179] Combined with enflurane, diltiazem is particularly depressant to conduction. Together, they may cause first-degree AV block, Mobitz I AV block, or sinus node dysfunction.[180]

Nifedipine administered in dogs during fentanyl/nitrous oxide anesthesia, decreased systemic vascular resistance accompanied by an increase in cardiac index and heart rate. In vitro, the combined treatment of nifedipine and volatile anesthetics, especially enflurane, additively depresses atrial rate and contractility. However, these effects appear less pronounced than the combination of volatile agents with diltiazem and especially verapamil.[181]

Nicardipine has a longer duration of action in the presence of isoflurane and produces greater initial hypotension with sevoflurane.[182]

Calcium channel blockers may potentiate effects of depolarizing and nondepolarizing neuromuscular blocking agents, although this is controversial. In contrast with β-adrenergic blocking agents, calcium channel blockers have not been shown to be effective in prevention of intraoperative ischemia.[183]

Other Antianginals

Novel therapeutic strategies have been developed for patients with ischemic heart disease and angina pectoris that were unsuccessfully managed with conventional medical or interventional approaches.

Ivabradine

Ivabradine is the first of a new class of drugs called I_f inhibitors. It selectively and specifically inhibits I_f, a sinus node-specific sodium-potassium inward current. It reduces heart rate at rest or exercise without decreasing myocardial contractility, atrioventricular conduction, and ventricular repolarization duration.[184] A double-blind trial comparing the antiischemic and antianginal effects of ivabradine to atenolol showed that ivabradine is as effective as atenolol in preventing exercise-induced angina in patients with chronic stable angina.[185] Ivabradine has been approved in Europe for the symptomatic treatment of chronic stable angina pectoris in patients with normal sinus rhythm who have a contraindication or intolerance to β-blockers. With the exception of reversible, transient visual symptoms described mainly as increases in brightness in limited areas of the visual field, no other adverse effects are attributed to ivabradine therapy.

Nicorandil

Nicorandil is a nicotinamide ester, which activates the adenosine triphosphate (ATP)-sensitive potassium channel. It dilates peripheral and coronary resistance arterioles, and because of a nitrate-like effect, it dilates systemic veins and epicardial coronary vessels. Consequently, nicorandil increases coronary blood flow, reduces preload and afterload, and has antianginal efficacy similar to oral nitrates, β-blockers, and calcium antagonists.[186] By opening ATP-dependent potassium channels, nicorandil may also mimic a natural process of ischemic preconditioning, protecting the heart from subsequent ischemic attacks. The IONA (Impact of Nicorandil in Angina) trial showed a significant improvement in outcome as a result of reduction in major coronary events by adding nicorandil to standard antianginal therapy in patients with stable angina.[186] Nicorandil is not available in the United States.

Inhibitors of Fatty Acid Oxidation

Two agents, ranolazine and trimetazidine, are presently available and represent this new class of drug. During episodes of acute myocardial ischemia, fatty acid levels rise, promoting their uptake and use as energy source by the myocardium. Because fatty acid oxidation is more oxygen inefficient than carbohydrate oxidation, this abrupt increase in circulating free fatty acids imposes a further deleterious effect on an already imbalanced oxygen supply–demand situation. Inhibition of fatty acid oxidation may increase glucose oxidation, which generates more ATP for each molecule of oxygen than fatty acid oxidation, thereby minimizing lactate accumulation.[187] Both drugs are virtually devoid of hemodynamic effects.

The efficacy of ranolazine has been studied in several clinical studies, such as the MARISA (Monotherapy Assessment of Ranolazine in Stable Angina) and CARISA (Combination Assessment of Ranolazine in Stable Angina) trials. Both MARISA and CARISA showed that ranolazine increases exercise capacity and provides antianginal effects on symptomatic patients with chronic angina.[187,188]

Similar benefits were shown in the TRIMPOL (Trimetazidine in Poland) II trial, which studied trimetazidine in patients already receiving metoprolol. The addition of trimetazidine produced significant improvement in exercise stress tests and anginal symptoms relative to metoprolol monotherapy.[189]

Neither ranolazine nor trimetazidine is available in the United States.

ANTIDYSRHYTHMIC AGENTS

Antidysrhythmic agents are indicated for prevention and treatment of symptomatic dysrhythmias and for therapy of asymptomatic dysrhythmias with malignant potential. Reasons for selecting one drug over another are frequently complex; the choice may depend on type of dysrhythmia, a particular drug's therapeutic index, a medication's effectiveness during electrophysiologic studies, or a patient's tolerance to side effects.

Antidysrhythmic drugs are classified on the basis of their major pharmacologic effects on myocardial electrophysiology, as originally proposed by Vaughan Williams[190] and now modified to include newer agents (Box 43–2). Although now loosely used to group drugs, this classification was originally proposed to rigorously classify patterns of pharmacologic action. This is a subtle but important difference. Many antidysrhythmics, although classified into one group or another, have (a) multiple actions in a given tissue, (b) different actions in different heart tissues, and (c) active metabolites with different actions than the parent compound.

Since the early nineties, the use of most antidysrhythmic drugs has been reassessed and dramatically limited because of increased awareness of their proarrhythmic potential and advances in ablation techniques. Moreover, recent clinical trials have demonstrated negative effects on survival in many situations where these drugs might have been given in the past. Finally, implantable cardiodefibrillators have largely replaced antidysrhythmic medications in the management of ventricular dysrhythmias.[191]

Agents with class I actions include drugs that affect the fast inward sodium current of phase O, the period of rapid depolarization of the action potential (Fig. 43–5). They have been further divided into three groups: IA, IB, and IC.

Class II actions refer to antidysrhythmic effects associated with β-adrenergic antagonism. Therefore, class II agents include all β-adrenergic blocking agents.

Class III agents block potassium repolarization currents and increase action potential duration (APD) and effective refractory period (ERP) in atrial and ventricular muscle, as well as in Purkinje fibers. The ERP-to-APD ratio is increased.

Class IV agents are represented by blockers of the L-type calcium channel, that is, calcium channel blockers. Among them only verapamil and diltiazem are effective for antidysrhythmic use.

Some newer drugs, such as adenosine and ibutilide, do not fit neatly into any of these categories (although ibutilide is categorized by some as a class III drug).

Class IA Agents

Antidysrhythmics with class IA action include quinidine, procainamide, and disopyramide (Table 43–10). They all decrease the maximal velocity (V_{max}) and amplitude of phase 0 depolarization of the action potential. The ERP, APD, and ERP-to-APD ratio are increased. Automaticity, represented by the decreased slope of phase 4 of the action potential, are decreased with these drugs. These agents produce measurable increases in refractoriness of cardiac tissue and lengthening of the QTc interval on the ECG.

Quinidine

Quinidine decreases automaticity in atrial and ventricular tissue and in the His-Purkinje and pacemaker fibers. Quinidine's direct effects on SA node automaticity are balanced by its anticholinergic effects, which speed conduction through the SA and AV nodes, causing little change in heart rate. ECG changes occur with quinidine; most noticeably, it prolongs the QT interval by up to 25% at therapeutic levels.

Quinidine also blocks the rapid component of the K channel, prolonging action potentials in most cardiac cells, especially at slow heart rates.[47] It has been used effectively for conversion of atrial fibrillation, atrial flutter,[192] and PSVT, and for maintenance of sinus rhythm after conversion.[193] In addition, it suppresses ventricular ectopy, tachycardia, and fibrillation.

Quinidine is available orally as a sulfate, gluconate, or polygalacturonate salt with 83%, 62%, and 60% quinidine content, respectively. Quinidine sulfate is typically initiated at 200 mg every 6 hours and increased to 800–2400 mg/d, titrated to drug levels and therapeutic effect. It undergoes hepatic metabolism (60–80%) and renal excretion (20–40%), with a variable half-life of 4–10 hours. The metabolites of quinidine also possess antidysrhythmic activity. Although it is available in an IV form, this route is usually avoided because of profound hypotensive and negative inotropic effects.

As with all antidysrhythmics, quinidine may be prodysrhythmic. Patients with CHF are at greater risk. With congenital prolongation of the QT interval or bradycardia associated with hypokalemia, quinidine, by further lengthening the QT interval, may initiate torsade de pointes, a serious, potentially lethal dysrhythmia.[194] If torsade de pointes occurs, therapy should include increasing heart rate with isoproterenol or pacing, correction of hypokalemia and hypomagnesemia, and discontinuation of quinidine.

Because of its anticholinergic effects on the AV node, quinidine may increase ventricular response in atrial fibrillation and flutter. Consequently, if it is used for conversion of atrial dysrhythmias, digoxin, verapamil, or a β-blocker should be administered concurrently. If quinidine therapy is initiated in a patient receiving digitalis, one must be aware that quinidine may double the digitalis plasma concentration, possibly leading to digitalis toxicity. Digitalis dosages should therefore be decreased by half. Evidence of quinidine-induced cardiac toxicity may be manifested by greater than 50% increase in QT interval, widening of QRS complexes, and SA or AV node disturbances. Noncardiac adverse effects typically occur with quinidine. In 30–40% of patients, therapy must be withdrawn because of gas-

Class IA Antidysrhythmic Agents

Drug	Usual Dosage and Interval	Effect on Electrocardiogram	Adverse Effects	Concentrations	Metabolism	Indications	Half-Life
Quinidine	PO: 200–400 mg q4–6h	Prolongs QRS, QT, and PR (+)	Diarrhea and other GI symptoms; cinchonism; hepatic granulomas and necrosis; thrombocytopenia; rashes; hypotension; heart blocks; tachyarrhythmias; torsade de pointes; fever; lupus-like syndrome	2–7 μg/mL	Hepatic (60–80%); renal (20–40%)	Ventricular and supraventricular arrhythmias, including PAT, AF atrial flutter, WPW, junctional tachycardias	4–10 h; increased in elderly
Procainamide	PO: 50 mg/kg/d in divided doses q3–4h or q6h (long-acting); IV loading no more than 100 mg q5min to 1 g (12 mg kg); IV maintenance 2–4 mg/min	Prolongs QRS, QT, and PR (+)	Lupus-like syndrome; confusion; disorientation; GI symptoms; rash; blood dyscrasias; fever hypotension; arrhythmias; torsade de pointes	4–10 mg/mL NAPA 10–20 μg/mL	Hepatic, excreted in urine by filtration and active secretion	As above	2–5 h; increased in renal failure
Disopyramide	PO: 100–200 mg q6h	Prolongs QRS, QT, and PR (+)	Anticholinergic effects; hypotension; heart failure; tachyarrhythmias; torsade de pointes; heart block; nausea; vomiting; diarrhea; hepatic toxicity; acute psychosis; agranulocytosis; constipation; hypoglycemia	2–8 μg/mL	Hepatic; 50 excreted unchanged in urine	As above	4–10 h; 8–18 h with renal dysfunction
Moricizine	200–300 mg TID	Prolongs QRS interval	May be prodysrhythmic; Congestive heart failure; intraventricular conduction delays	0.2–1.5 μg/mL	Hepatic; biliary and urinary excretion	Ventricular dysrhythmias	9.2 h

AF, atrial fibrillation; NAPA, N-acetylprocainamide; PAT, paroxysmal atrial tachycardia; WPW, Wolff-Parkinson-White Syndrome.
Data from Abramowicz M, ed. Drugs for cardiac arrhythmias. Med Lett Drugs Ther 1991;33:60.

trointestinal (GI) intolerance. Quinidine may cause CNS toxicity, as manifested by tinnitus and delirium. Other adverse effects include fever, rash, anaphylaxis, thrombocytopenia, hemolytic anemia, and agranulocytosis.

In surgical patients, quinidine should be continued preoperatively and resumed as soon as possible following surgery. If oral intake is impossible, IV procainamide or lidocaine may be substituted, depending on the original rea-

son for initiating quinidine therapy. Quinidine increases the neuromuscular blockade of succinylcholine and may worsen neuromuscular blockade in myasthenia gravis. Quinidine has fallen into disfavor because it worsens survival in patients with ventricular dysrhythmias.[195] Even in the presence of atrial dysrhythmias, where quinidine may be highly successful in maintaining sinus rhythm, it still has a negative effect on survival.[196]

Procainamide

Procainamide, an analogue of the local anesthetic procaine, has a pharmacologic effect and a set of clinical indications similar, but not identical, to those of quinidine. Although both are class IA agents, each may be effective in suppression of dysrhythmias that are unresponsive to the other drug. This is not surprising, since procainamide's major metabolite, *N*-acetylprocainamide (NAPA), actually has class III actions.[197] In addition, because procainamide is readily available in stable IV form, it is useful for acute management of atrial fibrillation and flutter, PSVT, and dysrhythmias associated with Wolff-Parkinson-White syndrome. It may also be used for acute suppression of ventricular dysrhythmias following acute MI, and in treatment of ventricular tachycardia. When given intravenously, it may produce vasodilatation by a mild ganglionic blocking action; consequently, loading doses should be given slowly over approximately 20–30 minutes while monitoring the QRS duration. A loading dose up to 1 g may be given, followed by an infusion at 1–4 mg/min. Procainamide undergoes acetylation to NAPA, with half the population being fast acetylators. Subsequently, both substances are renally excreted. Therefore, dosage should be adjusted in patients with renal dysfunction. Procainamide and NAPA levels may prove useful to facilitate dosage adjustment.

Procainamide has fewer anticholinergic properties than quinidine and disopyramide. As with quinidine, procainamide may be prodysrhythmic and may cause torsade de pointes.[194] Consequently, it should not be used in patients with prolonged QT interval, hypokalemia, or history of torsade de pointes. Chronic administration is associated with positive antinuclear antibody titers; however, only 15–20% of patients develop a lupus-like syndrome. It usually resolves with discontinuation of the drug. Preoperatively, procainamide should be continued until surgery. In the perioperative period, procainamide may be given as an IV infusion and used as a substitute for quinidine or disopyramide in treatment of atrial and ventricular dysrhythmias. Like quinidine, procainamide increases long-term mortality and is seldom used on a chronic basis.[195]

Disopyramide

Disopyramide is used to maintain sinus rhythm in patients with atrial flutter or atrial fibrillation and to prevent recurrence of ventricular tachycardia or ventricular fibrillation. Unlike quinidine and procainamide, it has significant negative inotropic effects. Even more than quinidine, it has substantial anticholinergic effects. If it is tolerated, little additional chronic toxicity occurs.

The usual dosage of disopyramide is 100–400 mg, three to four times daily, up to 800 mg total. Its half-life elimination is 4–10 hours and is usually increased in patients with cardiac or renal disease. Fifty percent is excreted unchanged by the kidney and the remainder as an active metabolite.

As with all class IA agents, disopyramide should not be used in patients with congenital prolongation of the QT interval, hypokalemia, or history of torsade de pointes. It may cause severe bradycardia in patients with sinus node dysfunction or conduction system disease. Because of negative inotropic effects, disopyramide is contraindicated in patients with CHF. Disopyramide is still used in management of dysrhythmias in patients with HOCM, for which its negative inotropic effect is an advantage. In HOCM, it can decrease the subaortic gradient and ameliorate symptoms without increasing mortality.[198] Like other class IA agents, disopyramide has largely been abandoned as a treatment of chronic dysrhythmias. Because of its anticholinergic effects, it is contraindicated in patients with glaucoma and obstructive uropathy. In addition, disopyramide may cause dry mouth, constipation, urinary retention, and esophageal reflux.

Moricizine

Moricizine, a phenothiazine derivative, has characteristics of class IA, class IB and class IC agents. Moricizine decreases V_{max} to an extent similar to class IA agents. As with IB agents, it shortens APD and increases the ERP-to-APD ratio. On the ECG, moricizine prolongs the QRS complex with little effect on the QT interval, a characteristic of class IC agents.

In clinical studies, moricizine has been effectively used for treatment of chronic complex ventricular dysrhythmias and prevention of ventricular tachycardia and fibrillation. However, in the Cardiac Arrhythmia Suppression Trial (CAST) II trial moricizine was shown to increase mortality in patients shortly after a myocardial infarction and did not improve survival during long-term therapy.[199] Moricizine use has therefore been largely abandoned.

Moricizine is well absorbed orally, undergoes hepatic metabolism, biliary and urinary excretion. In healthy volunteers, the half-life 1.5–3.5 was hours; however, cardiac disease may increase this to as long as 13 hours.

Recommended dosages are 600–900 mg three times daily. Adverse reactions include dizziness, nausea, and headaches. Intraventricular conduction delays may occur in up to 9% of patients. Moricizine may be prodysrhythmic or worsen CHF in 2–5% of patients.[47] Few data are available about interactions with anesthetic agents.

Class IB Agents

Drugs with class IB actions, such as lidocaine, mexiletine, tocainide, and phenytoin, have more moderate effects on phase O of the action potential (Table 43–11). Unlike class IA agents, they shorten APD and ERP and increase the ERP-to-APD ratio in the Purkinje fibers, but have little effect on the refractory periods in sinus node, atrium, and AV node, thus being ineffective against supraventricular tachycardias. They show little ECG effect. They exhibit rapid association and dissociation from the sodium channels.[47]

Lidocaine

Although lidocaine, the prototypical class IB agent, was first introduced as a local anesthetic, it is widely used in acute treatment and suppression of all ventricular dysrhythmias, except those associated with prolonged QT intervals and torsade de pointes. As with all class I agents, lidocaine decreases V_{max} to some extent. In addition to its typical type IB effects, lidocaine decreases the slope of phase 4 of the action potential, reducing automaticity. Like other IB agents, lidocaine has little effect on atrial tissue and thus is ineffective against supraventricular tachycardias.

TABLE 43–11.

Class IB Antidysrhythmic Agents

Drug	Usual Dosage and Interval	Effect on Electrocardiogram	Adverse Effects	Usually Effective Plasma Concentrations	Indications	Half-Life	Metabolism
Lidocaine (Xylocaine and others)	IV loading: 1 mg/kg given over 2 min, then 2 mg/kg over 20 min or 50 mg given over 1 min and repeated every 5 min × 3 or 20 mg/min infused over 10 min IV; maintenance for 24–30 h 30 μg/kg each min	No significant change	Drowsiness or agitation; slurred speech; tinnitus; disorientation; coma; seizures; paresthesia; cardiac depression, especially with excessive accumulation in heart failure or liver failure or infusions for more than 24 hours	1.5–6 μg/mg	Ventricular dysrhythmias	1.5–2.0 h	Hepatic; <10% excreted in urine
Phenytoin (Dilantin and others)	PO loading: 14 mg/kg; PO maintenance: 200–400 mg/d; IV loading: 50 mg q5min to total dose of 1000 mg (up to 12 mg/kg); IV maintenance: 200–400 mg/d	No significant change	Ataxia, nystagmus; drowsiness; coma blood dyscrasias; cardiac toxicity with rapid IV injection; fever; rash; hepatic granulomas and necrosis	5–20 μg/mL	Dysrhythmias associated with Digitalis toxicity	22 h	Hydroxylated in liver, excreted in urine
Mexiletine (Mexitil)	PO initial dose: 100–200 mg q8h taken with food; PO maintenance: 100–300 mg q6–12h, maximum 1200 mg/d	No significant change	GI upset; fatigue; nervousness; dizziness; tremor; sleep upset; convulsions; infrequent aggravation of arrhythmias; visual disturbances psychosis; fever; hepatic toxicity; blood dyscrasias	0.5–2 μg/mL	Ventricular dysrhythmias	10–12 h	Hepatic
Tocainide (Tonocard)	PO initial dose: 200–400 mg q8h; PO maintenance: 200–600 mg q8h, maximum 2400 mg/d	No significant change	GI upset; paresthesia; dizziness; tremor; confusion; nightmares; psychotic reactions; coma; seizures; rash; fever; arthralgia; infrequent cytosis; aplastic anemia; thrombocytopenia; hepatic granulomas; interstitial pneumonitis	3–10 μg/mL	Ventricular dysrhythmias	15 h	Hepatic biotransformation 55%; excreted unchanged in urine 45%

Data from Abramowicz M. ed. Drugs for cardiac arrhythmias. Med Lett Drugs Ther 1991;33:60.

Because lidocaine undergoes rapid first-pass elimination, it is unavailable as an oral agent. IV lidocaine is usually given as a 1 mg/kg bolus, followed by repeat small boluses of an additional 2 mg/kg over 15 minutes and an infusion of 1–4 mg/min. An infusion is necessary because of lidocaine's rapid distribution out of the central compartment with termination of the antidysrhythmic activity. Because elimination is significantly longer than central compartment redistribution, a steady-state lidocaine infusion can be discontinued without "tapering." The blood levels will gradually decrease over 8–10 hours.

Modifications of infusion rates are required in the elderly and in patients with liver disease or CHF with decreased liver blood flow. Normal individuals show great variability in plasma levels. Thus, the patient's ECG, blood pressure, and mental status should be carefully monitored so that infusions or boluses may be discontinued if toxicity develops. If dysrhythmias persist at usual doses and no toxic symptoms are present, lidocaine administration may be increased after a drug level has been obtained. If dysrhythmias persist with plasma lidocaine concentrations greater than 9 μg/mL, another agent should be used, even without symptoms of toxicity. Lidocaine provides little antidysrhythmic effect at levels less than 1.5 μg/mL, and toxicity often occurs at levels greater than 5 μg/mL.

Lidocaine has been used for the treatment of life-threatening ventricular arrhythmias, especially when associated with myocardial ischemia.

Although shown to be effective in prevention of ventricular fibrillation after acute myocardial infarction, meta-analyses of the effects of lidocaine on in-hospital mortality among patients with acute myocardial infarction suggest that despite a reduction in primary ventricular fibrillation, there is a small *increase* in the risk of death in the hospital among patients treated with lidocaine.[200] In light of this, its prophylactic use following myocardial infarction has fallen into disfavor. Although it remains in the advanced cardiac life support (ACLS) protocol, lidocaine is inferior to amiodarone (see Amiodarone below) in the management of pulseless ventricular tachycardia/fibrillation.[201] Potential adverse reactions to lidocaine include drowsiness, dizziness, confusion, delirium, dysarthria, dysesthesias (especially periorally), and even coma and seizures. Seizures may occur with nontoxic doses if they are given too quickly. Lidocaine may occasionally cause sinus and AV nodal dysfunction in patients with underlying conduction disease. In patients with atrial fibrillation, lidocaine may increase ventricular response rates. Multiple animal model studies have evaluated cardiac toxicity associated with lidocaine. Lidocaine clearly has cardiac toxicity, but this occurs at levels approximately 4 times higher than those associated with CNS toxicity. Characteristic ECG findings in these studies were sinus arrest, increased PR intervals and AV block, widening QRS complexes, ectopy, and tachydysrhythmias. In dogs, lidocaine, in combination with isoflurane and calcium channel blockers, caused hypotension and AV block, which was reversed with calcium chloride.[202]

Mexiletine and Tocainide

Mexiletine is an orally active congener of lidocaine with similar indications and modes of action. Mexiletine is indicated in the treatment of life-threatening ventricular arrhythmias in combination with class IA and even class II and class III agents.[203] It may be safer for patients with prolonged QT syndrome than class IA or IC agents. It undergoes predominantly hepatic elimination, with a half-life of 10–12 hours and may be safely administered to patients with renal failure.[204]

Mexiletine has little hemodynamic effect and is well tolerated in patients with CHF. Adverse reactions, such as dizziness, tremor, visual blurring, and nausea, are usually dose related. Rash occurs less often with mexiletine than with tocainide, but thrombocytopenia and positive antinuclear antibody testing occur occasionally. Mexiletine may be prodysrhythmic in 10% of patients. It should be continued perioperatively and restarted as soon as possible postoperatively. If oral intake is not possible, a lidocaine infusion may be substituted. Like other class IA agents, mexiletine increases long-term mortality and is infrequently used.[205]

Tocainide is an orally active, analogue of lidocaine indicated in the chronic treatment of complex ventricular dysrhythmias. Response to lidocaine is often, but not always, predictive of response to tocainide and mexiletine. Like lidocaine, tocainide is ineffective against supraventricular dysrhythmias. Tocainide and mexiletine are not necessarily interchangeable.

Following oral administration, peak blood concentrations occur at 1–2 hours. Tocainide undergoes both hepatic metabolism and renal elimination, with a 15-hour half-life. Adverse reactions following oral administration occur in approximately 40% of patients. These include nausea, vomiting, tremor, paresthesia and rash. Tocainide worsens symptoms of CHF in approximately 5% of patients and may be prodysrhythmic in 1–8% of patients. *Because tocainide can cause potentially fatal bone marrow aplasia and pulmonary fibrosis, it is no longer available in the United States.*

Phenytoin

Although mainly used as an anticonvulsant, phenytoin has been used in patients with prolonged QT syndromes, atrial and ventricular dysrhythmias, and chronic ventricular dysrhythmias. Since the advent of Fab fragments, phenytoin is now rarely used to treat digoxin toxicity. In addition to its class IB effects, much of phenytoin's antidysrhythmic activity is a result of centrally mediated sympatholysis. It is well tolerated orally in doses of 300 mg/d, titrated to serum blood levels and side effects. A usual loading dose is 1000 mg given at a rate that does not exceed 50 mg/min, while the ECG and blood pressure are monitored to prevent hypotension and cardiovascular collapse.

Phenytoin undergoes hepatic metabolism with excretion in the bile, enterohepatic reabsorption, and subsequent urinary excretion. It has a 22-hour half-life. Common adverse effects include nystagmus, ataxia, slurred speech, confusion, and dizziness. Rarely, reactions that are more serious include severe dermatitis, Stevens-Johnson syndrome, and possibly hematologic malignancies. In patients with liver disease or any altered metabolic state, or when given with a wide range of other medications, phenytoin levels should be reassessed.

Class IC Agents

Available class IC agents, such as flecainide and propafenone, have the greatest effect on phase 0 of the action potential with minimal effect on repolarization (Table 43–12). As previously mentioned, moricizine shares many

TABLE 43–12.

Class IC Antidysrhythmic Agents

Drug	Usual Dosage and Interval	Effect on Electrocardiogram	Adverse Effects	Usually Effective Plasma Concentration	Indications	Half-Life	Metabolism
Flecainide (Tambocor)	PO initial dose: 100 mg q12h, increase q4–6d if required, by 50 mg q12h; PO maintenance: up to 400 mg/d	Prolongs PR and QRS	Bradycardia; heart block; new ventricular fibrillation; sustained ventricular tachycardia; heart failure; dizziness; blurred vision; nervousness; headache; GI upset; neutropenia	0.2–1 μg/mL	Ventricular dysrhythmias	12–27 h; unchanged renally	Hepatic; 10–50% excreted
Encainide (Enkaid)	PO initial dose: 25 mg q8h, increase q4–6d if required to 35 mg q8h, and then to 50 mg q8h; maintenance: up to 200 mg/d	Prolongs PR and QRS	Bradycardia; heart block; new ventricular fibrillation; sustained ventricular tachycardia; heart failure; dizziness; headache visual disturbances; diarrhea; GI upset; glucose intolerance	Active metabolites preclude establishment	Ventricular dysrhythmias	12 h	Hepatic metabolism; renal excretion
Propafenone (Rythmol)	PO initial dose: 150 mg q8h, increase q3–4d if required; PO maintenance: 150–300 mg q8h	Prolongs PR and QRS	Bradycardia; heart block; new ventricular fibrillation; sustained ventricular tachycardia; heart failure; dizziness; light-headedness; metallic taste; dysgeusia; GI upset; bronchospasm	Active metabolites preclude establishment	Ventricular dysrhythmias	6–7 h	Hepatic metabolism; renal excretion

Data from Abramowicz M. ed. Drugs for cardiac arrhythmias. Med Lett Drugs Ther 1991;33:60.

of these properties as well. These drugs suppress automaticity of the SA node, slow AV node, His-Purkinje and ventricular conduction. On the ECG, PR and QRS intervals are lengthened, but QTc intervals are largely unchanged. Data from the CASTs that suggest increased mortality with class IC agents after MI have limited their use.[206] Type IC agents all profoundly suppress cardiac conduction, which may explain their proarrhythmic effects.

Flecainide

Flecainide is indicated in suppression of both ventricular and supraventricular tachycardias, including Wolff-Parkinson-White syndrome. Usual doses are 200–400 mg daily given in divided doses. Although it undergoes hepatic metabolism, approximately 30% of flecainide is renally excreted, with a usual half-life of 12–27 hours.[207]

As with all antidysrhythmics, flecainide has prodysrhythmic effects. Data from the CASTs have limited its use to pharmacologic cardioversion and maintenance of sinus rhythm in symptomatic atrial fibrillation in patients without heart disease and in patients with hypertension but no left ventricular hypertrophy.[206] Flecainide has a negative inotropic effect, can aggravate CHF in approximately 15% of patients, and can cause sinus arrest, AV block, and intraventricular conduction disturbances.[208] Because flecainide can increase pacemaker thresholds up to 200%, it should be used with caution in patients with conduction disease. Other adverse effects include dizziness, blurred vision, GI upset, and neutropenia. Flecainide dosages may need to be reduced when given with cimetidine or amiodarone. Conversely, digoxin and propranolol doses must be reduced when flecainide is introduced. Finally, β-adrenergic blocking agents and flecainide may have additive negative effects on myocardial contractility. Few data are available about interaction with anesthetics.

Encainide

Encainide is no longer readily available in the United States because the CASTs

showed increased incidence of fatal arrhythmias with encainide.[206] It remains available for compassionate use for those who were taking encainide prior to its discontinuation. Encainide's mode of action and indications are similar to those of flecainide. Its pharmacokinetics are complex. Ninety-three percent of the population (normal metabolizers) metabolizes encainide to active metabolites, yielding a 25% bioavailability and half-life between 1 and 12 hours for the various metabolites. In the remaining 7% of the population (slow metabolizers), encainide has a 90% bioavailability and a half-life as long as 20 hours.[209]

Propafenone

Propafenone, an antidysrhythmic agent approved for management of ventricular dysrhythmias, is a sodium channel blocker with mode of action similar to the other approved class IC agents, flecainide and encainide.[210] Because data from the Cardiac Arrhythmia Suppression Trial Investigators[206] suggested increased mortality in patients taking encainide and flecainide, these drugs were relabeled. Currently, they are only approved in patients with life-threatening dysrhythmias. Because propafenone has a mode of action similar to these two agents, it is also generally used for the same indications.

Propafenone has shown evidence in vitro and in vivo of β-adrenergic blocking properties. Oral propafenone increases human lymphocyte B-cell adrenoreceptor density, a phenomenon observed with other β-blockers. In healthy patients and asthmatic persons, propafenone decreases heart rate during exercise, increases airway reactivity to methacholine, and decreases hemodynamic response to isoproterenol.[210] As with other class IC agents, propafenone increases the QRS interval, even at normal heart rates. QT intervals are increased only to the extent that QRS intervals increase. The PR, AH, and HV intervals may also increase. Propafenone depresses sinus node automaticity and increases refractoriness in atrium, AV node, ventricle, and accessory pathways. It has a negative inotropic effect, which may reduce ejection fraction in normal subjects and produce symptoms of CHF in approximately 0.8–2.5% of patients. As with other class IC agents, propafenone may worsen conduction system disease.

After oral administration and absorption, propafenone undergoes a cytochrome P450 metabolism that varies genetically. In 93% of the population, the half-life is 6–7 hours; in the remaining 7% of the population, the elimination half-life is 12–32 hours.[210] Usual starting doses are 150 mg every 8 hours, which may be increased up to 1200 mg/d. Propafenone increases plasma concentrations of digoxin, warfarin, and metoprolol; consequently, dosages of these drugs may need adjustment.

In clinical studies, propafenone has been effective in suppression of frequent ventricular ectopy, nonsustained ventricular tachycardia, and exercise-induced ventricular ectopy. Propafenone has proven useful in prevention of atrial fibrillation and suppression of AV node and accessory pathway supraventricular dysrhythmias. Even when propafenone is not able to suppress these dysrhythmias, it is effective at slowing the heart rate.

Other adverse effects include worsening of asthma and bronchoconstriction, dizziness, and CNS and GI disturbances. Rare cases of cholestatic jaundice have been reported.[210]

Class III Agents

Class III agents include amiodarone, bretylium, sotalol, ibutilide, dofetilide, and azimilide (Table 43–13). Their predominant effect is to prolong APD and increase ERP via action on potassium channels; ERP to APD ratio is also increased. However, each of these agents has additional effects on other channels and receptors rendering this class of agents a very heterogenec one.

Amiodarone

Some physicians consider amiodarone is to be the most efficacious antidysrhythmic agent available; unfortunately, however, it is associated with a high incidence of side effects. It is a structural analogue of thyroid hormone and is highly lipophilic. Many of its side effects are caused by either its thyroxin-like structure or its large volume of distribution and affinity for many tissues.

The electrophysiologic effects of amiodarone are complex. Like all class III agents amiodarone delays repolarization and increases duration of the action potential. Its primary mechanism involves blocking K channels, thereby prolonging repolarization. In doing so, the ERP is increased and the incidence of reentry rhythms decreased in all cardiac tissues.[211] In addition to blocking K channels, amiodarone is a vasodilator, acting on cardiac and vascular smooth muscle. Consequently, it dilates coronary arteries and causes decreased afterload and oxygen consumption. It also noncompetitively antagonizes α and β receptors, blocks conversion of thyroxin to triiodothyronine, and blocks inactivated Na and Ca channels. As such, amiodarone's effects on the ECG are complex; it slows the sinus rate, prolongs PR interval and AV node conduction, widens QRS complex, and prolongs QT interval.[212]

Amiodarone is effective in prevention of ventricular tachycardia and fibrillation, in treatment of supraventricular tachycardias with and without preexcitation syndromes, and in conversion and control of paroxysmal atrial fibrillation and flutter or other dysrhythmias associated with hypertrophic cardiomyopathies. It does decrease the incidence of postoperative atrial fibrillation after open-heart surgery.[213] Intravenous amiodarone may improve short-term survival in patients with ventricular fibrillation or hemodynamically unstable ventricular tachycardia that persists despite defibrillation or recurs promptly after successful defibrillation.[201,214] The Antiarrhythmics Versus Implantable Defibrillator (AVID) trial, which included patients with an ejection fraction less than 40% and who had suffered spontaneous hypotensive ventricular tachycardia or cardiac arrest, showed an improved survival in patients in the implantable cardioverter-defibrillator (ICD) group. Nevertheless, despite its toxicity, the use of amiodarone is appropriate for the management of recurrent ventricular fibrillation or unstable ventricular tachycardia in patients with ICDs. In the intraoperative and postoperative settings, IV amiodarone can be used to treat a variety of ventricular and supraventricular arrhythmias. It can be used to convert new onset atrial fibrillation into sinus rhythm. In addition, its use is now ACLS recommended for the treatment of pulseless ventricular tachycardia and ventricular fibrillation refractory to defibrillation, stable ventricular tachycardia, wide complex supraventricular tachycardia, and atrial fibrillation.[215]

Amiodarone is highly lipophilic, with a very large volume of distribu-

TABLE 43–13.

Class III Antidysrhythmic Agents

Drug	Usual Dosage and Interval	Effect on Electrocardiogram	Adverse Effects	Usually Effective Plasma Concentration	Indication	Half-Life	Metabolism
Amiodarone (Cordarone)	PO loading:800–1600 mg/d 1–3 weeks then 600–800 mg/d for 4 weeks; PO maintenance: 100–400 mg/d cardia IV 150 mg over 10 min then 1 mg/min × 6 then 0.5 mg/min; may be rebolused for breakthrough arrhythmias	Prolongs PR, QRS, and QT	Bradycardia; heart block; new ventricular fibrillation; sustained ventricular tachycardia; torsade de pointes; GI upset; alcoholic-like hepatitis; phospholipidosis; ataxia; tremor; dizziness; acute pulmonary toxicity; pulmonary fibrosis; photosensitivity; blue-gray skin; corneal microdeposits; hyper- or hypothyroidism; increased serum cholesterol	Not established	Ventricular and supraventricular dysrhythmias	26–107 days	Hepatic
Bretylium (Bretylol and others, Bretylate in Canada)	IV loading: 5 mg/kg with additional doses of 10 mg/kg to maximum of 30 mg/kg (effect must be delayed); IV maintenance: 5–10 mg/kg q6h or continuous infusion 1–2 mg/min	No change; sinus bradycardia	Orthostatic hypotension; nausea and vomiting; increased sensitivity to catecholamines; initial increase in dysrhythmias	Not established	Ventricular dysrhythmias	8 h; increased in renal failure	Renal
Sotalol	PO: 40–80 mg q12h increased to 320 q12h as necessary; IV: 0.2 mg/kg initially, increasing to 1.5 mg/kg over 5 min	Prolongs PR and QT interval	Bradycardia; heart block; torsade de pointes; congestive heart failure; bronchospasm; worsening arrhythmics	0.8–2.6 mg/mL	Ventricular dysrhythmias (used for supraventricular arrhythmias in Europe)	12 h	Renal
Ibutilide	IV: 1–2 mg	Prolongs QT interval	Torsade de pointes		Atrial fibrillation and atrial flutter	2–12 h	Hepatic/renal
Dofetilide	PO: 0.125–0.5 mg q12h IV: 4–8 µg/mL	Prolongs QT interval	Torsade de pointes		Conversion of atrial fibrillation and atrial flutter to sinus rhythm and prevention of recurrence	7–13 h	Hepatic/renal

Data from Abramowicz M, ed. Drugs for cardiac arrhythmias. Med Lett Drugs Ther 1991;33:60.

tion; consequently, it needs a long time to reach stable plasma concentrations and has a very long and variable elimination half-life—26–100 days. The North American Society of Pacing and Electrophysiology (NASPE) has published guidelines for the use of amiodarone. With oral therapy, the recommended loading dose for ventricular arrhythmias is 800–1600 mg/d (usually in divided doses) for up to 3 weeks, followed by a maintenance level of 400–600 mg/d during the first year. The maintenance level can be further decreased to 200–300 mg/d. With intravenous therapy, an initial loading dose of 150 mg is given over 10 minutes. The loading dose should be followed by a continuous infusion of 1 mg/min for 6 hours followed by 0.5 mg/min thereafter. Amiodarone should be mixed in a 5% dextrose solution and the amiodarone concentration kept below 2 mg/mL if given through a peripheral vein so as to minimize the development of local phlebitis.[216] In pulseless ventricular tachycardia and fibrillation, 300 mg is given as a bolus.

Amiodarone has little negative inotropic effect, and is frequently used with caution in patients with CHF. It may cause symptomatic heart block, requiring permanent pacemaker insertion in approximately 4% of patients. Its incidence of prodysrhythmic effects is 1–2%; this is less than that associated with other antidysrhythmics.

Noncardiac effects of amiodarone are dose related and occur often. These include photosensitivity dermatitis (which sometimes results in an iridescent blue-gray discoloration), corneal micro deposition, hyper- and hypothyroidism, pulmonary infiltration and fibrosis, tremor, ataxia, neuropathies, myopathies, hepatitis, and gastrointestinal symptoms.[212]

The very long half-life makes preoperative discontinuation impossible. In the past, serious adverse effects have been reported for patients anesthetized while receiving amiodarone. This likely represents the degree of underlying disease in this patient population rather than the drug itself. A poorly understood postoperative acute respiratory distress syndrome (ARDS) has been described in patients taking oral amiodarone who undergo cardiac or noncardiac surgery.[217] Whereas, the hemodynamic consequences of chronic oral amiodarone therapy during noncardiac surgery are usually limited to hypotension, in the cardiac surgery AV nodal blockade, left ventricular dysfunction and extreme systemic vasodilatation have been reported. As a result, AV pacing, inotropes, and vasoconstrictors should be available and administered as necessary.[217] In an isolated animal heart model, amiodarone in conjunction with potent inhalation agents caused an additive decrease in heart rate and inotropy, along with prolongation of AV conduction time.[218] Despite its hemodynamic and pulmonary side effects, amiodarone remains a valuable therapy for perioperative life-threatening ventricular arrhythmias refractory to conventional therapy.

Bretylium

Bretylium has been approved for parenteral use in patients with life-threatening ventricular arrhythmias unresponsive to other therapies. Its use has been, by and large, usurped by amiodarone in newer ACLS protocols.

Bretylium has a direct class III action, with increased APD and ERP. In addition, after initially causing norepinephrine release from postganglionic adrenergic nerve terminals, it blocks further release of norepinephrine producing a state resembling chemical sympathectomy.[212] When given intravenously to patients without cardiac arrest, bretylium is administered as a 5-mg/kg loading dose over 10–20 minutes, which may be repeated up to a total dose of 20 mg/kg if no response occurs. Subsequently, a maintenance infusion of 1 to 4 mg/min may be used. Because bretylium is eliminated unchanged in the urine, maintenance infusions must be decreased if creatinine clearance is reduced. In cardiac emergencies, bretylium is given as a rapid bolus in doses of 5–10 mg/kg.

After an initial increase in blood pressure, bretylium can cause significant hypotension, especially in volume-depleted patients. Orthostatic hypotension occurs in almost all patients and may persist for days after drug discontinuation. It has minimal effects on myocardial contractility. Rapid infusion can cause nausea and vomiting in awake patients.

The anesthetic implications for patients receiving bretylium are worth noting. By blocking catecholamine release, bretylium causes the equivalent of a denervated state. Direct-acting catecholamines may cause exaggerated responses, and indirect agents may be less effective. Bretylium may also be used to treat bupivacaine-induced ventricular arrhythmias.[219]

Sotalol

Sotalol is another class III antiarrhythmic agent with mixed properties. It is a racemic mixture of *d*- and *l*-sotalol isomers. The *d* isomer has class III antiarrhythmic properties, blocking K channels and prolonging repolarization, whereas the *l* isomer prolongs repolarization and has noncardioselective β-blocking capabilities without any intrinsic sympathomimetic activity or membrane-stabilizing effects.[220] The β-blocking effects of sotalol occur at considerably lower doses than the class III effects.[221]

The electrophysiologic effects of sotalol include an increase in APD and prolongation of ERP. The prolongation of the APD is greater at slower heart rates (reverse use dependence). Automaticity is decreased and, in a manner similar to other β-blockers, sotalol decreases heart rate and slows conduction through the AV node. On ECG, the PR and QT intervals may increase.

The hemodynamic effects of sotalol are secondary to a combination of β-adrenergic antagonist-mediated negative inotropic effects and a propensity to increase contractility secondary to prolonged repolarization, which occurs maximally at slower heart rates.

Sotalol is FDA approved for treatment of life-threatening ventricular arrhythmias. It is also effective for treating supraventricular arrhythmias, as it slows sinus tachycardia, slows the ventricular response rate to atrial fibrillation, and converts atrial flutter and fibrillation to normal sinus rhythm. Sotalol appears to be as effective as β-blockers and amiodarone for the prevention of atrial fibrillation after cardiac surgery.[222]

Table 43–13 summarizes the usual dosage, effective plasma concentration, half-life metabolism, and side effects of sotalol. Notably, many of the adverse effects of sotalol are secondary to its β-blocking activity. These include fatigue, dizziness and dyspnea, aggravation of bronchospasm, hypotension, and bradycardias, much like other β-blockers. However, exacerbations of CHF occurs less frequently with sotalol.[220]

Like all other class III antiarrhythmic drugs, sotalol has an arrhythmogenic

TABLE 43–14.

Unclassified Antiarrhythmic Agents

Drug	Usual Dosages	Effects on Electrocardiogram	Adverse Reactions	Usually Effective Plasma Concentration	Indications	Half-Life	Metabolism
Adenosine	6–12 mg IV (may repeat 12 mg × 2)	Increased PR interval; AV block	High-grade block; asystole; hypotension; dizziness; nausea; headaches	0.5–2 μg/mL	Paroxysmal supraventricular tachycardias including Wolff-Parkinson-White syndrome	10 sec	Metabolized to inosine and adenosine monophosphate

Data from Abramowicz M, ed. Drugs for cardiac arrhythmias. Med Lett Drugs Ther 1991;33:60.

potential; ventricular tachyarrhythmias occur in approximately 4% of patients and torsade de pointes occur in approximately 2.5% of patients.[212] Predisposing factors include electrolyte disorders (hypokalemia, hypomagnesemia), diuretic therapy, female gender, bradycardia, and concurrent therapy with other drugs that prolong repolarization (e.g., amiodarone, disopyramide, and flecainide).

Studies using an animal heart model show that halothane may sensitize the heart to pharmacologic K channel blockade.[223] Caution should probably be taken when using halothane in patients taking sotalol, although there are no studies to support this. No data exist on the interactions between sotalol and anesthetics.

Ibutilide

Ibutilide has been approved for acute termination of atrial fibrillation or flutter of recent onset. Like other class III agents, it blocks outward potassium currents; however, unlike other class III drugs, ibutilide also blocks inward sodium currents through slow inward sodium channels. It thereby prolongs repolarization, the action potential duration, and the refractory period. It does not affect AV conduction or QRS duration on the ECG, but it does prolong the QT interval.[224]

The drug undergoes extensive first-pass metabolism and is renally excreted. It is not used orally. Intravenous dosage is usually 1 mg over 10 minutes and may be repeated a second time. Half-life varies between 2 and 12 hours.

In addition to the use for pharmacologic conversion or facilitation of electrical cardioversion of conventional atrial fibrillation, ibutilide may be used to convert atrial fibrillation that occurs after cardiac surgery.[225]

Ibutilide has no significant hemodynamic effects. Its major side effect is QT prolongation and torsade de pointes, which happens in approximately 2% of patients, especially those with left ventricular dysfunction.[212] In light of this, its use is limited to patients with preserved left ventricular function and normal QT intervals.

Dofetilide

Dofetilide is approved for acute conversion of atrial fibrillation and atrial flutter to sinus rhythm, and for prevention of recurrence of atrial fibrillation.[226]

It is a very potent K channel blocker that prolongs repolarization more prominently in the atria than in the ventricle.[212] Because it is a pure blocker of outward potassium currents, it does not have significant hemodynamic effects, does not depress cardiac function, and lacks extra cardiac effects.

It is partially metabolized in the liver and excreted predominantly in the urine, with an elimination half-life of 7–13 hours. The recommended dose is 0.125–0.5 mg twice daily, initiated under continuous ECG monitoring.[212] Higher-than-usual doses may be required in patients taking drugs that accelerate hepatic metabolism, such as phenytoin.

The most significant adverse effect is QT prolongation and torsade de pointes. Because of its proarrhythmic capabilities the American College of Chest Physicians guidelines do not recommend it for prevention and management of atrial fibrillation after cardiac surgery.[227]

Other Nonclassified Agents

Adenosine

Adenosine is an endogenous nucleotide natural to all cells of the body (Table 43–14). In pharmacologic doses, it slows conduction through the AV node and is proven highly efficacious as acute IV therapy for patients with paroxysmal supraventricular tachycardia in both reentry and accessory pathway (Wolff-Parkinson-White) dysrhythmias. Although adenosine does not convert atrial fibrillation or atrial flutter to sinus rhythm, it may be useful in their diagnosis. It may also terminate adrenergic-sensitive ventricular tachycardias originating from the right ventricular outflow tract.[47]

After IV administration, adenosine undergoes rapid redistribution to erythrocytes and cells of the vascular endothelium, with a half-life estimated at less than 10 seconds. Subsequently, it is metabolized to inosine or adenosine monophosphate. After a bolus of 6 mg, approximately 60% of patients with paroxysmal supraventricular tachycardia will convert to sinus rhythm within 1 minute. If the initial bolus is unsuccessful, 12 mg given intravenously will convert most of the remaining patients, for a cumulative effectiveness of 92%. Transient high-grade blocks, and even asystole, may be seen following adenosine administration. These usually resolve rapidly and without therapy. Dipyridamole blocks reuptake of adenosine, delaying its clearance and potentiating its effects, whereas caffeine and

TABLE 43–15.

Statins

Drug	Dose	Side Effects
Atorvastatin (Lipitor)	10–80 mg/d	Hepatotoxicity (elevation of aminotransferases); myopathy (factors associated with increased risk include advanced age, hepatic or renal dysfunction, perioperative periods, multisystem disease especially diabetes mellitus, hypothyroidism); proteinuria; headache; nausea
Fluvastatin (Lescol)	20–80 mg/d 80 mg SR/d	
Lovastatin (Mevacor)	20–80 mg/d	
Pravastatin (Pravachol)	10–80 mg/d	
Rosuvastatin (Crestor)	5–40 mg/d	
Simvastatin (Zocor)	5–80 mg/d	

methylxanthines are competitive antagonists, necessitating larger doses of adenosine to achieve clinical effect.[212]

Adenosine is contraindicated in patients with sick sinus syndrome and second- or third-degree AV block. Hypotension may develop, especially when higher dosages are used. Other adverse side effects include facial flushing, headache, chest pain, dyspnea, dizziness, and nausea. Adenosine may precipitate ventricular fibrillation in patients with Wolff-Parkinson-White syndrome when administered during preexcited atrial fibrillation.[228]

Adenosine is also used to induce ischemia in both laboratory models of coronary steal with flow-limiting stenosis and clinically to elicit ischemia in adenosine-thallium scan. Adenosine is not FDA approved for use as a vasodilator or for deliberate intraoperative hypotension. Preclinical studies showed that intrathecal adenosine might be effective in the treatment of acute and chronic pain.[229]

STATINS

Because patients with dyslipidemias are at an increased risk of developing atherosclerosis and subsequent coronary artery disease, lipid lowering is beneficial for both primary and secondary prevention of coronary heart disease, as shown in several studies involving large populations.[230–232] The statins are the most effective and best-tolerated agents for treating dyslipidemias, and have revolutionized the treatment of lipid abnormalities (Table 43–15).

The mechanism of action is competitive inhibition of 3-hydroxy-3-methylglutaryl coenzyme A reductase, which catalyzes an early, rate-limiting step in cholesterol biosynthesis, resulting in reduction of low-density lipoprotein cholesterol (LDL-C) levels, the major effect exerted by the statins.

The protective effect related to the use of statins cannot be completely explained by the lowering of LDL-C at baseline. Among the nonlipid-related mechanisms that may be involved are regression of atherosclerotic lesions, plaque stabilization, reduced inflammation, reversal of endothelial dysfunction, and decreased thrombogenicity.[233] Nonlipid properties may be observed earlier than lipid effects.

Several mechanisms may be responsible for the development of coronary ischemia and myocardial infarction in the perioperative setting but there is evidence that coronary plaque rupture, which leads to thrombus formation and coronary artery occlusion, is the most important mechanism.

Recently, several studies analyzed the effect of statin agents on perioperative cardiovascular mortality and morbidity in patients undergoing noncardiac surgery.[234–238] Results of these studies, most of them retrospective, showed a reduction in the perioperative cardiovascular events or mortality.

Statins are effective and generally safe. However, certain side effects are associated with their use, particularly hepatotoxicity and myopathy. Although the incidence of myopathy is low (0.01%), the risk of myopathy, and even of rhabdomyolysis, increases in proportion to plasma statin concentration. There are case reports of perioperative myopathy and rhabdomyolysis in patients treated with statins.[239] Although the benefit and the risk of continuing these agents remain to be demonstrated in large randomized clinical trials, the data strongly suggest that they should be continued through the perioperative period.

CHAPTER 44

Pharmacology of Local Anesthetics*

James E. Heavner, DVM, PhD

Local anesthetics are widely used to prevent or treat acute pain; to treat inflammatory, cancer, and chronic pain; and for diagnostic and prognostic purposes. Drugs classified as local anesthetics reversibly block action potential propagation in axons by preventing the sodium entry that produces the potentials.[1] However, other actions of these drugs, such as antiinflammation by interaction with G-protein receptors,[2] also are thought to be relevant to their use to prevent or treat pain. Nociceptive pain, as well as neuropathic pain, are targeted with this group of drugs. Any part of the nervous system, from the periphery to the brain, may be where local anesthetics act to produce a desired anesthetic or analgesic effect. A variety of formulations of local anesthetics, routes of administration, and methods of administration are used. The drugs are formulated commercially or by medical personnel according to the intended route of administration and/or to address specific concerns or needs. This chapter provides a concise review of the pharmacology of local anesthetics.

DISCOVERY AND EVOLUTION OF LOCAL ANESTHETICS

Cocaine, Procaine, and Lidocaine

Koller is credited with introducing local anesthetics into medical practice when he used cocaine to numb the cornea before operating on the eye.[3] Fundamental to the development of synthetic local anesthetics was isolation of cocaine by Neimann, in 1860, from coca beans, and elucidation of its chemical structure. Procaine was first synthesized in 1904, and lidocaine was first synthesized in 1943. Synthesis of molecules with local anesthetic activity paved the way for "tinkering" with the molecules by systematically modifying chemical structure and testing for a desired result, for example reducing toxicity, in developing new local anesthetics.

Roots of Modern Use

Figure 44–1 presents a chronology of the introduction of local anesthetics into clinical practice. Four amino ester-linked local anesthetics (see Three Parts of Local Anesthetic Molecules) appear in the figure: cocaine, procaine, tetracaine, and chloroprocaine. The other local anesthetics are amino amide linked. What is evident from the figure is the focus since 1955 on the development of amino amide- and not amino ester-linked local anesthetics. Reasons for this include the allergenic potential of amino ester-linked local anesthetics and the instability of amino ester bonds.

IMPORTANT CHEMICAL FEATURES

Three Parts of Local Anesthetic Molecules

All local anesthetic molecules in clinical use have three parts: lipophilic (aromatic) end, hydrophilic (amine) end, and a link between the ends (Fig.

KEY POINTS

1. Pharmacodynamics—Local anesthetics stop the propagation of action potentials in nerve axons by preventing the influx of sodium through voltage-gated sodium channels in the axon membrane. Other actions of local anesthetics, for example, effects on other voltage-gated ion channels and ligand-gated ion channels, may be important for their analgesic action and/or for undesired side effects.
2. Chemistry—Local anesthetics are weak bases with three structural parts: a hydrophilic end and a lipophilic end linked by an amino ester or an amino amide bond. The bond is the basis for classifying local anesthetics into 2 groups: the amino esters and the amino amides. Optical isomers of local anesthetics with an asymmetric carbon atom usually differ in potency, duration of action, and toxicity.
3. Expression of local anesthetic action—In vitro, there generally is a positive correlation between molecular weight of local anesthetic molecules and lipophilicity, protein binding, duration of action, potency, and toxicity; there is an inverse relation with speed of onset. In vivo expression of local anesthetic action is dependent on other factors as well, such as injection site, dose, intrinsic vasoactivity, and formulation. The manifestation of sensory versus motor block varies and is dependent on many factors, including the agent and type of block technique.
4. Pharmacokinetics—Local anesthetics usually are injected near the target site instead of relying on systemic circulation to carry them there (except, e.g., intravenous regional anesthesia and treatment of certain neuropathic pain states). Barriers to the diffusion of local anesthetics to their target vary and are dependent on injection site (e.g., epidural vs. intrathecal), influence dose, speed of onset, and duration of action. Local anesthetics that reach systemic circulation are widely distributed in the body. Hydrolysis of the amino ester bond by esterases in blood is the primary biotransformation process for amino ester-linked local anesthetics. Hepatic extraction and biotransformation are important elimination and biotransformation pathways for amino amide-linked local anesthetics.
5. Toxicity—Local anesthetic toxicity can be categorized as allergic, tissue, cardiovascular, central nervous system, and methemoglobinemia. Concerns about cardiovascular toxicity related to bupivacaine have driven a search for long-acting local anesthetics with less cardiotoxic action.
6. Formulation—Substances are sometimes added to local anesthetic formulations to preserve the molecules, to prevent microbial growth, to prevent systemic absorption, to enhance and/or prolong local anesthetic action, and to enhance spread of the local anesthetic.

*This chapter includes substantial material from Covino BG. Pharmacology of local anesthetic agents. In: McRogers, JH Timber, GB Covino, DE Longnecker, eds. Principles and Practice of Anesthesiology. Vol 2. St. Louis: Mosby Year Book, 1993: 1235–1257.

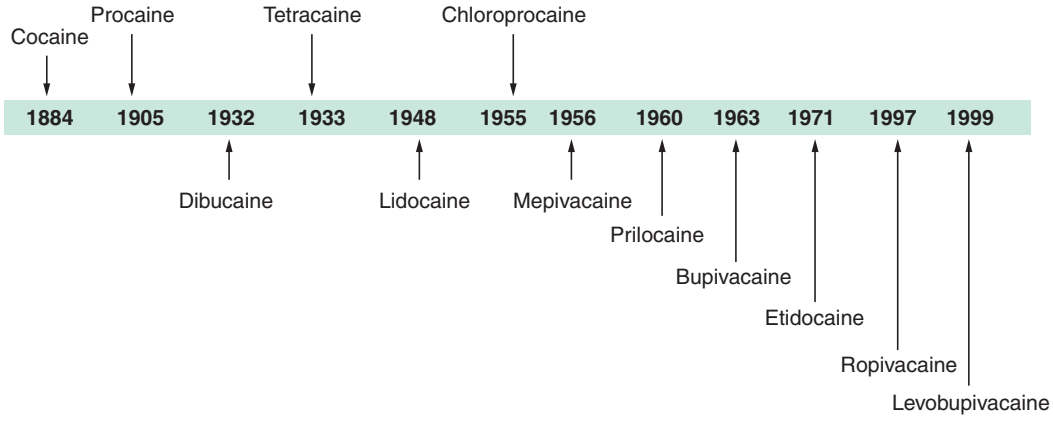

FIGURE 44–1. Chronology of the introduction of different anesthetics into clinical practice. Chloroprocaine (1955) is the last amino ester-linked local anesthetic introduced that is still in clinical use. (Courtesy of David A. Scott, Melbourne, Australia, 2000.)

44–2). The link contains either an amino ester or an amino amide bond and local anesthetics are designated as belonging to one of two groups: the amino ester-linked local anesthetics or amino amide-linked local anesthetics. Procaine is the prototypic amino ester-linked local anesthetic, and lidocaine is the prototypic amino amide-linked local anesthetic (Fig. 44–3).

Amino amides are extremely stable agents, whereas amino esters are relatively unstable in solution. Consequently, aqueous solutions of amino ester agents have relatively short shelf lives compared with solutions of amino amides, and are sensitive to exposure to high temperatures. The amino esters are hydrolyzed in plasma by cholinesterase enzymes, whereas the amino amide compounds undergo enzymatic biotransformation in the liver.

There are 2 varieties of amino amide local anesthetics based on the structure of the amino amide link. One variety is the aminoacyl amides, such as lidocaine and bupivacaine, and the other is the aminoalkyl amides such as dibucaine. The different structures influence the duration of action and biotransformation. Further distinction within the aminoacyl amide class is made based on whether the hydrophilic amino end is a straight carbon chain (e.g., lidocaine) or the amino nitrogen is within a ring structure (pipecoloxylidide, e.g., mepivacaine).

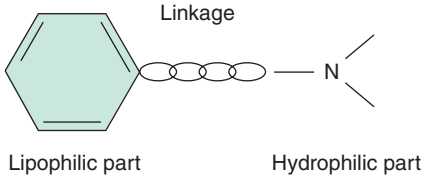

FIGURE 44–2. General structure of all local anesthetic molecules showing three parts.

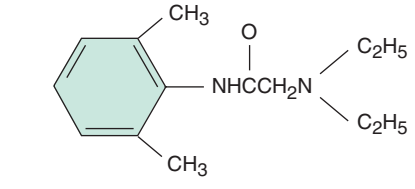
Chiral Forms

The newest additions to clinically available local anesthetics, ropivacaine (Fig. 44–4) and levobupivacaine, represent (a) the exploitation of technology that permits cost-favorable separation of racemic mixtures of local anesthetics into pure enantiomers and (b) the search for local anesthetics with greater safety margins. Simplistically stated, molecules with an asymmetric carbon atom exist in forms that are mirror images (i.e., exhibit "handness, chirality"), with images (enantiomer, stereoisomers) distinguished by how they rotate light according to the orientation of the structures in three dimensions. Various terms are used to refer to the different enantiomers; this chapter uses S and R to designate two different enantiomers. A racemic mixture contains equal amounts of the R and S isomers. Commercial formulations of ropivacaine and levobupivacaine contain the S enantiomer. Note that levobupivacaine is the S form of bupivacaine. The motive for marketing pure enantiomers is evidence that the S form is less toxic, more potent, and longer acting than the R form or the racemic mixture (Table 44–1).



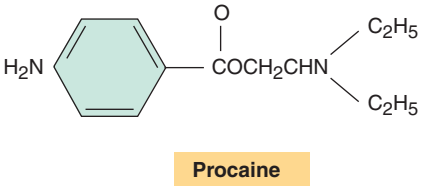


FIGURE 44–3. Structure of lidocaine and procaine.

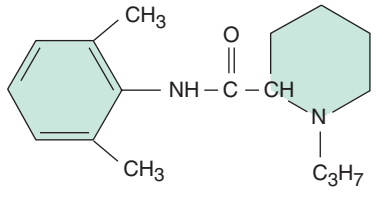
Lipid Solubility and Protein Binding

Testing modifications to the basic procaine and lidocaine structure revealed that increasing the molecular weight of the molecules by adding carbon atoms to either end of the structure or to the link generally increases lipid solubility, protein binding, and duration of action and toxicity, and influences biotransformation of the molecule (Figs. 44–5 and 44–6). There



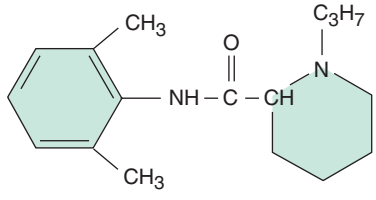


FIGURE 44–4. Clinical forms of ropivacaine. The only difference between the S- and R-isomers is their spatial orientation.

TABLE 44–1.

Anesthetic Duration and Toxicity of Local Anesthetic Isomers

Drug	Duration	Toxicity
Etidocaine	S=R	S=R
Mepivacaine	S>R	S=R
Bupivacaine	S>R	S<R
Ropivacaine	S>R	S<R

is a positive correlation between intrinsic local anesthetic potency and lipid solubility of local anesthetics.

Cation and Base Forms

Most local anesthetics have a tertiary amine on the hydrophilic end. Exceptions include prilocaine, which has a secondary amine and benzocaine, which has a primary amine. Tertiary amines have a positive charge (*cation*) or are uncharged (*base*). The ratio of cation to base is determined by the pK_a of the local anesthetic and the pH of the solution (Table 44–2). The unchanged forms of local anesthetics pass readily through cell membranes and hence speed of onset of local anesthetic block, at least theoretically, is increased by increasing the concentration of uncharged local anesthetic molecules injected.

Because local anesthetics are weak bases, increasing the pH ("alkalinization") of solution increases the ratio of base to cation. The Henderson-Hasselbalch equation can be used to quantitate the ratio:

$$pK_a(\text{local anesthetic}) - pH(\text{solution}) = \text{Log}\,([\text{cation}]/[\text{base}])$$

Sodium bicarbonate is used clinically to increase pH of local anesthetic solutions.

Important to note is that commercial aqueous solutions of local anesthetics are acidified, so the hydrophilic (cationic) state, which is water soluble, is favored. Overzealous alkalinization can cause local anesthetic molecules to precipitate from solution.

PHARMACODYNAMICS OF LOCAL ANESTHETICS

Neurophysiologic and Neuroanatomical Considerations

Reversible block of voltage-gated sodium channels in axons is generally thought to be how local anesthetics block sensory and motor function (Fig. 44–7). Some of the evidence supporting this is the following: (a) action potentials do not develop in axons exposed to local anesthetic; (b) sodium currents responsible for generation of action potentiations are blocked by these drugs; and (c) local anesthetics do not affect the transmembrane potential of axons. The "state" of the sodium channel (resting, open, inactivated) changes during the cycle of polarized, depolarized, repolarized. The order of affinity of local anesthetics for different channel states is open > inactivated > resting. Many investigators have shown that the block of propagation of action potentials is a function of frequency of depolarization, which supports the conclusion that the open state of the sodium channel is the primary target of local anesthetic molecules. This is referred to as "state-dependent block."

	Mepivacaine	Ropivacaine	Bupivacaine

Voltage-Gated Sodium Channels

Voltage-gated ion channels are ion channels (Na^+, K^+, Ca^{2+}, etc.) whose permeability is a function of transmembrane potential. There are a number of sodium channel subtypes that generally are divided into those that are tetrodotoxin sensitive (TTXs) and tetrodotoxin resistant (TTXr).[4]

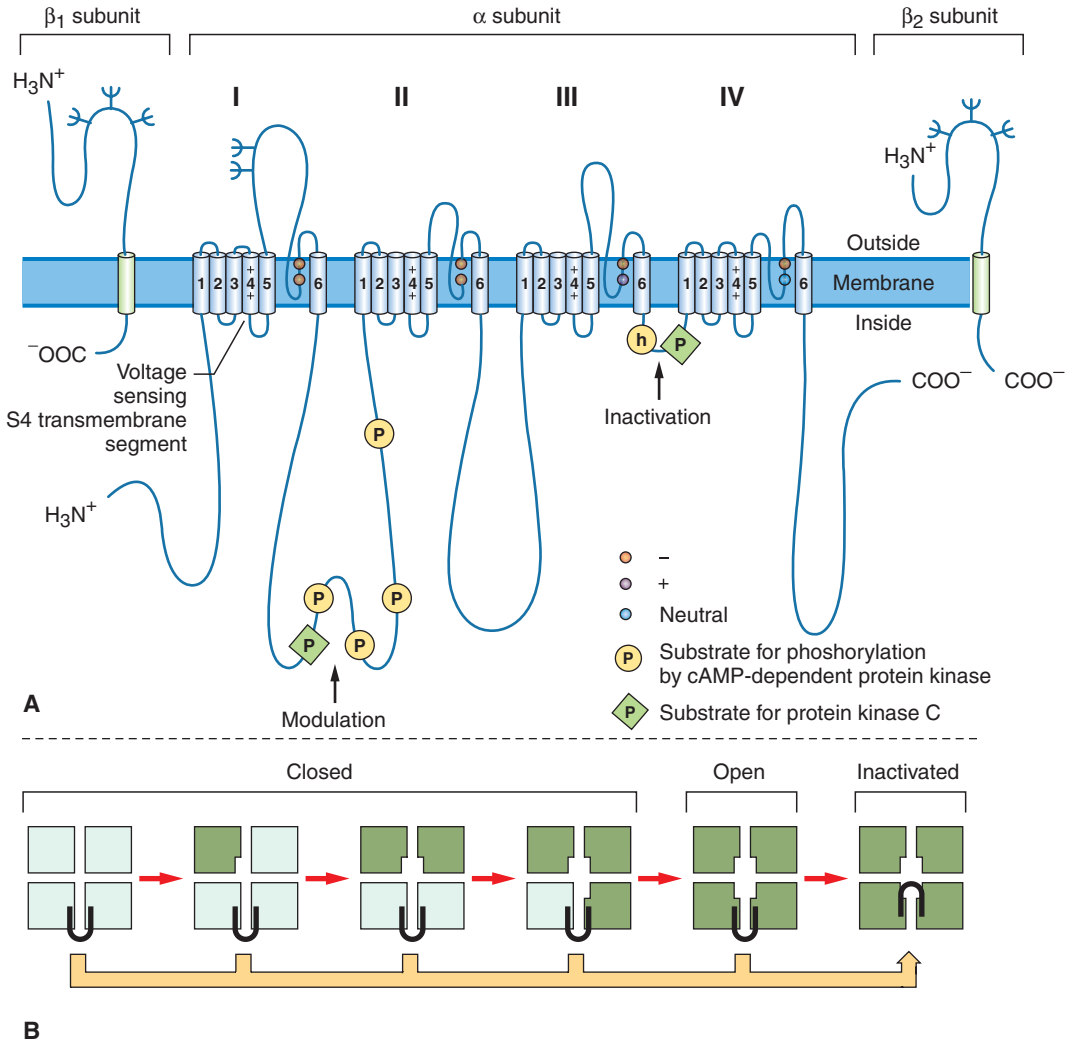

FIGURE 44–7. Structure and function of voltage-gated Na^+ channels. **A.** A two-dimensional representation of the α (center), β_1 (left), and β_2 (right) subunits of the voltage-gated Na^+ channel from mammalian brain. The polypeptide chains are represented by continuous lines with length approximately proportional to the actual length of each segment of the channel protein. Cylinders represent regions of transmembrane α helices. Ψ indicates sites of demonstrated *N*-linked glycosylation. Note the repeated structure of the four homologous domains (I through IV) of the α subunit. Voltage sensing: The S_4 transmembrane segments in each homologous domain of the α subunit serve as voltage sensors. (+) Represents the positively charged amino acid residues at every third position within these segments. An electrical field (negative inside) exerts a force on these charged amino acid residues, pulling them toward the intracellular side of the membrane. Pore: The S_5 and S6 transmembrane segments and the short membrane-associated loops between them (segments SS_1 and SS_2) form the walls of the pore in the center of an approximately symmetrical square array of the four homologous domains (see *B*). The amino acid residues indicated by circles in segment SS_2 are critical for determining the conductance and ion selectivity of the Na^+ channel and its ability to bind the extracellular pore blocking toxins tetrodotoxin and saxitoxin. Inactivation: The short intracellular loop connecting homologous domains III and IV serves as the inactivation gate of the Na^+ channel. It is thought to fold into the intracellular mouth of the pore and occlude it within a few milliseconds after the channel opens. Three hydrophobic residues (isoleucine–phenylalanine–methionine [IFM]) at the position marked *H* appear to serve as an inactivation particle, entering the intracellular mouth of the pore and binding to an inactivation gate receptor there. Modulation: The gating of the Na^+ channel can be modulated by protein phosphorylation. Phosphorylation of the inactivation gate between homologous domains III and IV by protein kinase C slows inactivation. Phosphorylation of sites in the intracellular loop between homologous domains I and II by either protein kinase C Ⓟ or cyclic adenosine monophosphate (AMP)-dependent protein kinase Ⓟ reduces Na^+ channel activation. **B.** The four homologous domains of the Na^+ channel α subunit are illustrated as a square array as viewed looking down on the membrane. The sequence of conformational changes that the Na^+ channel undergoes during activation and inactivation is diagrammed. Upon depolarization, each of the four homologous domains undergoes a conformational change in sequence to an activated state. After all four domains have activated, the Na^+ channel can open. Within a few milliseconds after opening, the inactivation gate between domains III and IV closes over the intracellular mouth of the channel and occludes it, preventing further ion conductance. (Reproduced with permission from Catterall W, Mackie K. Local Anesthetics. In Hardman JG, Limbird LE, Gilman AF, eds. The Pharmacological Basis of Therapeutics. 10th ed. New York: McGraw-Hill, 2001:370.)

Most sensory neurons generate TTXs currents. However, TTXr currents are present in a high proportion of smaller dorsal root ganglion neurons associated with nociceptive Aδ, and C fibers. Available evidence indicates that channels from both groups are involved in pain states as a result of changes in channel function and expression caused by disease or injury. Arguments have been put forth that local anesthetics might exert their pharmacologic action not only on Na^+ conductance, but also on other ionic conductances (e.g., K^+ and Ca^{2+}).[5,6]

TABLE 44–3.

Disposition Kinetics in Adult Human

Local Anesthetic	V_{dss} (L)	Cl (L/min)	$T_{1/2}\gamma$ (h)	Hepatic Extraction	Lipid Solubility	Protein Binding	Blood/Plasma Partitioning

Differential Block

Differential block, the block of pain perception without motor block for example, is observed clinically but the mechanism responsible for this is poorly understood. The clinical manifestations of differential block vary depending on the local anesthetic used.[7] For many years, differential block was ascribed to smaller axons being more sensitive than large ones to local anesthetics,[8] but this "size principle" was challenged.[9] Strichartz and Berde[7] cite a number of different factors that might contribute to differential block, including anatomical and relative sensitivity to sodium and potassium channels of different local anesthetics. Oda et al.[10] suggested that preferential block of TTXr sodium channels by ropivacaine in small dorsal root ganglia neurons (associated with nociceptive sensation) underlies differential block observed during epidural anesthesia with this drug.

Pain Relief by Systemic Administration

Another pharmacodynamic puzzle is the mechanism whereby systemically administered local anesthetic relieves pain. Analgesic effect has been reported following intravenous lidocaine administration in many acute and chronic conditions.[11–18] Subcutaneously injected bupivacaine reportedly produces analgesia via a systemic effect.[19] Normal or altered sodium channels located in various areas of the brain, spinal cord, or dorsal root ganglia, or in peripheral axons, are mentioned most frequently as the action sites. Zhang et al.[20] reported that in rats systemic lidocaine delivered via implanted osmotic pump reduces sympathetic nerve sprouting in dorsal root ganglion that is associated with some neuropathic pain behaviors. Takatori et al.[21] presented evidence that inhibition of nerve growth factor (NGF) stimulated tyrosine kinase activity of TrkA, a high-affinity receptor of NGF, might be involved in the suppression of neurite outgrowth by local anesthetics.

Ligand-Gated Ion Channels

Ligand-gated ion channels are channels whose permeability status depends upon the interaction between a ligand and a receptor that influences channel function. Many of these receptors interact with G proteins. Local anesthetics effect a number of biologic processes, including inhibition of G-protein coupled receptor signaling, that are potentially important pharmacodynamic actions of value in treating pain.

PHARMACOKINETICS OF INJECTED LOCAL ANESTHETICS

Distribution to the Target Site

The usual pharmacokinetics parameters (Table 44–3) presented for local anesthetics incompletely describe important details regarding distribution of these drugs from application sites to target and nontarget structures. It is well established that systemic absorption of local anesthetics correlates positively with the vascularity of the injection site (intravenous > tracheal > intercostal > paracervical > epidural > brachial plexus > sciatic > subcutaneous). The spinal cord meninges influence distribution of local anesthetics from the epidural and subarachnoid spaces. Intact skin is nearly a complete barrier to local anesthetic penetration. In the latter case, special local anesthetic formulations (e.g., eutectic mixture of local anesthetics [EMLA] cream, an eutectic mixture of lidocaine and prilocaine) or delivery methods (e.g., electrophoresis) are employed to facilitate transcutaneous transfer. The large number of different injection sites used (e.g., epidural, intrathecal, intrapleural, intraarticular, intramuscular, perineural, topical) and the variety of dosing methods (e.g., single shot, continuous infusion, intermittent infusion) make comprehensive discussion of all pharmacokinetic considerations beyond the scope of this chapter.

Absorption

In addition to the injection site, the vascular absorption of local anesthetic agents is related to dosage, addition of a vasoconstrictor agent, and specific agent employed. The high blood concentrations following intercostal administration are probably related to the multiple injections required for intercostal nerve blocks. As a consequence of this, local anesthetic solution is exposed to a greater vascular area, which results in a greater rate and degree of absorption. After thoracic paravertebral block, ropivacaine demonstrates a biphasic fast and slow absorption pattern.[22] The fast phase approximates the speed of intravenous injection and accounts for nearly half of ropivacaine absorption. When epinephrine (5 μg/mL) is added, systemic absorption and peak plasma concentration of ropivacaine is significantly reduced.

For most local anesthetic agents, a linear relationship exists between the amount of drug administered and the resultant peak venous plasma concentration. The mean venous plasma concentration of lidocaine increases from approximately 1.5–4 μg/mL as the total dose administered into the lumbar epidural space is increased from 200–600 mg. Depending on the site of administration, a peak blood concentration of 0.5–2.0 μg/mL is achieved for each 100 mg of lidocaine or mepivacaine injected. Simon et al.[23] reported that systemic absorption of ropivacaine following epidural administration was biphasic with higher absorption kinetics in younger than in older

patients. The absorption kinetics were in the same range as for other long-acting local anesthetics.

In general, the addition of epinephrine to local anesthetic solutions decreases the rate of vascular absorption of these agents.[24] Epinephrine 5 μg/mL (1:200,000) significantly reduces the peak blood concentrations of lidocaine and mepivacaine, regardless of the site of administration. However, peak blood concentrations of bupivacaine and etidocaine are minimally influenced by the addition of epinephrine following injection into the lumbar epidural space. On the other hand, the rate of vascular absorption of these agents is significantly decreased when epinephrine-containing solutions are employed for brachial plexus blockade.[25,26]

The rate of vascular absorption also varies, and is dependent on the specific local anesthetic agent. Lidocaine is absorbed more rapidly following brachial plexus and epidural blockade than is prilocaine, whereas bupivacaine is absorbed more rapidly than etidocaine.[24,26] Prilocaine is a less-potent vasodilator than lidocaine, which partly accounts for lower blood concentrations of prilocaine. The lower peak blood concentrations of etidocaine compared with bupivacaine may be related to the greater lipid solubility of etidocaine, which results in its sequestration by adipose tissue and a decreased rate of absorption. The differences in absorption rates are of practical clinical significance, as they permit the use of larger doses of prilocaine compared with lidocaine and of etidocaine compared with bupivacaine.

Systemic Distribution

The distribution of local anesthetic agents from systemic circulation can be described by a two- or three-compartment model.[27] The rapid disappearance (α) phase is believed to be related to uptake by rapidly equilibrating tissues, that is, tissues with a high vascular perfusion. The slower phase of disappearance from blood (β phase) is mainly a function of distribution to slowly equilibrating tissues and the biotransformation and excretion of the compound (Fig. 44–8). The α half-life ($T_{1/2\alpha}$) of prilocaine is shorter than that of lidocaine and mepivacaine, which indicates that prilocaine is redistributed at a significantly more rapid rate from blood to tissues than either of the other two drugs (Table 44–3). The $T_{1/2\alpha}$ of lidocaine and mepivacaine are similar. The half-life of the β disappearance phase ($T_{1/2\beta}$) of prilocaine is more rapid than that of lidocaine and mepivacaine, suggesting a more rapid rate of biotransformation. A comparison study reveals that etidocaine has a more rapid rate of tissue redistribution and biotransformation than bupivacaine.[28]

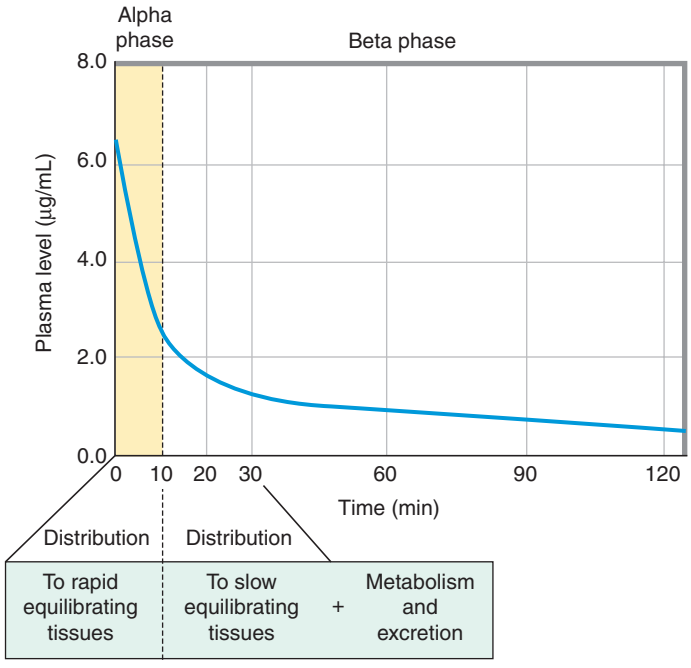

FIGURE 44–8. Plasma concentration curve of lidocaine following IV administration showing initial rapid rate of disappearance related to distribution to rapidly equilibrating tissues and slower rate of disappearance caused by distribution to slowly equilibrating tissues and biotransformation and excretion. (Reprinted from Covino BG. Pharmacology of local anesthetic agents. In: Rogers MC, Tinker JH, Covino BG, et al., eds. Principles and Practice of Anesthesiology. Vol. 2. St. Louis, MO: Mosby Year Book, 1993:1245, with permission from Elsevier.)

Local anesthetic agents are distributed throughout all body tissues, but the relative concentration in different tissues varies as a function of time, vascular perfusion, and tissue mass. Initially, local anesthetic agents are rapidly extracted by lung tissue so that the whole blood concentration of local anesthetics decreases greatly as they pass through the pulmonary vasculature.[29,30] Ultimately, the highest percentage of an injected dose of a local anesthetic agent is found in skeletal muscle, simply because the mass of skeletal muscle makes it the largest reservoir for local anesthetic agents.

Biotransformation and Elimination

The degradation of local anesthetic agents varies according to their chemical classification. Amino ester local anesthetic drugs are hydrolyzed in plasma by cholinesterase enzymes. Chloroprocaine shows the most rapid rate of hydrolysis (4.7 μmol/mL/h), compared with a rate of 1.1 μmol/mL/h for procaine and 0.3 μmol/mL/h for tetracaine.[31] Less than 2% of unchanged procaine is found in urine, whereas approximately 90% of *p*-aminobenzoic acid, which is a primary product of procaine hydrolysis, appears in urine. Only 33% of dimethylaminoethanol, the other hydrolysis product of procaine, is excreted unchanged.

The amino amide agents are biotransformed primarily in the liver.[32] Prilocaine undergoes the most rapid rate of hepatic metabolism, and lidocaine is biotransformed somewhat more rapidly than mepivacaine. In humans, the hepatic clearance of etidocaine is greater than that of bupivacaine, which suggests a more rapid rate of hepatic biotransformation for etidocaine. Evidence also exists that prilocaine may be biotransformed in the kidney, which would explain the rapid clearance of this agent compared with all other amino amides.[33]

The biotransformation of the amino amide-type agents results in the formation of a variety of metabolites. The biotransformation of lidocaine has been studied most extensively. The main pathway of lidocaine biotransfor-

mation in humans involves oxidative deethylation of lidocaine to monoethylglycinexylidide by cytochrome P450 IIIA4, followed by a subsequent hydrolysis of monoethylglycinexylidide to xylidine.

The excretion of the amino amide-type local anesthetic drugs occurs by way of the kidney. Less than 5% of the unchanged drug is excreted via the kidney into the urine. The major portion of the injected agent appears in the urine in the form of various metabolites. The renal clearance of the amino amide local anesthetic agents appears to be inversely related to their protein-binding capacity. Prilocaine, which has a lower protein-binding capacity than lidocaine, has a substantially higher clearance value than lidocaine.[34] Renal clearance also is inversely proportional to the pH of urine, suggesting that urinary excretion of these agents occurs by nonionic diffusion.

Patient age may influence the physiologic disposition of local anesthetics. The half-life of lidocaine following IV administration increased from an average of 80 minutes in human volunteers 22–26 years of age to 138 minutes in subjects ages 61–71 years.[35] Age-dependent disposition kinetics have been reported for ropivacaine following epidural administration, with elimination half-life significantly longer and clearance significantly decreased in older (>61 years) than in younger patients (18–40 years).[23]

The elimination of local anesthetic agents also is influenced by the individual patient's hepatic and cardiac function. For example, an average lidocaine half-life of 1.5 hours was reported in volunteers with normal hepatic function, whereas patients with liver disease demonstrated an average half-life of 5 hours.[36] In patients with congestive heart failure (CHF) the IV infusion of lidocaine results in significantly higher plasma concentrations of lidocaine than occurs in patients with normal cardiovascular function, indicating a decreased plasma clearance in patients with CHF.[37]

CLINICAL CONSIDERATIONS

Routes of Administration

The clinical profile of local anesthetic drugs varies, and is dependent on the type of regional anesthetic technique performed (Fig. 44–9). The shortest duration of action occurs following the intrathecal or subcutaneous administration of local anesthetics. The longest latencies and durations are observed following major peripheral nerve blocks, such as brachial plexus blockade. Intrathecal bupivacaine usually produces anesthesia within 5 minutes and persists for 3–4 hours.[38] For brachial plexus blockade, the onset time of bupivacaine is approximately 20–30 minutes, whereas the duration of anesthesia averages approximately 10 hours.[39] These variations in the onset and duration of anesthesia result from differences in the anatomy of the injection sites and the amount of drug employed for various types of regional anesthesia. In the subarachnoid space the lack of a nerve sheath around the spinal cord and the placement of the local anesthetic solution in the immediate vicinity of the spinal cord is responsible for the rapid onset of action. The relatively small amount of drug employed for spinal anesthesia probably accounts for the short duration of conduction block. For example, 50–75 mg of lidocaine and 10–15 mg of bupivacaine are usually employed for most spinal anesthetic procedures.

The onset of brachial plexus blockade is slow, as the anesthetic agent is usually injected some distance from the nerve roots and must diffuse through various tissue barriers before reaching the nerve membrane. The prolonged blockade is probably related to the decreased rate of vascular absorption from that site and the larger dose of drug employed for this regional anesthetic technique. For example, 400–600 mg of lidocaine and 100–150 mg of bupivacaine are usually employed for brachial plexus blockade.

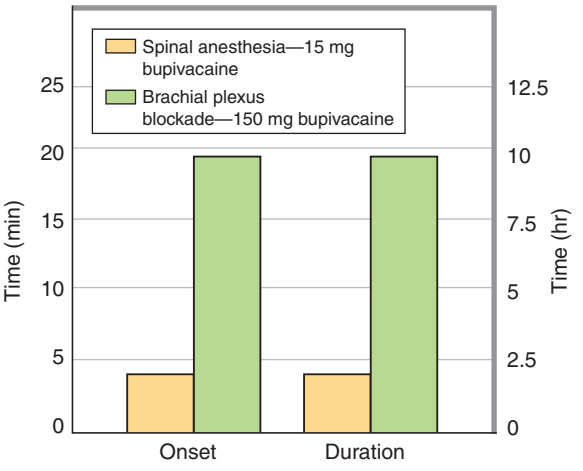

FIGURE 44–9. Comparison of onset and duration of spinal anesthesia and brachial plexus blockade with bupivacaine. (Reprinted from Covino BG. Pharmacology of local anesthetic agents. In: Rogers MC, Tinker JH, Covino BG, et al., eds. Principles and Practice of Anesthesiology. Vol. 2. St. Louis, MO: Mosby Year Book, 1993:1242, with permission from Elsevier.)

Clinical Manifestations of Potency

In vitro studies show a general positive correlation between lipid solubility of local anesthetics and potency (Fig. 44–10).[40,41] This presumably is because the nerve membrane that represents the site of action of local anesthetics consists primarily of lipids. However, the hydrophobicity and anesthetic potency are not as well correlated in intact animals and humans. The EC_{50} (median effective dose) of lidocaine, for example, is significantly less than that of mepivacaine in an isolated nerve, but in humans, little difference in anesthetic potency is apparent between these agents.[24] Etidocaine possesses a lower EC_{50} than bupivacaine in an isolated nerve, but etidocaine is approximately half as potent as bupivacaine in vivo[42,43]: 1–1.5% etidocaine is required to achieve a similar degree of epidural blockade as is produced by 0.5–0.75% bupivacaine.

The difference between potency in an isolated nerve and in a clinical situation is probably a function of the vasodilator or tissue redistribution properties of the various local anesthetics. Lidocaine is a more profound vasodilator than mepivacaine in humans. More rapid vascular absorption of lidocaine as a result of vasodilatation causing increased blood flow, results in fewer lidocaine molecules being available for neural blockade.

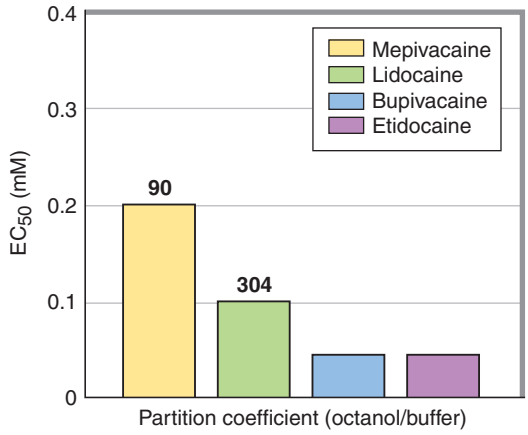

FIGURE 44–10. Relationship between concentrations of various local anesthetics required to cause 50% depression in amplitude of isolated nerve action potential (median effective concentration [EC50]) and partition coefficient values. (Reprinted from Covino BG. Pharmacology of local anesthetic agents. In: Rogers MC, Tinker JH, Covino BG, et al., eds. Principles and Practice of Anesthesiology. Vol. 2. St. Louis, MO: Mosby Year Book, 1993:1236, with permission from Elsevier.)

Hence, lidocaine and mepivacaine appear to possess similar anesthetic potencies clinically. The profound conduction-blocking activity of etidocaine in vitro is a result of its high lipid solubility. However, sequestration of etidocaine in adipose tissue in vitro, such as in the epidural space, results in fewer etidocaine molecules being available for neural blockade compared with bupivacaine.

Speed of Onset

In isolated nerves,[41,44] onset time of conduction block is correlated with the pK_a of the various agents (Fig. 44–11) and lipid solubility influences onset of action, too. The pK_a of local anesthetics and the pH of the anesthetic solution determine the degree of ionization of specific agents. This is because the degree of ionization influences the rate of diffusion of local anesthetics across the nerve sheath and membrane. The uncharged base form diffuses more easily than the charged cationic form.[45,46]

The pK_a of all local anesthetics, except benzocaine, varies from 7.6–9.1 and is greater than the physiologic pH (7.4) of tissue (Table 44–4). At a pH of 7.4, approximately 2% of procaine (pK_a of 9.1) exists in the base form. In contrast, 35% of mepivacaine, lidocaine, etidocaine, and prilocaine, which possess a pK_a of approximately 7.6, are present in the unionized forms. The pH of most local anesthetic solutions is approximately 5–6 because of the relatively low solubility of local anesthetics in solutions of higher pH. The inclusion of epinephrine in local anesthetic solutions results in a further decrease in pH to approximately 3–4.

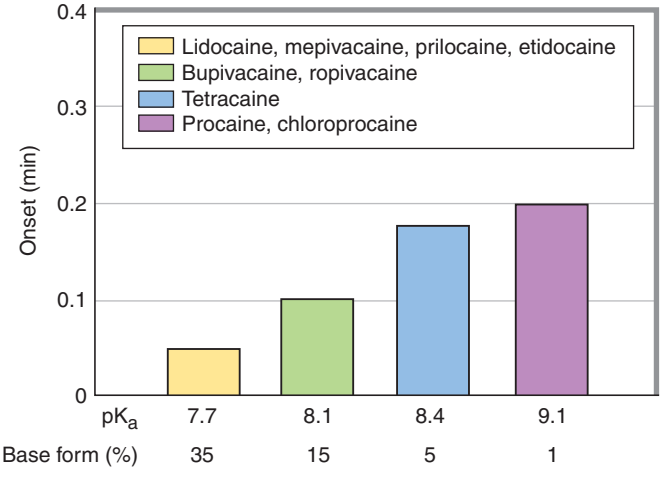

FIGURE 44–11. Relationship between onset of conduction block in isolated nerve and pK_a and percentage of local anesthetic present in base form. (Reprinted from Covino BG. Pharmacology of local anesthetic agents. In: Rogers MC, Tinker JH, Covino BG, et al., eds. Principles and Practice of Anesthesiology. Vol. 2. TABLE 44–4.

Dissociation Constants (Rounded)

Local Anesthetic	pK_a
Benzocaine	3.5
Mepivacaine	7.7
Lidocaine	7.8
Etidocaine	7.9
Prilocaine	7.9
Ropivacaine	8.1
Bupivacaine	8.1
Tetracaine	8.4
Cocaine	8.6
Dibucaine	8.8
Procaine	8.9
Chloroprocaine	9.1
Hexylcaine	9.3
Procainamide	9.3
Piperocaine	9.8

Studies in vitro clearly demonstrate the relationship among the pK_a of specific agents, the pH of anesthetic solution, and the onset of conduction block.[44–46] Agents with a relatively low pK_a, such as lidocaine and mepivacaine, show the most rapid onset of conduction block. Procaine, chloroprocaine, and tetracaine, which possess high pK_a values, demonstrate a longer latency. The onset of conduction blockade is also reduced by increasing the pH of the bathing solution.[45] Clinically, onset time may be influenced by the dose or concentration of local anesthetic employed.[43] For example, increasing the concentration of bupivacaine from 0.25–0.75% results in a significant acceleration in anesthetic effect. Despite its pK_a being approximately 9 and its onset of action in isolated nerves being relatively slow, chloroprocaine demonstrates a rapid onset of action in humans. This is because chloroprocaine's low systemic toxicity allows the use of high concentrations such as 3%. Lidocaine has been shown in some studies to produce a more rapid onset of epidural anesthesia than chloroprocaine when employed at the same concentrations. However, use of a 3% chloroprocaine solution results in a more rapid onset of conduction block compared with 2.0% lidocaine.[47]

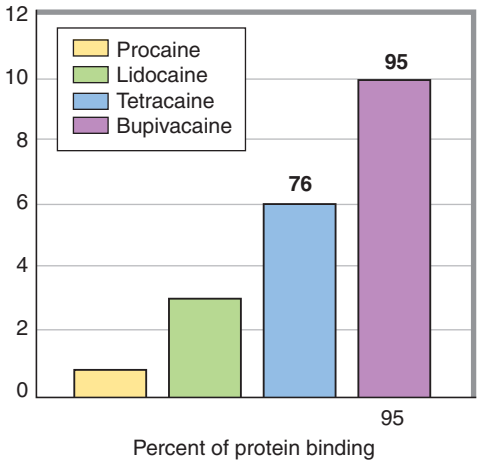

FIGURE 44–12. Relationship between duration of brachial plexus blockade of various local anesthetics and their degree of protein binding. (Reprinted from Covino BG. Pharmacology of local anesthetic agents. In Rogers MC, Tinker JH, Covino BG, et al., eds. Principles and Practice of Anesthesiology. Vol. 2. St. Louis, MO: Mosby Year Book, 1993:1238, with permission from Elsevier.)

Duration of Action

The various local anesthetics have greatly different durations of action and protein binding apparently is a determinant of duration (Fig. 44–12).[44] Procaine and chloroprocaine have a short duration of action; lidocaine, mepivacaine, and prilocaine have a moderate duration of anesthesia. Tetracaine, bupivacaine, levobupivacaine, etidocaine, and ropivacaine are associated with the longest durations of anesthesia. Procaine produces duration of brachial plexus blockade of 30–60 minutes—approximately 10 hours of anesthesia has been reported following the use of bupivacaine, etidocaine, and ropivacaine for brachial plexus blockade.

Local anesthetics are believed to act by binding to a protein receptor in the sodium channel,[3] and thus the greater protein binding of a specific agent presumably results in a longer period of sodium channel blockade and a longer duration of anesthesia. Plasma proteins have been used to measure protein binding of local anesthetics, assuming that binding to membrane proteins is similar to plasma protein binding.

Duration of action of the various agents is influenced by their peripheral vascular effects. Local anesthetics except cocaine generally tend to have a biphasic effect on vascular smooth muscle.[48–50] These agents cause vasoconstriction at low concentrations and vasodilatation at clinically employed concentrations. The protein kinase C Rho and p44/42 mitogen-activated protein kinase signaling pathways in calcium sensitization mechanisms may be involved in the biphasic action.[51]

Differences exist in the vasodilator activity of the various drugs. Lidocaine is a more potent vasodilator than mepivacaine or prilocaine. In vivo, the duration of anesthesia produced by lidocaine is shorter than that of mepivacaine or prilocaine. If epinephrine is added to solutions of these agents, the duration of action for all three drugs is similar. The duration of action of ropivacaine is similar to that of bupivacaine when the agents are administered for peripheral or central neural blocks.[52,53] However, ropivacaine produces a significantly longer duration of infiltration anesthesia than bupivacaine in animals, which appears related to ropivacaine's cutaneous vasoconstrictor effects (Fig. 44–13).[50,52]

Differential Sensory/Motor Block

Differential block is observed clinically but is poorly understood. Local anesthetic agents differ with respect to producing motor versus sensory block. The most significant separation between sensory anesthesia and motor blockades is produced by bupivacaine.[43] Depending on the concentration of bupivacaine employed, significant sensory anesthesia may be obtained with little inhibition of motor activity. Ropivacaine appears to provide a similar degree of sensory/motor separation.[54]

Bupivacaine and etidocaine are notably different in terms of their differential sensor/motor fiber-blocking activity (Fig. 44–14). Bupivacaine is widely used epidurally for obstetric procedures and relief of pain postoperatively because of its ability to provide adequate analgesia with minimal muscle weakness or paralysis, particularly as a 0.125% or 0.25% solution. In contrast, etidocaine shows little separation between blockade of sensory and motor fibers.[43]

Influence of Dose

An increase in the dose of local anesthetic usually results in a more profound depth of block, a prolongation of satisfactory anesthesia, and a decrease in the onset of block.[43,54] No clinically significant differences in onset, depth, and duration of anesthesia appear to

St. Louis, MO: Mosby Year Book, 1993:1239, with permission from Elsevier.)

exist when the same dose of local anesthetic is administered as a large volume of dilute solution or as a small volume of concentrated solution. A comparison of 15 mL of 2% prilocaine with 10 mL of 3% prilocaine (300 mg) and 30 mL of 2% prilocaine with 20 mL of 3% prilocaine (600 mg) for epidural blockade showed no difference in onset, adequacy, or duration of anesthesia, and onset, depth, and duration of motor blockade if the dose was maintained constant (Fig. 44–15).[55] However, the increase in total dose from 300 to 600 mg of prilocaine did result in a more rapid onset, a greater degree of satisfactory anesthesia, and a prolonged duration of anesthesia.

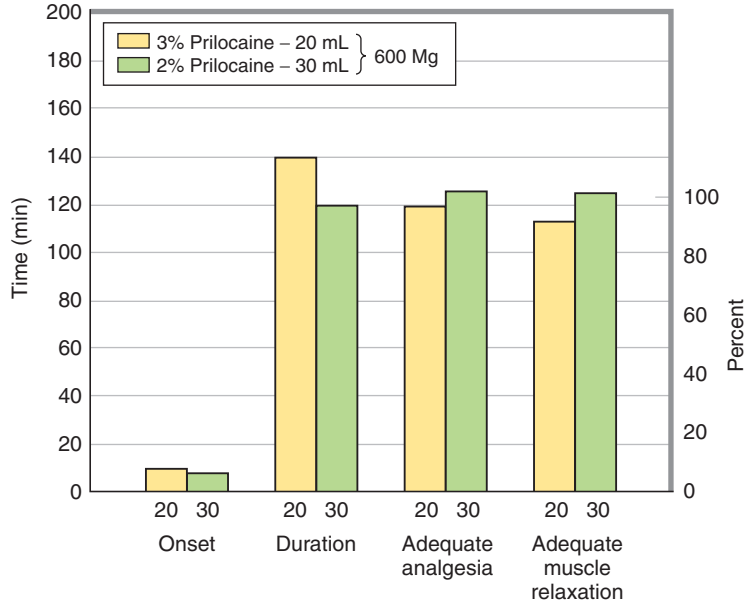

FIGURE 44–15. Relationship between onset, duration, and frequency of adequate analgesia and frequency of adequate muscle relaxation produced by prilocaine when used as either a 3% solution or a 2% solution for epidural blockade. (Reprinted from Covino BG. Pharmacology of local anesthetic agents. In: Rogers MC, Tinker JH, Covino BG, et al., eds. Principles and Practice of Anesthesiology. Vol. 2. St. Louis, MO: Mosby Year Book, 1993:1240, with permission from Elsevier.)

Similar studies of spinal anesthesia indicate little difference between the use of varying volumes of 0.5% and 0.75% bupivacaine if the total dose was constant (Fig. 44–16).[38] The volume of anesthetic solution may influence the spread of anesthetic in the epidural or subarachnoid space. For example, the level of anesthesia was 4.3 dermatomes higher when 30 mL of 1% lidocaine was injected epidurally compared with 10 mL of 3% lidocaine.[56] In general, increased dosage is usually achieved by the use of more concentrated anesthetic solutions, as the volume of solution that can be administered is usually restricted by the anatomy of the specific injection site.

FORMULATIONS

Purpose of Different Formulations

Local anesthetics are mixed with other substances during the manufacturing process or just prior to administration. Some objectives of this practice are to shorten onset time, limit absorption, increase intensity of action, stabilize local anesthetic molecule, and inhibit microbial growth. A 2004 issue of *Techniques in Regional Anesthesia and Pain Medicine* discussed in detail additives to local anesthetics.[57]

Mixtures of Local Anesthetics

Mixtures of local anesthetics have been employed by adding an agent, such as chloroprocaine or lidocaine, which have a relatively rapid onset, to a solution of bupivacaine, which has a slow but long duration of action. A mixture of 3% chloroprocaine and 0.5% bupivacaine was reported to produce a rapid onset and prolonged duration of brachial plexus blockade.[58] Subsequent epidural studies indicated that a mixture of chloroprocaine and bupivacaine resulted in a slower onset than chloroprocaine alone and a shorter duration than bupivacaine alone.[59] Isolated nerve studies demonstrate

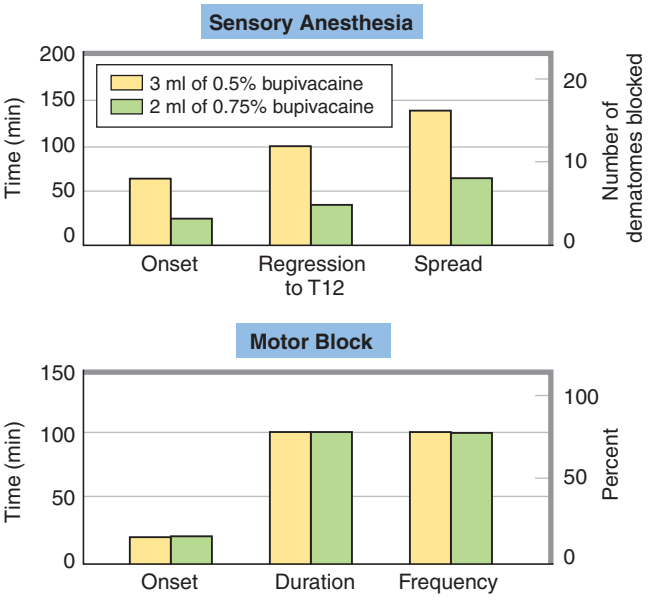

FIGURE 44–16. Relationship between onset, duration, and spread of sensory anesthesia and onset, duration, and frequency of motor block produced by bupivacaine when employed as either a 0.5% or a 0.75% solution for intrathecal use. (Reprinted from Covino BG. Pharmacology of local anesthetic agents. In: Rogers MC, Tinker JH, Covino BG, et al., eds. Principles and Practice of Anesthesiology. Vol. 2. St. Louis, MO: Mosby Year Book, 1993:1240, with permission from Elsevier.)

that the addition of a metabolite of chloroprocaine to bupivacaine significantly decreased the duration of conduction block compared with bupivacaine alone (Fig. 44–17).[60] To date, no similar antagonism has been demonstrated when lidocaine or mepivacaine is mixed with bupivacaine. One should remember that in terms of the potential systemic toxicity of mixtures of local anesthetics, the toxicity of local anesthetics is additive if an unintentional IV injection occurs.

Use of Vasoconstrictors

Epinephrine (1:200,000; 5 μg/mL) is frequently added to local anesthetic solutions to decrease the rate of vascular absorption.[24] This allows more anesthetic molecules to diffuse to the nerve membrane and thus improves the depth and duration of anesthesia. Epinephrine 1:200,000 has been reported to be the optimal concentration prolonging the duration of anesthesia of lidocaine for epidural or intercostals use. Other vasoconstrictor agents, such as norepinephrine and phenylephrine, have been used but do not appear to be superior to epinephrine. For example, equipotent concentrations of epinephrine and phenylephrine similarly prolong the duration of spinal anesthesia produced by tetracaine (Fig. 44–18).[61]

Epinephrine's ability to prolong the duration of anesthesia depends on the local anesthetic employed and the injection site. Epinephrine significantly extends the duration of both infiltration anesthesia and peripheral nerve blocks with most agents.[62,63] The duration of surgical epidural anesthesia, however, is not greatly prolonged when epinephrine is combined with prilocaine, bupivacaine, or etidocaine, but does result in a significant increase in the duration of epidural blockade produced by agents such as lidocaine.[64,65] Diluted solutions of bupivacaine employed for epidural analgesia in obstetric patients may be improved with the addition of epinephrine. The depth and duration of epidural analgesia in obstetric patients were improved when epinephrine 1:300,000 was added to 0.25% bupivacaine.[66] Although the addition of epinephrine may not significantly prolong the duration of surgical epidural anesthesia produced by 0.5–0.75% bupivacaine, a more profound degree of motor blockade has been observed following the use of bupivacaine with epinephrine.[64]

Epinephrine's ability to prolong spinal anesthesia may be partly related to a direct antinociceptive effect in the spinal cord. Adrenergic receptor agents exert a direct antinociceptive action in the spinal cord. For example, clonidine, an α_2-adrenergic agonist, produces analgesia following epidural administration.[67]

Epinephrine's effect on the onset of regional anesthesia is controversial. Some studies demonstrate a more rapid onset of conduction blockade, presumably because of the decreased vascular absorption of local anesthetics.[62] Others fail to demonstrate any difference in onset time.[68] This is attributed to the low pH of epinephrine-containing local anesthetic solutions, which favor the formation of the local anesthetics cationic form, which does not easily diffuse through nerve sheaths.

Carbonation and pH Adjustment of Local Anesthetics

Carbonation of local anesthetics results in a more rapid onset and a more profound degree of conduction blockade in an isolated nerve preparation.[45,69,70] The enhanced onset is believed to be related to a more rapid dissociation of the local anesthetic to the base form, a direct depressant ef-

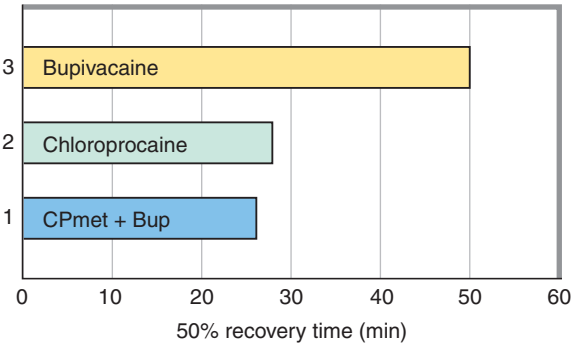

FIGURE 44–17. Recovery of conduction blockade in isolated nerve following exposure to bupivacaine alone, chloroprocaine alone, and mixture of a chloroprocaine metabolite and bupivacaine. fect of carbon dioxide (CO_2) on the nerve membrane, and a decrease in the axoplasmic pH from the diffusion of CO_2 intraneurally. The lower axoplasmic pH increases the rate of formation of the local anesthetic's active cationic form within the nerve. Although CO_2 clearly enhances the onset of local anesthetic-induced conduction block in an isolated nerve, discrepancies exist among clinical studies in which hydrochloride and carbonated local anesthetic solutions have been compared. Several investigations have demonstrated a significant decrease in the onset of epidural blockade with lidocaine carbonate compared with lidocaine hydrochloride.[71,72] However, other researchers have failed to observe a significant reduction in onset of epidural anesthesia with lidocaine carbonate.[73] Similarly, differing results concerning onset time have been reported when bupivacaine hydrochloride and bupivacaine carbonate were employed for brachial plexus blocks.[74,75] Although controversy may exist regarding the effect of carbonation on onset of anesthesia, most studies show that carbonated solutions do improve the depth of sensory and motor blockade when administered into the epidural space. Also, these solutions produce a more complete blockade of the various nerve roots when employed for brachial plexus blockade.

Alkalinization of local anesthetic solutions by the addition of solution bicarbonate has also been reported to decrease the onset of conduction blockade (Fig. 44–19).[76,77] An increase in the pH of the local anesthetic solution increases the amount of drug in the uncharged base form, which should enhance the rate of diffusion across the nerve sheath and nerve membrane. The use of pH-adjusted solutions of bupivacaine or lidocaine has been reported to significantly decrease the latency of brachial plexus and epidural blockade.[76,77] Again, controversy surrounds the improved onset of pH-adjusted local anesthetic solutions. Some investigators have failed to demonstrate an improved onset of brachial plexus or epidural blockade with the use of pH-adjusted solutions of bupivacaine or lidocaine.[78,79] The differences between these studies might be related to the magnitude of the pH change produced by the addition of bicarbonate. In the original study in which onset time for brachial plexus blockade was significantly reduced, the pH of bupivacaine with epinephrine was increased from 3.9 to 6.4.[77] In the subsequent study in which no effect on latency was observed, the pH of plain bupivacaine was increased from 5.5 to 7.0.[78] The amount of bicarbonate added to local anesthetic solutions depends on the particular local anesthetic. One milliliter of sodium bicarbonate is added to 10 mL of lidocaine, whereas 0.1 mL of bicarbonate is added to every 10 mL of bupivacaine. The latter agent is insoluble at a high pH, and the addition of excess bicarbonate will result in a precipitation of bupivacaine.

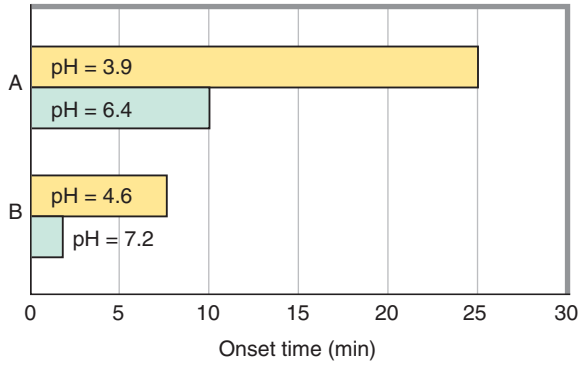

FIGURE 44–19. Comparison of onset of brachial plexus blockade with bupivacaine (A) and onset of epidural blockade with lidocaine (B) using solutions of varying pH. (Reprinted from Covino BG. Pharmacology of local anesthetic agents. In: Rogers MC, Tinker JH, Covino BG, et al., eds. Principles and Practice of Anesthesiology. Vol. 2. St. Louis, MO: Mosby Year Book, 1993:1243, with permission from Elsevier.)

Hyaluronidase, Liposomes, Microencapsulation

Hyaluronidase (tissue spreading factor) is sometimes added to local anesthetic solutions to facilitate spread of solution at the injection site, thereby affecting speed of onset and extent of a block. This seems only to be useful when local anesthetic is injected in the orbit preparatory to ophthalmologic surgery. Hyaluronidase may be injected with local anesthetic during epidural neurolysis to treat pain with positive benefit. Various attempts have been made to prolong the duration of action of local anesthetics by loading them into liposomes or microcapsules, but no such formulations have been approved by the FDA for marketing.

TOXICITY

Table 44–5 shows categorizes the toxic effects of local anesthetics.

TABLE 44–5.

Categories of Local Anesthetic Toxic Reactions

Localized or Systemic	Systemic	Localized
Allergic reactions	Cardiac/vascular Central nervous system Methemoglobin	Tissue toxicity

Allergic Reactions

True allergic reactions are associated with amino ester-linked local anesthetics, not amino amide-linked ones. In a study of anaphylactic and anaphylactoid reactions (n = 789) occurring during anesthesia, Mertes et al.[80] found no such reactions to local anesthetics. However, Mackley et al.[81] reported that of 183 patients who were patch tested, 4 had positive reactions to lidocaine, 2 of whom had histories of sensitivity to local injections of lidocaine manifested by dermatitis. They concluded that contact-type IV sensitivity to lidocaine might occur more frequently than previously thought. It is common, but inappropriate, to refer to all adverse events as "allergic reactions."

Tissue Toxicity

Tissue toxicity, primarily myotoxicity and neurotoxicity can be produced by all local anesthetics if "high" concentrations are used. Signs and symptoms of varying degrees of neuropathy (e.g. transient neurologic symptoms, cauda equina syndrome) have been reported following spinal anesthesia with, for example, 2% and 5% lidocaine. In a recent systematic review, Zaric et al.[82] compared the frequency of transient neurologic symptoms and neurologic complications after spinal anesthesia with lidocaine with that after other local anesthetics. The results showed that the risk for developing transient neurologic symptoms after spinal anesthesia with lidocaine was higher with lidocaine than with bupivacaine, prilocaine, procaine, or mepivacaine.

Systemic Toxicity

Methemoglobinemia

A variety of local anesthetics reportedly may produce methemoglobinemia. Prilocaine is the local anesthetic for which there appears to be greatest risk for this to occur. A dose–response relationship exists between the amount of prilocaine administered epidurally and the degree of methemoglobinemia. In general, doses of prilocaine of 600 mg are required for the development of clinically significant levels of methemoglobinemia.[83] The formation of methemoglobinemia is believed to be related to prilocaine's chemical structure. This agent lacks a methyl group in the benzene ring. The metabolism of prilocaine in the liver results in the formation of *O*-toluidine, which is responsible for the oxidation of hemoglobin to methemoglobin.[84] The methemoglobinemia associated with prilocaine is spontaneously reversible or may be treated by IV methylene blue.

Cardiovascular and Central Nervous System

As concentration of local anesthetic in systemic circulation increases, various cardiovascular system and central nervous system signs and symptoms appear (Fig. 44–20). The relative CNS and cardiovascular toxicity of local anesthetics has been of interest, especially after Albright[85] reported unexpected cardiovascular toxicity of bupivacaine. In animal studies, the ratio of doses of bupivacaine that produced convulsive activity and cardiovascular collapse[86] was lower than for other local anesthetics such as lidocaine. Human volunteer studies of doses required to produce early features of CNS and cardiovascular system toxicity by ropivacaine and levobupivacaine demonstrated the doses were about equal and higher than for bupivacaine.[87–89]

Brown et al.[90] reviewed records of patients who had seizures while undergoing brachial plexus, epidural, and caudal regional anesthetics. No adverse cardiovascular, pulmonary or nervous system events were associated with any of the seizures, including in 16 patients who received bupivacaine blocks.

In dogs, the relative CNS toxicity of bupivacaine, etidocaine, and lidocaine is 4:2:1,[91] which is similar to the relative potency of these agents for the production of regional anesthesia in humans. IV infusion studies in human volunteers have also demonstrated an inverse relationship between the intrinsic anesthetic potency of various agents and the dosage required to induce CNS toxicity.[92,93]

The rate of IV administration alters the toxicity of local anesthetic agents.[93] In human volunteers, an average dose of 236 mg of etidocaine and a venous blood concentration of 3.0 µg/mL resulted in CNS symptoms when 10 mg/min was infused. When the infusion rate was increased to 20 mg/min, an average of 161 mg of etidocaine, which produced a venous plasma concentration of approximately 2 µg/mL, caused symptoms of CNS toxicity.

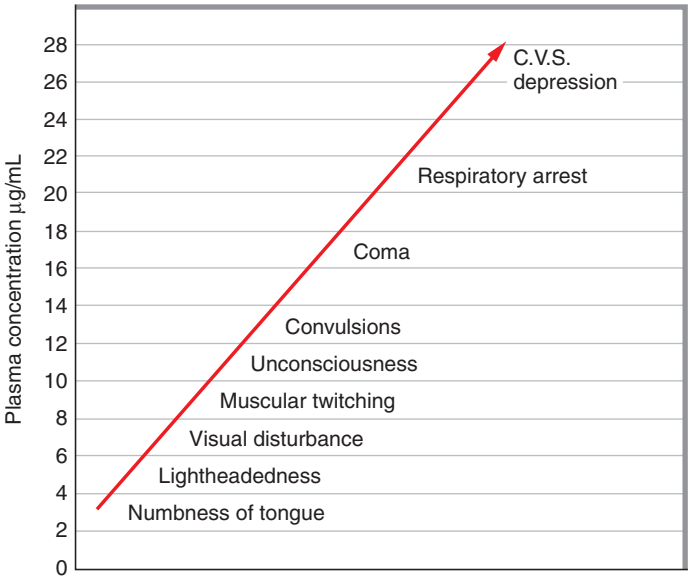

FIGURE 44–20. Plasma concentration of lidocaine versus systemic toxicity.

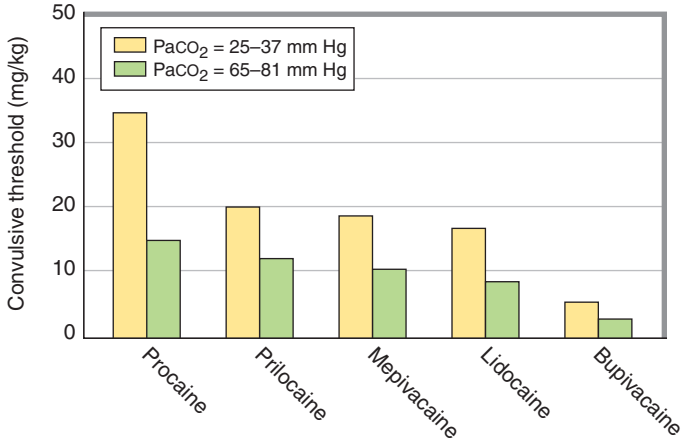

FIGURE 44–21. Relationship between convulsive threshold doses of various local anesthetics and arterial CO_2 tension ($Paco_2$). (Reprinted from Covino BG. Pharmacology of local anesthetic agents. In: Rogers MC, Tinker JH, Covino BG, et al., eds. Principles and Practice of Anesthesiology. Vol. 2. St. Louis, MO: Mosby Year Book, 1993:1247, with permission from Elsevier.)

Acid–base status can alter the CNS activity of local anesthetic agents. In cats, the convulsive threshold of various local anesthetics is inversely related to the arterial CO_2 tension ($Paco_2$)[94] (Fig. 44–21). An increase in $Paco_2$ from 25 to 40 mm Hg to a range of 65 to 81 mm Hg decreases the convulsive threshold of procaine, mepivacaine, prilocaine, lidocaine, and bupivacaine by approximately 50%. A decrease in arterial pH also decreases the convulsant threshold of these agents. Respiratory acidosis, with a resultant increase in $Paco_2$ and a decrease in arterial pH, consistently decreases the convulsant threshold of local anesthetic agents. However, an elevation in both $Paco_2$ and arterial pH, as may occur during metabolic alkalosis, does not increase CNS toxicity to the same degree.

Hypercarbia increases cerebral blood flow, which probably results in a greater uptake of local anesthetic by the brain. In addition, diffusion of CO_2 into neuronal cells decreases intracellular pH and thus increases the intracellular cationic form of the local anesthetic agents. This form does not diffuse well across the nerve membrane, so ion trapping occurs. Hypercarbia and/or acidosis also decrease the plasma protein binding of local anesthetic agents, which will increase the proportion of free drug available for diffusion into the brain.[95,96] On the other hand, acidosis also decreases the percentage of the local anesthetic existing in the base form, which should decrease the rate of diffusion into neuronal cells.

Local anesthetics have a direct effect on both cardiac muscle and vascular smooth muscle. These agents alter the heart's electrical and mechanical activity. Studies using the intact, isolated mammalian heart in vitro show that highly lipid-soluble, extensively protein-bound, highly potent local anesthetics (e.g., tetracaine, bupivacaine, etidocaine) are much more cardiotoxic than are the less-lipid-soluble, protein-bound, potent local anesthetics (e.g., lidocaine, mepivacaine, prilocaine).[97] Bupivacaine has a potent depressant effect on electrical conduction in the heart primarily via an action on voltage-gated sodium channels that generally govern the initial rapid depolarization (phase 0) of cardiomyocytes. The S forms of bupivacaine are less cardiotoxic than the R form. Bupivacaine actions other than on voltage-gated sodium channels probably also contribute to dose-dependent cardiotoxic effect of this local anesthetic.

Local anesthetics decrease the maximal rate of depolarization in Purkinje's fibers and ventricular muscle because of an inhibition of sodium channels in cardiac membranes.[98–100] Action potential duration and the effective refractory period are also decreased by local anesthetics. However, the ratio of effective refractory period to action potential duration is increased both in Purkinje's fibers and in ventricular muscle.

Qualitative differences exist between the various local anesthetic agents. Bupivacaine depresses the rapid phase of depolarization (V_{max}) in Purkinje's fibers and ventricular muscle to a greater extent than does lidocaine.[98–100] In addition, the rate of recovery from a use-dependent block is slower in bupivacaine-treated than in lidocaine-treated papillary muscles.[101] This slow rate of recovery results in an incomplete restoration of V_{max} between action potentials, particularly at high heart rates. In contrast, recovery from lidocaine is complete, even at rapid heart rates. These differential effects of lidocaine and bupivacaine may explain the antidysrhythmic properties of lidocaine and the dysrhythmogenic potential of bupivacaine.

Bupivacaine, and to a lesser degree etidocaine and ropivacaine, can produce severe cardiac dysrhythmias, including ventricular fibrillation, in various animal species.[86,102–106] Ventricular dysrhythmias are rarely seen with lidocaine, mepivacaine, or tetracaine. Although the dysrhythmogenic action of bupivacaine is probably related primarily to an inhibition of the fast sodium channels in the cardiac membrane, evidence also exists that this agent may block the slow calcium channels.[107] These electrophysiologic effects of bupivacaine may result in conduction abnormalities, leading to a reentrant type of dysrhythmia similar to a torsade de pointes dysrhythmia.[103]

The dysrhythmogenic activity of bupivacaine is believed to result primarily from a direct cardiac effect. Isolated guinea pig hearts perfused with bupivacaine revealed evidence of conduction block, bigeminy, and trigeminy.[108] In addition, ventricular fibrillation occurred in intact pigs in which bupivacaine was injected directly into the left anterior descending coronary artery.[105] On the other hand, the injection of bupivacaine directly into certain regions of the brain may result in cardiac dysrhythmias, which may indicate a relationship between the CNS and cardiotoxic effects of bupivacaine.[109,110]

Electrophysiologic studies in intact dogs and in people shown that high blood levels of local anesthetics prolong conduction time through various parts of the heart as indicated by an increase in the PR interval and QRS duration. Extremely high concentrations of local anesthetics depress spontaneous pacemaker activity in the sinus node, resulting in sinus bradycardia and sinus arrest.

Local anesthetic agents also depress myocardial contractility. All local anesthetics exert a dose-dependent negative inotropic action on isolated cardiac

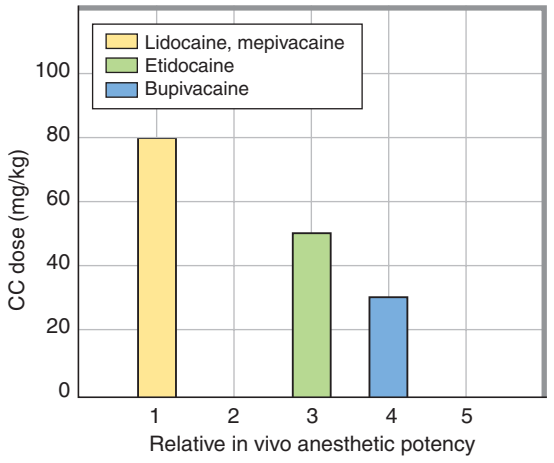

FIGURE 44–22. Relationship between dose of various local anesthetics that causes cardiovascular collapse (CC) and in vivo anesthetic potency of these agents. (Reprinted from Covino BG. Pharmacology of local anesthetic agents. In: Rogers MC, Tinker JH, Covino BG, et al., eds. Principles and Practice of Anesthesiology. Vol. 2. St. Louis, MO: Mosby Year Book, 1993:1249, with permission from Elsevier.)

tissue that is proportional to the conduction blocking potency of the various agents in isolated nerves (Fig. 44–22).[111] For example, bupivacaine, tetracaine, and etidocaine produce the greatest degree of myocardial depression. The agents of moderate anesthetic potency (i.e., lidocaine, mepivacaine, prilocaine) are intermediate in terms of their negative inotropic action. Procaine and chloroprocaine, which are the least-potent local anesthetics, require the highest concentration to decrease cardiac contractility.

In dogs, tetracaine is approximately 8–10 times more potent than procaine as a local anesthetic and as a myocardial depressant.[112] Hemodynamic studies in closed-chest anesthetized dogs have shown that tetracaine, etidocaine, and bupivacaine caused a 50% decrease in cardiac output at doses of 10–20 mg/kg, whereas doses of 30–40 mg/kg of lidocaine, mepivacaine, prilocaine, and chloroprocaine were required for a similar decrease in cardiac output. A dose of 100 mg/kg of procaine was needed to reduce cardiac output to 50%.

Most local anesthetic agents exert a biphasic effect on peripheral vascular smooth muscle.[48,49] Low concentrations of lidocaine and bupivacaine produced vasoconstriction in the cremaster muscle of rats, whereas high concentrations increased arteriolar diameter, indicative of vasodilatation. In vivo studies also demonstrate that low doses of local anesthetics decrease peripheral arterial flow without any change in blood pressure, whereas higher doses increase blood flow. Cocaine causes vasoconstriction because of its ability to inhibit the uptake of norepinephrine by storage granules.[113] Studies indicate that ropivacaine causes cutaneous vasoconstriction, whereas bupivacaine produces vasodilatation.[51]

In a review of the cardiotoxicity of modern local anesthetics, Mather and Chang[114] concluded that as compared with bupivacaine, although ropivacaine and levobupivacaine may be seen as "safer," they must not be regarded as totally "safe."

Factors Influencing Cardiovascular Toxicity

Specific Agents

Although the CNS is more susceptible to the toxic effects of local anesthetics than the cardiovascular system, differences exist in the margin between the dose of various agents that causes convulsions and the dose that results in cardiovascular collapse (Fig. 44–23). A cardiovascular collapse (CC)-to-convulsive (CNS) dose ratio of 7.1 + 1.1 was reported for lidocaine in adult sheep, indicating that 7 times as much drug was required to induce irreversible cardiovascular collapse as to cause convulsions.[115] The CC:CNS ratio for bupivacaine was 3.7 + 0.5 and for etidocaine, 4.4 + 0.9. The CC:CNS blood level ratio of lidocaine was 3.6 + 0.3, compared with values of 1.6–1.7 for bupivacaine and etidocaine. At the time of cardiovascular collapse, high concentrations of bupivacaine and etidocaine were present in the myocardium compared with lidocaine, which suggests that the enhanced cardiac toxicity of these more potent agents may result from a greater myocardial uptake.

Pregnancy

Data regarding the effects of pregnancy on the cardiovascular toxicity of local anesthetic is not conclusive.

Acidosis and Hypoxia

Hypercarbia, acidosis, and hypoxia potentiate the negative chronotropic and inotropic action of lidocaine and bupivacaine in isolated cardiac tissue.[116] The combination of hypoxia and acidosis greatly potentiates the cardiodepressant effects of bupivacaine. Hypoxia and acidosis also increase the frequency of cardiac dysrhythmias and the mortality rate in sheep following the IV administration of bupivacaine.[116] Hypercarbia, acidosis, and hypoxia

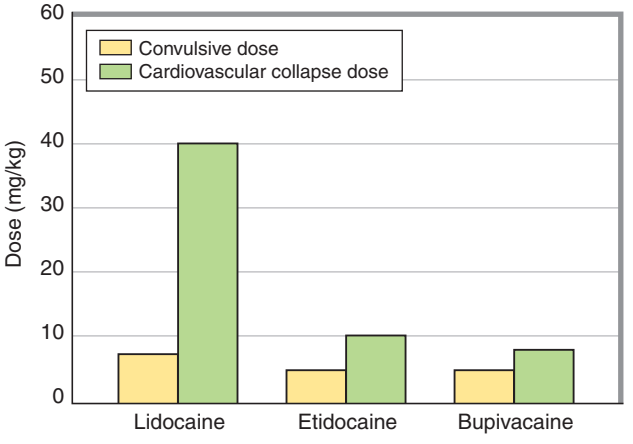

FIGURE 44–23. Relationship between dose of lidocaine, bupivacaine, and etidocaine that causes CNS toxicity and dose that produces cardiovascular collapse. (Reprinted from Covino BG. Pharmacology of local anesthetic agents. In: Rogers MC, Tinker JH, Covino BG, et al., eds. Principles and Practice of Anesthesiology. Vol. 2. St. Louis, MO: Mosby Year Book, 1993:1249, with permission from Elsevier.)

occur very rapidly in some patients following seizure activity because of the rapid unintentional intravascular injection of local anesthetic agents.[118] Thus the cardiovascular depression observed in some patients following the accidental IV injection of bupivacaine may be related in part to the severe acid–base changes that occur during toxic reactions to this agent.

Measures to prevent systemic toxic reactions to local anesthetics include following dose recommendations, injecting aliquots over time, avoiding unintentional intravascular injections, and monitoring vital signs during injection. Blanket recommended doses versus block-specific recommended doses were discussed recently.[119,120] Drug administration must be stopped should signs or symptoms of toxicity develop. Seizures induced by local anesthetics are usually self-limiting, and require maintenance of respiratory gas exchange and control of muscle contractions (e.g., intubation, oxygenation, short-acting muscle paralysis). Drugs such as propofol, thiopental, and benzodiazepines are effective against these seizures.

Cardiovascular toxicity is treated according to American Heart Association guidelines, depending on the nature of the toxicity. Recent evidence suggests that in some instances, lipid emulsion infusion may be beneficial.[121]

SPECIFIC LOCAL ANESTHETICS

Local Anesthetics in Clinical Use

Table 44–6 lists generic and trade names of local anesthetics. Undoubtedly, lidocaine is most commonly used to prevent procedure-related pain and for diagnostic tests. Intermediate- to long-acting local anesthetics, such as ropivacaine, levobupivacaine, and bupivacaine, are used for therapy.

Table 44–7 lists topical anesthetics and dosage forms. Most of the forms are available without prescription. A 5% lidocaine patch (Lidoderm) is approved by the FDA for controlling postherpetic neuralgia.

Amino Ester Agents

Local anesthetics in this class have an ester linkage to benzoic acid or its derivatives. The amino ester-linked local anesthetics most commonly used clinically are procaine, chloroprocaine, and tetracaine. All of these agents were introduced into clinical practice by 1955.

TABLE 44–6.

Generic and Trade Names of Local Anesthetics

Generic Name	Trade Name(s)
Benoxinate	Dorsacaine; Novesine
Bupivacaine	Marcaine; Sensorcaine
Butacaine	Butyn
Chloroprocaine (2-chloroprocaine)	Nesacaine
Cyclomethycaine	Surfacaine
Dibucaine	Nupercaine; Percaine
Etidocaine	Duranest
Hexylcaine	Cyclaine
Levobupivacaine	Chirocaine
Lidocaine	Xylocaine; Xylotox
Mepivacaine	Carbocaine; Polocaine
Piperocaine	Metycaine
Prilocaine	Citanest
Procaine	Novocain; Planocaine
Proparacaine	Opthaine; Ocu-Caine
Ropivacaine	Naropin
Tetracaine	Pontocaine; Pantocaine

As these local anesthetics are administered chiefly as the chloride or sulfate slats, it is more accurate to specify procaine hydrochloride than just procaine. Because the latter is the active species, it is the usually used term.
Modified with permission from deJong RH. Local Anesthetics. St. Louis: Mosby-Year Book, 1994.

Procaine

Procaine was the first synthetic local anesthetic agent introduced into clinical practice. It is a relatively weak local anesthetic with a slow onset and a short duration of action. Its systemic toxicity is relatively low because of rapid plasma hydrolysis. Procaine is hydrolyzed to *p*-aminobenzoic acid, which is responsible for the allergic reactions associated with repeated use of procaine. Procaine is used primarily for infiltration anesthesia, diagnostic differential spinal blocks in certain pain states, and obstetric spinal anesthesia.

TABLE 44–7.

Topical: Local Anesthetics and Available Dosage Forms

Benzocaine	Lidocaine/prilocaine
Cream	Cream
Ointment	Lidocaine/tetracaine
Topical aerosol	Patch
Benzocaine and menthol	Pramoxine
Lotion	Cream
Topical aerosol solution	Lotion
Butamben	Pramoxine and menthol
Ointment	Gel
Dibucaine	Lotion
Cream	Tetracaine
Ointment	Cream
Lidocaine	Tetracaine and menthol
Film-forming gel	Ointment
Ointment	
Patch	
Cream

Chloroprocaine

Chloroprocaine has rapid onset of action, short duration, and low systemic toxicity. It undergoes hydrolysis by human plasma esterases about 4 times faster than procaine. Chloroprocaine is primarily employed for epidural analgesia and anesthesia in obstetrics because of its rapid onset and low systemic toxicity in the mother and fetus. However, frequent injections are required to provide adequate pain relief during labor. Sometimes, epidural analgesia is established in the pregnant patient with chloroprocaine, followed by a longer-acting agent such as bupivacaine. Chloroprocaine has also proved of value for various regional anesthetic procedures in ambulatory surgical patients for whom surgery is not expected to exceed 30–60 minutes.

Concern about potential myotoxicity and neurotoxicity have haunted chloroprocaine.

Tetracaine

Tetracaine is used primarily for spinal anesthesia. It may be employed as an isobaric, hypobaric, or hyperbaric solution for spinal blockade, although hyperbaric solutions of tetracaine are probably employed most often. Tetracaine provides a relatively rapid onset of spinal anesthesia, excellent qualities of sensory anesthesia, and a profound block of motor function. Plain solutions of tetracaine produce an average duration of spinal anesthesia of 2–3 hours, whereas the addition of epinephrine can extend anesthesia to 4–6 hours.

Tetracaine is rarely used for other forms of regional anesthesia because of its extremely slow onset of action and the potential for systemic toxic reactions when larger doses are employed.

Cocaine

Cocaine was the first agent successfully employed clinically for the production of local anesthesia. It has limited use in modern anesthesia practice because of its relatively high potential for systemic toxicity and addiction liabilities. It is listed as a schedule II drug in the United States. Cocaine is an excellent topical anesthetic agent and it produces vasoconstriction at clinically useful concentrations. As a result, it is still sometimes employed to anesthetize and constrict the nasal mucosa before nasotracheal intubation and otolaryngologists use cocaine during nasal surgery because of its topical anesthetic and vasoconstrictor properties. It is the only local anesthetic that inhibits the reuptake of catecholamines in the central and peripheral nervous systems.

Amino Amide Agents

Amino amide-linked local anesthetics most commonly used clinically are lidocaine, mepivacaine, ropivacaine, bupivacaine, and levobupivacaine. The first step in the biotransformation of the tertiary amine forms typically is dealkylation of the amino nitrogen by cytochrome P450 in the liver.

Lidocaine

Lidocaine, the first of the amino amide-type local anesthetics to be introduced into clinical practice, remains the most versatile and most frequently used drug in this class. It is popular because of its inherent potency, rapid onset, moderate duration of action, and topical anesthetic activity. Solutions of lidocaine are available for infiltration, peripheral nerve blocks, and epidural anesthesia. In addition, hyperbaric lidocaine is useful for spinal anesthesia of 30–60 minutes' duration. Lidocaine is also used in ointment, jelly, viscous, and aerosol preparations for a variety of topical anesthetic procedures. Lidocaine currently is still the only agent officially approved in the United States for IV regional anesthesia.

Lidocaine is sometimes given intravenously as an antiepileptic agent, as an analgesic for certain chronic pain states, and as a supplement to general anesthesia. It is administered intravenously for the treatment of ventricular dysrhythmias.

Mepivacaine

Mepivacaine has a local anesthetic profile similar to that of lidocaine. It can produce a profound depth of anesthesia with a relatively rapid onset and a moderate duration of action. Mepivacaine may be used for infiltration, peripheral nerve blocks, and epidural anesthesia, and in some countries, 4% hyperbaric solutions of mepivacaine are also available for spinal anesthesia.

It is ineffective as a topical anesthetic agent. The metabolism of mepivacaine is greatly prolonged in the fetus and newborn; thus this agent is not usually employed for obstetric anesthesia. Mepivacaine appears to be somewhat less toxic in adults than lidocaine and has less vasodilator activity than lidocaine. Because of the difference in vasoactivity, mepivacaine provides a somewhat longer duration of anesthesia than lidocaine when used without epinephrine. Mepivacaine seems to be particularly useful for brachial plexus blockade when large volumes of anesthetic solutions without epinephrine are given.

Ropivacaine

Ropivacaine is prepared as the pure S isomer rather than a racemic mixture. Onset of action, potency and duration of sensory nerve blockade appear similar for ropivacaine and bupivacaine, but ropivacaine is a less potent and short-acting agent in terms of motor fiber blockade. Toxicity studies suggest that ropivacaine is less cardiotoxic than bupivacaine, although ropivacaine still possesses some dysrhythmogenic potentia.

Bupivacaine

Bupivacaine was the first local anesthetic that combined the properties of an acceptable onset, long duration of action, profound conduction blockade, and significant separation of sensory anesthesia and motor blockade. This agent is used for various regional anesthetic procedures, including infiltration, peripheral nerve blocks, and epidural and spinal anesthesia. The average duration of surgical anesthesia with bupivacaine varies from approximately 3 to 10 hours. Its longest duration of action occurs with major peripheral nerve blocks such as brachial plexus blockade.

The major advantage of bupivacaine appears to involve epidural obstetric analgesia for labor when satisfactory pain relief for 2–3 hours is achieved, which significantly decreases the need for repeated injections in the pregnant patient. Moreover, adequate analgesia is usually achieved without significant motor blockade such that the patient in labor is able to move her legs. This differential blockade of sensory and motor fibers is also the basis for the widespread use of bupivacaine for postoperative epidural analgesia and for certain chronic pain states.

Levobupivacaine

The clinical profile of levobupivacaine, the S isomer of bupivacaine, is essentially the same as the profile of racemic bupivacaine except with somewhat wider therapeutic index for cardiac toxicity and systemic toxicity.

Prilocaine

The clinical profile of prilocaine is also similar to that of lidocaine. Prilocaine has a relatively rapid onset of action while providing a moderate duration of anesthesia and a profound depth of conduction blockade. Because this agent

causes significantly less vasodilatation than lidocaine, it can be used without epinephrine.

Prilocaine biotransformation produces aminophenols that oxidize hemoglobin to methemoglobin thus limiting its clinical use. The primary use of prilocaine is in EMLA cream, a eutectic mixture of prilocaine and lidocaine for topical application.

Etidocaine

Etidocaine is characterized by very rapid onset, prolonged duration of action, and profound sensory and motor blockade. It has a significantly more rapid onset of action than bupivacaine. Concentrations of etidocaine required for adequate sensory anesthesia produce profound motor blockade. As a result, etidocaine is primarily useful as an anesthetic for surgical procedures in which muscle relaxation is required. Consequently, this agent is of limited use for obstetric epidural analgesia and postoperative pain relief, as it does not provide a differential blockade of sensory and motor fibers. The drug is used infrequently in North America.

Dibucaine

Dibucaine is only available for topical anesthesia in the United States. It is more potent than tetracaine, although the onset of action of the two agents is similar. The duration of spinal anesthesia is slightly longer with dibucaine. The degree of hypotension and depth of motor blockade appear to be less in patients receiving intrathecal dibucaine than in those receiving tetracaine into the subarachnoid space, although the spread of sensory anesthesia is similar in the two groups.

Benzocaine

This local anesthetic is used exclusively for topical anesthesia. Benzocaine is available in a variety of proprietary and nonproprietary preparations. The most common forms used in an operating room setting are aerosol solutions for endotracheal administration and ointments for lubrication of endotracheal tubes. One should remember that benzocaine also can cause methemoglobinemia.

SECTION D

Regional Anesthesia

CHAPTER 45

Incorporating Regional Anesthesia into Anesthetic Practice

Richard W. Rosenquist, MD
and David L. Brown, MD

Incorporating regional anesthesia into an established anesthesia practice demands that the physicians involved understand and make preparations to address the following:

- Management of regional anesthesia through the perioperative period;
- The clinical indications for the regional anesthetic chosen;
- The resources necessary to perform the blocks efficiently and effectively; and
- Establishment of an institutional strategy to optimize the introduction of new techniques.

Far too often physicians desire to immediately transfer "techniques" they have learned into their own practices. That strategy is often destined to fail as the four areas of understanding clearly need to be managed to predictably and reliably introduce regional anesthesia into established practices. This chapter explores each of these necessary steps for successful introduction of regional anesthesia into a practice and expands on them so that you are able to individualize a plan for your own institution and practice.

CONCEPT OF THE CONTINUUM OF ANESTHESIA CARE: THE PERIOPERATIVE PERIOD

Physicians who desire to add regional anesthesia techniques to their own practice are most successful if they fundamentally are truly outstanding physicians and, as a result, excellent anesthesiologists. These physicians must be true perioperative physicians. They *must* be able to understand patient medical problems, surgeons' operative requirements, and regional anesthesia techniques, as well as recovery pattern, nursing requirements, rehabilitation,

KEY POINTS

1. The one overriding benefit of regional anesthesia techniques is that they do not need to end as the patient leaves the operating room at the end of the intraoperative period.
2. The patient education process is most effective if started in the surgeon's office at the time of the visit at which the decision for operation is completed. Both the surgeon and the nurses need to understand the general concepts and goals of anesthesia and are often strong coadvocates of better perioperative analgesia for their patients.
3. The perioperative period should be designed so that regional anesthesia does not delay or slow down a surgical day. Surgical delay is one of the most important items to avoid if you desire to successfully add regional anesthetic techniques to your practice.
4. Regional anesthesia techniques should be selected and performed on the basis of clear indications so as to maximize benefit and minimize complications.
5. The preoperative anesthetic note should clearly outline that the patient has been informed of the risks and benefits of the entire anesthetic experience, including the regional anesthetic portion, if that is applicable to the patient.
6. Patients should have regional anesthetics performed in settings where full monitoring, resuscitation equipment, and supplies are available.
7. When a practice has added continuous regional anesthetic techniques (either epidural or continuous peripheral nerve block techniques), it is important that round-the-clock coverage and followup is available to the patient and hospital if the patient remains as an inpatient.
8. One of the most important technical items in the intraoperative period with regional anesthesia is to recognize that if a block is not 100%, the anesthesiologist should be the only individual aware of that fact. This means that if the block is not working as well as desired, general anesthesia or deep sedation should be added efficiently.
9. If a patient is to be discharged with a continuous catheter technique, a clear understanding of catheter and pump management, limb protection, catheter removal, breakthrough pain control, and contact numbers must be assured.
10. Anesthesiologists need to continue their own regional anesthesia education by attending continuing education conferences and workshops that help them to have a more complete understanding of the topic and learn new techniques for introduction into their practice. This enables anesthesiologists to continue the education of physicians, nurses, and others regarding regional anesthesia advances.

and potential complications from the surgical procedure performed. Only if all of these are incorporated into decisions about regional anesthesia will the patient, surgeon, anesthesiologist, and nursing staff be coadvocates of the proposed new technique.

In today's surgical and anesthetic environment, our intraoperative general anesthetic care has advanced to a level where it is unusual to find clear advantages for regional anesthesia when considered during the isolated intraoperative period. There are exceptions, of course. Nevertheless, regional anesthesia may be better termed "regional analgesia," as one seeks to incorporate that concept into a practice. The one overriding benefit of regional anesthesia techniques is that they do not need to end as the patient leaves the operating room at the end of the intraoperative period. Rather, when effectively chosen, these regional techniques can be extended either through appropriate drug selection, or via catheter insertion and continuous infusion of medication. Either of these choices may help transition the patient from the intraoperative to the postoperative period and to nearly full recovery without significant pain. Examples of this include using new, extended-release depot preparations of morphine in the epidural space to extend analgesia, or by inserting *home going* peripheral nerve plexus catheters to provide local anesthetic analgesia into the immediate and more distant postoperative period.[1–4]

A key step in successfully introducing regional anesthesia to an established practice is insuring that preoperative evaluation and education of the patient includes an explanation of regional anesthesia and that realistic patient expectations are established. Far too often patients are under the misunderstanding that because they choose a regional anesthesia technique, they will be "awake" during their surgical procedure. Experts in regional anesthesia are nearly always capable of providing outstanding sedation and anxiolysis for the entire perioperative period for patients undergoing a regional technique. This observation fits with these anesthesiologists being excellent physicians and understanding that it is a rare patient who wants to be, or should be allowed to be, unsedated for a surgical procedure. The patient education process is most effective if started in the surgeon's office at the time of the visit at which the decision for operation is completed. Both the nurses and the surgeon need to understand the general concepts and goals of anesthesia, including regional anesthesia techniques. Once they understand these concepts, they are often strong coadvocates of better perioperative analgesia for their patients.

When considering patient education, the most important concept is that realistic expectations for both patient and the patient's family are outlined. The patient's expectations should be focused around anesthesia, sedation, postoperative analgesia, and what side effects the patient might experience so that, for example, a "numb" arm does not bother the patient on arrival in the recovery room or discharge to the floor or home. In setting these expectations, it is important that the anesthesiologist and institution design an analgesia transition program that addresses resolution of the regional anesthetic. As an example, outstanding brachial plexus anesthesia and analgesia for an upper-extremity operation can frustrate a patient and the patient's family if the block abruptly wears off while the patient is expecting to sleep through the night and no oral medication regimen has been planned to ease that transition. When setting expectations for surgeons, a key element is that the perioperative period is designed so that regional anesthesia does not delay or slow down a surgical day. This demands that anesthesiologists and institutional leaders be creative about incorporating regional blocks and techniques into their practices. My experience is that surgical delay is one of the most important items to avoid if you desire to successfully add regional anesthesia techniques to your practice.

CLINICAL INDICATION FOR REGIONAL ANESTHESIA

After considering the continuum of anesthesia care in the entire perioperative period, the next step for successful introduction of regional techniques into a practice is to develop clear indications for the use of these techniques. It must be remembered that the dominant focus for regional anesthesia is regional analgesia and the ability to minimize opioids and other intravenous agents in the immediate perioperative period. Additional advantages of regional anesthesia techniques include the ability to avoid airway manipulations in patients who evidence difficult airway characteristics, or those with full stomach considerations. This does not mean that regional anesthetics should be applied in every full-stomach situation, but a mature clinical risk-to-benefit approach to many emergency patients suggests that the use of effective regional anesthesia does modify risk. Finally, there are selected patients in whom specific regional techniques may provide significant physiologic advantages. As example, in a patient with obstructive cardiomyopathy, the intravascular volume shifts from both general anesthesia vasodilatation and/or neuraxial anesthesia vasodilatation may be avoided, to the patient's advantage, by the use of a brachial plexus nerve block. Another example might be a patient with end-stage pulmonary disease, who requires open reduction internal fixation of a hip fracture. This clinical setting might be effectively handled with a continuous spinal anesthetic and minimal sedation, rather than a general anesthetic with tracheal intubation.

In a patient who is undergoing regional anesthesia, there must be clear documentation of both the technical procedure and the indications for the regional technique in the patient's chart. This is another opportunity for the anesthesiologist to educate both surgeons and nurses about the primary reason why the regional anesthesia technique was chosen. In my opinion, anesthesiologists frequently do not take advantage of the educational opportunities present in writing clear and effective progress notes in a patient's record. The preoperative anesthesia note should clearly outline that the patient has been informed of the risks and benefits of the entire anesthesia experience, including the regional anesthesia portion, if applicable to the patient.

The increasing number of drugs being developed that impact coagulation demands that anesthesiologists interested in adding regional techniques to their practice fully understand the implications of these anticoagulants and platelet-active drugs. For example, consensus statements for the use of neuraxial anesthesia techniques in relation to the use of various anticoagu-

lant and antiplatelet agents were published by the American Society of Regional Anesthesia and Pain Medicine (ASRA) in 2003.[5] Recent data outlining a 10-year Swedish experience with anticoagulants and neuraxial anesthesia underscore the need to understand the potential risks and benefits of this drug and technique combination.[6] The Swedish results reiterated the danger of using more than one agent with anticoagulant or antiplatelet activity in combination. They also identified subgroups of patients at markedly increased risk; for example, elderly females with osteoporosis undergoing total knee arthroplasty under epidural analgesia and receiving once-per-day low-molecular-weight heparin have a 1 in 1800 incidence of epidural hematoma. The data to develop clear consensus statement guidelines regarding the use of anticoagulants and antiplatelet agents in conjunction with peripheral regional anesthetics is extremely limited. It has been suggested that the ASRA consensus guidelines for neuraxial anesthesia be applied to all regional anesthesia techniques. This may be too restrictive. In most cases, techniques performed in areas that are easily compressed in the event of bleeding may be appropriate. Others, such as paravertebral or subclavian blocks, should be avoided unless coagulation parameters are normal.

RESOURCES REQUIRED FOR EFFICIENT PRACTICE

A common stumbling block for practices desiring to add regional anesthesia expertise to their practice is to have too few anesthesiologists skilled in the techniques. There must be critical masses of personnel, resources for the techniques, as well as interest in the techniques, for these to be added successfully to an anesthesia practice. Many practices often seek to have a single individual provide the regional anesthesia expertise. This is nearly always doomed to failure as that individual cannot be present 24 hours a day, year-round. Rather, it seems important to have enough physicians with the technical skills and interest in these anesthesia approaches to be able to provide consistent delivery of regional anesthesia throughout the day, week, and year. In addition to the physician resources, it is often helpful to have allied health personnel help to prepare patients and supplies for the regional techniques to optimize timing of the technical performance of the regional anesthetic. This may be with a technician who is well trained in assisting the physicians, a nurse anesthetist who is skilled in this area of practice, or a registered nurse who works for the practice or hospital and has an interest in and a desire to grow this part of the practice.

For the physicians, there must be a complete understanding of anatomy and regional anesthesia technical skills so as to safely and reliably perform the nerve blocks. Patients should have regional anesthesias performed in settings where full monitoring, resuscitation equipment, and supplies are available. These are major anesthesia techniques and need to be treated as such. Monitoring should meet American Society of Anesthesiologists (ASA) standards for performance of an anesthetic.[7] Delays in the surgical day can often be minimized if many of the regional anesthesias are performed outside the operating room itself. This serves two functions. First, it allows the regional anesthesia to be performed while the surgical team is still preparing the operating room. Second, it gives the injected local anesthetic additional time to effectively anesthetize the desired region. This, of course, demands that regional anesthesia block rooms, or at least regional anesthesia block areas, are established outside the operating room. In many practices, this could be accomplished in areas of the preoperative holding or of postoperative anesthesia recovery. The ideal is to have induction rooms near the operating rooms. Within these areas of the hospitals, regional anesthesia carts with supplies easily at hand and with appropriate monitoring and resuscitation gear are critical for effectively caring for these patients.

As the regional anesthetic practice is established, allied health staff assisting physicians with the technical features of these nerve blocks need to be trained and to have regional block protocols developed so that they are most effective. This demands significant planning and communication to effectively implement this practice.

When a practice has added continuous regional anesthesia techniques (either epidural or continuous peripheral nerve block techniques), it is important that round-the-clock coverage and followup are available to the patient and hospital if the patient remains as an inpatient. Even the most successful technical regional anesthetic can be viewed as unsuccessful if this part of the practice is not accounted for in the development phase of adding regional anesthesia to a practice. Other ideas to ease the transition of regional anesthetic techniques into a practice are to use regional anesthesia continuous infusion pumps that differ from general intravenous infusion pumps used throughout the hospital with tubing that has no injection ports. This difference helps to minimize the inappropriate administration of other intravenous drugs through regional block catheters. Drug swaps remain one of the dilemmas of modern medicine and the use of different pumps and tubing helps to minimize this type of error and potential neurotoxicity. New devices with the capability to read barcodes and recognize appropriate or inappropriate drugs for the device may provide additional safety in the future. Successful introduction and continued use of regional anesthetic techniques requires that physicians stay abreast of the latest technologies, such as ultrasound guidance or the use of stimulating catheters for catheter placement.[8,9]

OPTIMIZING INSTITUTIONAL INTRODUCTION OF REGIONAL ANESTHESIA

Once the preceding three major elements are understood and a group decides to move ahead with introduction of regional anesthesia or expansion of regional anesthesia into its practice, strategies need to be developed to optimize this introduction. First, a core group of regional anesthesia physicians who agree, in principle, on the plan must be established. It is most effective if, as a system is rolled out, a small number of surgeons and surgical procedures are used as the initial clinical settings so that "success" can be validated more quickly. One of the easiest ways to cause an introduction of regional anesthesia to a practice to fail is to try to be all things to all patients and all surgeons at the outset. It is important to emphasize that successful introduction of regional anesthesia to a practice demands that all involved perceive that regional anes-

thesia is truly an advantage to the patient, to the surgeon, to the anesthesiologist, and to the institution. Collins et al.[10] provided clear evidence for this as they examined the impact of a regional anesthesia–analgesia program for outpatient foot surgery. They documented a marked increase in regional anesthesia use, no decrease in operating room efficiency, reduced postanesthesia care unit and discharge time, decreased analgesic use, and decreased nursing interventions for analgesia.

An important technical item in the intraoperative period with regional anesthesia is to recognize that if a block is not 100%, the anesthesiologist should be the only individual aware of that fact. This means that if the block is not working as well as desired, general anesthesia or deep sedation should be added efficiently. This demands that anesthesiologists interested in this practice understand enough about regional anesthesia and sedation to blend the two techniques so that patients are effectively sedated and do not have any painful memories of either block insertion or eventual surgical manipulations. The potential for this transition from conscious sedation to deep sedation or general anesthesia should be explained in advance so that patients have realistic expectations regarding the plan of management.

Successful use of regional anesthesia also requires education and training of the nursing staff and development of care protocols. This often begins in the postanesthesia care unit where the limb must be protected. If the patient is to be discharged, the patient and family must be educated about how to protect the limb until recovery from the block has occurred. If the patient is to be discharged with a continuous catheter technique, a clear understanding of catheter and pump management, limb protection, catheter removal, breakthrough pain control, and contact numbers must be assured. In some settings, this may require training home health nurses to facilitate the process. On the inpatient side, education regarding limb protection, neurologic evaluations, breakthrough pain, and issues with anticoagulation and ambulation must be completed.

Once the techniques are well established within an institution and the anesthesiologists are interested, the anesthesiologists need to continue their own regional anesthesia education by attending continuing education conferences and workshops that help them to an even more complete understanding of the topic and to learn new techniques for introduction into their practice. This enables these anesthesiologists to continue the education of nurses and others interested in regional anesthesia advances. This is a critical component of successful introduction of the practice of regional anesthesia.

Once it is effectively introduced, the registered nurses within an institution often are its most vocal advocates, as they see firsthand the difference between patients having effective regional anesthesia and those having either ineffective regional anesthesia, excessive opioid analgesia, or uncontrolled pain in the perioperative period.

CONCLUSION

The introduction of regional anesthesia to an established anesthesia practice is no different than the introduction of any new technique to a practice. There must be expertise, planning, and a group of physicians and support staff interested in the entire perioperative period who can coordinate the necessary personnel and resources to provide state-of-the-art medical care.

CHAPTER 46

Neuraxial Anesthesia

Daniel T. Warren, MD, and
Spencer S. Liu, MD

With more than 100 years of use, neuraxial anesthesia has enjoyed much success and endured controversy. With the stage set by the developments of the hollow needle and syringe, the discovery of neuraxial anesthesia was born out of mishap in 1885 when Corning was experimenting with effects of cocaine on the spinal nerves of dogs. Bier brought spinal anesthesia into clinical use for surgery in 1898, but only after self-experimentation and a personal experience with a well-described postdural puncture headache. Epidural anesthesia gained widespread attention in the setting of labor analgesia, maintaining the medical community's interest in neuraxial blockade despite rapid advancements in techniques for general anesthesia in the 1940s and 1950s. More recently, the introduction of continuous catheter techniques, combined spinal–epidural anesthesia, and various neuraxial anesthetic adjuvants has allowed further opportunities to provide our patients the benefits of neuraxial blockade.

ANATOMY

Neural Structures

A thorough appreciation for the anatomy of the spinal structures is necessary for appropriate technique, patient selection, and management of neuraxial anesthesia. The spinal structures are identified by cervical, thoracic, lumbar, sacral, and caudal regions (Fig. 46–1). The spinal cord begins at the base of the brainstem and continues caudad terminating as the conus medullaris, typically at the level of L1-L2 in the adult. The cord shows cervical and lumbar enlargements to accommodate the increased neuronal supply of the limbs. Rootlets emerge from the dorsal and ventral surface of the spinal cord and converge to form the respective ventral and dorsal roots of the spinal nerves at each spinal level (Fig. 46–2).

Cerebrospinal Fluid

As with the brain, the spinal cord and portions of the spinal nerves are bathed in cerebrospinal fluid (CSF), which provides protection for these structures and participates in maintaining homeostasis. The CSF is secreted mainly by the choroid plexuses located on the roofs of the lateral, third, and fourth ventricles, and reabsorbed mainly through the arachnoid villi which project into the parasagittal venous sinuses and to a much lesser extent through the epidural veins of the vertebral column. It typically has a density range of 1.00028–1.00100 g/mL.[1] CSF volume and its clinical consequences are discussed in the Clinical Pharmacology section below.

Meninges

As with the brain, spinal cord, nerve roots and CSF are enveloped by three membranes: the pia mater, arachnoid mater, and the dura mater (Figs. 46–2 and 46–3). The innermost pia mater is intimately lining the surface of the cord and nerve roots. It is a highly vascular and permeable membrane. The arachnoid mater approximates the outermost membrane, the dura mater. Within the boundaries of the arachnoid is the subarachnoid space, home to the CSF, trabecular network, and dentate ligaments. The subarachnoid space extends laterally with the dura as nerve root "sleeves," with the accompanying CSF as far as the dorsal root ganglion. The spinal dura mater extends from the level of the foramen magnum, where it is contiguous with cranial dura, to the level of S2 in most adults. Here the subarachnoid space terminates as the dura fuses with the filum terminale (pial extension), and then with the coccygeal periosteum. Between the dura mater and arachnoid mater resides the subdural space, which contains little more than a small amount of serous fluid. This space is often implicated as a culprit in complications such as a total spinal following an intended epidural administration of local anesthetic and failed spinal anesthetics.

Vertebrae

The neural structures of the spinal cord are protected by the bony vertebral column comprised of 7 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 4 coccygeal vertebrae (Fig. 46–1). The vertebrae of the sacral and coccygeal regions are fused to form the sacrum

KEY POINTS

1. A systematic and rational approach based on a thorough three-dimensional understanding of anatomy should be used when accessing the subarachnoid and epidural space.
2. Anesthetic doses, agents, and combinations of agents should be individualized so as to optimize neuraxial blockade for a given clinical setting.
3. Hypotension and bradycardia associated with neuraxial anesthesia should be identified early and treated aggressively in an attempt to prevent cardiovascular collapse and poor outcome.
4. Our understanding of potential neurotoxicity and the nature of transient neurologic symptoms (TNS) are continuing to evolve. However, there is growing consensus that TNS may not represent direct neural toxicity.
5. Evaluating the appropriateness of neuraxial procedures in patients receiving anticoagulant and antiplatelet medications is a challenge. Clinicians should be familiar with the recommendations presented by the American Society of Regional Anesthesia and Pain Management in the consensus statement addressing these issues.
6. When suspicion of spinal hematoma or abscess is credible, definitive diagnosis with appropriate imaging and prompt decompression within 4–6 hours of onset of neurologic symptoms is crucial to improve chances of recovery of function.
7. Developing an understanding of the nature of combined spinal–epidural anesthesia and facility with its techniques can expand a clinician's armamentarium of tools to provide neuraxial anesthesia and optimize patient care.

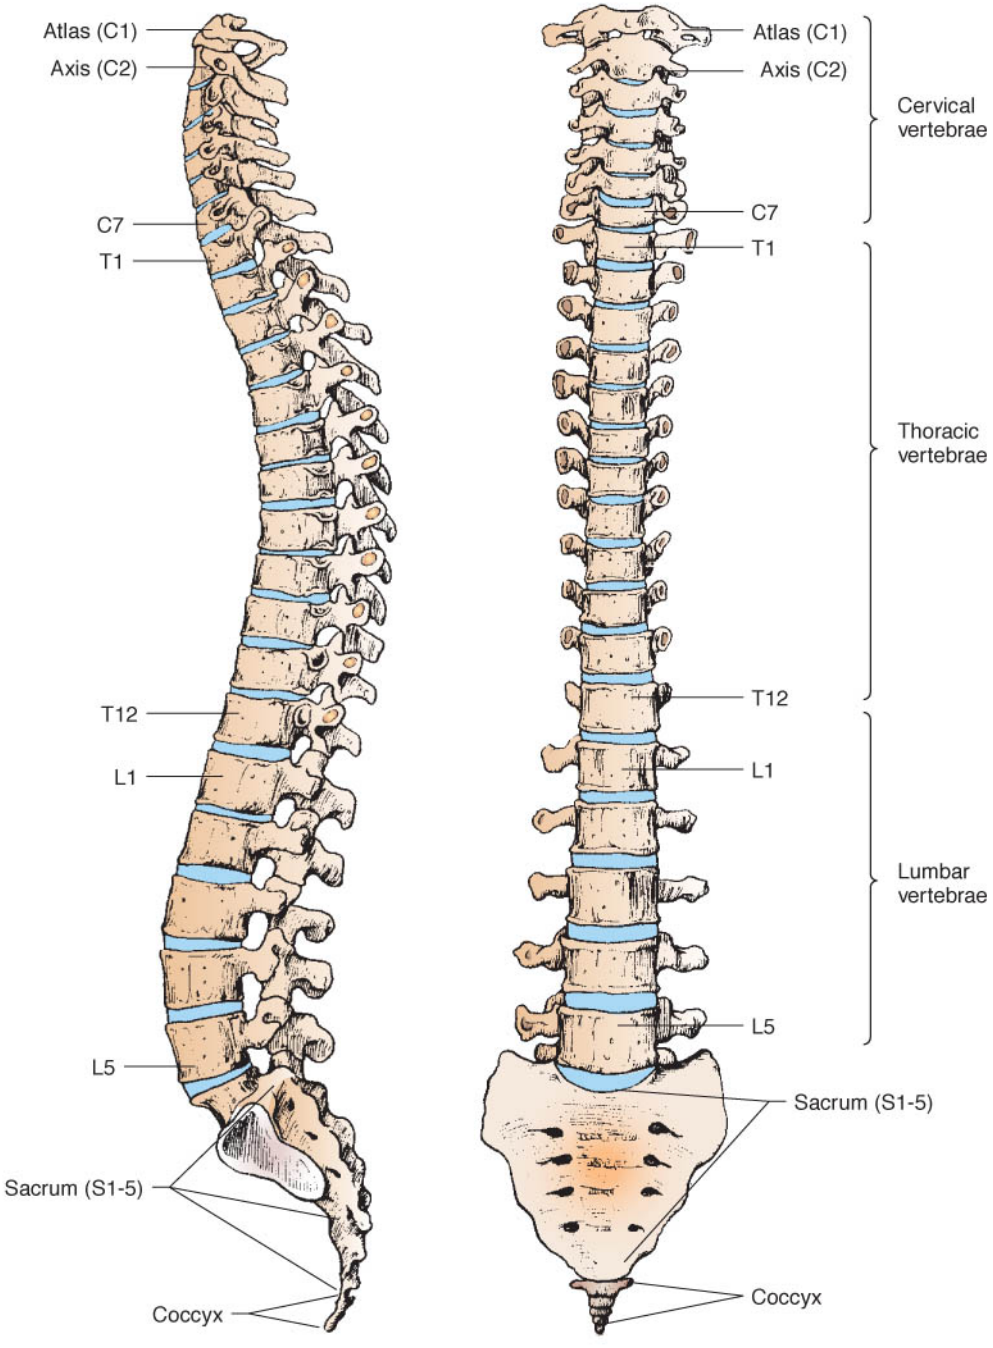

FIGURE 46–1. Regions of the spinal column.

and coccyx, respectively. Cervical and lumbar lordotic curves and thoracic kyphotic curves of the normal spine allow for advantageous distribution of mechanical forces and spinal movements. A typical vertebra consists of a pillar-like vertebral body joined by the pedicles to the posterior elements, namely the laminae, superior and inferior articular processes, transverse processes, and the spinous process. The vertebrae have regional characteristics that are relevant to the techniques used to access the neuraxis in clinical situations. The figures depict relevant features of representative thoracic and lumbar vertebrae (Fig. 46–4).

Intervertebral Disks and Ligaments

The endplates of the vertebral bodies are joined to one another by the intervertebral disks (Fig. 46–2), consisting of the outer annulus fibrosus and the inner nucleus pulposus. Further structural support comes from the anterior and posterior longitudinal ligaments running along the ventral and dorsal aspects of the vertebral bodies respectively. Along with the supraspinous ligament traversing superficially, the deeper interspinous ligament joins the spinous processes to one another (Fig. 46–3). Adjacent lamina are interconnected by the ligamentum flavum, together forming the posterior wall of the

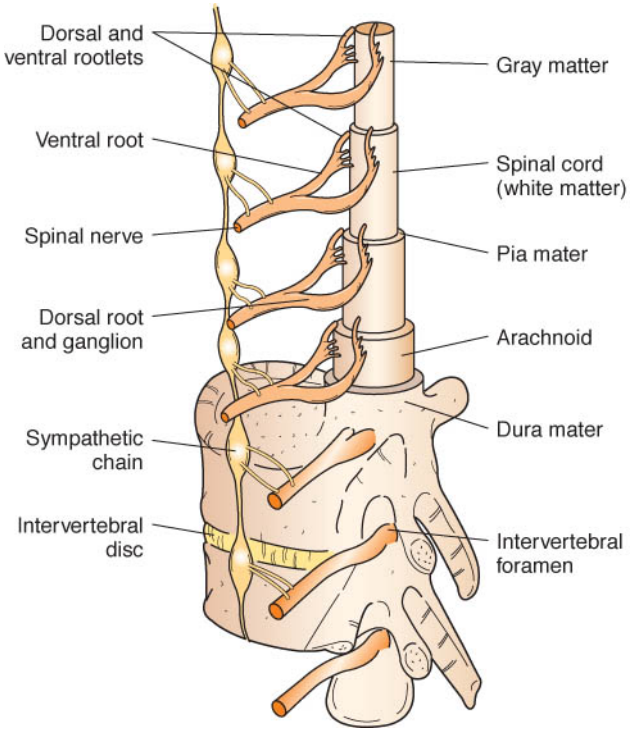

FIGURE 46–2. The spinal cord, along with the emerging root structures, are enveloped by the meninges as depicted in this figure.

spinal canal. This ligament forms embryologically from two (right and left) separate neural crest structures. These ligamenta meet in the midline at an acute angle, but have an inconsistent degree of fusion. Incomplete fusion results in sagittal gaps, which are variable not only between individuals, but also among spinal levels within a given patient. Cervical and upper thoracic levels have a higher rate of failed fusion compared to levels below T3-T4 (as high as 50–70%) and are thus perhaps more difficult for epidural access using the loss or resistance technique.[2]

Epidural Space

The epidural space (also referred to as extradural and peridural space) lies between the dura and the borders of the spinal canal (Fig. 46–3). Anteriorly, this border is the posterior longitudinal ligament; posteriorly, it is the vertebral lamina and adjoining ligamentum flavum (Fig. 46–3). The spinal epidural space runs from the level of the foramen magnum to the sacral hiatus, which is bound by the sacrococcygeal ligament. The lateral borders of the epidural space are partially delineated by the vertebral pedicles, but this space extends laterally through the intervertebral foramina to communicate with the paravertebral spaces on each side. The epidural space is somewhat compartmentalized by the sections of the dura abutting the ligamentum flavum, vertebral lamina, and other borders of the vertebral canal (Fig. 46–3B). However, these compartments are joined by a "potential space" that is opened by injection of fluid or air, thus connecting the compartments and revealing a more continuous communication.

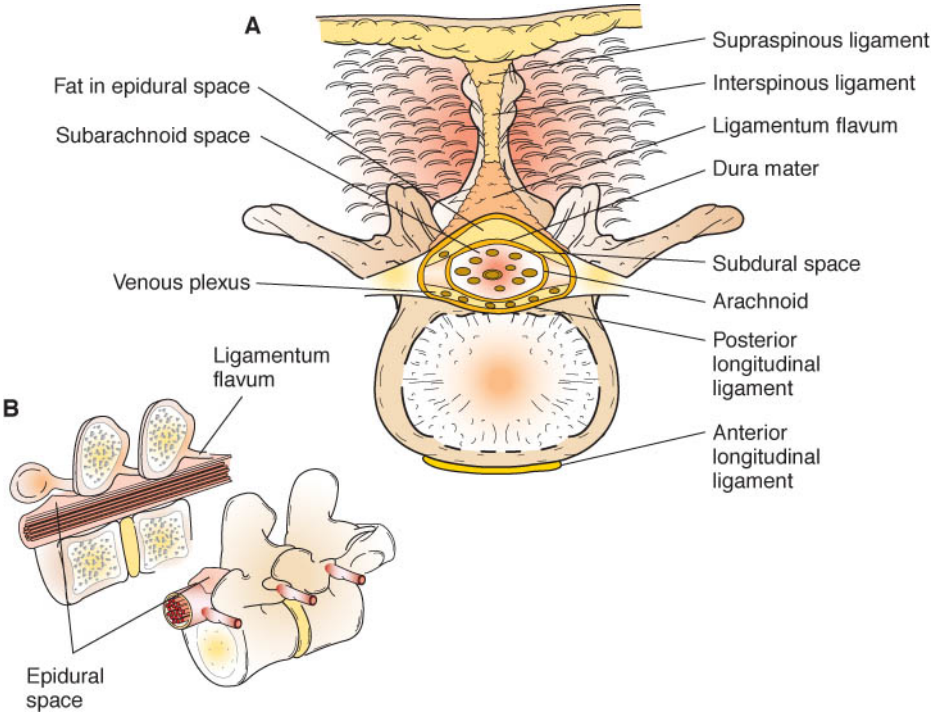

FIGURE 46–3. A. Cross-sectional view of the lumbar region depicting the location of the epidural space and other anatomical structures associated with neuraxial procedures. As demonstrated in (**B**), the epidural space is somewhat compartmentalized, but continuous via "potential space" pathways that expand with injection of liquid.

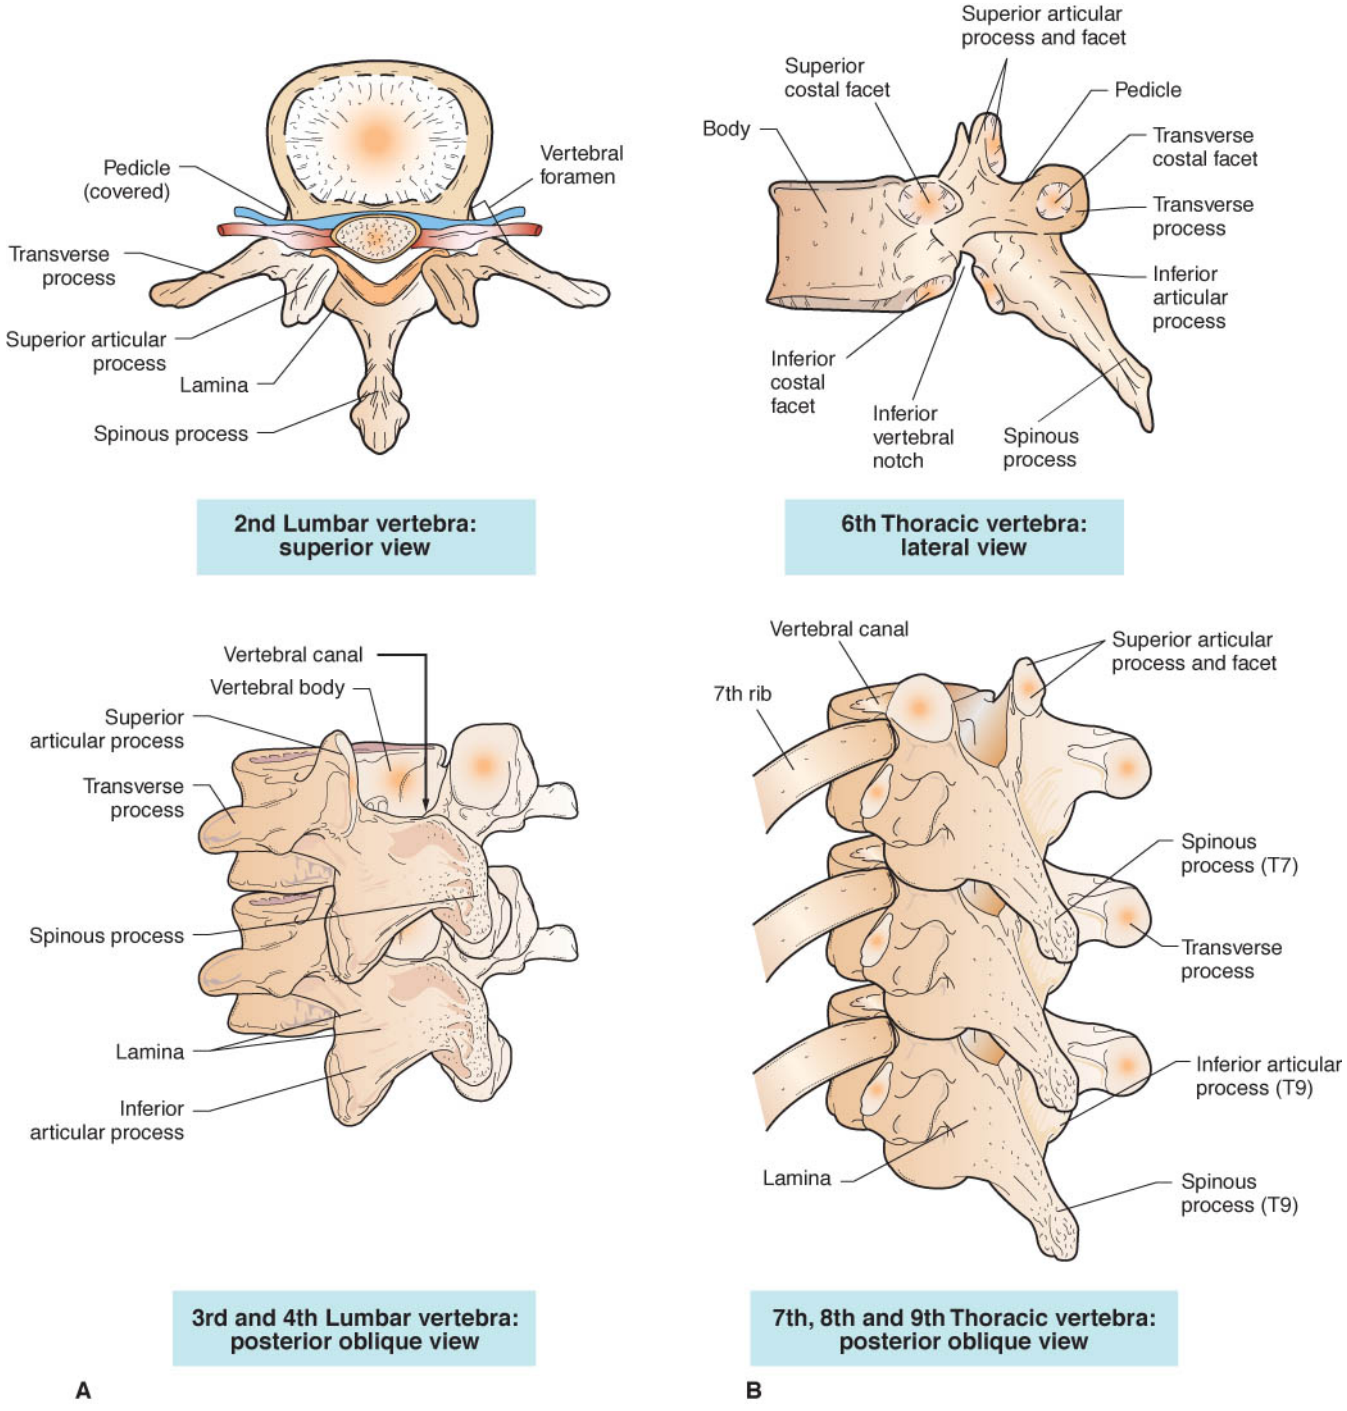

FIGURE 46–4. Anatomic structures associated with (**A**) lumbar and (**B**) thoracic vertebrae.

The contents of the epidural space include epidural fat, venous plexus, and segmental arteries. The epidural fat is largely located in the posterior and lateral aspects of the epidural space. This fat plays a role as a site for depot sequestration of epidurally administered local anesthetics and opioids as a function of the lipid solubility of the drug.[3] The plexus of epidural veins (Batson plexus) is principally within the anterior and lateral portions of the epidural space, with rare presence in the posterior aspect. These veins communicate with the azygous system, and thus can become engorged in the setting of increased intraabdominal pressure.

EQUIPMENT

Spinal Needles

Although many designs have been introduced throughout the history of spinal anesthesia, the needles commonly used today can be generally classified as either "cutting needles" or "pencil-point needles" (Fig. 46–5). The Quincke-style needle, one of the most frequently used cutting needles, has a medium-length bevel, coming to a sharp point, which cuts through dural and arachnoid structures as it passes to the subarachnoid space. In contrast, pencil-point needles (often called "atraumatic"), such as the Green,

Whitacre, Sprotte, and Gertie-Marx, have a rounded, noncutting tip. The latter three have openings on the side rather than at the tip. Efforts to minimize the incidence of postdural puncture headache have driven the advancement of needle design. More recent designs include tapered needles, and return of stylet-point needles, such as the "Ballpen (Rusch, France) needle." Needle gauge usually ranges from 27 to 18, with the smaller-gauge needles requiring an introducer needle.

Epidural Needles and Catheters

Needles for accessing the epidural space need to be able to facilitate catheter insertion and techniques for identification of the epidural space. Currently, the most commonly used needle is the Tuohy needle (Fig. 46–5D). The design of this needle has undergone many modifications, but is characterized by a curved, or Hubber, tip. This curved tip decreases coring of tissue during insertion, but has been employed chiefly to attempt directional control of catheter insertion. Epidural needles are typically 16–20 gauge and accompanied by a tight-fitting stylet. Larger-gauge needles are less likely to be deflected by firm ligaments and osseous structures, and may provide a more reliable "loss-of-resistance" for identification of the epidural space.[4]

Commercially available catheters for cannulation of the epidural space are composed of polyurethane, nylon, or silicone-based material. Catheters with wire-wound reinforcement are designed to prevent kinking of the lumen and to increase durability, thus making them useful for postoperative analgesic infusions. Several variations of catheters have been brought to the market with options for multiorifice tips, metal stylets, and varying stiffness.

PATIENT SELECTION

The success of neuraxial anesthesia begins with proper patient selection and creation of an environment that is conducive to a variety of regional anesthetic techniques. Principally, the surgical procedure should be able to be performed with a sensory block level that is tolerable and safe for the patient under the appropriate positioning, monitoring, and supplemental medication/sedation for the patient's given condition. Lower-extremity, pelvic, and lower-abdominal procedures can be suited for spinal or epidural anesthesia. Procedures in the perineum usually are more suited to spinal anesthesia because of the potential for sacral nerve sparing with epidural anesthesia. Upper abdominal procedures usually require sensory levels that are not comfortably attainable with regional techniques alone, and would require "supplementation" with light general anesthesia.

It is imperative that the patient be able to cooperate and tolerate the experience, from placement of the block, to block resolution. This can be accomplished through proper preoperative evaluation of the patient's maturity and affect, and appropriate informed consent discussions regarding risks, benefits, alternatives, and patient expectations in light of the requirements of the procedure.

Absolute contraindications to neuraxial anesthesia are few in number, but include patient refusal, significant hypovolemia, infection at the site of needle entrance, increased intracranial pressure, and significant coagulopathy. Relative contraindications require analysis of the risks and benefits for a given patient and situation. Unfortunately, this often needs to be done in light of the current medicolegal environment. Commonly encountered conditions are minor coagulopathy, sepsis/bacteremia, and preexisting neurologic conditions, such as peripheral neuropathy, multiple sclerosis, and other demyelinating processes.

TECHNIQUE FOR NEURAXIAL ANESTHESIA

Patient Positioning and Preparation

In addition to confirming patient consent and understanding, one should also verify the availability of equipment and medications to manage airway compromise and hemodynamic perturbations. The patient should have proper monitoring and supplemental oxygen during neuraxial anesthesia. Most patients prefer to have sedation administered prior to beginning neuraxial anesthesia, but judicious use of agents like midazolam and fentanyl should not significantly impair oxygenation or the patient's ability to reliably report paresthesia or other signs of unintended trauma.

The lateral decubitus position (Fig. 46–6) is most often used for spinal anesthesia. The patient should have hips and knees flexed with head approximating the knees in effort to relax the lumbar lordotic curve and accentuate the interlaminar aperture. This position is useful when employing spinal anesthesia for one-sided procedures, placing the operative side down if using hyperbaric solutions, or operative side up for hypobaric preparations (a technique commonly employed for hip surgery).

Alternatively, neuraxial access can also be obtained with the patient in the sitting position (Fig. 46–7), bending forward to relax the lordotic curve of the lumbar spine. Advantages of this position are that it facilitates the iden-

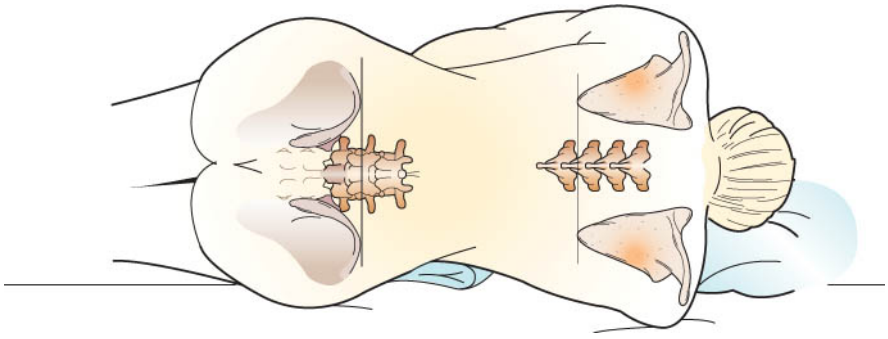

FIGURE 46–6. Lateral decubitus position for neuraxial procedures. The patient is positioned with the head tucked down, hips flexed, and back rounded in efforts to maximize the aperture of the interlaminar space. Lines depicting the levels of the iliac crests and scapulae are commonly employed anatomical landmarks to identify the levels of L4 and T7, respectively. However, these landmarks are often unreliable.

tification of the midline in obese or anatomically distorted patients and augments CSF pressure at the needle entrance site, enhancing CSF flow through the needle when performing lumbar puncture. It is also used to accomplish "saddle block" anesthesia for procedures limited to the perineum by administering hyperbaric spinal preparations to the intrathecal space and having the patient remain sitting for at least 5 minutes after injection. If the patient is going to be in the prone position for procedures such as perianal surgery, a hypobaric technique can be employed. This is accomplished by positioning the patient for surgery prone with hips flexed and lumbar spine relaxed (jackknife) (Fig. 46–8), then accessing the subarachnoid space, using a syringe to aspirate for confirmation of CSF flow. Once a hypobaric solution is administered, it is recommended that the patient remain in a flat or head-down position for at least 30 minutes to prevent unintended rostral "floating" of the anesthetic.

Accessing the Subarachnoid Space

Several techniques have been described for inserting a needle percutaneously into the subarachnoid space, each having specific advantages in different clinical situations. By developing skill with multiple techniques, the practitioner can be prepared to adapt to the clinical challenges presented. Despite the position and technique to be used, a standard approach should begin with identifying the midline, and palpating the iliac crests. The intercrest line (Fig. 46–6) is classically described as crossing the level of the fourth lumbar vertebra, or the L3-L4 or L4-L5 interspace. The most commonly used and easily mastered technique for needle insertion is the midline approach. After identification of the desired interspace for lumbar puncture, skin wheal is raised over the interspace and appropriate infiltration of local anesthetic is fanned along the midline. It is useful to firmly place 2 fingers of the nondominant hand parallel to the axis, straddling the lateral borders of the interspace (Fig. 46–9). When using small-gauge spinal needles, an introducer needle is first inserted in the sagittal plane between the spinous processes, initially parallel to the plane of the surface of the back. The introducer is then stabilized by grasping the hub with the digits of the nondominant hand as the spinal needle is passed through the bore of the introducer and advanced in the sagittal plane. The path of travel for the needle in the midline approach is through skin, subcutaneous tissue, supraspinous ligament, interspinous ligament, ligamentum flavum, and, finally, through the dura and arachnoid matter into the subarachnoid space. As the needle tip passes beyond the ligamentum flavum and through the dura, a change in resistance, and possibly a "pop," can be appreciated. At this point, the stylet is withdrawn from the spinal needle, and the hub is inspected for free flow of CSF. If bone is contacted prior to entering the thecal sac, the practitioner should reassess the angle of projection and ensure that it is within the sagittal plane. If no correction toward the midline is needed, the most fruitful adjustment is usually an attempt to gradually "walk" the needle tip in a cephalad direction until the subarachnoid space is encountered. If free flow of CSF is in question, rotating the bevel or side hole of the needle through the four quadrants can help ensure proper placement of the needle opening. Once satisfied with needle placement, the dosing syringe (typically a Luer slip style), which was previously prepared with the intended agent, is firm-

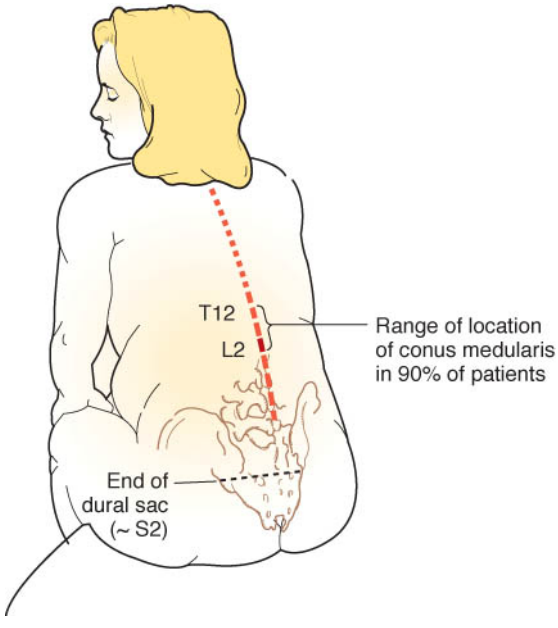

FIGURE 46–7. A patient in the sitting position, with the spine curved to relax the lordotic curve on the lumbar region. The approximate range of cord termination in 90% of patients is from T12 to L2.

FIGURE 46–8. Patient positioned in the prone-jackknife position for surgery to be performed under hypobaric spinal anesthesia. Note that the head is below the level of the hips to ensure that the anesthetic "floats" to the caudad portion of the intrathecal space.

ly attached to the hub of the spinal needle. Aspiration of CSF into the syringe is final confirmation of subarachnoid placement; the agent is slowly injected while keeping the needle tip immobile. Once the injection is complete, the patient should be placed in the intended position to effect the spread of the agent, or into the appropriate position for surgery. The advantages of the midline approach include simplicity and the stability provided by the relatively avascular sagittal plane through the interspinous ligament.

The paramedian technique (Fig. 46–10), although routinely used by some, should be mastered to the same level as the midline technique because of its advantages in common clinical situations. When the midline approach is difficult, the paramedian approach may still allow access to the subarachnoid space when presented with inability to obtain adequate patient positioning (maintained lumbar lordosis), obesity, term pregnancy, heavily calcified interspinous ligament (common in elderly patients), or scoliosis. This advantage is a consequence of the larger interlaminar aperture presented via the path of the paramedian approach, especially when lumbar lordosis is retained. Although variations have been described, in the lumbar region this approach begins with identification of the superior aspect of the caudad spinous process of the interspace to be accessed. The percutaneous entry point is identified 1 cm lateral to this superior tip of the spinous process. After raising a skin wheal and appropriate infiltration with local anesthetic, the introducer and/or spinal needle are advanced through the anesthetized region, directed approximately 10–15° toward midline, and at a slightly cephalad angle. This path will traverse skin, subcutaneous tissue, paraspinous muscle, ligamentum flavum, and dura and arachnoid matter to reach the subarachnoid space. If bone is encountered prior to dural puncture, it is most likely the caudad lamina, in which case the needle should be "walked" cephalad, then medial, until the thecal sac is breached.

FIGURE 46–9. Fingers of the nondominant hand are used to identify the lateral borders of the interspace of interest. This aids in developing a three-dimensional mental image of the anatomical structures to facilitate neuraxial access.

The Taylor approach (Fig. 46–11) is a variation of the paramedian technique; it capitalizes on the breadth of the L5-S1 interspace (typically the largest interspace) and the palpable and relatively constant location of the posterior superior iliac spines (PSISs). Once a PSIS is identified, a skin wheal is raised 1 cm medial and caudad to its inferior border. After appropriate infiltration of local anesthetic, the spinal needle (typically at least 22 gauge) is directed approximately 45° medial and cephalad toward the L5-S1 interspace. Again, if bone is contacted, the correction needed is a greater cephalad angle to "walk off" of the superior aspect of the sacrum.

Accessing the Epidural Space

Although the pathway and approach to the epidural space are the same for the subarachnoid space, the technical skills to correctly and reliably access and identify the epidural space require more experience to develop than those for dural puncture.[5] Again, both midline and paramedian approaches are used for needle placement and the patient can be placed in either the sitting or lateral position. In contrast to spinal anesthesia, the epidural space theoretically can be accessed at any vertebral level. Because of the differences in the projecting angles of the spinous processes in the lumbar and midthoracic regions, an angle of approach closer to the plane of the surface of the back is used when performing thoracic epidural placement.

With the midline approach, the desired interspace is identified by palpation as described above, and a skin wheal is raised with local anesthetic at the site of intended needle entrance, which should be in the sagittal plane at the midpoint between the spinous processes. The needle is inserted through the skin, subcutaneous tissue, and supraspinous ligament, and into the interspinous ligament. With the blunter tip of the larger-gauge needles used for

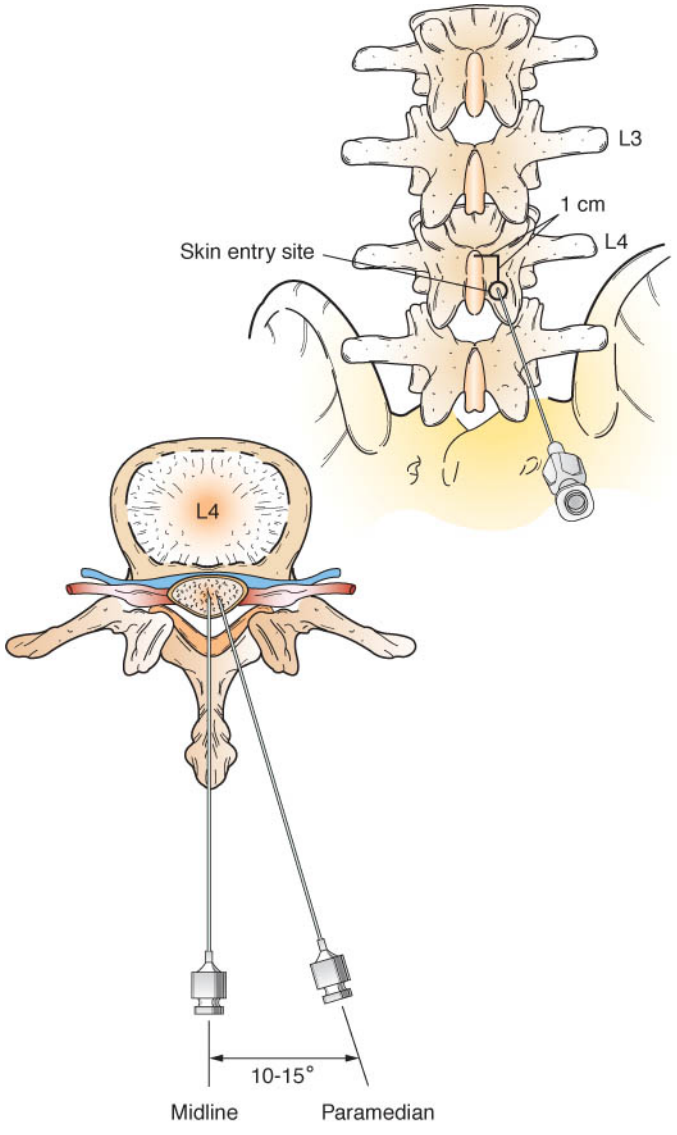

FIGURE 46–10. In the paramedian approach for lumbar neuraxial access, an entrance site is identified 1 cm lateral and caudad to the superior aspect of the inferior spinous process. After appropriate local anesthetic is infiltrated, the needle is typically inserted to touch down on the lamina, then walked, first medially, then cranially, to step off of the lamina.

epidural anesthesia, passage into the interspinous ligament is typically met with a "crunchy" sensation. Patients who are not sedated might either hear or feel this "crunching," and should be reassured if report of this is elicited. If in the sagittal plane, further advancement of the needle should place the tip in the ligamentum flavum, which provides increased resistance to the needle.

Alternatively, if the paramedian approach is used, as may be preferable in the thoracic region, the interspinous ligament is not encountered. If attempting access in the thoracic region, the appropriate needle entrance site is 1 cm lateral to the inferior aspect of the superior spinous process of the interspace desired. The needle is advanced through an anesthetized skin wheal, subcutaneous tissues, paraspinous muscle, and to the lamina of the inferior vertebra, providing a reference depth. The needle tip is walked medially until the base of the spinous process is encountered, which will be noted to have a shallower depth. The needle tip is then marched superiorly until it "walks off" of the lamina, and should encounter resistance as it meets the ligamentum flavum.

With either approach, correct passage of the needle tip through the ligamentum flavum and into the epidural space without breaching the dura can be accomplished by employing several different methods for identifying the epidural space. The most commonly used method is the loss of resistance (LOR) technique using saline or air, although saline may be preferred, given the risk of headache if air is unintentionally injected into the subarachnoid space. A low-resistance syringe made of glass or plastic is filled with 1–2 mL of sterile saline, as well as 1 small (0.2-mL) air bubble (Fig. 46–12). This syringe is attached to the epidural needle once the tip has been placed into the ligamentum flavum. The degree of resistance to injection of the saline is assessed by determining if the bubble compresses without allowing injection of fluid. If little resistance is encountered, the needle tip is either not yet reaching the ligamentum flavum, or perhaps has passed through to the epidural space. If uncertain, careful advancement of the needle by a few millimeters could be considered in an attempt to reach the ligament, but one might wish to withdraw and reattempt placement. Once this ligament is identified, the needle is advanced slowly, with constant pressure on the syringe plunger, until the resistance to injection is reduced. A dramatic loss of resistance is reassuring of the passage of the needle tip just beyond the ligamentum flavum and into the epidural space.

An alternative technique is the "hanging drop" of Gutierrez. This relies on a negative pressure in the epidural space to aspirate a visible drop of fluid from the hub of the needle into the lumen of the epidural space itself (Fig. 46–13). This negative pressure is encountered just as the tip of the needle enters the epidural space and is much more reliable in the thoracic and cervical regions. One theory of the nature of this negative pressure is that it is created by the tip of the needle tenting the dura, thus increasing risk of dural puncture. This technique is best used in the thoracic region with a sitting patient. It may helpful in the setting of combined spinal–epidural anesthesia because of minimal saline entering the epidural space and less chance of a "false return" being interpreted as CSF.[6]

Newer techniques for identifying the epidural space are being described. The use of electrical nerve stimulation via a conducting catheter allows for confirmation of placement of the catheter within the epidural space by confirming appropriate stim-

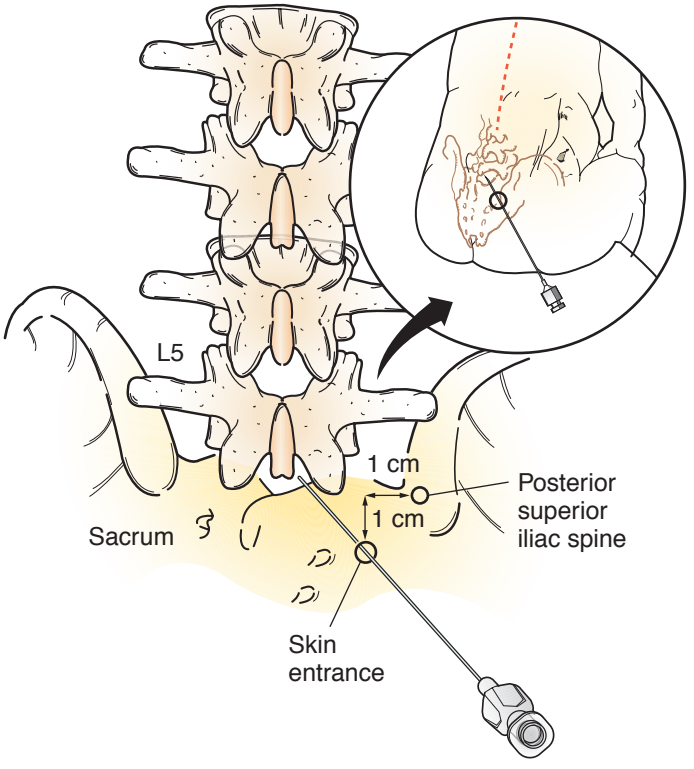

FIGURE 46–11. The Taylor approach begins with identification of the posterior superior iliac spine (PSIS). The skin entrance site is 1 cm medial and 1 cm caudad to the PSIS. The needle is then directed approximately 45° medial and cephalad to enter the L5-S1 interspace.

ulation threshold.[7] Additionally, the myotomal distribution of the stimulation can lend information regarding the spinal level of the catheter tip. Lechner et al.[8] describe an apparatus for use in epidural access that produces both audible and visual indication of the pressure encountered at the tip of an attached epidural needle. Using this device allows a two-handed advancement of the epidural needle while awaiting the drop in pressure that is characteristic of entering the epidural space. Further testing and study is needed to determine the appropriate usefulness of these new methods.

FIGURE 46–12. Photo depicting a glass loss-of-resistance syringe attached to an epidural needle. The syringe is filled with saline and a small (0.2-mL) bubble of air. The bubble provides visual indication of "compression" resultant of resistance to injection that is characteristic of the ligamentum flavum.

CLINICAL PHARMACOLOGY

Distribution, Uptake, and Elimination

Prior to reaching the site of action, anesthetic agents injected into the subarachnoid space undergo dilution within the CSF via mass effect. It has long been postulated that CSF circulation played a role in distribution of anesthetic agents; however, this has not been reliably demonstrated. The uptake of anesthetic agents by the spinal cord and nerve roots depends on the concentration of agent at a given region and lipid content of the tissue. Elimination of local anesthetics from the subarachnoid space and spinal cord is determined by regional blood flow and vascular reabsorption, not metabolism of the anesthetic within the intrathecal space. Drugs administered in the epidural space must diffuse into the CSF and neural tissues to exert conduction blockade. The epidural fat acts as a reservoir for injected agents with great affinity for lipophilic agents. The elimination of drug from the epidural space is largely dependent on regional blood flow.

Factors Affecting Block Height

Spinal Anesthesia

The ability to affect and predict block height is important for producing reliable and manageable spinal anesthesia. Many parameters have been studied as potential determinants of block height (Table 46–1). The most significant physiologic parameter related to block height is CSF volume. Unfortunately, easily measurable physical features, such as height, weight, gender, and age, do not correlate well with CSF volume.[9] However, it has been observed that obese individuals have lower CSF volumes than those who are not obese. Although some studies show a slight influence of age and height on peak block levels,[10,11] these are weak correlations with inadequate predictive power to influence clinical practice.

Baricity, drug dose (mass), and patient position relative to baricity of the agent are the most important factors influencing block height. Baricity is defined as the ratio of the specific gravity of the local anesthetic solution to the specific gravity of CSF.

Solutions with a density greater than 1.0015 g/mL (3 standard deviations above mean patient CSF density) can be expected to behave as a hyperbaric

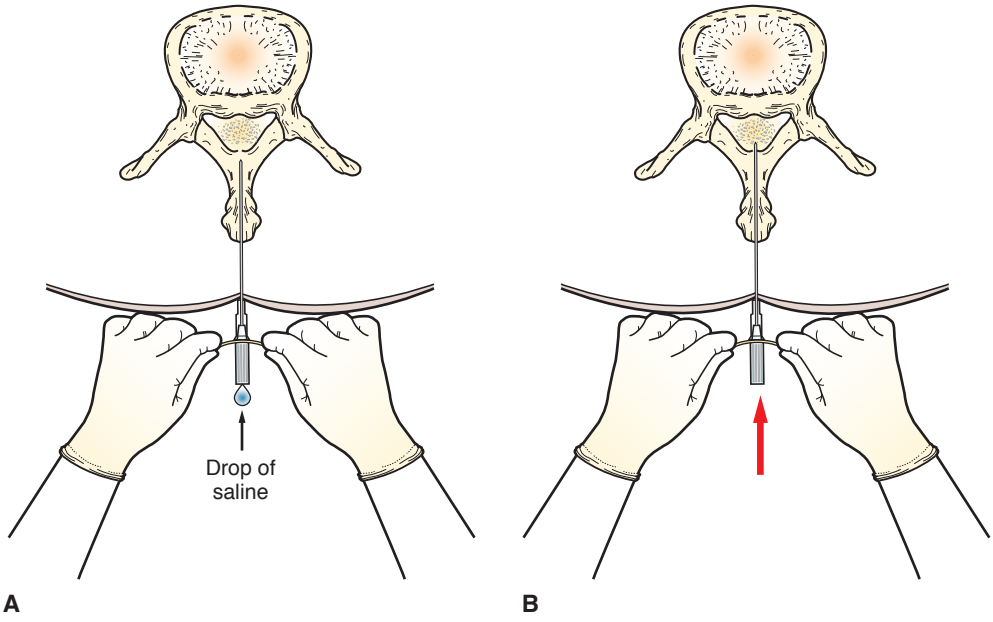

FIGURE 46–13. The "hanging drop" technique is performed by first placing a drop of saline at the "mouth" of the needle hub (**A**). The needle is then advanced while monitoring the drop of fluid. The drop is drawn into the needle when the epidural space is entered (**B**).

solution (Table 46–2). Hyperbaric solutions are typically prepared by the addition of dextrose to the solution. However, it should be noted that plain 2-chloroprocaine behaves in a hyperbaric fashion. Once injected into the subarachnoid space, hyperbaric solutions migrate "downhill" to the dependent portions of the spinal column. Thus, for a patient in the sitting position, the agent sinks to the sacral regions to produce a "saddle block." In the supine patient, hyperbaric agents injected at or above the apex of the lumbar lordotic curvature will migrate to the thoracic kyphosis, hence the tendency for a peak block of T4–6 in most supine patients. Manipulation of patient position after hyperbaric subarachnoid injection can enhance either migration of the agent to the thoracic region (head down position), or to the sacral region (head up or sitting position).

Isobaric solutions have a density that is clinically equivalent to that of CSF. Thus, once injected into the subarachnoid space, the agent neither sinks nor floats. This can be advantageous because patient position does not affect block height. In such a scenario, peak block height is more determined by dose of anesthetic agent (mass effect), but individual CSF density and volume contribute.[16] It should be noted that it may be difficult to achieve block heights above the midthoracic region because of the tendency of isobaric solutions to "stay put" in the lumbar region after injection.

Hypobaric solutions have a distinct advantage in perianal surgery or other procedures that require a head down or jackknife position, or for lateralized procedures when the patient cannot lie on the operative side. These preparations are formed by diluting anesthetic agents in distilled water, achieving a density of less than 0.9990 g/mL. With a patient in the prone position with the head down, an intrathecal

Tetracaine 0.5% in 5% dextrose	1.0133
Lidocaine 5% in 7.5% dextrose	1.0265
Procaine 10% in water	1.0104
2-Chloroprocaine 2% in saline	1.0012

Data from Horlocker TT and Wedel DJ[12]; Bodily MN, Carpenter RL, and Owens BD[13]; Greene NM[14]; and Na KB and Kopacz DJ.[15]

injection is performed, and subsequently the agent "floats" to the sacral region, giving excellent anesthesia to the perineal and perianal region. As mentioned previously, the patient must be recovered in the head-down position for a reasonable amount of time to prevent unintentional rise of the block.

Other Factors The volume and concentration of isobaric spinal agents have not been shown to affect block height when using a constant dose.[17] In contrast, when using hyperbaric preparations, baricity seems to overcome alterations in dose and volume, showing similar block heights with a range of doses if concentration is held constant. This highlights the propensity for hyperbaric preparations to settle to the dependent portions of the spinal canal.

Injection site can influence the nature of spinal blockade. If using hyperbaric preparations, injection low in the lumbar region can cause failure to achieve expected block height and cephalad block density as a result of sacral pooling and absence of agent above the lordotic curve. However, if injection is made at or above L2-3, then block height and success is more reliable. For isobaric solutions, block height can be reduced by as much as 2 dermatomes per interspace when comparing administrations at L2-3, L3-4, and L4-5.[11] The manner of injection is thought to have influence on block characteristics. Investigations into the effect of barbotage show no impact on peak block height, although it does seem to reduce the time from injection to achievement of peak block height.[18]

Epidural Anesthesia

In contrast to spinal anesthesia, epidural anesthesia produces a segmental block that is related to the site of injection of local anesthetic. Most procedures that are amenable to spinal anesthesia could also be served by epidural anesthesia that produces a similar block height (Table 46–3). Unless a caudal approach is performed, the potential for sacral nerve sparing with epidural blockade (because of increased epidural fat and nerve root size in the low lumbar and sacral regions) may preclude its use in perineal procedures. When planning an epidural anesthetic, the choice of local anesthetic, dose, and injection site must be appropriate for the given procedure and the clinical scenario.

Injection of local anesthetic into the lumbar epidural space is typically suited for lower-extremity and lower-abdominal procedures, but increasing the dose and volume is necessary to get extension to midthoracic levels. In general, one can think of administering 2 mL of local anesthetic solution for each additional dermatome to be blocked. When administering anesthetic to the thoracic region, the dose is typically reduced by 30–50%, compared to the lumbar region, to accommodate the decreased volume and compliance of the thoracic epidural space and to avoid unwanted cephalad spread. Thoracic epidural injections tend to not extend caudally to the degree that is seen with lumbar injections, thus are reserved for procedures in the thorax and upper abdomen.

When considering the ranges that are typically used for surgical anesthesia, concentration of the anesthetic solution has little effect on extent of the epidural block, but increased block density is observed with higher concentrations. Increasing the volume of solution injected for a given total dose will have a minor effect on cephalad spread (about 4 dermatomes when increasing from 10–30 mL), but will compromise density and quality of the block. Patient position also has no demonstrable effect on lateralization of the block or cephalad spread, but is often used clinically.

The effect of patient age on epidural block height and dose requirement seems to be only clinically relevant in extremes of age, but some studies suggest as much as a 40% reduction in dose requirement when comparing 60–79-year-old patients with 20–39-year-old patients.[19] This is attributed to the increased likelihood of spinal canal stenosis and decreased epidural compliance in the older population. In similar scale, the influence of height and weight on the spread of epidural block is small,[20] and usually not clinically relevant unless considering the extremes of the spectrum.

The effect of pregnancy on the spread of epidural blockade is unclear. Some studies suggest that an observed increased cephalad spread of blockade is a result of an effect of altered abdominal anatomy. However, similar increases seen in early pregnancy suggest that this may be an effect of altered sex steroid levels increasing the sensitivity to anesthetic agents.[21]

TABLE 46–3.

Required Block Height for Common Surgical Procedures

Surgical Procedure	Block Height
Upper abdominal surgery	T4–5
Cesarean section	
Lower abdominal (appendectomy, inguinal herniorrhaphy)	T6–8
Pelvic procedures	
Transurethral resection of prostate	T10
Obstetric vaginal delivery	
Hip and lower extremity (with thigh tourniquet)	
Lower extremity	L2–3
Perineal procedures (limited to exterior)	S1–2

In summary, physical characteristics seem to have little if any clinical effect on epidural block spread for a narrow range of variability. However, clinical judgment may allow for reducing the initial epidural dose for a patient who is very short, very old, and morbidly obese. Conversely, more aggressive dosing can be used for the patient who is very young, tall, and thin. Comorbidities and other challenges may determine the appropriate dose regimen: a failed technique as a result of inadequate block vs. treating the complications resulting from a block that is higher than intended.

CLINICAL ASPECTS OF NEURAXIAL AGENTS

Local Anesthetics

Local anesthetic agents are discussed in Chap. 44 in detail, but some clinical points relating to neuraxial anesthesia are addressed here. The choice of neuraxial agents is determined by the nature and estimated time of the surgical procedure, as well as postoperative issues such as disposition. Tables 46–4 and 46–5 list representative durations for doses of spinal and epidural agents. For spinal anesthesia, increasing the dose of agent administered prolongs the block, and unless counteracted by positioning and baricity, it may also increase peak block height. Longer-acting local anesthetics, such as bupivacaine, levobupivacaine, tetracaine, and

TABLE 46–4.

Typical Dose-Response Effects of Spinal Local Anesthetics

Local Anesthetic	Dose (mg)	Peak Block	Duration of Sensory Block (min)	Duration of Motor Block (min)	Time Until Discharge (min)	Anesthetic Success Rate (%)
Lidocaine	30					0
	40	T4 (T2–10)	130 (26)	93 (24)	173 (34)	90
	60	T3 (T2–10)	162 (32)	128 (31)	216 (33)	90
	80	T3 (T1–7)	170 (24)	142 (32)	236 (46)	97
Bupivacaine[a]	5	T5 (T4–7)	123 (27)	50 (20)	181 (30)	75
	7.5	T8 (T4–11)	144 (25)	75 (24)	202 (28)	100
	10	T8 (T6–10)	194 (26)	100 (24)	260 (30)	100
	15	T5 (T4–7)	343 (28)	150 (24)	471 (35)	100
Mepivacaine	30	T9 (T2–L5)	158 (32)	116 (38)	180 (34)	72
	45	T6 (T2–12)	182 (38)	142 (37)	191 (29)	100
	60	T5 (T2–L1)	203 (36)	168 (36)	233 (52)	100
Ropivacaine	8	T9 (T4–L1)	130 (27)	107 (25)	165 (45)	63
	10	T8 (T4–L2)	152 (44)	135 (31)	174 (38)	83
	12	T8 (T4–L1)	176 (42)	162 (37)	199 (52)	93
	14	T9 (T3–L1)	192 (48)	189 (44)	233 (52)	100
Procaine	100	T5 (T1–10)	120 (23)	100 (30)	244 (43)	83
Prilocaine	50	T6 (T1–10)	128 (38)	165 (37)	253 (55)	100
2-Chloroprocaine[b]	30	T8 (T6–L1)	103 (12)	54 (23)	103 (12)	NA
	40	T7 (T3–T10)	114 (14)	69 (16)	113 (14)	NA
	60	T4 (C6–T6)	132 (23)	100 (13)	141 (21)	NA

NA, Clinical data not available. Increasing doses of spinal local anesthetics increase duration of both anesthesia and recovery. Dose-response data allow selection of appropriate dose for planned anesthetic duration. Isobaric solutions are glucose free. Hyperbaric solutions contain glucose or dextrose
[a]Levobupivacaine is equipotent.
[b]2-chloroprocaine spinal anesthesia is currently an off-label use.
Data from Liu SS and McDonald SB,[22] except data for 2-chloroprocaine is from Kopacz DJ.[38]

ropivacaine are typically chosen for longer procedures (greater than 120 minutes). Lidocaine, mepivacaine, and prilocaine are considered to be of intermediate duration. Short-acting local anesthetics include procaine and 2-chloroprocaine, which are used for appropriately brief procedures.

Long-Duration Agents

Bupivacaine and levobupivacaine have the benefit of having very low incidence of transient neurologic symptoms (TNS) when used for low-dose spinal anesthesia.[23] However, the variability in time to complete resolution of the block and achievement of discharge criteria provides a challenge in the ambulatory setting. Bupivacaine and levobupivacaine are employed in epidural anesthesia when a longer block is desired. The use of 0.5% solutions is typical, but the using 0.75% solutions or adding epinephrine may provide increased motor block. Levobupivacaine is approximately equipotent to bupivacaine with the exception of less systemic toxicity.

Ropivacaine was introduced to reduce the risk of cardiotoxicity that is associated with bupivacaine and was released for clinical use in 1996. When used as a spinal agent, ropivacaine has a clinical profile similar to bupivacaine at equipotent doses (ropivacaine is 60% as potent as bupivacaine) with little risk of TNS.[24] Ropivacaine is used in concentrations of 0.5–1% for epidural anesthesia, providing blockade of somewhat shorter duration than bupivacaine. There is some evidence that ropivacaine may have less motor block when compared to bupivacaine when used for labor analgesia.[25]

Although tetracaine is used less commonly at this time, it remains the agent that provides the most reliable hypobaric spinal block (tetracaine 2% in water). It should be noted that the use of vasoconstrictors might increase the risk of TNS with tetracaine.[26]

TABLE 46–5.

Duration of Sensory Block for Commonly Used Local Anesthetics for Epidural Anesthesia

Local Anesthetic	Concentration	Time Until 2 Dermatome Regression (min)	Time Until Complete Regression
2-Chloroprocaine	2–3%	45–60	100–160
Lidocaine	1.5–2%	60–100	160–200
Mepivacaine	1.5–2 %	60–100	160–200
Bupivacaine	0.5–0.7%	120–240	300–460
Levobupivacaine	0.5–0.75%	105–290	390–780
Ropivacaine	0.5–1%	90–180	240–420

Intermediate-Duration Agents

Lidocaine has enjoyed widespread popularity and safety as a neuraxial agent, but it has undergone increasing scruti-

ny regarding neurotoxicity given the high incidence of TNS seen when used for ambulatory spinal anesthesia (see Neurologic Complications below). To avoid this issue, lower doses of lidocaine have been investigated, usually requiring adjuvant agents to provide suitable reliability of spinal blockade. Lidocaine is used in concentrations of 1.5% and 2% for epidural anesthesia to provide reliable blockade for procedures lasting less than 120 minutes. However, continuous catheter techniques commonly employ lidocaine, with reinjection typically required every 60–90 minutes.

Mepivacaine has a clinical profile similar to that of lidocaine when used as a neuraxial agent, although it has higher potency (1.3:1 compared with spinal lidocaine).[27] It also seems to have similar concerns regarding the high incidence of TNS when used for outpatient spinal anesthesia, depending on concentration of agent.[28] It is used in concentrations of 1–2% for epidural anesthesia, again with similar performance to lidocaine.

Prilocaine is an amide local anesthetic with pharmacologic properties similar to those of lidocaine when used as a spinal anesthetic.[29] However, it shows a much lower incidence of TNS compared to spinal lidocaine, and thus may be a favorable agent for ambulatory spinal anesthesia. Currently, prilocaine is not available in the United States, but it is used commonly in Europe.

Short-Duration Agents

Having a place in history as the first synthesized local anesthetic, procaine has been used for spinal anesthesia since the early 1900s. Procaine provides brief spinal anesthesia, but has limited clinical usefulness given the rate of block failure (see Table 46–4) and the incidence of side effects. For reasons that are poorly understood, spinal procaine carries a higher risk of nausea than do other local anesthetics (odds ratio [OR] 3:1).[30] Although it has a lower incidence of TNS than spinal lidocaine (Table 46–6), spinal procaine is clearly not enticing when seeking a suitable agent for outpatient spinal anesthesia.

2-Chloroprocaine has received increased attention in regards to the current issues of ambulatory anesthesia and concerns of relative neurotoxicities of neuraxial agents. One year after its introduction into clinical use, in 1952, Foldes and McNall described successful use of a preservative-free preparation of 2-chloroprocaine for spinal anesthesia in 214 patients. Subsequently, 2-chloroprocaine enjoyed increasing popularity as an agent for epidural anesthesia, particularly in the obstetric population. Unfortunately, reports of accidental intrathecal injection of large volumes of Nesacaine-CE intended for the epidural space, resulting in several cases of neurotoxicity with lower-extremity paralysis and sacral nerve dysfunction, came to attention in the 1980s. The combination of the antioxidant sodium bisulfite in the presence of low pH was assumed to be responsible for the neurotoxicity,[31,32] and the formulation of 2-chloroprocaine was changed. Currently, two of the three commercially available formulations of 2-chloroprocaine (Nesacaine-MPF, Astra Pharmaceuticals, Wilmington, DE, and generic chloroprocaine, Bedford Pharmaceuticals, Bedford, OH) are preservative free and antioxidant free. Given the availability of these new preparations and growing concerns about the TNS associated with lidocaine, 2-chloroprocaine has been reinvestigated for off-label use as a short-acting spinal anesthetic. Work by Kopacz et al. shows 2-chloroprocaine to provide a reliable spinal anesthesia with consistent time to resolution and achievement of discharge criteria without identifiable occurrence of TNS.[33–38]

It should be noted that 2% 2-chloroprocaine behaves in a hyperbaric fashion,[36] and that the addition of epinephrine to spinal 2-chloroprocaine is not recommended because of consistent and disturbing reports of flu-like symptoms in volunteers receiving this combination.[33] One should also bear in mind that a recent laboratory study observed direct neurotoxicity from high doses of preservative-free 2-chloroprocaine in a rat model that was equivalent to 2% lidocaine.[39] Thus, the complete risk-to-benefit ratio of off-label use of spinal 2-chloroprocaine is not completely known.

The use of 2% and 3% 2-chloroprocaine is an appropriate choice for epidural anesthesia of short duration. Following the release of Nesacaine-MPF containing ethylenediaminetetraacetic acid (EDTA), reports of back pain upon block resolution were associated with high volumes of injected agent (greater than 40 mL).[40] This is thought to be caused by tetanic spasm of the paraspinous muscles resulting from chelation of calcium by the EDTA. Given the above concerns, it may be prudent to use only 2-chloroprocaine preparations that are preservative and antioxidant free for neuraxial blockade.

TABLE 46–6.

Typical Incidences of Transient Neurologic Symptoms (TNS) with Outpatient Spinal Anesthesia

Local Anesthetic	Patient Position	TNS (%)
Lidocaine 2–5%	Supine	6
Lidocaine 3%	Prone	0.4
Lidocaine 0.5%	Knee arthroscopy	17
Lidocaine 5%	Knee arthroscopy	16
Lidocaine 5%	Lithotomy	24
Bupivacaine (0.25–0.75%)	Supine	0–1
	Knee arthroscopy	0–1
	Lithotomy	0–1
Mepivacaine 1.5%	Knee arthroscopy/mixed	6–8
Mepivacaine 4%	Mixed	30
Ropivacaine 0.25%	Supine	1
Ropivacaine 0.2–0.35%	Knee arthroscopy	0
Procaine 5%	Knee arthroscopy	6
Prilocaine (2–5%)	Mixed	3–4

Bupivacaine and ropivacaine consistently result in low incidences of TNS, whereas lidocaine typically results in the highest incidences. Other local anesthetics are intermediate in incidence of TNS.
Data from Liu SS and McDonald SB,[22] and YaDean JT, Liguori GA, and Zayas VM.[28]

Analgesic Adjuncts

Initial interest in adjuvant medications for neuraxial anesthesia centered around increasing the duration and in-

TABLE 46–7.

Analgesic Adjuvants for Neuraxial Anesthesia

Agent	Dose	Typical Anesthetic Effect	Comments
Clinically Useful			
Fentanyl	Spinal: 10–25 μg	25% increase in duration of surgical anesthesia 33% increase in anesthetic success with small doses of local anesthetic 60% incidence of easily treated pruritus	No delay of anesthetic recovery
	Epidural: 1–2 μg/kg	2-fold reduction in volatile anesthetic requirements Decreased visceral pain with cesarean section	Bolus administration may act at spinal level, infusions act systemically
Clonidine	Spinal: 15–45 μg	29% increase in duration of motor block 37% increase in anesthetic success with small doses of local anesthetic Mild perioperative sedation and decrease in heart rate and blood pressure	No delay of anesthetic recovery
	Epidural: 150 μg	2–3-fold increase in duration of sensory anesthesia Increased time to first analgesic request	Less oxygen desaturation, pruritus, and urinary retention compared to opioids
Epinephrine	Spinal: 0.1–0.6 mg	Dose-related increase in surgical anesthesia and motor block	Dose-related increase in time until recovery of the same or greater magnitude
	Epidural: 5 μg/mL	Increased duration, intensity of block with lidocaine and 2-chloroprocaine Minimal effect with ropivacaine	Decreased plasma levels with lidocaine and bupivacaine, but not ropivacaine
Investigated			
Neostigmine	Spinal: 6.25–50μg	Dose-related increase in surgical anesthesia and motor block	Dose-related increase in time until recovery of the same or greater magnitude
	Epidural: 1–4 μg/kg	Dose dependent analgesic effect Increased time to first analgesic request	Reports of sedation with higher doses

Utility and safety of other agents (ketamine, ketorolac, midazolam) not fully determined.
Date from references 41, 43–46, 48, 56–57, 60, 62, 65–72, 86, 89, and 94.

tensity of blockade. As the percentage of operations performed in the ambulatory setting increases, interest is shifting to finding adjuncts that will provide faster recovery without compromising anesthetic reliability (Table 46–7).

Opioids

The potent analgesic effects of neuraxial opioids have been exploited to improve perioperative analgesia and reduce the supraspinal side effects of sedation and respiratory depression seen with systemic opioids. Neuraxial opioids that diffuse into the spinal cord exert spinal analgesia by modulating A-δ and C-fibers to decrease afferent nociceptive input,[41] inhibiting Ca^{2+} influx presynaptically, and increasing K^+ conductance and hyperpolarize ascending neurons postsynaptically.[42]

Owing to its hydrophilic nature, neuraxial morphine provides highly selective, prolonged spinal analgesia, but is not typically used to augment intraoperative anesthesia because of slow onset. The lipophilic opioids, such as fentanyl, are more suited for intraoperative use in the intrathecal space because of rapid onset, modest duration, and lower risk of delayed respiratory depression. The addition of 10–25 μg fentanyl to low-dose lidocaine and bupivacaine spinal anesthetics dramatically improves anesthetic success without delaying achievement of discharge criteria for ambulatory patients.[43,44] However, when used with the ultrashort-acting spinal anesthetic 2-chloroprocaine, fentanyl can slightly delay discharge (95 vs. 104 minutes) and increase pruritus.[35]

The administration of epidural fentanyl can reduce volatile requirements more than intravenous fentanyl (more than 2-fold at 2 μg/kg).[45] The method of delivery of epidural fentanyl may be important for optimal effect. Ginosaur et al.[46] showed that when epidural fentanyl is given as a bolus, it imparts segmental analgesia consistent with spinal level of action, but if given as an infusion, the analgesia is mediated through systemic uptake and supraspinal effect, as is seen with sufentanil and alfentanil.[47]

α_2-Agonists

Interest in α_2-agonists, such as clonidine, has been rising in the field of regional anesthesia given their ability to enhance neuraxial analgesia without the respiratory depression and pruritus common to opioids. As with analgesia, the sedation, hypotension, and bradycardia seen with neuraxial clonidine are dose dependent.[48] Additionally, less urinary retention is seen with intrathecal clonidine than with intrathecal morphine.[49] Clonidine exerts its analgesic effects by binding to α_2-adrenoreceptors (on primary afferent, substantia

gelatinosa, and several brainstem nuclei attributed to analgesic mechanisms), attenuating A-δ and C-fiber nociception, producing conduction blockade via increased potassium conductance,[50,51] as well as increasing acetylcholine and norepinephrine in the CSF, inhibiting the release of substance P.[51] Although clonidine rapidly redistributes systemically to the periphery after epidural or spinal administration as a consequence of lipophilicity, the analgesic effect is spinally mediated as evidenced by the lack of correlation between time of analgesia and peripheral blood levels. Through extensive testing for neurotoxicity and safety in several animal models, neuraxial clonidine shows no histopathologic or behavioral evidence of detriment.

Although previously investigated as a sole anesthetic,[52] the majority of the clinical use of intrathecal clonidine is in combination with a variety of local anesthetics to produce dose-dependent prolongation of both sensory and motor block.[53–56] Showing a promising role in ambulatory anesthesia, De Kock et al.[57] demonstrated that the addition of as little as 15 μg of clonidine to ropivacaine 8 mg for spinal anesthesia in outpatients undergoing knee arthroscopy produced a considerable increase in anesthetic success (from 70–90%) without significant effect on recovery time. However, increasing the dose to 45 μg increased resolution of motor and sensory block and time to void from 170 to 215 minutes. Adding clonidine to local anesthetics intensifies and prolongs epidural blockade and can reduce local anesthetic dose requirement.[58,59] The typical dose of clonidine for addition to local anesthetics for epidural bolus administration is 150 μg, or 2 μg/kg.[60–62] Klimscha et al. demonstrated that the addition of 150 μg of clonidine to 10 mL of 0.5% bupivacaine for epidural anesthesia increased the mean duration of anesthesia from 1.8 to 5.3 hours, reduced pain scores, and increased time to first postoperative analgesic request.[61] These benefits of clinical doses of neuraxial clonidine typically persist for around 3 hours and can be achieved without increasing hemodynamic instability more than local anesthetic alone or significantly altering responsiveness to resuscitation drugs.[62–65]

Vasoconstrictors

Vasoconstricting agents, namely epinephrine and phenylephrine, are commonly added to local anesthetic solutions and have a long history of clinical use with the intention to prolong the anesthetic effect, provide more reliable block, and intensify anesthesia and analgesia.[66–69] Vasoconstriction, and thus decreased blood flow, can reduce uptake of local anesthetics into the circulation, thus maintaining concentrations at the site of injection and reducing peak plasma concentrations. Additionally, intrinsic analgesic effects of epinephrine are exerted via stimulation of presynaptic α_2 adrenoreceptors found at the terminals of primary afferents. These receptors are also found centrally on neurons in the superficial laminae of the spinal cord and several brainstem nuclei that participate in analgesic mechanisms.

For spinal anesthesia, epinephrine is commonly employed in a typical dose of 0.2 mg (although doses of 0.1–0.6 mg have been described), which when added to a bupivacaine spinal anesthetic, increases time of regression to L2 by 25%.[70,71] The addition of epinephrine to spinal anesthetics prolongs motor block and delays the return of bladder function, which is problematic for ambulatory surgery patients trying to achieve discharge criteria. Chiu et al.,[72] using volunteers, showed that adding 0.2 mg epinephrine to 50 mg hyperbaric lidocaine prolonged surgical anesthesia (as demonstrated by tolerance of transcutaneous electrical stimulation) by 30 minutes, whereas time to void and discharge time were increased by 80 minutes.

As for concerns of safety, intrathecal epinephrine by itself, in clinically relevant doses, shows no neurotoxicity in humans. Spinal cord blood flow is well maintained in the dog and cat model in doses up to 0.5 mg.[73] However, it is suggested that epinephrine may contribute to the neurotoxicity of local anesthetics. Additionally, epinephrine is associated with a case report of cauda equina syndrome after single-shot lidocaine spinal anesthesia.[74] Smith and Kopacz reported consistent flu-like symptoms when epinephrine was added to spinal 2-chloroprocaine in a volunteer study.[33] Phenylephrine may increase the risk of TNS as suggested by Sakura et al. in a study of tetracaine spinal anesthesia.[26]

With epidural anesthesia, the typical use of epinephrine is in concentrations of 1:200,000, or 5 μg/mL. The clinical effect of epinephrine on duration of anesthesia depends on the local anesthetic used. Epinephrine is more effective at prolonging the anesthetic duration of shorter-acting agents, such as lidocaine and 2-chloroprocaine. Adding 1:200,000 epinephrine to 2% lidocaine will nearly double the time to resolution of blockade.[75] Agents with longer duration of action show much less prolongation of anesthesia with the addition of epinephrine. Adding epinephrine to ropivacaine will intensify the block, but will not prolong the duration of epidural anesthesia or affect plasma levels.[67] This is likely a result of the inherent vasoconstricting effects of ropivacaine. Other agents do show reduction of plasma levels when epinephrine is added.[66,68] Epinephrine 1:200,000 will decrease plasma lidocaine and chloroprocaine levels by 20–30%, but will decrease plasma bupivacaine levels only by 10–20%. The effect of epinephrine on plasma levels of local anesthetics has long been thought to be caused by constriction of the epidural venous plexus, reducing blood flow and slower uptake of local anesthetics. More recent evidence implies that reduced dural blood flow and increased hepatic clearance may be more important in this phenomenon.[76] Its potential to prolong discharge times and delay bladder function limits the usefulness of adding epinephrine to epidural agents for ambulatory surgery. The premixed solutions of local anesthetics with epinephrine that are commercially available are prepared more acidic in efforts to preserve the potency of the epinephrine. Because this lower pH slows the onset of block and inhibits the vasoconstricting actions of epinephrine, adding "fresh" epinephrine to local anesthetic solutions at the time of use is preferred. When phenylephrine is added to epidural solutions, the systemic absorption results in increased vascular resistance without the benefit of increased contractility or chronotropy seen with epinephrine. Minding this, phenylephrine is typically only used in the subarachnoid space.

Neostigmine

The acetylcholinesterase inhibitor neostigmine has been investigated as a neuraxial analgesic adjunct because of its ability to provide analgesia without hemodynamic depression. Unfortunately, its tendency to induce nausea and delay recovery from neuraxial

blockade limits clinical use. Intrathecal neostigmine inhibits the breakdown of acetylcholine in the spinal cord via reversible inhibition of acetylcholinesterase. Animal models suggest that acetylcholine plays a role in spinal analgesia through stimulation of cholinergic receptors in the substantia gelatinosa and superficial laminae of the dorsal horn of the spinal cord,[77–79] and perhaps through stimulating nitric oxide production in the spinal cord.[80] Whereas intrathecal injection of cholinergic agonists stimulates all receptors of a particular class, neostigmine increases endogenous acetylcholine in a manner dependent on the tonic production of this neurotransmitter within each particular region of the spinal cord. Hood et al.[81] evaluated safety, analgesic efficacy, and side effects of intrathecal neostigmine in volunteers. All doses produced analgesia without sedation, pruritus, respiratory depression, hypotension, or bradycardia; however, there was dose-related motor weakness, decreases in deep tendon reflexes, urinary incontinence, and nausea and vomiting. Further studies in patients revealed similar responses of nausea and vomiting that proved to be prolonged and difficult to treat.[82–86] Liu et al.[86] showed that when added to low-dose (7.5 mg) bupivacaine spinal anesthetics, 50 μg of neostigmine enhanced motor and sensory block, but delayed achievement of discharge criteria. Doses of 6.25 and 12.5 μg did not prolong anesthesia but still elicited nausea and delayed discharge. Intrathecal neostigmine does counteract hypotension resulting from bupivacaine spinal anesthesia in rats,[87] but these effects are not reproducible in human subjects.[88] Low and moderate doses of neostigmine are considered to have little or no cardiovascular effects.

Lauretti et al.[89] studied the analgesic effect of epidural neostigmine, in doses from 1 to 4 μg/kg added to epidural lidocaine, and showed a dose-independent analgesic effect, increasing time to first analgesic request from 3.5 to 8 hours. Other studies report similar results with doses in the range of 1–10 μg/kg, without reporting increased nausea,[90–95] but reporting some suggestion of sedation.[94]

Ketamine

Ketamine is a noncompetitive antagonist of *N*-methyl-D-aspartate (NMDA) receptors, but also has actions at monoaminergic receptors, opioid receptors, voltage-sensitive calcium channels, muscarinic receptors, and local anesthetic actions through sodium channel blockade.[96] Commercially available as a racemic mixture, the S enantiomer is far more potent at NMDA receptors.[97] Though not approved for neuraxial use, animal models suggest that preservative-free ketamine lacks neurotoxicity.[98] Ketamine was first used intrathecally as a sole anesthetic by Bion in 1984.[99] Hawksworth et al. reported an intolerable rate of anesthetic failure and psychometric side effects at doses of 0.7–0.95 mg/kg.[100] Other investigators found similar problems when combining ketamine with bupivacaine for spinal anesthesia.[101] Epidural administration of ketamine at 0.5–1 mg/kg does reduce intraoperative[102–104] and postoperative[102–105] analgesic requirements without increased side effects. Ozyalcin et al. demonstrated decreased pinprick hyperalgesia and touch allodynia in thoracotomy patients receiving epidural versus intramuscular ketamine.[104] Further work continues to delineate potential applications for chronic neuropathic pain, preemptive analgesia, and modulation of opioid tolerance.

Ketorolac

Ketorolac tromethamine is a nonselective, but cyclooxygenase (COX)-1 preferring, nonsteroidal antiinflammatory drug that has received interest given demonstrated involvement of spinal COX enzymes in postoperative hypersensitivity and pain.[106,107] There is evidence that ketorolac may enhance analgesic effects of intrathecal clonidine[108] and have analgesic synergy with intrathecal morphine[109] in rat models. A phase I safety study of preservative-free ketorolac in healthy volunteers using single bolus doses of 0.5–2 mg showed no immediate or delayed neurologic detriment.[110] This study revealed no significant effect on blood pressure or motor function, but also showed no decrease in pain with heat stimuli. Further human investigations are underway with the hope of identifying the clinical role of intrathecal ketorolac.

Alkalinization and Carbonation

Alkalinizing local anesthetic solutions to raise the pH closer to the pK_a of the local anesthetic, thereby increasing the proportion of the nonionized form available to cross cell membranes, is thought to speed the onset of epidural anesthesia. Although this is well demonstrated with peripheral nerves in vitro,[111] studies attempting to demonstrate this clinically in epidural anesthetics are sometimes conflicting.

Most studies show that alkalinization speeds onset of epidural blockade with lidocaine,[112–117] bupivacaine,[112,118,119] mepivacaine[112,120,121] and chloroprocaine[122,123] by up to 10 minutes. Ropivacaine seems to not show faster onset with alkalinization,[124] but as with the other drugs, there is evidence that alkalinization can intensify epidural anesthesia and improve spread to sacral dermatomes.[113,116,117,125] One trend that is noted is that the effects of alkalinization are greatest on solutions containing epinephrine, whether freshly added or prepackaged. This is perhaps a result of pH-dependent vasoconstrictive actions of epinephrine. Alternatively, this may be attributed to the fact that commercially available epinephrine-containing solutions are prepared at lower pH (usually with bisulfite), ranging from 3.2 to 4.2, in efforts to preserve the epinephrine.

Typically recommended volumes of 8.4% sodium bicarbonate to be added to local anesthetic solutions are 1 mL per each 10 mL of lidocaine or mepivacaine, 0.1 mL per 10 mL of bupivacaine, and 0.3 mL per 10 mL of 2-chloroprocaine. Because of the tendency to precipitate, it is not recommended to add sodium bicarbonate to ropivacaine solutions. It should be noted that the degree of alkalinization is limited by precipitation and all preparations should be inspected for precipitation before administration. Alternatively, the carbonate salts of local anesthetics have a more rapid onset of epidural blockade than standard hydrochloride preparations.[126] However, carbonated drugs are of limited availability and may be more prone to induce hypotension with epidural administration.[127]

PHYSIOLOGY OF NEURAXIAL ANESTHESIA

Neurophysiology

Neural blockade by local anesthetics is discussed in Chap. 44, thus this section highlights some of the clinical aspects specific to neuraxial blockade. After intrathecal injection of local anesthetics, drug is found in the spinal cord as

well as in the spinal nerve rootlets within the CSF. After epidural injection, local anesthetic is found in spinal nerves in the epidural space, spinal nerve rootlets within the CSF, and within the spinal cord. Consequently, conduction blockade may take place at multiple sites along the neural pathway for both spinal and epidural anesthesia, and the exact mechanisms are unknown.[128] Previous studies do provide some insight into primary sites of action. After spinal anesthesia, somatosensory evoked potentials from the tibial nerve (peripheral nervous system) are abolished, whereas direct spinal cord stimulation remains unchanged.[129,130] These findings lend support to the theory that the spinal nerve rootlets are the primary site of action of spinal anesthesia and not the spinal cord. Animal studies suggest that the mechanism of action of epidural anesthesia is similar to spinal anesthesia. Measurement of evoked potentials in monkeys again indicates that the primary site of action of epidural anesthesia is the spinal nerve rootlets.[131] Interestingly, epidural anesthesia does not produce complete conduction block, as measurement of somatosensory evoked potentials from the tibial nerve are only modestly changed following induction of epidural anesthesia. Furthermore, magnitude of change in somatosensory evoked potentials does not correlate with intensity of epidural block.[132] This finding is similar to peripheral nerve block, and investigators suggest that anesthesia occurs from loss of information coding inherent in the oscillations of the action potential instead of from complete loss of conduction. Finally, the ability of spinal but not epidural anesthesia to completely suppress somatosensory evoked potentials from the tibial nerve offers objective support for the clinical impression that spinal anesthesia is more intense and complete than epidural anesthesia.

In addition to direct conduction blockade within the CNS, spinal and epidural anesthesia produce sedation that is unrelated to systemic levels of agent, but which correlates with block height.[133] Animal studies using electroencephalogram (EEG) monitoring and direct brain stimulation during spinal anesthesia suggest this is the result of a decrease in reticular activating system activity from decreased tonic afferent input from the anesthetized region.[134] One may note decreased requirements for supplemental sedation during high spinal blockade from this direct sedative effect. Previous clinical studies examining use of propofol and midazolam suggest that spinal anesthesia per se decreases sedative requirements by approximately 30–50% with clinically relevant spinal block heights.[135,136] This direct sedative effect of epidural anesthesia also becomes clinically relevant when a combined epidural-general anesthesia technique is performed. The use of epidural anesthesia or analgesia reduces volatile anesthetic requirements by 20–30% during surgery when general anesthesia is titrated to either hemodynamics or bispectral index monitoring.[137,138]

Respiratory Physiology

With spinal or epidural blockade to midthoracic levels, pulmonary function, gas exchange, and control of breathing are generally preserved in patients without preexisting respiratory disease.[139] Many patients will report a subjective sensation of dyspnea as a consequence of reduced sensation of expansion of the chest wall with inspiration. However, resting tidal volumes, respiratory rate, minute ventilation, and lung volumes are maintained in healthy patients.[140,141] Preservation of gross pulmonary function—even with relatively high thoracic level blocks—is explained by the fact that the diaphragm is the primary muscle of ventilation and is innervated by the cervical plexus (C3-5). In contrast, accessory respiratory muscles (abdominal, intercostal) do play a role in active expiratory function and small block-height-dependent decreases in peak expiratory flow can be observed (11% reduction at T8 vs. 17% reduction at T4).[142] Active expiratory function plays a role in ability to cough, thus spinal anesthesia may impair ability to clear secretions.[139] Overall, healthy patients easily tolerate these mild changes, but patients with severe pulmonary disease may not. However, previous studies indicate that patients with chronic lung disease do not suffer from significant reductions in vital capacity or forced expiratory volume at 1 second (FEV_1) during spinal anesthesia.[139]

Control of breathing during spinal anesthesia is not altered significantly although earlier studies demonstrated a small decrease in resting end-tidal PCO_2.[143] While hyperventilation as a consequence of anxiety may cause lowering of the PCO_2, the hypocapnia is speculated to result from a lack of proprioceptive input from the abdomen and chest wall during spinal anesthesia, resulting in an increased drive to breathe.[143] It has been reported that spinal anesthesia with bupivacaine in unpremedicated patients increased ventilatory responsiveness to CO_2.[144] The rare respiratory arrest after spinal anesthesia is thought to result from brainstem hypoperfusion secondary to decreased cardiac output rather than the direct effects of local anesthetics on the brainstem, as the concentration of local anesthetic in the ventricular fluid is not high enough to result in medullary depression.

Preoperative discussions usually impart tolerance of the subjective dyspnea, but at times judicious sedation can be used to quell anxieties. It should be noted that sedative medications used to facilitate neuraxial blockade are more likely to impact the patient's respiratory status than the blockade itself.[140] This is likely a result of both reduction in respiratory drive and initiation of paradoxical respiration from upper airway obstruction.

Cardiovascular Physiology

The perturbations of cardiovascular function during neuraxial anesthesia are perhaps the most critical factors to consider in evaluating the risk to patients and in preventing adverse outcomes. In the nonobstetrical population, the incidences of hypotension and bradycardia after spinal anesthesia are approximately 33% and 13%, respectively.[22,127] Large epidemiology studies from France, Scandinavia, and the United States indicate that the risk of cardiac arrest after spinal anesthesia is approximately 0.1–1:1,000 and 1:10,000 after epidural anesthesia.[145] Although cardiac arrest after spinal anesthesia appears to be distressingly common, a recent study suggests that survival is better for cardiac arrest during neuraxial block than during general anesthesia (65% vs. 31%).[146] This may be a result of enhanced vigilance, as several risk factors for bradycardia and hypotension have been identified for spinal anesthesia (Table 46–8). Risk factors for epidural anesthesia are probably similar but have not been fully identified because of the decreased frequency of occurrences. An appreciation for the mech-

TABLE 46–8.

Risk Factors for Moderate Bradycardia (Pulse <50 bpm) and Hypotension during Spinal Anesthesia

Risk Factor	Odds Ratio
Bradycardia	
Baseline heart rate <60 bpm	4.9
ASA physical status P1 (versus ASA physical status P3 or P4)	3.5
Prolonged PR interval	3.2
Use of β-blocking drugs	2.9
Sensory level above T5	1.7
Hypotension	
Sensory level above T5	3.8
Age >40 years	2.5
Baseline SBP <120 mm Hg	2.4
Spinal puncture above L2-3	1.8

Data from Carpenter RL, Caplan RA, Brown DL, et al.,[30] and Salinas FV, Sueda LA, and Liu SS.[139]

anisms involved in these physiologic derangements allows early recognition and prompt treatment of potentially detrimental situations.

Cardiovascular changes seen with spinal anesthesia are caused by blockade of the sympathetic efferent fibers, and thus generally are related to block height.[147] Both arterial and venous relaxation contribute to hypotension, resulting from decreases in systemic vascular resistance (SVR) and cardiac output. SVR decreases to a greater degree in patients aged 69–80 (26% from baseline) than in young healthy subjects (13–18% from baseline).[148] Venodilation causes increased pooling of blood in the capacitance vessels, thus reducing central blood volume. This decreases venous return to the heart, resulting in reduced preload and reduced cardiac output.

Although heart rate is typically maintained, bradycardia can occur with spinal anesthesia in 10–15% of cases and unexpected circulatory collapse remains a dreaded complication with a potentially grave outcome. In addition to the risk factors of age younger than 50 years, ASA physical status P1, and concomitant use of β-blockers, the incidence of bradycardia increases with increased block height with 75% of occurrences associated with sensory block above T5[30] (Table 46–8). Cardioaccelerator fibers originate from T1 to T5 and thus sympathetic blockade above T5 is thought to allow parasympathetic predominance over heart rate, mediated via the vagus nerve. However, some studies of heart rate variability demonstrate that even with high thoracic blockade, the balance between sympathetic and parasympathetic systems can remain in balance.[149,150] Reports of bradycardia/asystole and circulatory collapse in patients with blocks too low to be attributed solely to sympathectomy are further evidence that other factors may play important roles. Bradycardia may be induced by an increase in baroreceptor reflex activity.[151] With redistribution of blood to capacitance vessels and decreased venous return to the heart, resulting decreased filling pressures, intracardiac stretch receptors within the right atrium and left ventricle have been suggested to participate in a bradycardic response (Bezold-Jarisch reflex; Fig. 46–14).[152,153] Maintaining preload and aggressive treatment of bradycardia may help improve the safety of spinal anesthesia.[154]

Efforts have been made to investigate the usefulness of heart rate variability analysis for predicting hypotension after spinal anesthesia for cesarean section to assess the underlying balance of patients' autonomic systems.[155,156] Although small and limited, these studies demonstrate that measurements of heart rate variability are predictive of hypotension in this patient population. Heart rate variability is extracted from the patient's electrocardiogram (ECG) and analyzed based on the preponderance of low versus high frequencies to determine subsets of patients who are at risk and who would benefit from additional prophylactic interventions (see next paragraph). Computer-aided analysis is being developed, as currently this is not a common analysis of the ECG. More research is needed, but this appears to be a promising clinical tool to direct selective therapy aimed at preventing hypotension with spinal anesthesia.

The prevention and prompt treatment of hypotension and bradycardia during spinal anesthesia is essential in protecting the patient from untoward outcomes. The practice of administering a crystalloid bolus prior to spinal anesthesia has been a standard method for preventing hypotension induced by neuraxial blockade. Behind this is an effort to maintain central blood volume, and, therefore, venous return to the heart, so as to preserve cardiac output. However, studies reveal a more complicated interaction between fluid loading, hemodynamic effects, and efficacy for prevention of hypotension in the nonobstetric population. For example, prophylactic bolusing of 500–1500 mL of crystalloid may be ineffective for prevention of

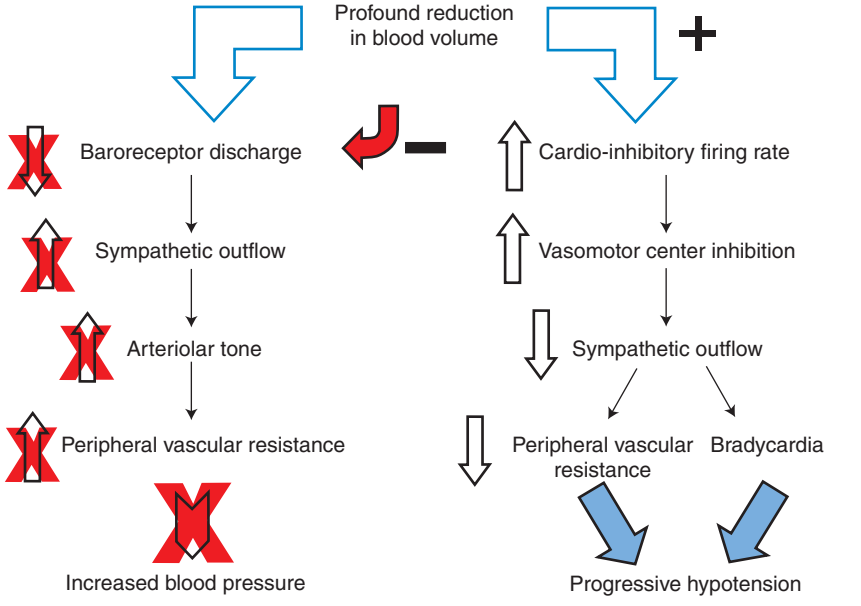

FIGURE 46–14. A proposed mechanism for the participation of the Bezold-Jarisch reflex (BJR)-type cardioinhibitory pathways (*right*) in the cardiovascular collapse after neuraxial anesthesia. It is suggested that the redistributive hypovolemia produced by neuraxial blockade results in paradoxical bradycardia and inhibition of the baroreceptor reflex pathway (*left*), which results in progressive hypotension.

hypotension in normovolemic patients if performed prior to induction of spinal anesthesia,[157–159] but may be effective if performed later during the actual performance of spinal anesthesia.[160] This may be a result of the rapid redistribution of crystalloids out of the intravascular compartment, thus providing only a fleeting contribution to venous return.[161] Furthermore, a crystalloid bolus does not adequately address other factors contributing to hypotension, namely heart rate and SVR, and may actually decrease SVR.[162] In contrast, the administration of colloid solutions is more effective in maintaining intravascular volume caused by favorable pharmacokinetics[162,163] and may actually increase SVR.[162] Prophylactic administration of 500–1000 mL of colloid solution prior to induction of spinal blockade more effectively prevents hypotension but can grossly affect fluid balance in the patient. In regards to treatment of hypotension in the setting of established hypovolemia, crystalloid remains a suitable choice because of altered volume kinetics in such a setting.[164] The technique of spinal anesthesia may also be altered to attenuate resultant vasodilatation and hypotension. Sympathetic block is somewhat dose dependent, thus selection of an appropriate dose is helpful. The use of unilateral spinal anesthesia for unilateral lower-extremity procedures allows limited spread of sympathetic block and has been investigated. Typically, a small dose of hyperbaric local anesthetic is injected and the patient is kept in the lateral position (operative side down) for 15 minutes. Casati et al. showed a decreased rate of hypotension in patients with intentionally asymmetric spinal blocks compared to conventional bilateral blockade (5% vs. 22%).[165] Incidence of hypotension is reduced with epidural compared to spinal anesthesia, and placement of a catheter with gradual titration of epidural local anesthetic dose allows time for treatment of the gradual sympathectomy.

Effective treatment of hypotension should be tailored to the clinical situation at hand, with consideration of alterations in SVR and cardiac output. Vasopressors with α-adrenergic agonist activity, such as phenylephrine and metaraminol, are quite effective for increasing SVR. However, this may be at the expense of a decrease in cardiac output as a response to the increase in afterload.[166] In light of this, it is thought that the use of mixed α- and β-adrenergic agonist drugs, like ephedrine, may be more appropriate for the treatment of hypotension induced by neuraxial blockade as a result of the ability to augment heart rate and cardiac output as well as SVR. Ephedrine is most often administered as an intermittent intravenous bolus of 5–10 mg, but may also be given via continuous infusion or intramuscularly as a depot of 25–50 mg. Atropine in doses of 0.4–1 mg intravenously can be used to treat moderate bradycardia if ephedrine is ineffective. In the case of precipitous bradycardia, or in situations unresponsive to the previously mentioned interventions, one should not hesitate to consider administration of epinephrine. Closed claims data analysis suggests that the lack of early administration of epinephrine is a management pattern in spinal anesthesia that leads to cardiac arrest with poor outcome.[167]

Although similar hemodynamic changes are seen with epidural anesthesia, these tend to be better tolerated than changes seen with spinal anesthesia, perhaps because of a more gradual and titratable onset. Nonetheless, sudden bradycardiac cardiac arrest has been described with epidural anesthesia.[168] Risk of sudden cardiovascular collapse from epidural anesthesia may be influenced by the addition of epinephrine to the epidural solution. With the typical dose range used for epidural anesthesia, systemic levels of epinephrine remain low, producing a β-adrenergic effect of vasodilatation, increased heart rate, and myocardial contractility. Ward et al.[169] evaluated the cardiovascular effects of epidural blockade to T5 using lidocaine with and without epinephrine. Mean arterial pressure decreased 20% in the epinephrine group, compared to 10% in the plain lidocaine group. However, the group with epinephrine also showed a 20–30% increase in cardiac output. Bonica suggested that this systemic β-adrenergic effect of epinephrine might prevent the potential cardiovascular collapse from epidural blockade.[170]

Gastrointestinal, Hepatic, and Genitourinary Physiology

The sympathectomy of spinal anesthesia results in a relaxation of sphincters, constriction of the bowel, and an increase in secretions caused by "parasympathetic dominance." This imbalance of the autonomic nervous system is also thought by some to explain the occurrence of nausea seen with spinal anesthesia. Hepatic blood flow is related to mean arterial pressure, and thus maintained if the patient is hemodynamically stable.[171] Likewise, renal blood flow and renal function are preserved during spinal anesthesia when perfusion pressure is adequate.[172] Urinary retention after spinal anesthesia is the most noteworthy and clinically significant concern in regards to the genitourinary system. Postoperative urinary retention occurs in approximately 16% of patients in the recovery unit.[173]

After the induction of spinal anesthesia, the urge to void (normal detrusor function) is abolished within 60 seconds.[174,175] Recovery of the ability to void normally does not return until sensory anesthesia has regressed to the S3 sacral segment.[174] Prolonged inhibition of normal detrusor function with the use of long-acting local anesthetics such as bupivacaine may allow bladder overdistension and urinary retention. In a study of healthy male patients undergoing nonurologic surgery after spinal anesthesia comparing 100 mg lidocaine to 10 mg bupivacaine, the time to return of normal detrusor function was significantly longer in the bupivacaine group (233 ± 31 vs. 462 ± 61 minutes).[174] The cystometric capacity (the bladder volume at which patients feel an urge to void prior to spinal anesthesia) in this study was between 500 and 600 mL and the patients in the bupivacaine group generated an average of 875 ± 385 mL of urine, far exceeding the cystometric capacity and suggesting that the use of long-acting local anesthetics may lead to bladder overdistension and urinary retention. Other factors such as age (older than 50 years), volume of intraoperative fluid administration, and type of surgical procedure also influence rate of urinary retention.[173]

Concern for postoperative urinary retention is especially important in the ambulatory setting, where the traditional requirement to void after spinal anesthesia often leads to prolonged delays in discharge.[176] However, optimal use of short-acting local anesthetics for ambulatory spinal and epidural anesthesia has not been associated with urinary retention.[177] A recent study of ambulatory surgery patients discharged prior to voiding after short-acting spinal anesthesia demonstrated

significantly shorter discharge times with no reports of urinary retention.[178] Thus, the risk of urinary retention appears to be low after short-acting spinal anesthesia and further prospective study is needed to confirm this practice (discharging patients prior to voiding after short-acting spinal anesthesia) in a large population.

COMPLICATIONS OF NEURAXIAL ANESTHESIA

Postdural Puncture Headache

Appreciated since perhaps the first spinal anesthetic, postdural puncture headache (PDPH) remains a common complication of spinal anesthesia and is seen in as much as 50% of cases of unintentional dural puncture during epidural anesthesia. Reported incidence of PDPH following spinal anesthesia varies greatly, depending on the types of needles used and patient population. Although rates as high as 40% are seen with 22-gauge beveled-tip needles,[179] the use of smaller-gauge pencil-point needles has decreased the risk of PDPH after spinal anesthesia to approximately 1%.[180] The traditional mechanism of PDPH is believed to involve the loss of CSF from the thecal sac and a "sagging" of the brain while standing or sitting upright. This is thought to result in traction on the meninges, meningeal vessels, and, at times, traction on the cranial nerves leading to cranial nerve palsy. MRI studies demonstrating reduced CSF volume[181] and meningeal enhancement postgadolinium during PDPH[182] lend support to this theory of CSF loss and meningeal irritation.

There are also data suggesting vasodilatation of cerebral vessels may be important in etiology of PDPH.[183] The headache is typically positional, being most severe while standing and nearly eliminated when supine. Patients usually describe a band-like aching pain in the frontal and occipital regions, posterior neck pain, and at times nausea, tinnitus, photophobia, and diplopia. Differentiation from infectious meningitis is important and usually based on positional nature of symptoms, lack of fever, and if necessary, normal peripheral white cell count and CSF profile.

Although traditionally held to the contrary, patient gender and postoperative recumbency are not related to incidence of PDPH.[184] Although the incidence of PDPH decreases with increasing patient age,[184] factors that are in the control of the clinician to reduce the occurrence of PDPH include the use of smaller-gauge needles, pencil-point needles, and longitudinal orientation of the bevel if a cutting needle is used.[184,185] The mechanisms in play for the latter two factors are not entirely clear. The classically described scenario is that of more dural fibers being cut by a transversely oriented cutting bevel, and thus a more substantial hole in the dura. However, given that the dural fibers are not actually longitudinally arranged, rather, randomly, the number of these fibers cut should not depend on bevel orientation. It has been suggested that the longitudinal tension placed on the meninges tends to pull open a transversely oriented defect, and thus allow for more CSF leakage. As for pencil-point needles, the supposition that they cause less trauma to the meninges is questionable. Reina et al. suggest that Whitacre needles produce more trauma, as evidenced by electron microscopy images, and that the reduced loss of CSF may be a result of an "edematous plug" resulting from greater inflammatory reaction.[181]

Conservative management of PDPH includes bedrest, oral analgesics, adequate hydration, and caffeine. Patients should be reassured that the symptoms are likely to resolve within 1 week without further invasive treatments. If the patient is not responding adequately to conservative treatments or is having prolonged symptoms, an epidural blood patch can be considered. This is usually performed by accessing the epidural space within 1 interspace of the suspected dural tear and injecting 10–20 mL of autologous blood in an aseptic fashion. This is intended to form a clot, or "patch," over the dural defect, preventing further leakage of CSF. Additionally, this volume will tamponade the dural sac and restore buoyant support to the brain, explaining the near-immediate relief that many patients report. The reported success of epidural blood patch is reported to be in the range of 70–95%, with those who fail to improve with an initial patch showing the same range of response to a repeat procedure. The effectiveness of prophylactic blood patch administration is controversial with some studies showing no benefit and others reporting greater than 50% success in preventing PDPH.[186] It appears that it may be reasonable and effective if using larger volumes (15–20 mL) in high-risk patients.[187]

In the search for alternatives to epidural blood patch, administration of saline[188] and dextran[189] have been performed but without prolonged relief of symptoms. Other substances, such as fibrin glue, have been used in the epidural space with some success,[190,191] but further investigation is needed to determine the potential benefits and safety of such procedures.

Infectious

Infectious complications following neuraxial anesthesia are rare, but can arise in the form of meningitis and epidural abscess. In a large and relatively complete retrospective review, Moen et al. estimated the incidence of meningitis to be less than 1 in 50,000 following spinal anesthesia and about 1 in 90,000 after epidural procedures; and the incidence of epidural abscess to be 1 in 37,000 following epidural blocks.[192] The source of microorganisms can be from contaminated equipment or injected solutions, or from patient source, namely bacteremia. It is speculated that lumbar puncture may disrupt the blood–brain barrier and allow transfer of blood-borne bacteria into the spinal space. Animal studies support this theory, but also show pretreatment with antibiotics to drastically reduce this risk.[193]

Epidural anesthesia for surgical procedures may have a similar risk profile, but the use of indwelling epidural catheters for continuous analgesic infusions provides an additional risk of serving as a wick for surface infections to migrate along the tract to become a deep infection or epidural abscess. However, both surveillance studies and studies examining rates of bacterial contamination of epidural catheter tips indicate that risk is low.[192,194] Patients with postoperative catheters should be under surveillance for signs of infection, having the catheter site inspected daily. If signs of surface infection present, the catheter should be removed and the site monitored for improvement, with or without the initiation of antibiotics as deemed suitable. If the patient presents with severe back pain, and/or new neurologic deficits that are not explained by the analgesic infusion, then the diagnosis of epidural abscess must be considered and MRI or CT performed if appropriate. Du Pen et al. showed successful nonsurgical man-

agement of infections associated with chronic tunneled epidural catheters.[195] However, in the setting of neurologic compromise, prompt diagnosis and surgical evacuation is imperative to permit recovery if an epidural abscess is identified.

Hemorrhagic Complications

With any invasive procedure, the fear of inducing bleeding in a noncompressible region enters the risk-to-benefit analysis. With neuraxial procedures, hematoma can develop in the epidural, subdural, or intrathecal space, with the potential for devastating neurologic outcome. The estimated incidence of spinal hematoma in the absence of anticoagulant and antiplatelet medications is less than 1 in 150,000 neuraxial blocks.[196] The majority of cases of spinal hematoma are in patients receiving anticoagulants or with impaired hemostatic function from hepatic dysfunction or thrombocytopenia.

The usual presenting symptoms are back pain and motor and/or sensory deficit that is not explained by the administered anesthetic/analgesic agents. In patients with such symptoms, especially in the setting of anticoagulants, definitive diagnosis should be sought without delay. A review by Vandermeulen et al.[197] indicated that early identification by MRI or CT and surgical decompression performed within 4–6 hours of presentation is associated with good neurologic recovery. This review also highlighted the importance of coagulation status at the time of epidural catheter removal with report of 15 patients suffering epidural hematoma associated with this event.

The American Society of Regional Anesthesia and Pain Medicine has released a consensus statement to address the concerning issues surrounding neuraxial procedures in patients receiving anticoagulant and antiplatelet medications.[196] Some of the recommendations from this statement are presented here, but this in no way substitutes for a full review of the information provided by the Consensus Conference. One should also consider that any patient who is receiving combinations of the following medications is likely at further increased risk and appropriate caution taken.

Oral anticoagulants should be stopped 4–5 days prior to planned intervention and international normalized ratio (INR) measured prior to neuraxial procedures. In patients with indwelling epidural catheters who have had warfarin therapy initiated, a lower-extremity neurologic examination protocol should be followed and the INR should be confirmed to be less than 1.5 prior to epidural catheter removal.

The use of aspirin and nonsteroidal antiinflammatory drugs is not considered to increase the risk of hemorrhagic complications with neuraxial procedures. However, clopidogrel and ticlopidine should be discontinued for at least 7 days and 14 days, respectively, before neuraxial techniques. Given shorter half-lives, the glycoprotein (GP) IIb/IIIa antagonists only need to be held for 24–48 hours to allow return of platelet function.

Patients receiving subcutaneous heparin for thromboprophylaxis are not considered to be at increased risk for spinal hematoma, but considerations should be made with regards to timing of procedures in light of the peak onset of 2 hours after administration of heparin dose. Intraoperative anticoagulation with IV heparin is acceptable if given 1 hour after and discontinued 2–4 hours (and normal partial thromboplastin time [PTT] confirmed) before block placement or catheter removal.

Low-molecular-weight heparins (LMWHs) present added management concerns given the prolonged action (especially in patients with decreased renal clearance) and difficulty in measuring the induced alterations in coagulation status. Current recommendations state that patients receiving thromboprophylactic doses should have neuraxial procedures delayed 10–12 hours after last dose. If receiving "treatment" dosing (1 mg/kg twice a day), a delay of 24 hours is recommended. Following neuraxial procedures, initiation of LMWH therapy should be delayed 6–8 hours for daily dosing or 24 hours for twice-daily dosing.

Neurologic Complications

Neurologic injury from neuraxial procedures is rare, but it remains a fervently held fear among many patients. The overall incidence of persistent neurologic injury associated with neuraxial blocks is reported to be approximately 0.08–0.16%; however, the vast majority of these reported cases fail to show evidence that the block was directly causative.[198] Potential mechanisms of neurologic injury following neuraxial anesthesia include direct needle or catheter trauma, neurotoxicity of injected substances (intended agents or unintended chemicals), infectious complications, hemorrhagic complications, or spinal cord ischemia. The majority of perceived injuries are related to persistent paresthesia or motor weakness, but cauda equina syndrome is also scarcely reported.

Although paresthesia is reported in as much as 6% of patients during needle placement for spinal anesthesia, this rarely results in persistent neurologic deficit.[199] Similarly, most paresthesias associated with indwelling epidural catheters are likely to dissipate following removal of the catheter.[200] Despite its rare occurrence, paresthesia during block placement is considered a risk factor for persistent paresthesia. Patients experiencing this should be reassured and queried postoperatively regarding their neurologic status.

Attention has been focused on the issues surrounding neurotoxicity of local anesthetics and common additives because of identification of several cases of cauda equina syndrome associated with continuous spinal anesthesia via microcatheters. Although the injuries in these cases have been attributed to pooling and maldistribution of the local anesthetic within the thecal sac caused by the nature of administration through a catheter,[201] there are reports of similar injuries from single-shot lidocaine spinal anesthetics using relatively high doses (>75 mg) with epinephrine.[74] Despite the long history of relative safety, animal data exist to suggest that all local anesthetics have some potential to cause neural injury; however, lidocaine and tetracaine appear to have a greater potential for neurotoxicity than bupivacaine at clinically relevant concentrations.[202] Drasner has presented recommendations for lidocaine spinal anesthesia, including limiting the dose to 60 mg, avoiding epinephrine, and restricting concentrations to 2.5% or less,[203] although little evidence exists to support these proposals. The concerns of dose, concentration and adjuvants might be applicable to all local anesthetics.

A much more commonly reported complication following neuraxial anesthesia is TNS. These symptoms, initially termed "transient radicular irritation" in 1993,[204] are described as back pain radiating to the buttocks and/or the lower

extremities. Although TNS has been reported following spinal anesthesia with all local anesthetics, it is more common with lidocaine, showing an incidence in prospective studies to be between 4% and 36%.[23] Drastic variation in the observed rates of TNS (Table 46–6) lends support to the theory that multiple factors are involved in its development. Factors demonstrated to contribute to the incidence of TNS include the use of lidocaine (relative risk of 4.35 compared to other local anesthetics),[205] lithotomy position, knee arthroscopy, and early ambulation (as in outpatient surgery) (Table 46–6).[204]

The etiology of TNS remains elusive, but proposed culprits include direct neurotoxicity of local anesthetics, stretching of neural structures via positioning and muscle relaxation, needle trauma, and muscular spasm. The evidence against neurotoxicity being the principal cause of TNS includes lack of motor deficit and electrophysiologic changes during acute symptoms,[206] as well as its response to nonsteroidal antiinflammatory drugs and other modalities treating muscular discomfort.

Systemic Toxicity and Epidural Test Dose

It is important to verify correct placement of needles and catheters in the epidural space prior to initiating epidural anesthesia. Unintentional subdural or subarachnoid dosing can result in high blocks or "total spinals," whereas intravascular injection can result in seizures or cardiovascular collapse. Subdural injection is rare and may be difficult to recognize, as CSF will not be aspirated from the needle or catheter. The clinical pattern is one of an unusually high block after administration of local anesthetic.[208] Unintentional subarachnoid injection is a more common occurrence with incidences of "total spinals" ranging from 0.3% to 0.6%. It is important to realize that an epidural catheter may migrate into the subarachnoid space at any time during use. Unintentional intravascular injection is probably more common with incidences of systemic toxic reactions (ranging from mild CNS symptoms to seizures) ranging from 2% to 0.01%.[208] Again, it is important to realize that an epidural catheter may migrate into the intravascular space at any time during use.

Although efficacy is uncertain, it is standard practice to administer a test dose prior to initiating full epidural anesthesia.[208] This test dose is meant to detect unintentional placement of the needle or catheter into either the subarachnoid or intravascular space. A 3-mL volume of local anesthetic is the primary component of a test dose. Theoretically, subarachnoid injection of this local anesthetic will produce a much more rapid and profound sensory and motor block than epidural injection. However, changes can be subtle and will require time to develop. Previous reports indicate that 2–4 minutes are required prior to development of sensory or motor block after subarachnoid injection of 3 mL of 1.5% lidocaine.[208,209] Subarachnoid injection of a bupivacaine test dose (3 mL 0.25–0.5%) produces spinal blocks with highly variable onset time and spread and is probably not a reliable indicator.[208] Use of a test dose to detect subarachnoid placement is not without risk, as previous publications have reported high spinal anesthesia requiring tracheal intubation after 3 mL of 1.5% lidocaine or 0.5% bupivacaine.[208] The local anesthetic component can also be used to detect intravascular injection by assessing symptoms of CNS irritability such as tinnitus, perioral tingling, metallic taste, and dizziness. Detection ability is limited as the standard 3-mL test dose (45 mg lidocaine or 15 mg bupivacaine) contains insufficient local anesthetic to reliably produce such symptoms. Previous studies suggest that larger doses, such as 100 mg or 1 mg/kg of lidocaine or >25 mg of bupivacaine, levobupivacaine, or ropivacaine, are required in the unsedated patient.[208,210] Administration of even modest doses of sedation further reduces the ability of patients to report these symptoms (40% reduction in sensitivity).[211]

Epinephrine is commonly added to the local anesthetic dose to increase sensitivity for detection of intravascular injection. Addition of 15 μg is the standard dose of epinephrine; it will consistently produce increases in heart rate and systolic blood pressure and reduction in T-wave amplitude within 60–120 seconds in healthy patients (Table 46–9).[208,212] Use of β-blockers, advanced age, and addition of general or spinal anesthesia all decrease the hemodynamic response to this dose of epinephrine and reduced criteria should be applied in these circumstances.[208,213,214] Intravascular injection of epinephrine may be of concern in patients with hypertension, patients at risk for myocardial ischemia, and in obstetrical patients, and potential risks should be considered in these patients.

The best method for avoiding systemic toxicity from local anesthetics is through prevention. Toxic systemic levels can occur by unintentional intravenous or intraarterial injection, or by systemic absorption of excessive doses placed in the correct area. Unintentional intravascular and intraarterial injections can be minimized by frequent syringe aspiration for blood, use of a test dose of local anesthetic (see

TABLE 46–9.

Use of Epinephrine Test Doses to Detect Intravascular Injection

Patient Type	Hemodynamic Criteria for Intravascular Injection of 15 μg of Epinephrine
Healthy surgical patient	HR increase >20 bpm SBP increase >15 mm Hg T-wave amplitude decreased by ≥25% on ECG
β-Adrenergic blockade	HR unreliable SBP increase >15 mm Hg
Age >60 years	HR increase >9 bpm SBP increase >15 mm Hg
General anesthesia	HR increase >8 bpm SBP increase >13 mm Hg
Spinal anesthesia	HR increase >20 bpm SBP unreliable

HR, heart rate; SBP, systolic blood pressure.
All responses occur within 2 minutes of injection.

above), and either slow injection or fractionation of the rest of the dose of local anesthetic.[215] Detailed knowledge of local anesthetic pharmacokinetics will also aid in reducing the administration of excessive doses of local anesthetics. Ideally, heart rate, blood pressure, and the electrocardiogram should be monitored during administration of local anesthetics. Pretreatment with a benzodiazepine might also lower the probability of seizure by raising the seizure threshold.

CONTINUOUS SPINAL ANESTHESIA

Because of the density and reliability of spinal anesthetic blockade, attempts to extend the duration and graduate the dosing of agents led to techniques for continuous spinal anesthesia (CSA). Almost a century ago, malleable spinal needles were left within the subarachnoid space to allow redosing during prolonged procedures, and, later, Tuohy placed catheters in the intrathecal space. The development of microcatheters (29–32 gauge) in the 1980s led to a revisiting of this technique with hopes of titrating and prolonging spinal blockade with reduced incidence of PDPH as compared to Tuohy's 15-gauge catheters. Unfortunately, beyond the problems of breakage and knotting, these catheters are associated with several reports of cauda equina syndrome, usually with 5% hyperbaric lidocaine used as the agent. The hypothesis is that the small-bore catheters led to a "sacral pooling" of the hyperbaric agents, limiting spread and dilution of the drug in the CSF, unmasking the neurotoxic potential of lidocaine at such a concentration. The FDA subsequently removed these microcatheters from the market, as did the Canadian authorities. Although some practitioners still employ continuous spinal anesthesia using larger-gauge catheters, the risks and benefits must be weighed carefully for the given situation. If CSA is to be undertaken, precautions should be taken to not advance the catheter beyond 3 cm within the intrathecal space, avoid dextrose-containing preparations, give adequate time for spread and distribution of the agent prior to additional dosing, and be prepared to abandon the technique if sacral pooling is suspected.

COMBINED SPINAL–EPIDURAL ANESTHESIA

Combined spinal–epidural anesthesia (CSEA) is an increasingly popular technique, with an estimated 10-fold increase in use in the past decade.[216] Its advantages include rapid onset, dense neuraxial block, ability to titrate spread and duration of block, and lower total drug dosage when compared to epidural anesthesia. Potential disadvantages include increased time to perform the dual technique, intrathecal migration of epidural drug and/or catheter, effects of increased epidural pressure from injection of solutions on spinal block, and decreased ability and reliability of epidural test dosing. Although a seemingly simple combination of two routine techniques for neuraxial anesthesia, the interactions between the two can be subtle, can impact clinical management, and have not been fully determined.

Patient Selection and Clinical Applications

Obstetrics

CSEA has been most widely accepted in the obstetric population. The concept of the "walking epidural" has become popular among patients, where intrathecal opioid allows rapid onset of analgesia without motor blockade. Lipid-soluble opioids, such as fentanyl (up to 25 μg) and sufentanil (up to 10 μg), are commonly used to provide dose-dependent analgesia for 60–90 minutes.[217] Opioids are also commonly combined with small doses of local anesthetics, such as bupivacaine, to either prolong this initial spinal analgesia or to reduce side effects by decreasing the required dose of opioids. Previous dose response studies indicate that 2.5 mg of bupivacaine combined with either 15 μg of fentanyl or 2.5 μg of sufentanil provides satisfactory analgesia while reducing incidences of nausea and pruritus, when compared to larger doses of opioid.[218,219] Recent comparisons suggest that the newer local anesthetics ropivacaine and levobupivacaine are approximately equipotent for CSEA for labor analgesia and essentially interchangeable with bupivacaine for labor analgesia.[220,221] Preservation of motor function is an important goal after CSEA for labor analgesia, and sophisticated testing of positional sense and motor function after CSEA indicates little effect from the initial spinal dose (2.5 mg bupivacaine + 5 μg fentanyl).[222] However, subsequent injection of a standard test dose (45 mg lidocaine + 15 μg epinephrine) to confirm epidural catheter placement or the initiation of continuous epidural analgesia appears to degrade motor function and positional sense.[222,223] Addition of other less commonly used adjuncts to standard doses of opioids can also increase duration of analgesia. For example, addition of 200 μg of epinephrine or 50 μg of clonidine to opioid is equivalent to adding 2.5 mg of bupivacaine and can provide an additional 30 minutes of analgesia.[217] Despite the apparent preservation of motor function, large clinical trials have not observed a decrease in incidence of cesarean section when CSEA is compared to conventional epidural analgesia, although the incidence is similar to systemic analgesia.[224–226]

As an anesthetic for cesarean section, CSEA offers a rapid, titratable block, good muscle relaxation, and the ability to use reduced doses of local anesthetic. Several clinical trials have compared CSEA to epidural anesthesia with lidocaine or bupivacaine combined with fentanyl. These studies report more rapid onset, better motor block, decreased anxiety levels, decreased shivering, and greater patient satisfaction with CSEA.[227,228] Incidences of side effects were similar in that the severity of hypotension did not differ, nor did the incidence of postdural puncture headaches, backaches, nausea, or vomiting.[227,228] When compared to conventional single-shot spinal anesthesia, use of CSEA offers the potential advantage of using a smaller initial dose of spinal anesthetic with the epidural catheter available, should the block be insufficient. Such an approach theoretically offers the advantage of greater individual titration with reduction in side effects and faster recovery from conduction block. However, results from studies are inconsistent, with some trials observing faster motor recovery with this approach[229] and others not discerning a reduced dosing need for spinal anesthesia with epidural supplement.[230,231] A potential disadvantage of the CSEA technique versus the single-shot technique is an increased incidence of transient paresthesia during placement of the spinal needle. A previous study randomizing

patients undergoing cesarean section to CSEA versus conventional spinal anesthesia observed incidences of paresthesia of 37% versus 9%. There were no long-term complications, and the authors speculated that the CSEA technique might lead to deeper tissue penetration as a mechanism for increased incidence of transient paresthesia.[232]

Ambulatory Anesthesia

The dose of local anesthetic determines both anesthetic success and duration of recovery. Availability of the epidural catheter for a rescue anesthetic allows use of minimal doses of spinal local anesthetic with resultant rapid recovery and discharge (Table 46–4) and represents an alternative or complementary strategy to use of analgesic additives. Several clinical trials have determined minimally effective doses for ambulatory knee arthroscopy using this approach. For example, initial doses of spinal lidocaine 40 mg or mepivacaine 45 mg[233,234] have been determined to be optimal doses for CSEA by previous dose–response studies. However, induction of a CSEA technique probably takes more time than conventional spinal anesthesia, and no current data are available to assess relative cost benefit of increased induction time versus decreased recovery time with CSEA. Thus, final conclusions on the role of CSEA in a busy ambulatory surgery center remain to be determined.

Techniques and Equipment

The most widespread approach used in the literature is the needle-through-needle technique. A number of commercial kits are available. The simplest version is a Tuohy needle (or equivalent) through which a long, small-gauge spinal needle (24–30 gauge) is passed. Epidural needles with a "back hole" are also available, configured to allow placement of the spinal needle through a separate conduit so as to avoid angulation of the spinal needle (Fig. 46–15). Recent studies suggest that use of a back-hole needle may offer advantages over a conventional needle through needle technique. A randomized trial in parturients observed decreased incidence of paresthesia (14% vs. 42%) and failure to obtain CSF on the first attempt (8% vs. 28%) with the back-hole needle.[235] The separate conduit for the spinal needle may also reduce risk of toxicity from metal fragments caused by needle friction.[236] Metal fragments have been proposed as a cause of aseptic meningitis, following the observation of notches in epidural needle tips.[237] However, recent evaluations using atomic absorption spectrography and photomicrography did not demonstrate metal fragments even after up to 5 spinal needle passes, and suggest the notches were caused by malleability of the metal.[238]

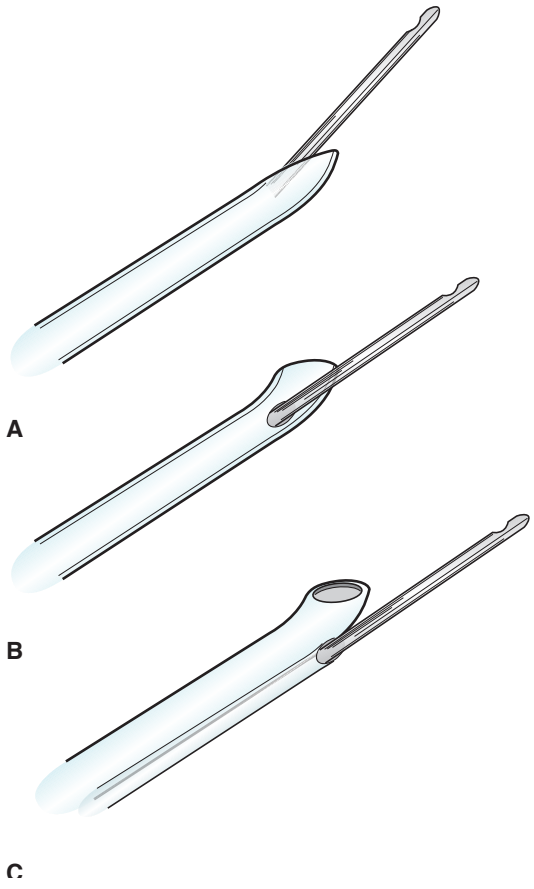

FIGURE 46–15. Styles of needles for combined spinal-epidural anesthesia. Depicted are (**A**) "conventional" Tuohy with a long spinal needle exiting the curved tip; (**B**) "back-eyed" needle with spinal needle exiting through the eye; and (**C**) "double-barrel" design, with a separate bore for passage of a spinal needle. Notice the difference in the angle of projection of the spinal needle passing out of the "conventional Tuohy" tip, as compared to *B* and *C*.

As an alternative to the needle-through-needle technique, the double-segment method also offers the ability to place the epidural catheter and administer a test dose prior to placing the spinal block. Typically, the epidural and spinal portions are performed at different interspaces. By first introducing the catheter, there exists the potential risk of damaging the catheter with the spinal needle. Furthermore, creating two separate cutaneous punctures could lead to increased incidence of adverse events, including backache, headache, infection, and hematoma.[239] A recent study demonstrated greater acceptance by surgical patients of the needle-through-needle over the double-segment technique (85% vs. 67%).[240] That same study also showed a significantly longer time to perform the double-segment technique without decreasing the failure rate of spinal anesthesia, although other studies suggest a higher failure rate with the needle-through-needle technique.[240]

Potential Complications

Failure of Spinal Anesthesia

The combined technique is associated with a higher failure rate of spinal anesthesia than conventional spinal anesthesia. The most recent data suggests about a 5% incidence, improved from older reports of 10–25%.[216] There are a number of reasons for failure to occur. (a) Smaller-gauge spinal needles with long lengths are typically used. These needles lead to slower return of CSF and a greater resistance to injection. (b) Because the epidural needle has penetrated the tissue

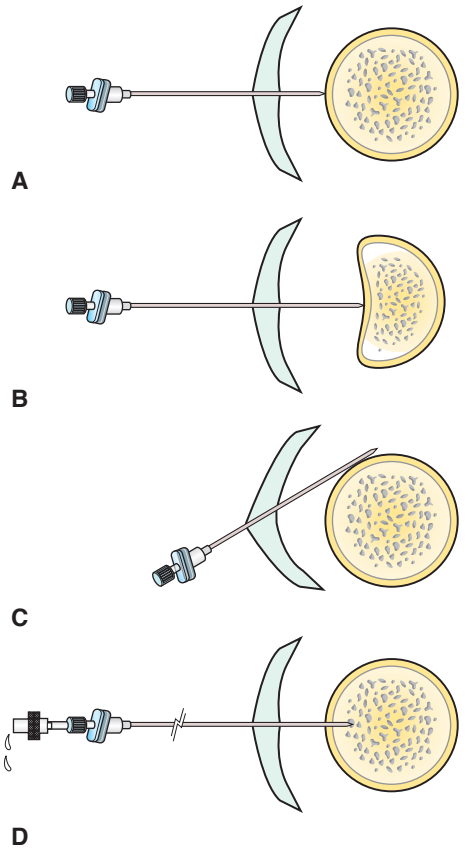

FIGURE 46–16. Various reasons for not achieving successful spinal anesthesia when attempting combined spinal–epidural anesthesia. **A.** Inadequate length of spinal needle, or epidural needle not advanced far enough. **B.** Spinal needle rents the dura, but does not achieve puncture. **C.** Angle of advancement deviates too far from midline. **D.** Successful dural puncture with return of CSF.

planes, there is little to anchor the spinal needle in place. Although a Luer lock apparatus is available, it locks at a fixed needle length and can result in not reaching or traversing the dura.[27] (c) Any deviation from midline can lead to missing the dura altogether (Fig. 46–16). (d) If loss-of-resistance technique used saline, a false return of saline in the spinal needle rather than CSF can occur. Kopacz et al. recommend the hanging drop method within the epidural needle to aid identification of dural puncture in this situation.[6] Negative pressure from tenting the dura with the spinal needle will cause an inward movement of the drop of fluid followed by return of CSF. (e) Finally, patient positioning and duration between spinal injection and completion of epidural catheter placement can change the characteristics of the spinal block.

Failure of Epidural Anesthesia

There are no controlled randomized prospective studies addressing the failure of epidural anesthesia or analgesia with the combined technique.[22] The incidence of failure is unlikely to be higher with the combined technique; however, the difficulty in early testing with a needle-through-needle technique may lead to late recognition of a misplaced catheter. Prior injection of spinal anesthetic precludes testing the epidural catheter for intrathecal placement, and epidural injection of a test dose can lead to increased height of spinal block (see Intrathecal Effects of Epidural Agent below).[243] Reliability of detecting an intravascular test dose using 15 μg of epinephrine remains intact in healthy individuals using heart rate and systolic blood pressure criteria, although the developing spinal block will reduce the magnitude of hemodynamic response to epinephrine.[214]

Intrathecal Effects of Epidural Agent

The intrathecal effects of epidurally administered drugs can occur through migration of the epidural catheter through the dural puncture, leakage of epidural anesthetic through the dural hole, and pressure effects of epidural injection. The likelihood of passing an epidural catheter through a dural hole is very small, provided a 24-gauge or smaller spinal needle is used. This has been demonstrated using in vitro models and in vivo epiduroscopy.[244] However, intrathecal catheter placement is possible if the epidural needle (17–18 gauge) initially rented the dura. Migration later in the anesthetic course is no more likely than with conventional epidural techniques.

Although significant clinical effects of leakage of epidural local anesthetic or opioid through the small-gauge dural puncture is unlikely, significant leakage of epidural agents can occur through large dural rents such as with a "wet tap."[245,246]

Pressure effect is the observation that increasing epidural volume can "squeeze" the CSF compartment and thus raise the cephalad spread of spinal drugs. A recent myelographic evaluation demonstrated that the subarachnoid space's diameter decreased to 25% after 10 mL normal saline was injected through an epidural catheter.[247] The ability to increase dermatomal spread by epidural volume appears to be time dependent. Sensory block extension can be significant (3–4 dermatomes) if epidural saline or air is injected soon after or before bupivacaine spinal anesthesia.[243,248] This block enhancement may be clinically significant, as a recent clinical trial reported that CSEA required 20% less local anesthetic than single-shot spinal anesthesia.[249] However, if delayed until two-segment regression has begun, there is no increase in sensory blockade level[250]; in fact, it can even result in shorter duration of anesthesia.[251]

CHAPTER 47

Paravertebral Anesthesia

Holly Evans, MD, FRCPC, and
Stephen M. Klein, MD

Paravertebral nerve block (PVB) involves injection of local anesthetic close to the spinal nerve roots within the paravertebral space (PVS). The resulting unilateral or bilateral segmental anesthesia and analgesia of thoracic or lumbar dermatomes has multiple applications. This chapter describes paravertebral anatomy and PVB techniques. The physiologic effects are discussed in relation to the advantages, disadvantages, and contraindications for PVBs. The chapter also summarizes the existing literature outlining the use of PVBs for surgical procedures.

PARAVERTEBRAL ANATOMY

Thoracic Paravertebral Anatomy

The thoracic PVS is a wedge-shaped space that lies on each side of the vertebral column. Detailed descriptions of the anatomic features of the PVS are available.[1–7]

Figure 47–1 illustrates the boundaries of the thoracic PVS. The space is limited posteriorly by the superior costotransverse ligament. At each dermatomal level, this ligament extends from the lower border of the transverse process above to the upper border of the rib below (Fig. 47–2). Anterolaterally, the thoracic PVS is limited by the parietal pleura. The medial base of the thoracic PVS is defined by the posterolateral segment of the vertebral body, the intervertebral disk, the intervertebral foramen and its contents.

The PVS is continuous medially with the epidural space via the intervertebral foramen; in addition, dural sleeves extend into the PVS.[1,5,8] Laterally, the thoracic PVS is continuous with the intercostal space lateral to the transverse processes. Communication with the contralateral PVS may occur by contact through the prevertebral[9,10] or epidural spaces.[2] The PVS is continuous superiorly and inferiorly across the heads and necks of adjacent ribs. The precise cranial limit has not been fully elucidated; however, cervical spread of injectate has been observed after thoracic PVB.[2] Caudally the thoracic PVS was previously thought to be limited by the origin of the psoas major muscle;[11] however, continuity with the PVS below the diaphragm has been supported by studies documenting the lumbar spread of dye following thoracic injection.[2,12,13]

The contents of the thoracic PVS include the endothoracic fascia, the spinal nerves, the sympathetic chain, the intercostal vessels, lymphatics, and loose fatty tissue (Fig. 47–3). The endothoracic fascia is the deep, fibroelastic fascia of the thoracic cavity.[14,15] It is continuous medially with the prevertebral fascia that covers the vertebral bodies and intervertebral disks,[15] superiorly with the scalene fascia, and inferiorly with the fascia transversalis of the abdomen.[2,14] Karmakar[2] described the endothoracic fascia as dividing the thoracic PVS into two potential fascial compartments: the anterior "extrapleural paravertebral compartment" and the posterior "subendothoracic paravertebral compartment." It appears the anterior compartment contains loose areolar connective tissue (subserous fascia)[7] and the sympathetic trunk,[2,16] whereas the posterior compartment contains the intercostal nerves.[2,16]

The spinal nerves emerge from the intervertebral foramina and course through the thoracic PVS as a collection of small nerve rootlets devoid of fascial covering.[2,4,17,18] Early in the course of the spinal nerve, the posterior primary ramus branches to supply the posterior vertebral muscles, ligaments, facet joints and the overlying skin (Fig. 47–3). The sympathetic chain traverses anteriorly within the thoracic PVS[2] and communicates with the spinal nerves through the preganglionic white rami communicantes and the postganglionic grey rami communicantes (Fig. 47–3). The intercostal arteries (originating from the descending aorta), as well as the hemiazygos and accessory hemiazygos veins,[19] pass through the thoracic PVS. Lymphatic drainage is to local nodes and subsequently to tributaries of the thoracic duct which form a plexiform network around the vertebral bodies.[20]

Several features of the thoracic spine are important because they serve as landmarks for performing PVBs. Because the spinous processes in the thoracic spine are steeply angulated, they lie in the same transverse plane as the transverse processes of the vertebra below (i.e., spinous process of T5 is at the same horizontal level as the transverse process of T6) (Fig. 47–2). A spinal nerve exits through its intervertebral foramen to enter the PVS caudal to the transverse process of the same name (i.e., T5 nerve root passes inferior to the T5 transverse process). In adults, the thoracic transverse processes project laterally a mean distance of 3.2 cm from midline (range: 2.1–4.2 cm) [8] and the mean depth from skin to thoracic PVS is 55 mm.[21] Depth is greater in the upper thoracic spine (mean: 77 mm at T1) compared to the mid- and lower thoracic spine (mean: 50 mm at T6);[21] in addition, considerable variation exists as a result of body habitus (mean depth to T1 PVS is 67.5 mm if body mass index [BMI] <25, 78 mm if BMI 25–30, and 84 mm if BMI >30).[21]

Lumbar Paravertebral Anatomy

The lumbar paravertebral region possesses generally unique features. While

KEY POINTS

1. A paravertebral nerve block involves conduction block of the spinal nerve within the paravertebral space.
2. Dense sensory, motor, and sympathetic block results.
3. Unilateral or bilateral, thoracic or lumbar segmental block can be obtained.
4. Common indications include thoracic surgery, breast surgery, and hernia repair.
5. Benefits include diminished stress response to surgery; decreased opioid consumption; reduced opioid-related side effects (nausea, vomiting, sedation); hemodynamic stability as well as preservation of pulmonary mechanics; lower-extremity strength; and bladder function.
6. Potential side effects are rare and include pleural puncture, pneumothorax, intrathecal or epidural injection, and local anesthetic toxicity.

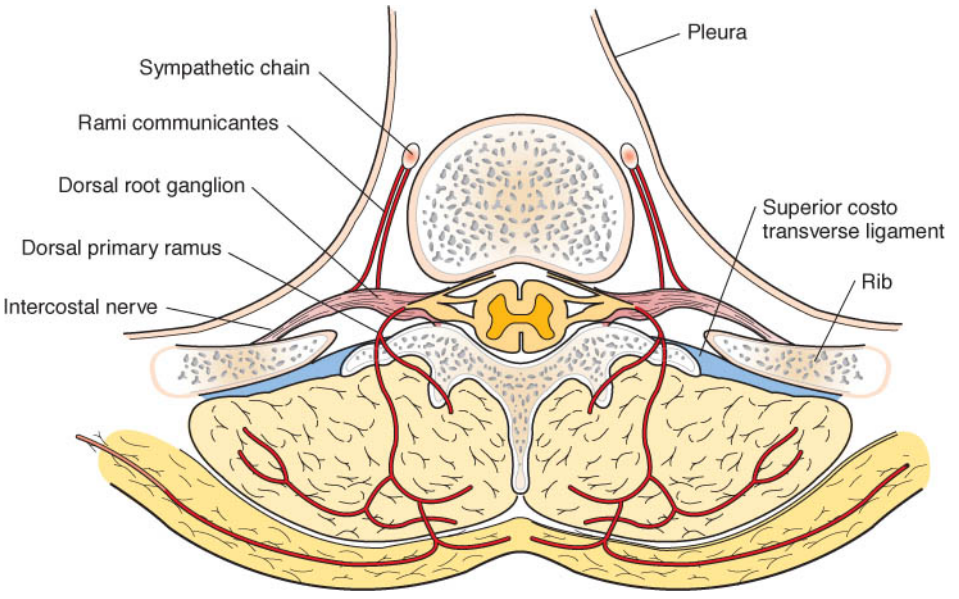

FIGURE 47–1. Transverse section of the thoracic spine depicting the boundaries, contents and structures surrounding the paravertebral space. (Reproduced with permission from Eason MJ and Wyatt R.[3])

the medial boundary of the lumbar PVS is similar to that described for the thoracic PVS, other differences exist. The posterior boundary of the lumbar PVS is formed by the transverse processes and paravertebral muscles. The anterior margin of the lumbar PVS is formed by the fascia transversalis, which is the fascial lining of the intraabdominal cavity. The fascia transversalis in the abdomen is continuous with the endothoracic fascia in the thoracic PVS (Fig. 47–4).[14] The fascia transversalis blends posteromedially with the anterior layer of the quadratus lumborum fascia and with the psoas fascia (Fig. 47–5).[22] The cephalad part of the psoas and quadratus lumborum fascias are thickened to form the medial and lateral arcuate ligaments, respectively. The medial arcuate ligament is attached medially to the body of L2 and laterally to the transverse process of L1. The lateral arcuate ligament passes from the lateral aspect of the L1 transverse process to the inferior border of the twelfth rib. The transversalis fascia is in direct communication with the endothoracic fascia at the medial and lateral arcuate ligaments as well as at the aortic hiatus. And, it is via these communications that there exists continuity between the thoracic and abdominal PVS.[2,14,23]

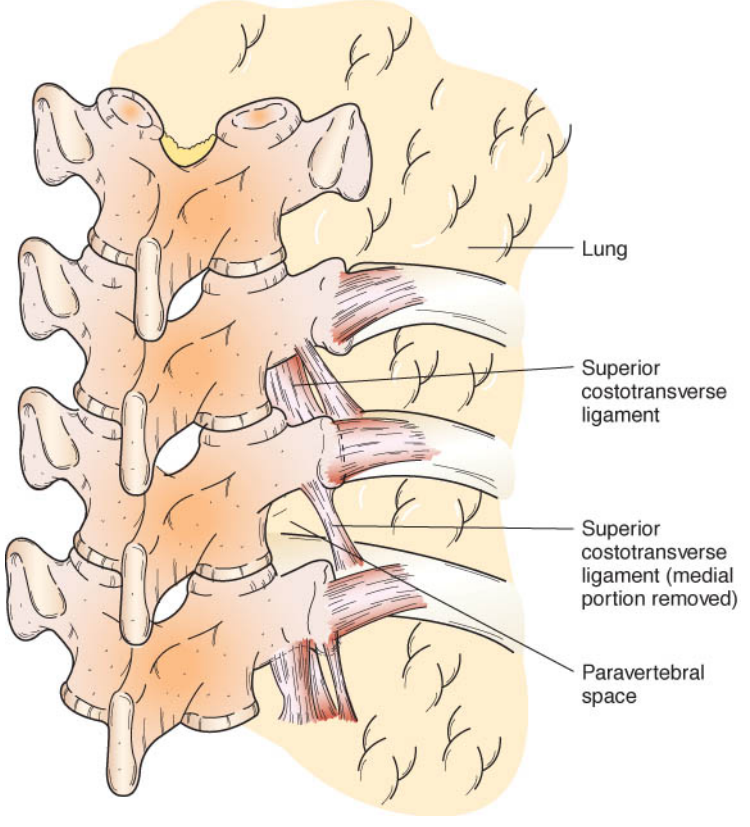

FIGURE 47–2. Posterior view of the thoracic spine depicting the relationship between the superior costotransverse ligament and the paravertebral space. Reprinted from Greengrass R, Steele S. Paravertebral blocks for breast surgery. Tech Reg Anesth Pain Manage 1998;2:8–12, with permission from Elsevier.

The lumbar nerve roots course through the lumbar PVS and subsequently combine to form the nerves of the lumbar plexus. The subcostal, iliohypogastric, ilioinguinal and lateral femoral cutaneous nerves course anterolaterally over the quadratus lumborum muscle. The genitofemoral and, more distally, the femoral and obturator nerves pass over the anterolateral surface of the psoas muscle. Accordingly, local anesthetic injected into the PVS has the potential to block a segment of the lumbar plexus.

Several features of the lumbar spine's bony anatomy deserve men-

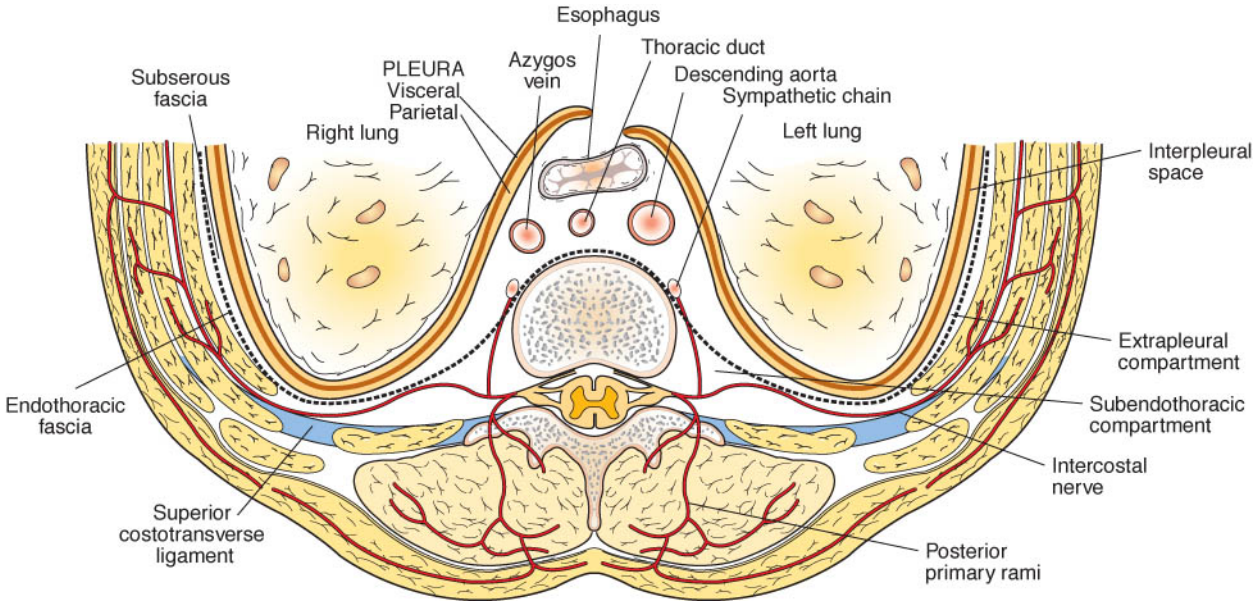

FIGURE 47–3. Midthoracic transverse section depicting the contents of the paravertebral space (including the endothoracic fascia) and surrounding structures. (Reproduced with permission from Karmakar MK.[2])

tion. The spinous process of a lumbar vertebra projects posteriorly with less angulation than in the thoracic spine (Fig. 47–6). As a result, a given transverse process lies at the same horizontal level as its corresponding spinous process. In addition, the transverse processes in the lumbar region do not articulate with the ribs and are much smaller and thinner in the anteroposterior plane in contrast to the thoracic spine.

HISTORY

Hugo Selheim, an obstetrician, is credited with the development of paravertebral anesthesia in 1905.[2] Arthur Lawen, a surgical resident, subsequently refined Sellheim's technique[2] and performed PVBs on patients presenting with abdominal pain. This provided acute pain relief, which facilitated abdominal muscle relaxation and palpation. Subsequent laparotomy or autopsy allowed identification of the underlying pathology. As a result, detailed information was collected on the segmental innervation of various thoracic and abdominal organs. These pioneers are credited with early development of the familiar segmental dermatome map (Fig. 47–7). Selheim, Lawen, and subsequently Kappis further expanded the use of PVBs for surgical anesthesia in attempt to reduce complications and improve survival in the early years of general and spinal anesthesia.[2] The technique fell into disfavor for several decades until a publication by Eason and Wyatt renewed interest in this modality.[3]

PARAVERTEBRAL BLOCK TECHNIQUE

The patient can be positioned sitting, prone, or lateral decubitus (side to be blocked uppermost). The neck is flexed,

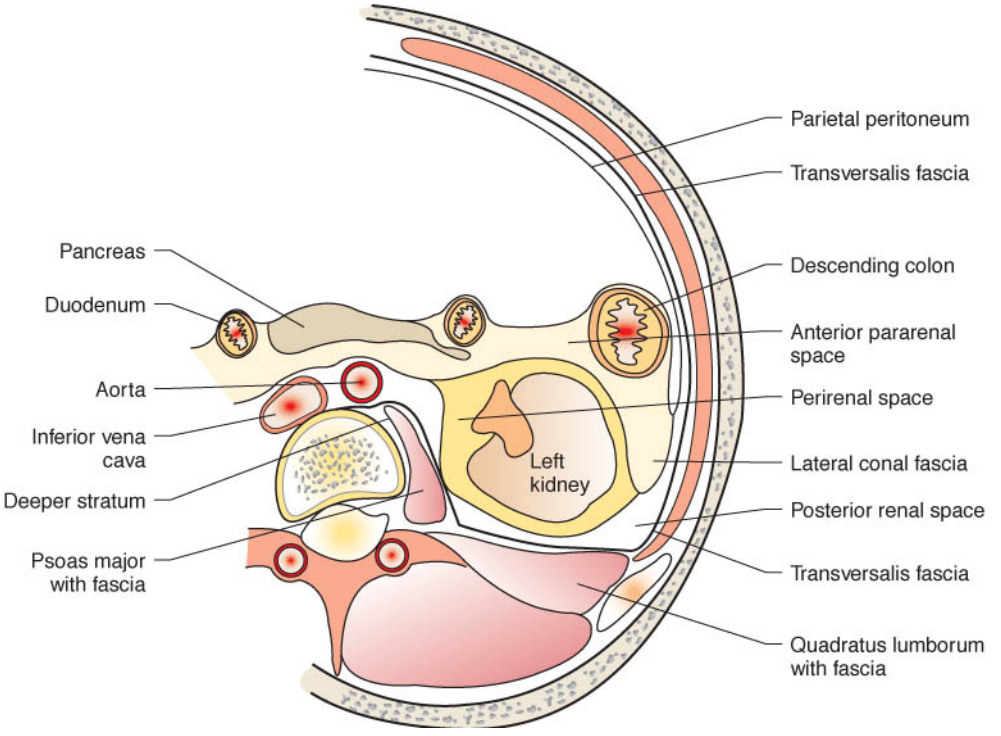

FIGURE 47–5. Upper abdominal transverse section depicting the relationship between the fascia transversalis and the fascia of the psoas major and quadratus lumborum muscles. Karmakar MK, Gin T, Ho AM. Ipsilateral thoraco-lumbar anaesthesia and paravertebral spread after low thoracic paravertebral injection. the back is rounded, and the shoulders retracted forward, similar to positioning for a thoracic epidural. Appropriate sedation is useful for anxiolysis and analgesia.

The levels (spinal nerve roots) to be blocked are selected based on the surgical procedure, for example, T1 to T6 for mastectomy and axillary dissection (Table 47–1 and Fig. 47–7). The spinal nerve root is located following identification of its corresponding transverse process. In the thoracic spine, a given transverse process is located in the same horizontal plane as the spinous process of the vertebra above (e.g., the T4 transverse process is at the level of the T3 spinous process) (Fig. 47–2). Spinous processes are generally palpable in the midline with the most prominent spinous process in the neck representing C7, the lower border of the scapula corresponding to T7, and the intercristal line marking L4. The superior aspect of the desired spinous process is identified and, in adults, a mark is drawn 2.5 cm lateral from the midline (Fig. 47–8). The skin is cleaned with disinfectant and subcutaneous infiltration of local anesthetic is given at all needle entry sites. A number of techniques have been described to identify the PVS.

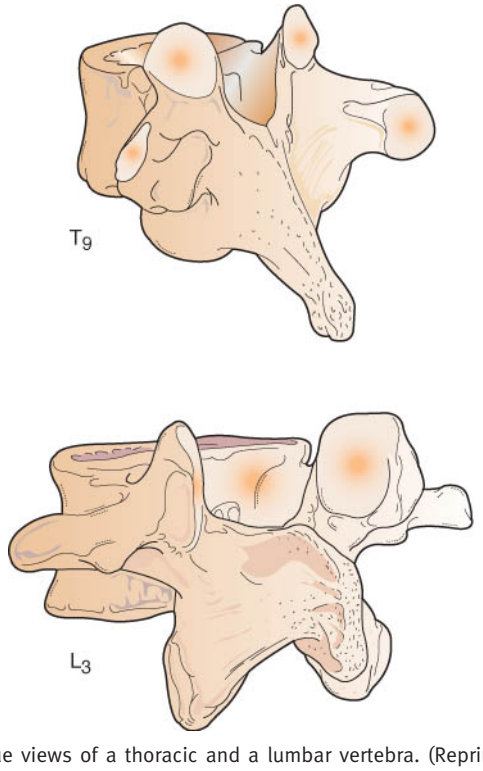

FIGURE 47–6. Oblique views of a thoracic and a lumbar vertebra. (Reprinted from Covino BG, Scott DB, Lambert DH. In: Handbook of Spinal Anaesthesia and Analgesia. Philadelphia, PA: WB Saunders, 1994, with permission from Elsevier.)

Anatomic or Loss-of-Resistance Technique

Identification of the thoracic PVS can be made when a tactile "pop" is noted as the needle passes through the superior costotransverse ligament. Alternatively, loss of resistance to injected air or saline may be used; however, this end point is more sub-

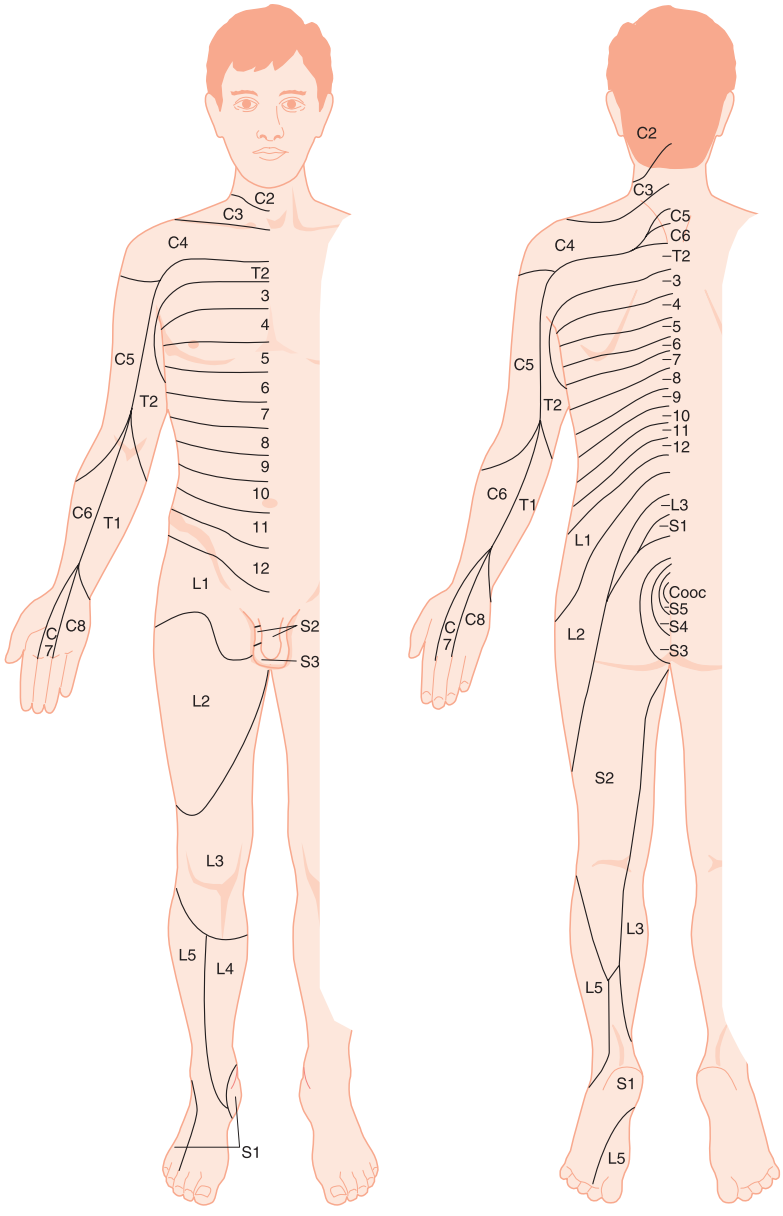

FIGURE 47–7. Dermatomal distribution of spinal nerves. (Reprinted from Covino BG, Scott DB, Lambert DH. In: Handbook of Spinal Anaesthesia and Analgesia. Philadelphia, PA: WB Saunders, 1994, with permission from Elsevier.)

tle and subjective than with epidural anesthesia.

A 10-cm, 22-gauge Tuohy needle is inserted in a horizontal plane 2.5 cm lateral to the midpoint of the superior border of the appropriate spinous process in adults. The needle is advanced to contact the transverse process, withdrawn to the subcutaneous tissue, and then redirected caudal to the transverse process (Fig. 47–9). The needle is slowly advanced until a change in resistance is perceived. This occurs approximately 1 cm past the depth at which the transverse process is contacted. The depth from skin to thoracic PVS varies by vertebral level and patient habitus.[21]

A cautious approach is warranted if bone is contacted deep to the transverse process as this may represent the rib. Further advancement of the block needle past the rib can result in pleural puncture and pneumothorax. This risk can be minimized when the block needle is redirected caudally after initial bony contact. If the rib is unintentionally contacted first, caudal redirection will bring the block needle in contact with the transverse process at a shallower depth (Fig. 47–10). Subsequently, a more accurate estimation of the depth of the PVS is provided and the risk of pleural puncture is decreased. In contrast, an alternate approach has been described in which the needle is redirected cephalad to the transverse process. If initial contact is made with the rib, cephalad redirection will not bring the needle into contact with the transverse process. Further advancement of the needle deep to the rib increases the possibility of pleural puncture and resulting pneumothorax.

When the thoracic PVS has been located, 3–5 mL of local anesthetic is typically injected at each level. The syringe containing local anesthetic is aspirated for air, blood, or cerebrospinal fluid prior to injection. Injection should occur without resistance. Local anesthetic doses may need to be adjusted when multiple or bilateral PVBs are performed.

Nerve block adequacy is confirmed by appropriate thoracic dermatomal sensory block, intercostal muscle motor block, and sympathectomy-related changes such as vasodilatation and increased skin temperature.

Lumbar PVBs involve a modification of the thoracic technique. The needle entry site for each spinal nerve corresponds to the spinous process of the same level, making correction for spinous process angulation unnecessary in the lumbar region. In addition, after contact with the lumbar transverse process, the block needle is advanced no more than 0.5 cm anteriorly. This is because the lumbar transverse processes are thinner in the anteroposterior plane compared to the thoracic spine. Finally, the loss of resistance upon entrance into the lumbar PVS is less-well defined compared to that felt in the thoracic spine. This may be related to the lack of the costotransverse ligament in the lumbar region.

Nerve Stimulation

The spinal nerve can be located in the PVS using a nerve stimulator and a 10-cm, 21- or 22-gauge short-bevel insulated stimulating needle. The needle is inserted as previously described. Direct paraspinal muscle stimulation is observed initially as the needle passes through these muscles. Further advancement caudad to the transverse process brings the stimulating needle in close proximity to the spinal nerve and leads to intercostal or abdominal muscle contractions depending on the level of stimulation. As for other peripheral nerve blocks, appropriate

TABLE 47–1.

Clinical Applications for Paravertebral Nerve Blocks

Surgical Procedure	Levels Blocked
Thoracotomy	T4–T9
Thoracoscopy	T4–T9
Rib fractures	Level of fracture with 1 level above and below
Cardiac surgery	T2–T6 bilaterally
Mastectomy, breast surgery	T2–T6
Mastectomy with axillary dissection	T1–T6 with superficial cervical plexus block
Breast biopsy	Level of lesion with 1 level above and below
Inguinal hernia repair	T10–L2
Umbilical hernia repair	T9–T11 bilaterally
Incisional hernia repair	According to level of repair
Ileostomy closure	T8–T12
Nephrectomy	T8–T12
Cholecystectomy	T6–T10
Appendectomy	T10–T12
Adjunct for shoulder surgery (subdeltoid incision)	T1–T2
Adjunct for hip surgery	T11–T12 with lumbar plexus block
Bone marrow aspiration	T11–L2 bilaterally
Iliac crest bone harvesting	T11–L1
Labor analgesia	T10 bilaterally for first stage of labor
Chronic pain	According to condition

Data from Karamaker MK;[2] Richardson J and Lonnquist PA;[23] and Greengrass R, and Buckenmaier CC 3d.[102]

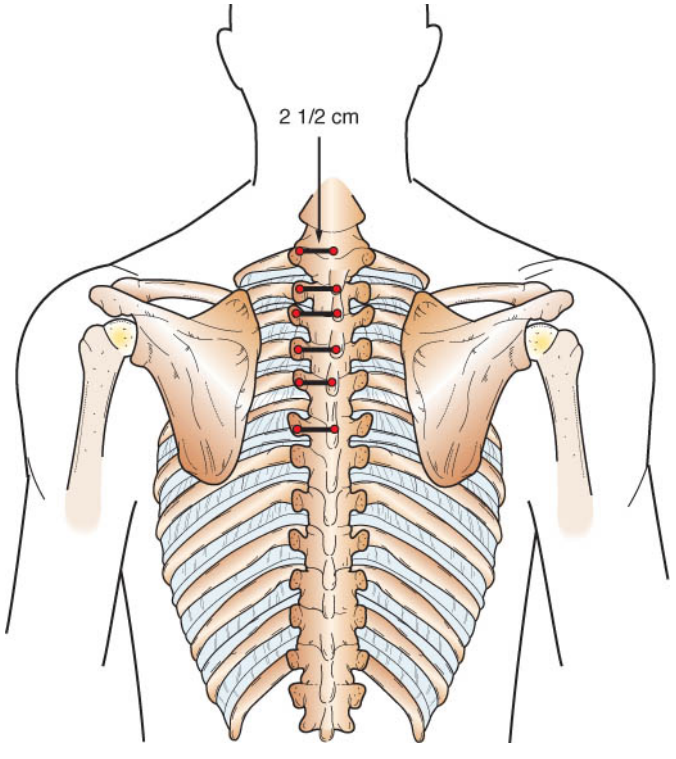

FIGURE 47–8. Skin markings for paravertebral blocks performed for left mastectomy. Reprinted from Greengrass R, Steele S. Paravertebral blocks for breast surgery. Tech Reg Anesth Pain Manage 1998;2:8–12, with permission from Elsevier.

needle placement is confirmed when muscle contractions persist with a current of 0.5–0.6 mA. Isolated posterior spinal muscle contraction should not be accepted as this may represent direct muscle activation or stimulation of the posterior ramus of the spinal nerve root after it diverges from the spinal nerve.

Proponents of this technique describe its usefulness in challenging cases (e.g., morbid obesity, ankylosing spondylitis) and as a way to minimize the occurrence of pneumothorax, although this has yet to be proven.[24]

Other Techniques

Injection of Radiographic Contrast Dye

Injection of contrast dye and radiologic examination can be used to confirm proper paravertebral needle location. Dye spread occurs in either a longitudinal distribution or a segmental, cloud-like dispersal (Fig. 47–11).[7] Naja et al.[25] hypothesized that dye dispersion is dependent on the location of the needle with respect to the endothoracic fascia. They conjectured that needle position posterior to the endothoracic fascia would be associated with segmental, cloud-like dye spread and needle position anterior to the endothoracic fascia with more longitudinal dye distribution.[25]

Pressure Transduction

Pressure measurement has been described to confirm paravertebral needle placement.[26] When the needle tip is in the erector spinae muscle, the measured pressure is higher during inspiration (mean: 29.6 mm Hg) than expiration (mean: 19.4 mm Hg).[26] This is thought to occur as a result of greater muscle activity during inspiration or as a result of muscular compression caused by the expanding chest cage.[23] As the needle is advanced into the PVS, there is a sudden lowering of pressures and expiratory pressure becomes higher (7.6 mm Hg) than inspiratory pressure (3.3 mm Hg).[26] Unintentional puncture is identified when subatmospheric pressures are recorded both during inspiration and expiration.

Ultrasound-Assisted Technique

Ultrasound imaging can be used to provide an estimate of the location and depth of the transverse process.

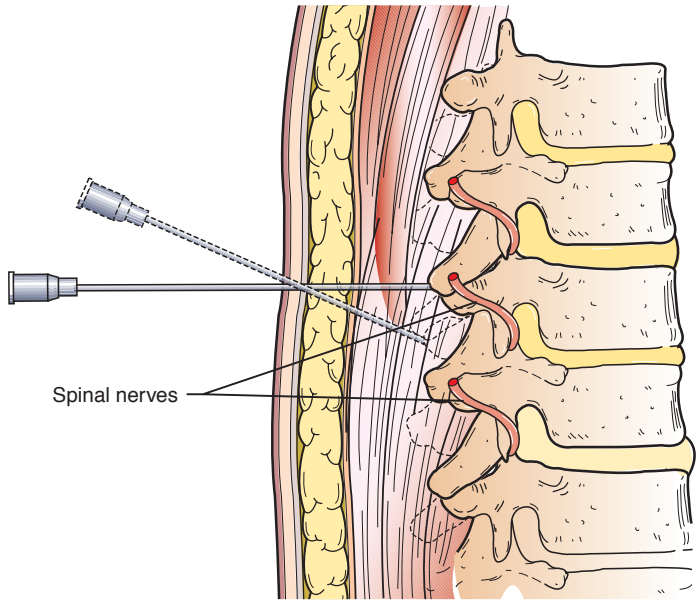

FIGURE 47–9. Paravertebral nerve block technique. Following identification of the transverse process, the block needle is redirected inferiorly and advanced into the paravertebral space. Reprinted from Greengrass R, Steele S. Paravertebral blocks for breast surgery. Tech Reg Anesth Pain Manage 1998;2:8–12, with permission from Elsevier.

Pusch et al.[27] found a close correlation between the needle depth from skin to transverse process and the estimated depth as measured by ultrasound. Moreover, there was also close correlation between the needle depth to the thoracic PVS and the ultrasound-estimated depth to the parietal pleura.

Continuous PVBs

Placing a continuous catheter into the PVS can be used to extend the duration of postoperative analgesia provided by single-injection PVBs. This is typically reserved for more invasive surgery associated with intense postoperative pain, such as thoracotomy and subcostal incisions. Insertions methods are usually modifications of single injection techniques. A single-injection 22-gauge 10-cm Tuohy needle is initially used to estimate the depth of the transverse process and paravertebral space. A larger-bore (e.g., 18 gauge) Tuohy needle capable of accommodating a 20-gauge epidural catheter is then substituted. Extension tubing or a hemostatic valve is used to create a closed circuit with the needle to mitigate entrainment of air if the pleura is punctured. The catheter is threaded 1–2 cm into the paravertebral space to minimize the risk of migration. Consequently, a catheter with a single distal orifice is used to reduce leakage of local anesthetic solution outside of the paravertebral space. A novel insertion method described for thoracic surgery is to place the catheter under direct vision in the surgical field (Fig. 47–12).[4,23] At the completion of the thoracotomy just prior to chest closure, the surgeon strips away the parietal pleura in the paravertebral gutter at the level of the incision, 2 dermatomes cephalad and 2 dermatomes caudad. A small defect is made in the extrapleural fascia. A Tuohy needle is then introduced percutaneously and a catheter is placed into the PVS through the small defect in the extrapleural fascia. The parietal pleura is repositioned and sutured in place.

Effect of Technique on Distribution of Injectate

Paravertebral anesthesia can be provided with one injection using a large volume of local anesthetic deposited at one single level. The theoretic advantage of a single-needle insertion is a reduction in the incidence of side effects such as pleural puncture or pneumothorax. Alternatively, PVBs may be performed with multiple injections using a small volume of local anesthetic at each level injected. The theoretic advantage of this method is more extensive and complete anesthesia of the desired dermatomes. Insufficient evidence exists to determine which technique is most effective; current practice is both institution and practitioner dependent.

A single-level paravertebral injection of 10–15 mL of local anesthetic in

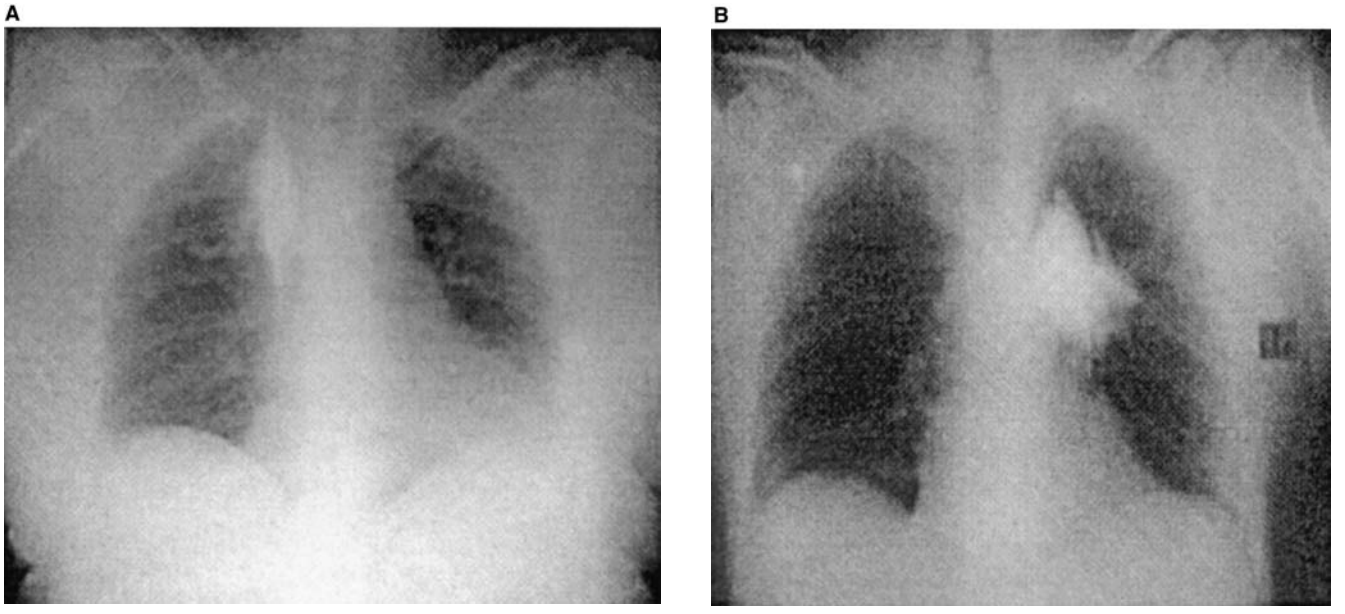

FIGURE 47–11. Chest radiographs taken following injection of radiocontrast dye into the paravertebral space depicting (**A**) longitudinal and (**B**) cloud-like spread. (Reproduced with permission from Naja MZ, Ziade MF, El Rajab M, et al.[25])

adults,[12,28,29] and 0.5 mL/kg in children,[7] achieves a mean sensory block of 4–5 dermatomes, independent of age, height, weight, or sex. Few studies have been designed to rigorously investigate the potential effect of dose or volume of injectate on spread within the PVS. One study in adults has shown no association between these variables,[28] whereas another study of pediatric patients has found a moderate to strong correlation between injected volume and segmental spread of dye.[7] It has been proposed that there may be an age-related loss of connective tissue leading to greater spread of injectate in adults.[28]

Additional factors do affect the spread of injectate within the PVS. Purcell-Jones et al.[8] studied single-injection PVBs using the loss of resistance technique. They radiographically showed greater craniocaudal distribution of solution (5.5 mL) when the PVB was associated with epidural spread. They found sensory anesthesia in a mean 1.43 dermatomes when injectate was confined to the PVS; 2.27 dermatomes when injectate was primarily in the PVS but also spread to the epidural space; 4.66 dermatomes when injectate was confined to the epidural space; and 6.6 dermatomes when injectate was primarily in the epidural space but also spread to the PVS. In all instances, the spread of contrast dye was greater than the observed sensory block. Cheema et al.[12] studied patients who received a single-injection PVB using loss of resistance with 15 mL of local anesthetic and dye. They found that the mean extent of vasodilatation (sympathetic block) was 8 dermatomes, which exceeded the mean sensory block of 5 dermatomes. Interestingly, they also discovered that a greater proportion of the solution injected into the PVS spread in a caudad direction. The distribution of craniocaudal spread is also influenced by the direction in which the solute is injected. Saito et al.[29] performed single-injection PVBs with 12 mL of local anesthetic. When all the injectate was given with the needle bevel directed caudally, sensory block developed in a mean of 5.2 dermatomes, whereas when half the injection was made with the needle bevel directed cephalad and half caudad, sensory block developed in a mean 7.7 dermatomes.

TABLE 47–2.

Local Anesthetic Regimen for Paravertebral Nerve Blocks

Single-level injection	Children: 0.5 mL/kg up to 20 mL local anesthetic Adults: 10–20 mL local anesthetic (i.e., ropivacaine 0.5% with epinephrine 1:400,000)
Multiple-level injections	Thoracic spine: 3–4 mL local anesthetic per segment Lumbar spine: 5–7 mL local anesthetic per segment (i.e., ropivacaine 0.5% with epinephrine 1:400,000)
Continuous infusion	0.1–0.2 mL/kg/h local anesthetic (i.e., ropivacaine 0.2%)

TABLE 47–3.

Beneficial Effects of Paravertebral Nerve Blocks

- Dense sensory, motor, and sympathetic nerve block
- Unilateral or bilateral segmental block
- Wide application for various surgical procedures
- Decreased stress response to surgery[35]
- Low postoperative opioid requirements[41,68,88]
- Infrequent opioid-related side effects (nausea, vomiting, sedation)[41,68,88]
- Postoperative analgesia similar or better than epidural[68,92]
- Hemodynamic stability[43,68]
- Preservation of pulmonary function[65,68]
- Preservation of lower-extremity motor strength
- Preservation of bladder function[43,68]
- Enhanced perioperative efficiency[31,42]

Cheema et al.[12] theorized that stratification of connective tissue within the thoracic PVS may lead to tracking of injectate such that small differences in needle placement could have important consequences. This was supported by Naja et al.[25] who hypothesized that the endothoracic fascia affects the spread of injectate and may function as a mechanical barrier to diffusion. This was inferred after two distinct patterns of spread of radiographic contrast dye were observed following thoracic PVB with a nerve stimulator. Longitudinal spread occurred more commonly in association with low nerve-stimulating current (0.5 mA), whereas localized, cloud-like spread occurred more commonly with higher nerve-stimulating current (2.5 mA). Although it was not known with certainty where injections were made relative to the endothoracic fascia, the authors conjectured that longitudinal spread was associated with injection anterior to the endothoracic fascia and that cloud-like spread was associated with injection dorsal to the endothoracic fascia. Because of the unpredictable variability in spread of block, more information about the anatomy, permeability, and importance of the endothoracic fascia within the PVS is required.

Local Anesthetic Regimen

Various local anesthetics can be used for PVBs. Bupivacaine and ropivacaine are the most frequently studied agents and the duration of analgesia is similar to that obtained with brachial plexus anesthesia. Ropivacaine has a sound safety profile and provides analgesia for 12–24 hours. Epinephrine is frequently added to the local anesthetic solution to indicate intravascular injection, to reduce the peak local anesthetic blood level,[30] and to improve analgesia. Epinephrine produces a 25% reduction in the mean peak arterial concentration of ropivacaine and delays the time to peak arterial and venous concentrations.[30] Some practitioners add opioids or clonidine to the local anesthetic mix;[31,32] however, this has not been extensively studied. Table 47–2 outlines standard dosing regimens. A single-level injection is typically performed with 0.5 mL/kg of dilute local anesthetic solution in children, and 10–20 mL in adults. Multiple-level injections are accomplished in adults with 3–4 mL of local anesthetic per segment in the thoracic region, and 5–7 mL per segment in the lumbar area. Continuous PVBs are managed with 0.1–0.2 mL/kg/h of dilute local anesthetic.

ADVANTAGES

Table 47–3 summarizes the advantages of PVBs. PVBs provide block of afferent nerve activity leading to dense body wall anesthesia and postoperative analgesia. Richardson et al.[33] performed somatosensory evoked potential testing on patients before and after they received a single-injection block. They discovered complete abolition of the evoked potentials at the level of the paravertebral injection in 100% of patients (Fig. 47–13). They commented that such reliable afferent block does not often occur following epidural anesthesia[34] and they postulated that by this mechanism, PVBs may prevent central sensitization and the development of chronic pain conditions.

PVBs also modify the stress response to surgical stimulation. Giesecke et al.[35] studied open cholecystectomy patients under general anesthesia and discovered that those who also received a single injection PVB had lower plasma adrenalin and cortisol concentrations ($p < 0.05$) as well as a smaller rise in plasma glucose concentration ($p < 0.025$) compared to similar patients who did not received PVBs.

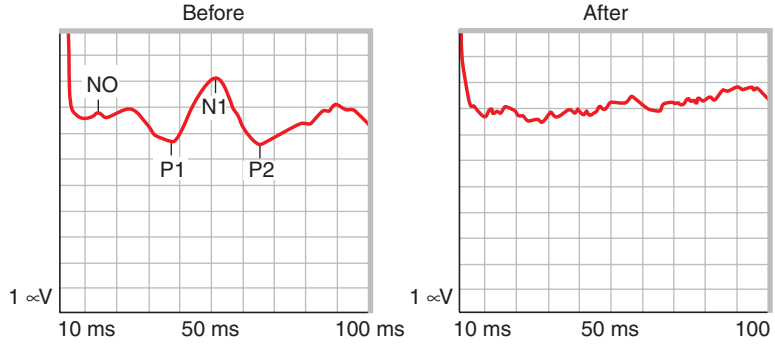

FIGURE 47–13. A somatosensory evoked potential recording from T3 before and after deposition of paravertebral bupivacaine at T2. Latencies and amplitudes were measured and the evoked potential was abolished after the block. (Reproduced with permission from Lippincott Williams & Wilkins. Richardson J, Jones J, Atkinson R.[33])

Patients who receive PVBs have lower postoperative opioid consumption and a reduced incidence of opioid-related side effects compared to those who receive intravenous opioid analgesia.[31,36–42] PVBs are associated with more frequent preservation of lower-extremity motor strength, greater hemodynamic stability, and less urinary retention when compared to epidural analgesia.[43] Additionally, this technique has the potential to provide improved analgesia with a reduced risk of pleural puncture and local anesthetic toxicity compared to intercostal and intrapleural analgesia.

CONTRAINDICATIONS

Absolute Contraindications

Absolute contraindications to use of PVBs[2,4] are similar to those of other percutaneous techniques. PVBs should be avoided in patients with skin infections at the proposed needle entry site and in those with an empyema or a deep infection within the chest. A paravertebral tumor is considered by some to contraindicate PVB because of the risk of tumor seeding. In addition, this technique is avoided in the setting of local anesthetic allergy, patient refusal, and severe hemodynamic instability.

Relative Contraindications

Relative contraindications[2,44] to use of PVBs include a severe chest deformity, such as kyphoscoliosis, which increases the risk of pneumothorax or unintentional subarachnoid injection. Similarly, patients who have had a prior thoracotomy are at higher risk of pleural puncture and pneumothorax because of paravertebral scarring and potential obliteration of the thoracic PVS. Nevertheless, operator experience and/or the use of fluoroscopy produces successful blocks in these circumstances with few complications. Coagulopathy represents a relative contraindication to PVB. Based on the increased compliance of the PVS compared with the epidural space, the neurologic impairment from a paravertebral hematoma will be less than from an epidural hematoma.[44]

ADVERSE EFFECTS

Potential complications for PVBs are summarized in Table 47–4. The incidence rates were obtained from several studies, including two large series.[8,9,41,45–49,51,52,55,61] Naja et al.[45] provide data on multilevel PVBs performed on 662 adult and pediatric patients using nerve stimulation. Lonnqvist et al.[46] reported their results from single-level PVBs performed with the loss-of-resistance technique in 367 adult and pediatric patients.

The most commonly reported adverse event is technique failure. A failure occurs when a PVB does not succeed in providing adequate surgical anesthesia or when general anesthesia is required to complete the procedure. The published incidence of block failure is 6.1–10.7%,[41,45–48] and is relatively similar among different operators and different institutions. Interestingly, the incidence of failure was slightly higher in a series in which a single-level PVB was performed using the loss-of-resistance technique (10.7%)[46] compared to a study in which multilevel PVBs were performed using nerve stimulation (6.1%).[45]

Unintentional vascular puncture occurs in up to 6.8% of PVBs,[45] and when recognized prior to injection of local anesthetic is of little consequence. Blood pressure and heart rate are generally maintained within normal limits after both unilateral and bilateral PVBs.[2] Hypotension has been reported in up to 5.0% of patients[46]; however, it is usually mild and easily managed. Other common side effects of PVBs include localized hematoma or pain at the site of injection. These are usually self-limiting and do not require treatment.

Unintentional pleural puncture can result from deep insertion of the nerve block needle. A pneumothorax may result and is considered a serious adverse event. An early warning sign includes cough during needle insertion. Aspiration of air occurs if the lung has been punctured or if air has been introduced into the pleural cavity by the needle.[2] Shortness of breath or pleuritic chest pain may follow the PVB. To establish the diagnosis and manage the pneumothorax, a chest radiograph is often required. Many pneumothoraces that result from PVBs are small and can be treated conservatively.[2] Although there are no studies directly comparing the incidence of pleural puncture or pneumothorax using various PVB techniques, the frequency in two large series can be contrasted. The incidence of pleural puncture and pneumothorax in adults were 0.9% and 0.3%, respectively, in the series of patients who received single-level PVBs using loss-of-resistance technique[46]; similarly, these adverse effects occurred in 0.8% and 0.5% in the series of adults who received multilevel PVBs using nerve

TABLE 47–4.

Incidence of Complications following Paravertebral Nerve Blocks[8,9,41,45–49,51,52,55,61]

Complication	Mean Incidence: Adult Patients (%)	Mean Incidence: Pediatric Patients (%)
Block failure[41,46]	6.1–10.7	0–6.2
Inadvertent vascular puncture[45,46]	3.8–6.8	0–4.2
Hypotension[45,46]	4.0–5.0	0
Localized hematoma[45,46]	2.4	0
Localized pain[45]	1.3	0

stimulation.[45] Performance of bilateral PVBs doubled the incidence of pneumothorax compared to unilateral PVBs.[45] Pulmonary hemorrhage is a rare respiratory complication that has been reported following PVB.[49] The risk of both pneumothorax and pulmonary hemorrhage is believed to be increased in patients who have an obliterated PVS from scar tissue as a result of previous thoracotomy.[49]

Studies on the spread of injectate within the PVS have shown spread of contrast dye into the epidural space in a variable proportion of patients;[8] however, the magnitude with which epidural block contributes to paravertebral anesthesia is unpredictable.[2,45,46] Subarachnoid injection,[50] total spinal anesthesia, and postdural puncture headache[51] are rare adverse events. They can result either from needle entry into the subarachnoid space or into dural extensions around the spinal nerve roots. The hemodynamic effects of an unintentional thoracic subarachnoid injection can be significant and may require deliberate resuscitation.

Extensive cephalad spread of local anesthetic to the brachial plexus or the stellate ganglion may occur and result in a brachial plexus block[2] or Horner syndrome,[23] respectively. These effects are temporary and patients should be reassured.

Systemic absorption of local anesthetic with resulting toxicity is rare.[52] Local anesthetic plasma levels following paravertebral injections have been extensively studied. Following a bolus dose of 0.75–1.5 mg/kg bupivacaine, mean peak serum levels varied from 0.705 μg/mL[53] to 1.45 μg/mL[54] in adults, and from 1.03 μg/mL[55] to 1.60 μg/mL[56] in children. Karmakar et al. administered a single-level PVB with 2 mg/kg ropivacaine and randomized patients to receive a solution with or without epinephrine. They found that epinephrine decreased mean peak serum concentration of ropivacaine from 2.47 μg/mL to 1.85 μg/mL and increased mean time to peak serum concentration from 7.5 minutes to 11.25 minutes.[30] In other studies, the median time to peak plasma bupivacaine levels ranged from 5 minutes[53] to 25 minutes.[54] Continuous infusion of 0.2–0.5 mg/kg/h of bupivacaine for up to 4 days results in variable mean peak plasma bupivacaine levels. Several studies of adult and pediatric patients report levels between 1.6 μg/mL and 2.5 μg/mL.[55–57] However, other investigators have found mean peak plasma bupivacaine concentrations as high as 5.43 μg/mL,[54,58] with some individuals as high as 7.48 μg/mL.[54] Despite these high plasma concentrations, no patients in these studies manifested clinical signs of local anesthetic systemic toxicity. Although total bupivacaine increases steadily during paravertebral infusion, free bupivacaine remains unchanged[57] as a result of a perioperative increase in α_1-acid glycoprotein, a serum protein that binds local anesthetics. This may explain the low incidence of clinical local anesthetic systemic toxicity seen even among patients with plasma bupivacaine concentrations that are considered above the toxic threshold. Chapter 44 fully discusses the diagnosis and management of local anesthetic toxicity.

There are case reports of serious neurologic complications related to PVBs. Cases of incomplete transverse myelitis occurred in association with the use of efocaine,[59] whereas a Brown-Sequard syndrome resulted from paravertebral injection of alcohol.[60] In more recent publications, neurologic injury is rarely reported.[45,46] There is only one case report of chronic segmental pain following PVBs[61]; some authors,[23] however, believe that this complication occurs more frequently but is often attributed to nerve injury from surgical dissection.

CLINICAL APPLICATIONS

Table 47–1 summarizes the various indications for PVBs, which are described in detail below.

Thoracic Surgery

The use of PVBs for postoperative analgesia following thoracotomy has been investigated in both adults[36–40] and children.[55,62] A commonly used approach involves preoperative PVBs to provide intraoperative analgesia in addition to a continuous local anesthetic infusion via a paravertebral catheter for postoperative analgesia. Preoperative PVBs are performed to provide sensory block from T4 to T9. This can be achieved with either single or multiple level injections. A paravertebral catheter can either be placed percutaneously by the anesthesiologist preoperatively or by the thoracic surgeon under direct vision at the time of chest closure.

In a prospective, randomized, placebo-controlled trial, Berrisford et al.[36] documented the beneficial effects of continuous PVBs for thoracotomy patients. They found lower pain scores ($p < 0.01$), reduced opioid consumption (8.6 mg vs. 119 mg over 5 days), fewer postoperative pulmonary complications (8% vs. 52.4%; $p < 0.05$) and better preservation of pulmonary function ($p < 0.01$) in the group who received bupivacaine compared to saline. Comparable results were obtained in a number of studies with similar design.[37–40] An additional advantage of PVBs involves a potential reduction in the incidence of postthoracotomy neuralgia.[63]

Continuous PVBs have a number of theoretical advantages over both continuous interpleural and intercostal blocks. The PVBs more reliably achieve block of the dorsal ramus of the spinal nerve. This is important as much of the pain that results from thoracotomy stems from the paraspinal muscles and other areas innervated by the dorsal ramus. In addition, greater cephalocaudal spread of local anesthetic occurs and results in more extensive block with continuous PVB compared to the other two modalities.[64] Despite these theoretical advantages, prospective studies comparing continuous PVBs versus interpleural[65] and versus intercostal[66] infusions of local anesthetic failed to show a difference between groups in pain scores and opioid consumption. Nevertheless, PVBs were associated with better preservation of lung function as measured by forced vital capacity and forced expiratory volume in 1 second.[65]

Continuous PVBs have also been compared to intermittent boluses of epidural morphine for postthoracotomy analgesia. Dauphin et al.[67] found that these two modalities resulted in similar pain scores and supplemental intravenous morphine consumption.

A number of prospective, randomized trials exist comparing continuous PVBs (local anesthetic alone) versus epidurals (local anesthetic with or without opioid).[43,68–70] In a study by Richardson et al.,[68] the group receiving PVBs had lower postoperative pain scores at rest ($p = 0.02$) and with coughing ($p =$

0.0001) as well as lower cumulative morphine consumption over 48 hours ($p \leq 0.008$). However, Bimston et al.[70] failed to replicate these findings. A number of investigators have shown a lower incidence of side effects such as nausea,[68] vomiting,[68] hypotension,[43,68] and urinary retention[43,68,70] with PVBs compared to epidurals.

Studies of the effects of PVBs on postoperative lung function are conflicting and further investigation is still necessary. Richardson et al.[68] documented that the postoperative peak expiratory flow rate as a fraction of preoperative value was 0.73 in the PVB group compared to 0.54 in the epidural group ($p < 0.004$), suggesting better preservation of lung function with PVBs. In contrast, Kaiser et al.[69] measured pre- and postoperative forced vital capacity and forced expiratory volume in 1 second and found no significant different between the two modalities.

In addition to their usefulness for thoracotomies, PVBs also have been used successfully for other indications. In a prospective, randomized, placebo-controlled trial of patients having pleurectomy, Mozell et al.[71] established that continuous PVB with bupivacaine provided lower pain scores, reduced opioid consumption and better preservation of pulmonary function than placebo. Paravertebral analgesia has also been used to provide analgesia for rib fractures in patients with head[72] and spinal cord[73] injuries. In patients with head injury, paravertebral analgesia reduced the need for potentially sedating analgesics and enhanced neurologic assessment.[72] Unilateral PVBs were administered instead of an epidural block in patients with lumbar spinal cord injury because the PVBs enhanced assessment of lumbosacral spinal cord function.[73] Moreover, paravertebral analgesia provides quality analgesia and has beneficial effects on pulmonary function among patients with traumatic chest injury.[74] Additional applications have been in the treatment of pain following thoracoscopy[75] and in the management of chest pain caused by pleural effusion.[76]

Breast Surgery

PVBs can be used as the sole intraoperative anesthetic or as an analgesic supplement to general anesthesia for breast surgery. The block may be performed as a single injection or as injections at multiple levels. The dermatomal levels blocked depend on the surgical procedure (Table 47–1). A block of T2-6 is required for mastectomy. When mastectomy and axillary dissection is scheduled, extending the block to include the T1 dermatome is essential. Supplementing with a superficial cervical plexus block can also enhance analgesia at the superior aspect of the incision. Breast biopsy requires block of the dermatome involved in addition to 1 level cephalad and 1 level caudad. Long-acting local anesthetics such as ropivacaine or bupivacaine can provide postoperative analgesia for up to 23 hours.[77]

A number of prospective, randomized trials exist comparing general anesthesia versus PVBs for breast surgery.[31,41,42,78] Pusch et al.[41] performed a single injection block with bupivacaine using the loss of resistance technique at T4 in patients having breast cancer surgery. They found rapid onset of block with skin incision occurring within 15 minutes of the block. Additionally, they documented a shorter emergence time in the group who had PVBs ($p < 0.01$). The PVB group had lower pain scores during the 13 hours of the study ($p < 0.05$) and received fewer analgesics ($p < 0.01$). There was less-painful restricted motion ($p < 0.001$) and a reduced incidence of postoperative nausea and vomiting ($p < 0.05$) in the PVB group. Paravertebral anesthesia with propofol sedation was inadequate in 6% of patients; however, in these patients, supplemental analgesia with intravenous fentanyl was sufficient to avoid conversion to general anesthesia. Naja et al.[31] used a nerve stimulator and performed injections at multiple levels with a mixture of lidocaine, bupivacaine, epinephrine, fentanyl, and clonidine. They showed an analgesic benefit for the first 5 days postoperatively and also documented a shorter length of hospital stay among patients who received PVBs ($p < 0.01$). Klein et al.[42] studied patients having unilateral or bilateral cosmetic and reconstructive breast surgery and also showed similar benefits including lower verbal pain scores up to 72 hours after surgery. In addition, they were able to reduce intraoperative induction time from 24 minutes with general anesthesia to 4 minutes with PVBs by using a preoperative block area. Terheggen et al.[78] studied patients having minor breast surgery and performed PVB with bupivacaine via a catheter placed at T3-4. The PVBs reduced intraoperative fentanyl requirements and lowered postoperative pain scores only in the first 90 minutes. Thereafter, pain was minimal.

Hernia Repair

PVBs can be used for surgical anesthesia or for analgesia as a supplement to general anesthesia for inguinal, umbilical, or incisional hernia repair. When performed for inguinal hernia repair, block of the T10 through L2 dermatomes is typically required. This can be achieved by a single injection in the low thoracic PVS or by injections at multiple levels.

Two prospective series provided evidence for the safety and efficacy of PVBs used as the sole anesthetic for inguinal hernia repair.[79,80] Klein et al.[79] demonstrated that bupivacaine PVBs provide surgical anesthesia within 15–30 minutes and prolonged postoperative analgesia with a mean time to first opioid of 22 hours. In a study by Weltz et al.,[80] the failure rate requiring conversion to general anesthesia was 6.7%; however, these investigators documented low pain scores for 48 hours postoperatively. Two prospective studies have evaluated the efficacy of PVBs compared to other anesthetic techniques for inguinal hernia repair. In a nonrandomized study, Naja et al.[81] compared multilevel PVBs from T12 to L2 versus general anesthesia versus spinal anesthesia. The patients in the PVB group had better postoperative analgesia, a lower incidence of postoperative nausea and vomiting (0 [PVB] vs. 21% [general anesthesia] vs. 19% [spinal anesthesia]; $p < 0.001$) and a shorter duration of hospital stay (1.2 days [PVB] vs 2.9 days [general anesthesia] vs. 2.5 days [spinal anesthesia]; $p < 0.0001$). Although Naja et al. did not comment on this, another potential advantage of PVBs over spinal anesthesia involves a lower incidence of postoperative urinary retention. In a randomized trial, Wassef et al.[82] compared lidocaine PVBs to field blocks performed with both lidocaine and bupivacaine. The PVBs were associated with less-frequent intraoperative supplementation (20% vs. 41%; $p < 0.01$), a lower rate of conversion to general anesthesia (0 vs. 6.7%) and greater patient satisfaction ($p < 0.05$).

Alternatively, PVBs can supplement another primary anesthetic technique

(e.g., general or spinal anesthesia) to provide postoperative analgesia. In a prospective, randomized study of patients having inguinal hernia repair under general anesthesia, Klein et al.[83] compared postoperative analgesia from ropivacaine PVBs to ilioinguinal-iliohypogastric nerve blocks with wound infiltration. They found reduced opioid consumption intraoperatively ($p = 0.02$) and in the postanesthesia care unit ($p = 0.002$), as well as a lower antiemetic use ($p < 0.001$), in the PVB group; however, there was no subsequent difference in pain scores and opioid use.

When PVBs are used for repair of umbilical hernias of moderate size, a bilateral block from T9 to T11 is required. In a nonrandomized study, Naja et al.[32] compared PVB to general anesthesia. PVBs were performed using a nerve stimulator and a mixture of lidocaine, bupivacaine, epinephrine, fentanyl, and clonidine. Interestingly, 10% of patients in the PVB group required supplemental analgesia as a result of unanticipated extension of the surgical field. Nevertheless, PVBs had a number of benefits, including lower pain scores and reduced opioid requirements, for up to 48 hours ($p < 0.001$). PVBs were also associated with a decreased incidence of postoperative nausea and vomiting (3.3% vs. 26.7%; $p < 0.05$) and shorter length of hospital admission (2.3 days vs. 4.1 days; $p < 0.05$).

Finally, PVBs can be used for incisional hernia repair and are performed according to the dermatomal levels involved. Block from T8 to T12 has also been employed for ileostomy closure.[84]

Renal Surgery

Unilateral PVBs are well-suited to provide postoperative analgesia following renal surgery. A catheter for continuous local anesthetic infusion can be placed percutaneously by the anesthesiologist preoperatively. Alternatively, a catheter can be placed under direct vision by the surgeon at the time of wound closure.[85] This is accomplished by lifting the psoas fascia from the lateral edge of the incision to the lateral border of the vertebral bodies, continuing this dissection cephalad, inserting an epidural catheter percutaneously and advancing it cranially within the PVS. In a randomized, prospective, placebo-controlled trial, Awwad et al.[85] found reduced pain scores for 3 days ($p < 0.026$) and decreased opioid consumption (13.3 mg vs. 40.13 mg over 3 days; $p < 0.001$) in the group who received continuous PVB with bupivacaine when compared to saline. Lonnqvist et al.[86,87] have used continuous PVBs in children having renal surgery. In a nonrandomized study, they compared the postoperative analgesia obtained from paravertebral versus epidural bupivacaine[87] and found decreased opioid consumption in the PVB group.

Cholecystectomy

Few studies exist that evaluate the efficacy of PVBs for postoperative analgesia following open cholecystectomy by subcostal incision. Giesecke et al.[35] suggest that PVBs reduce the stress response to surgery; however, Bigler et al.[61] found no benefit from continuous PVB when compared to thoracic epidural. More recently, PVBs have been used to provide postoperative analgesia for laparoscopic cholecystectomy. In a prospective, randomized study Naja et al.[88] randomized patients receiving general anesthesia to have PVBs or opioid analgesia. Although there was no difference between groups in time to first oral intake or length of hospital stay, patients who received PVBs had lower pain scores ($p < 0.05$), reduced opioid consumption over 36 hours ($p < 0.05$), and a decreased incidence of postoperative nausea and vomiting ($p < 0.05$).

Orthopedic Surgery

PVBs can be used as an adjunct to other peripheral nerve blocks or as the sole regional technique for the treatment of postoperative pain in orthopedic patients. In patients receiving an interscalene brachial plexus block for shoulder surgery, the addition of T1-2 PVBs provides more complete shoulder analgesia. And, in combination with a lumbar plexus block, T11-12 PVBs provide more comprehensive analgesia for patients having hip surgery. Alternatively, PVBs from T12 to L4 and from L2 to S1 have been used to provide postoperative analgesia following total hip and knee arthroplasty, respectively.[89]

Bone Marrow Aspiration

Bilateral PVBs from T11-L2 can be used to provide intraoperative anesthesia and postoperative analgesia for patients having bone marrow aspiration. This technique provides an alternative option when general and/or spinal anesthesia are contraindicated (e.g., mediastinal tumor and chemotherapy-related thrombocytopenia).

Cardiac and Vascular Surgery

PVBs have been used both for analgesia following cardiac surgery and for peripheral vascular procedures.

In a prospective, observational study, Canto et al.[90] performed continuous bilateral ropivacaine PVBs at T3-4 for patients having open-heart surgery with cardiopulmonary bypass. They reported excellent analgesia, a low complication rate, and facilitation of early tracheal extubation. Moderate hypotension and bradycardia were repeatedly observed and presumed because of sympathectomy; however, dopamine support was required in only 6.4% of patients.

Bilateral T4-5 continuous PVBs have also been successfully used for postoperative analgesia following minimally invasive coronary artery bypass.[91] In a prospective, randomized trial, Dhole et al.[92] compared continuous PVB versus epidural analgesia and found no significant differences between the techniques with respect to analgesia.

Paravertebral analgesia following major abdominal vascular surgery was described in an observational study by Richardson et al.[93] They placed bilateral paravertebral catheters at T10 in 8 patients and administered an infusion of bupivacaine. The continuous PVBs provided excellent postoperative analgesia with preserved hemodynamic stability.

Hepatic Surgery

In a case report, Ho et al.[94] describe the use of a right thoracic paravertebral catheter for hepatectomy and cite their preference for this technique over epidural analgesia in patients who have or may develop a coagulopathy.

In an additional case report, Hall et al.[95] illustrate the use of continuous paravertebral analgesia for the pain associated with a traumatic liver fracture managed conservatively.

Labor Analgesia for Obstetrics

Bilateral PVBs have been used to provide analgesia for laboring obstetrical patients in whom epidural anesthesia is unattainable or contraindicated. In a case series, Nair et al.[96] described using bilateral T11 and T12 PVBs to obtain labor analgesia for patients with coagulation abnormalities (prolonged bleeding time, syndrome of hemolysis, elevated liver enzymes, and low platelets) and lumbar spinal anomalies

(neuroblastoma, spina bifida occulta). Suelto et al.[97] underline the limitation of this technique in providing analgesia for the second stage of labor as well as for caesarian section.

Chronic Pain

Several authors have published descriptions of the use of PVBs in the management of chronic pain. Kirvela et al.[98] provided retrospective information on 32 patients having 281 PVBs for chronic chest wall pain. Results were similar for those patients with postthoracotomy chest pain and those with postmastectomy pain. Among the thoracic surgical patients, immediate pain relief occurred in 99% of cases; however, prolonged pain relief was rare: 58% were pain free at 1 month, 30% at 2 months, 8% at 4 months, and only 3% at 5 months. Among the breast cancer patients, 88% were pain free for less than 1 month and only 6% were pain free for more than 5 months. Antila et al.[99] observed similar results in a population of patients who had chronic thoracic pain related to malignant disease with poor prognosis. Limited data exist on the use of PVBs for pain relief from acute herpes zoster[100] and postherpetic neuralgia.[101] Neurolytic PVBs are generally avoided because of the risk of neurologic damage.

CONCLUSION

The PVB is a technique that offers dense, long-lasting, segmental anesthesia and analgesia. This block takes advantage of the unique anatomical structure and contents of the PVS. Local anesthetic is delivered at discrete locations to achieve site-specific block of both the dorsal and ventral rami, as well as the sympathetic chain. In contrast to neuraxial techniques, PVBs offer the flexibility of either unilateral or bilateral blockade and avoid many of the side effects associated with more centrally administered local anesthetics.[43,68,70] The density of the achieved block is highlighted in the profound analgesia that results and in the mitigation of the surgical stress response.[35] Despite these advantages, the greatest impediments to wider scale adoption of this technique are the low but consistent failure rate of up to 10%[46] and the concern of pneumothorax.

By peripherally targeting individual nerve roots or segmental innervation the technique has wide-scale applicability for nearly all procedures of the thorax and abdomen, as well as the lower extremities. It has been most extensively studied after thoracotomy, demonstrating profound block, excellent analgesia, opioid sparing and reduction in opioid- and epidural-related side effects.[36–40] In addition, PVBs offer better preservation of pulmonary function and a reduced frequency of postoperative pulmonary complications.[36–40] The magnitude of these outcome differences suggests that PVBs are underused, particularly in procedures such as thoracic surgery where iatrogenic pneumothorax is of limited concern.

The technique of PVB has also been validated as an effective sole intraoperative anesthetic and as an analgesic adjunct for breast surgery[31,41,42,78] and inguinal hernia repair,[79–82] two of the most commonly performed outpatient surgical procedures. When used for ambulatory surgery, PVBs facilitate recovery and have the potential to hasten discharge and reduce costs. Efficacious results have also been produced for procedures as diverse as cardiac surgery,[90,91] cholecystecomy,[35,61,88] and labor.[96] In short, the ability to provide site-specific segmental anesthesia makes PVB one of the most useful and broadly applicable peripheral nerve block techniques.

CHAPTER 48

Peripheral Nerve Blocks*

Denise J. Wedel, MD, and
Terese T. Horlocker, MD

The techniques of peripheral neural blockade were developed early in the history of anesthesia. American surgeons Halsted and Hall[1,2] described the injection of cocaine into peripheral sites, including the ulnar, musculocutaneous, supratrochlear, and infraorbital nerves, for minor surgical procedures in the 1880s. James Leonard Corning[3] recommended the use of an Esmarch bandage in 1885 to arrest local circulation, thus prolonging the cocaine-induced block and decreasing the uptake of that local anesthetic from the tissues. This concept was furthered by Heinrich F.W. Braun,[4] who substituted epinephrine, a "chemical tourniquet," in 1903. Braun[5] also introduced the term *conduction anesthesia* in his 1905 textbook on local anesthesia, which described techniques for every region of the body. In 1920, the French surgeon, Gaston Labat, was invited by Charles Mayo to teach innovative methods of regional anesthesia at the Mayo Clinic. During his appointment there, Labat authored *Regional Anesthesia: Its Technic and Application*.[6] Published in 1922, Labat's text popularized regional anesthesia in the United States by describing techniques already familiar to European surgeons and anesthesiologists. Importantly, Labat described the use of infiltration, peripheral, plexus, and splanchnic blockade (using cocaine and procaine) for surgery to the head and neck, intrathoracic, intraabdominal, and extremities, as general and neuraxial anesthesia were not widely accepted and/or considered more dangerous. Thus, while the techniques of peripheral neural blockade were developed early in the history of anesthesia, the improved safety of neuraxial and general anesthesia supplanted their use and their application diminished.

*Modified with permission from Wedel DJ, Horlocker TT: Nerve blocks. In: Miller RD, ed. Anesthesia. 6th ed. Philadelphia: Churchill Livingston, 2005:1685–1717.

The introduction of long-acting local anesthetics and adjuvants, the refinement of imaging modalities to facilitate neural localization, as well as innovations in equipment technology, including stimulating needles and catheters and portable infusion devices, have increased the success rate and popularity of peripheral blockade. Undoubtedly, peripheral nerve blocks represent a new era in regional anesthesia and analgesia. Competence in these techniques is crucial to future practice models.

Peripheral blockade is a well-accepted component of comprehensive anesthetic care, with a role not only within the operating suite, but also within the arena of postoperative and chronic pain management. With appropriate selection and sedation, these techniques can be used in all age groups. Skillful application of peripheral neural blockade broadens the anesthesiologist's range of options in providing optimal anesthetic care.

TECHNIQUES FOR LOCALIZING NEURAL STRUCTURES

Several methods of needle localization have been described, including fascial "pops," elicitation of one or more paresthesias, perivascular/transarterial injection, electrical stimulation, and field infiltration. More recently, direct imaging using ultrasonography, fluoroscopy, computer tomography (CT), and magnetic resonance imaging (MRI) have been used. Although there is no definitive study that identifies the "best" method for needle placement, generalities are possible. For example, elicitation of a paresthesia appears to be equivalent to electrical stimulation. Success rate and onset time with both paresthesia and nerve stimulation techniques are further improved if multiple injections are performed.[7] A recent Cochrane review evaluating single-, double-, and multiple-injection techniques for axillary block reported that multiple-injection techniques were associated with fewer block failures and improved motor blockade compared to both single and double injections.[8] Conversely, the time to perform single injection is less, but the time required to perform supplementary blocks increased the time to readiness for surgery. Unfortunately, there are insufficient data to compare other outcomes, such as safety.[8] Although used chiefly for axillary blockade, transarterial injection is variably successful; a two-injection transarterial technique

KEY POINTS

1. In performing peripheral nerve blocks, elicitation of a paresthesia is equivalent to electrical stimulation. Success rate and onset time are improved if multiple stimulations are performed, particularly with axillary blockade.
2. The use of ultrasonography for peripheral blockade improves the quality of blockade and decreases onset time. However, overall success rate is not substantially altered.
3. The role of stimulating versus nonstimulating catheters for continuous peripheral nerve blocks to improve success rate is an active area of research.
4. Diaphragmatic paresis in 100% of patients undergoing interscalene block, even with dilute local anesthetic solutions. Phrenic nerve paresis has also been reported following both supraclavicular and infraclavicular approaches, but with less frequency.
5. Continuous lower-extremity peripheral blockade consistently provides superior analgesia compared to conventional systemic opioid therapy. In addition, continuous femoral nerve block improves outcome and rehabilitation following total knee replacement and is superior to epidural analgesia.
6. Because the sciatic nerve divides into its tibial and peroneal components 7–10 cm above the knee, popliteal fossa block should be performed at this level.
7. Total local anesthetic dosage should be determined and kept within acceptable limits. Accumulation with time may occur with continuous techniques.
8. The frequency of neurologic complications following peripheral blockade is less than that associated with neuraxial techniques. Neurotoxicity and direct-needle trauma are the major etiologies of neurologic complications.

is comparable to either single-injection paresthesia or nerve stimulator approaches. Finally, success rate with a fascial pop or click is variable and may be more reliable in pediatric (compared to adult) patients.[7]

Ultrasound guidance (with and without neural stimulation) is increasing used for peripheral blockade. Initial applications involved upper-extremity techniques, because of capability of the ultrasound to penetrate relatively superficial soft-tissue structures.[9,10] However, visualization of lower-extremity anatomy was recently described.[11] Major advantages of ultrasonography include the ability to identify the neural structure, eliminating the need for "blind" needle placement, and observance of the spread of local anesthetic during injection. For example, investigators have noted that equal distribution of local anesthetic within the neural sheath is associated with successful block.[12] Real-time visualization of local anesthetic spread during injection allows the proceduralist to redirect the needle, as necessary to assure adequate distribution. The overall usefulness of ultrasonography remains to be determined. Existing knowledge suggests that ultrasound-guided blockade may be associated with a decreased performance time and local anesthetic requirement, more rapid onset, and superior quality blockade compared to nerve stimulation alone. However, overall success rate has not been reportedly increased. Importantly, neural structures are not always visualized by ultrasonography and in obese patients or "deep" techniques, such as psoas compartment or proximal sciatic blockade. Thus, ultrasound guidance is not possible in patients in whom the technique would be theoretically most useful.[13,14]

CHOICE OF LOCAL ANESTHETIC

The choice of local anesthetic for a peripheral nerve block obviously depends to some degree on the duration of the surgical procedure; however, other factors are also important. Local anesthetic and the addition of adjuvants for peripheral nerve block are dependent on the anticipated duration of surgery, the need for prolonged analgesia, and the timing of ambulation/weight-bearing postoperatively. Prolonged blockade for 24 hours (or greater) may occur with long-acting agents such as bupivacaine, levobupivacaine, or ropivacaine. Although this feature may result in excellent postoperative pain relief for the inpatient, it may be undesirable or cause for concern in the ambulatory patient because of the potential for falls with a partially insensate/weak lower extremity. Likewise, prolonged upper-extremity blockade may impede the ability to perform daily tasks, such as dressing and grooming. Consequently, a medium-acting agent may be more appropriate in the outpatient setting for orthopedic procedures with minimal to moderate postoperative pain. In general, equipotent concentrations of the long-acting amides have a similar onset and quality of block. However, bupivacaine may have a slightly longer duration than levobupivacaine or ropivacaine. Likewise, higher concentrations are more likely to be associated with profound sensory *and* motor block, whereas infusions of 0.1–0.2% bupivacaine or ropivacaine may not result in motor blockade (and allow complete weight bearing with lower-extremity techniques). Recent investigations suggest that increasing the local anesthetic concentration alters the character (i.e., degree of sensory and/or motor block), but not the duration.

The lowest effective dose and concentration should be used to minimize local anesthetic systemic and neural toxicity. It is important to note that the recommendations for maximum doses of local anesthetics were established by the manufacturers (Table 48–1).[15] Maximum doses based on patient weight (with the exception of the pediatric population) also are not evidence based. Recommendations for 24-hour doses of local anesthetics also were established without controlled studies. In essence, the safe dose of a local anesthetic should be individualized based on site of injection, patient age, and the presence of medical conditions that affect local anesthetic pharmacology and toxicity. These considerations are believed to be most critical when large doses of local anesthetics are injected, or in association with repeated blocks/continuous infusions because of the potential for local anesthetic accumulation.

Adjuvants

Epinephrine

Epinephrine decreases local anesthetic uptake and plasma levels, improves the quality of block, and increases the duration of postoperative analgesia during lower-extremity peripheral blockade.

TABLE 48–1.

Recommended Maximum Doses of Local Anesthetics

Local Anesthetic	Maximum Dose (mg)
2-chloroprocaine	800
With epinephrine	1000
Lidocaine	300
With epinephrine	500
Mepivacaine	400
With epinephrine	550
Bupivacaine	175
	400 mg/24 h
With epinephrine	225
Levobupivacaine	150
	400 mg/24 h
With epinephrine	NA
Ropivacaine	225
	800 mg/24 h
With epinephrine	225

Epinephrine also allows for the early detection of intravascular injection. Importantly, concentrations of epinephrine ranging from 1.7–5 μg/mL (1:600,000 to 1:200,000 dilution) reduce the uptake and prolong the blockade of medium duration local anesthetics to a similar extent. However, concentrations of 1.7–2.5 μg/mL have little effect on nerve blood flow, which theoretically may reduce the risk of nerve injury for patients with a preexisting angiopathy or neuropathy. In addition, larger doses of epinephrine injected systemically may cause undesirable side effects in patients with known cardiac disease. Concerns regarding neural or cardiac ischemia must be balanced with the need to detect intravascular injection. In general, because of the high doses of local anesthetics administered during peripheral block, the benefits of adding epinephrine outweigh the risks.[16]

Commercially prepared solutions with epinephrine have a lower pH than those in which it is freshly added, resulting in a higher percentage of ionized drug molecules. These ionized molecules do not readily cross the neural membrane, delaying the onset of local anesthetic action after injection. Epinephrine should not be added for ankle block. The addition of epineph-

rine to local anesthetics with intrinsic vasoconstrictive properties, such as ropivacaine, may not increase block duration, but would still facilitate detection of intravascular injection.

Clonidine

Clonidine consistently prolongs the time to first analgesia when added to intermediate-acting agents during brachial plexus blockade. The effect is most likely peripherally mediated and dose dependent. Side effects such as hypotension, bradycardia, and sedation do not occur with a dose less than 1.5 μg/kg or with a maximum dose of 150 μg. Conversely, the efficacy of clonidine as an adjuvant for lower-extremity single injection and continuous techniques is less defined. Most studies report a modest (20%) prolongation with the addition of clonidine to long-acting local anesthetic solutions.[7,14,17]

Opioids

Although opioids, including morphine, sufentanil, and fentanyl, are often added to lumbar plexus infusions, there are no convincing data to suggest that block onset, quality, or duration is improved when opioids are added to the local anesthetic solution.[7,14]

Systemic Local Anesthetic Toxicity

The potential for systemic local anesthetic toxicity would seem to be very high for peripheral nerve blocks because of the relatively large doses of local anesthetic commonly injected and the proximity of needle/catheter insertion to vascular structures and highly vascularized muscle beds. The few cases of systemic toxicity requiring resuscitation occurred shortly after injection, suggesting that it is accidental intravascular injection, rather than systemic absorption, that is the mechanism. Prevention and treatment of local anesthetic toxicity is dependent on the injection of an appropriate volume and concentration of local anesthetic, the use of a vasoconstrictor adjuvant slow injection with frequent aspiration, and increased vigilance for the early detection and treatment of toxic reactions. It is notable that local anesthetic levels peak at approximately 60 minutes following deposition following peripheral block. Thus, patients should be appropriately monitored for signs and symptoms of rising blood levels for this duration. Resuscitation equipment and medications should also be readily available.

UPPER-EXTREMITY BLOCKS

Successful regional anesthesia of the upper extremity requires knowledge of brachial plexus anatomy from its origin as the nerves emerge from the intervertebral foramina to its termination in the peripheral nerves. Detailed anatomic knowledge enables the anesthesiologist to choose the appropriate technique for the intended surgical procedure and to salvage "inadequate" blocks with local anesthetic supplementation. Without mastery of the anatomy, luck rather than skill will be the primary determinant of successful neural blockade. Also important is an understanding of the side effects and complications of upper-extremity regional techniques, as well as the clinical application of available local anesthetics for these blocks. Finally, one must not underestimate the role of appropriate sedation during placement of the block as well as during the surgical procedure. Many a "perfect" regional anesthetic technique has been undone by inadequate management of sedation.

Cervical Plexus Blockade

Blockade of the cervical plexus is briefly discussed because of the overlapping innervation of the cervical and brachial plexus. Supplementation of a proximal brachial plexus technique with a deep or superficial cervical plexus block is often required to assure complete blockade of the surgical site.

The cervical plexus is derived from the C1, C2, C3, and C4 spinal nerves and supplies branches to the prevertebral muscles, strap muscles of the neck, and phrenic nerve. The deep cervical plexus supplies the musculature of the neck segmentally, as well as the cutaneous sensation of the skin between the trigeminally innervated face and the T2 dermatome of the trunk. Blockade of the superficial cervical plexus results in anesthesia of only the cutaneous nerves.

Clinical Applications

Blocks of the cervical plexus are easy to perform and provide anesthesia for surgical procedures in the distribution of C2 to C4, including lymph node dissections, plastic repairs, and carotid endarterectomy. The ability to monitor the awake patient's neurologic status continuously is an advantage of this anesthetic technique for the latter procedure and has resulted in an upsurge in the popularity of this technique.[18,19] Bilateral blocks can be used for tracheostomy and thyroidectomy.

Techniques

Superficial Cervical Plexus The superficial cervical plexus is blocked at the midpoint of the posterior border of the sternocleidomastoid muscle. A skin wheal is made at this point, and a 22-gauge, 4-cm needle is advanced, injecting 5 mL of solution along the posterior border and medial surface of the sternocleidomastoid muscle (Fig. 48–1). It is possible to block the acces-

sory nerve with this injection, resulting in temporary ipsilateral trapezius muscle paralysis.

Deep Cervical Plexus The deep cervical plexus block is a paravertebral block of the C2 to C4 spinal nerves as they emerge from their foramina in the cervical vertebrae (Fig. 48–2). The traditional approach uses three separate injections at C2, C3, and C4. The patient lies supine with the neck slightly extended and the head turned away from the side to be blocked. A line is drawn connecting the tip of the mastoid process and the Chassaignac tubercle (transverse process of C6); a second line is drawn 1 cm posterior to this first line. The C2 transverse process lies 1–2 cm caudad to the mastoid process, where it can usually be palpated. The C3 and C4 transverse processes lie at 1.5-cm intervals along the second line. After skin wheals are raised over the transverse processes of C2, C3, and C4, three 22-gauge, 5-cm needles are advanced perpendicular to the skin entry site with a slight caudad angulation. The transverse process is contacted at a depth of 1.5–3 cm. If a paresthesia is obtained, 3–4 mL of solution is injected after careful aspiration for blood and cerebrospinal fluid. If no paresthesia is elicited initially, the needle is walked along the transverse process in the anteroposterior plane until a paresthesia is obtained.

This block can also be performed with a single injection of 10–12 mL at the C4 transverse process.[20] Cephalad spread of the local anesthetic usually anesthetizes the C2 and C3 nerves. Cervical plexus anesthesia can also be observed after injection at the interscalene level for brachial plexus blockade. Maintenance of distal pressure and a horizontal or slightly head-down position may facilitate the onset of cervical plexus blockade using the interscalene technique.

Side Effects/Complications

Although these blocks are technically straightforward, needle placement for the deep cervical block allows local anesthetic injection in close proximity to a variety of neural and vascular structures. Reported complications and side effects include intravascular injection, blockade of the phrenic and superior laryngeal nerve, and spread of local anesthetic solution into the epidural and subarachnoid spaces.

Brachial Plexus Anatomy

The brachial plexus is derived from the anterior primary rami of the fifth, sixth, seventh, and eighth cervical nerves and the first thoracic nerve, with variable contributions from the fourth cervical and second thoracic nerves. After leaving their intervertebral foramina, these nerves course anterolaterally and inferiorly to lie between the anterior and middle scalene muscles, which arise from the anterior and posterior tubercles of the cervical vertebra, respectively. The anterior scalene muscle passes caudad and laterally to insert into the scalene tubercle of the first rib; the middle scalene muscle inserts on the first rib posterior to the subclavian artery, which passes between these two scalene muscles along the subclavian groove. The prevertebral fascia invests both the anterior and middle scalene muscles, fusing laterally to enclose the brachial plexus in a fascial sheath.

Between the scalene muscles, these nerve roots unite to form three trunks, which emerge from the interscalene space to lie cephaloposterior to the subclavian artery as it courses along the upper surface of the first rib. Therefore, the "superior" (C5 and C6), "middle" (C7), and "inferior" (C8 and T1) trunks are arranged accordingly and are not in a strict horizontal formation, as often depicted. At the lateral edge of the first rib, each trunk forms anterior and posterior divisions that pass posterior to the midportion of the clavicle to enter the axilla. Within the axilla, these divisions form the lateral, posterior, and medial cords, named for their relationship with the second part of the axillary artery. The superior divisions from the superior and middle trunks form the lateral cord, the inferior divisions from all three trunks form the posterior cord, and the anterior division of the inferior trunk continues as the medial cord.

At the lateral border of the pectoralis minor, the three cords divide into the peripheral nerves of the upper extremity. The lateral cord gives rise to the lateral head of the median nerve and

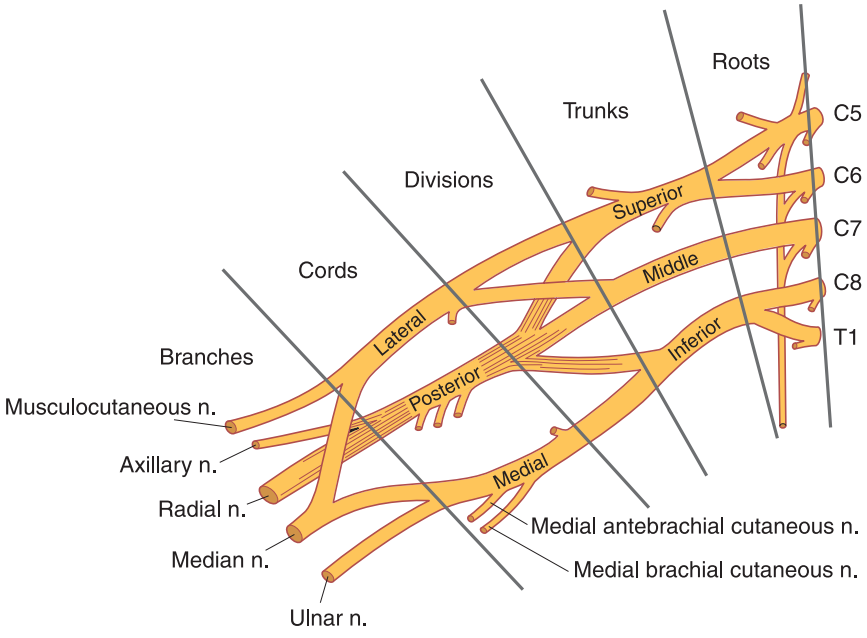

FIGURE 48–3. Roots, trunks, divisions, cords, and branches of the brachial plexus. (Reprinted from Wedel DJ, Horlocker TT. Nerve blocks. In: Miller RD, ed. Anesthesia. 6th ed. Philadelphia: Churchill Livingston, 2005:1686–1717, with permission from Elsevier.)

the musculocutaneous nerve; the medial cord gives rise to the medial head of the median nerve, as well as the ulnar, the medial antebrachial, and the medial brachial cutaneous nerves; and the posterior cord divides into the axillary and radial nerves (Fig. 48–3).

Aside from the branches from the cords that form the peripheral nerves as described, several branches arise from the roots of the brachial plexus providing motor innervation to the rhomboid muscles (C5), the subclavian muscles (C5 and C6), and the serratus anterior muscle (C5, C6, and C7). The suprascapular nerve arises from C5 and C6 and supplies the muscles of the dorsal aspect of the scapula, as well as making a significant contribution to the sensory supply of the shoulder joint.

Branches arising from the cervical roots are usually blocked only with the interscalene approach to the brachial plexus. Figure 48–4 shows the sensory distributions of the cervical roots and the peripheral nerves.

Interscalene Block

Clinical Applications

The principal indication for interscalene block is surgery on the shoulder. Blockade occurs at the level of the upper and middle trunks. Although this approach can be used for forearm and hand surgery, blockade of the inferior trunk (C8 through T1) is often incomplete and requires supplementation at the ulnar nerve for adequate surgical anesthesia in that distribution.[21] In addition, supplementation with a suprascapular nerve

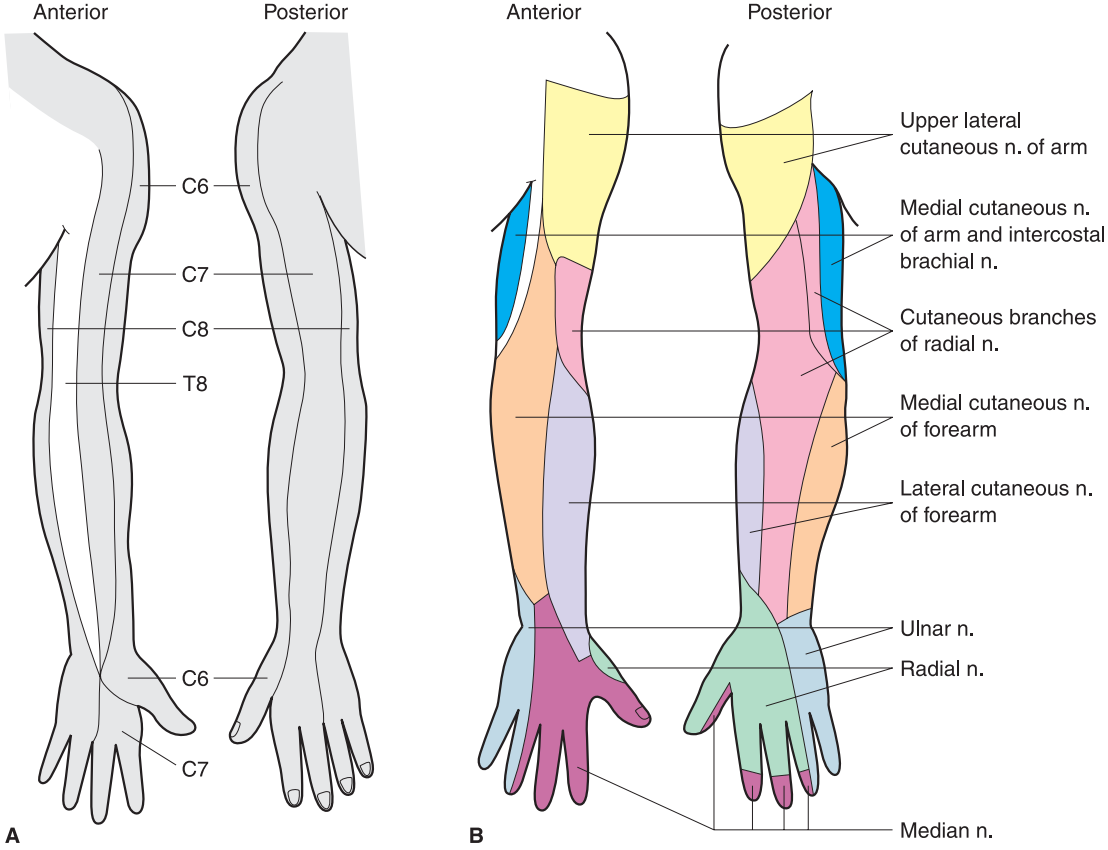

FIGURE 48–4. **A.** Cutaneous distribution of the cervical roots. **B.** Cutaneous distribution of the peripheral nerves. (Reprinted from Wedel DJ, Horlocker TT. Nerve blocks. In: Miller RD, ed. Anesthesia. 6th ed. Philadelphia: Churchill Livingston, 2005:1686–1717, with permission from Elsevier.)

block may further prolong the analgesic effect.[7]

Technique

The brachial plexus shares a close physical relationship with several structures that serve as important landmarks for the performance of interscalene block. In its course between the anterior and middle scalene muscles, the plexus is superior and posterior to the second and third parts of the subclavian artery. The dome of the pleura lies anteromedial to the inferior trunk.

This technique can be performed with the patient's arm in any position and is technically simple because of easy identification of necessary landmarks.[22] The patient should be in the supine position with the head turned away from the side to be blocked. The posterior border of the sternocleidomastoid muscle is readily palpated by having the patient briefly lift the head. The interscalene groove may be palpated by rolling the fingers posterolaterally from this border over the belly of the anterior scalene muscle into the groove. A line is extended laterally from the cricoid cartilage to intersect the interscalene groove indicating the level of the transverse process of C6. Although the external jugular vein often overlies this point of intersection, it is not a constant or reliable landmark.

The use of a nerve stimulator or elicitation of a paresthesia is recommended with this technique so as to place the local anesthetic solution accurately. After ordinary sterile precautions and injection of a skin wheal, a 22- to 25-gauge, 4-cm needle is inserted medially with a 45° caudad and slightly posterior angle (Fig. 48–5). The needle is then advanced until a paresthesia (usually C5 and C6 dermatomes) or nerve stimulator response is elicited. This usually occurs at a very superficial level. Paresthesia/motor response to the arm *or* shoulder are equally efficacious.[23] If a blunt needle bevel is used, a "click" may be detected as the needle passes through the prevertebral fascia. Should bone be encountered within 2 cm of the skin, it is likely to be a transverse process, and the needle may be "walked" across this structure to locate the nerve. Likewise, contraction of the diaphragm indicates phrenic nerve stimulation and anterior needle placement; the needle should be redirected posteriorly to locate the brachial plexus.

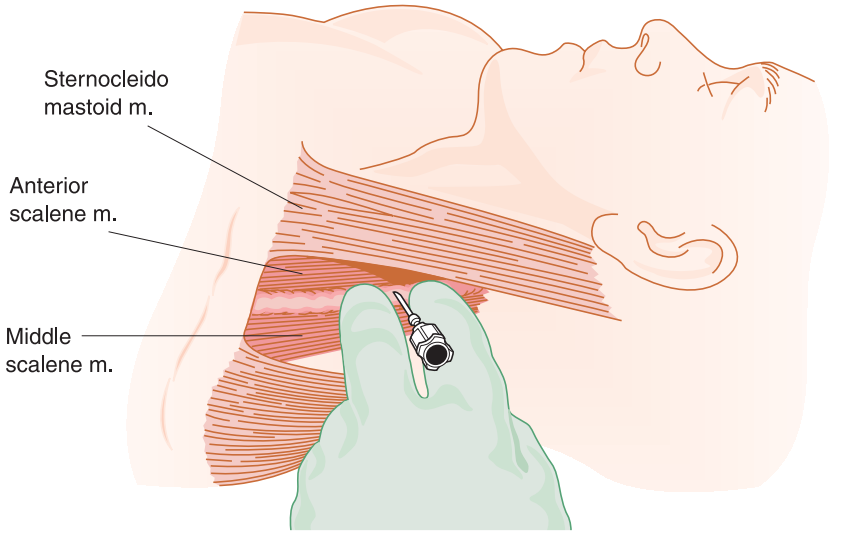

FIGURE 48–5. Interscalene block. The fingers palpate the interscalene groove, and the needle is inserted with a caudad and slightly posterior angle. (Reprinted from Wedel DJ, Horlocker TT. Nerve blocks. In: Miller RD, ed. Anesthesia. 6th ed. Philadelphia: Churchill Livingston, 2005:1686–1717, with permission from Elsevier.)

Once the appropriate paresthesia or motor response is obtained, the needle is stabilized. The use of flexible extension tubing facilitates the maintenance of the needle position while aspiration and injection occur. After negative aspiration, 10–40 mL of solution is injected incrementally, depending on the desired extent of blockade. Radiographic studies suggest a volume-to- anesthesia relationship with 40 mL of solution associated with complete cervical and brachial plexus block.[22] Clinical studies, however, indicate variable blockade of the lower trunk, which includes the ulnar nerve, even with large volumes of solution.[21] Digital pressure above the injection site and downward massage along with a 45° head-up position may facilitate caudad spread and blockade of the lower trunk.

Side Effects/Complications

Ipsilateral phrenic nerve block resulting in diaphragmatic paresis occurs in 100% of patients undergoing interscalene blockade,[24] even with dilute solutions of local anesthetics, and is associated with a 25% reduction in pulmonary function.[25,26] This effect is probably a consequence of anterior spread of the solution over the anterior scalene muscle and may cause subjective symptoms of dyspnea. Although rare, respiratory compromise can occur in patients with severe respiratory disease. A case of lower-lobe collapse (at home) during continuous interscalene infusion has been reported, documenting the need for careful patient selection and ongoing monitoring.[27]

Involvement of the vagus, recurrent laryngeal, and cervical sympathetic nerves is rarely significant, but the patient experiencing symptoms related to these side effects may require reassurance. The risk of pneumothorax is low when the needle is correctly placed at the C5 or C6 level because of the distance from the dome of the pleura.

Severe hypotension and/or bradycardia (Bezold-Jarisch reflex) have been reported in awake, sitting patients undergoing shoulder surgery under interscalene block. The etiology is presumed to be stimulation of intracardiac mechanoreceptors (by decreased venous return), producing an abrupt withdrawal of sympathetic tone, as well as enhanced parasympathetic output. This results in bradycardia, hypotension, and syncope. The frequency is decreased when prophylactic -blockers are administered.[28]

Nerve damage or neuritis can occur in any peripheral nerve block, but it is uncommon and usually is self-limited. Some surgical approaches to the shoulder are associated with neurologic risk to the brachial plexus, for example, total shoulder arthroplasty.[29] In such cases, interscalene block should be

placed postoperatively for pain relief after the surgical service has ascertained and documented that no neurologic damage has occurred. Epidural and intrathecal injections have been reported with this block, a finding emphasizing the importance of inserting the needle in a caudad direction. The proximity of significant neurovascular structures may increase the risk of serious neurologic complications when interscalene block is performed in heavily sedated or anesthetized patients.[30]

Several vascular structures are in close proximity to a correctly placed needle. Local anesthetic toxicity as a result of intravascular injection should be guarded against by careful aspiration and incremental injection. Seizure activity secondary to this complication is particularly undesirable following rotator cuff surgery, because the repair can be compromised by the associated muscular activity.

Supraclavicular Block

Clinical Applications

Indications for supraclavicular block are surgery to the elbow, forearm, and hand. Blockade occurs at the distal trunk–proximal division level. At this point, the brachial plexus is compact and a small volume of solution produces rapid onset of reliable blockade of the brachial plexus. An additional advantage is that the block can also be performed with the patient's arm in any position.

Reliable supraclavicular blockade requires elicitation of a paresthesia or motor response. The classic block may be somewhat difficult to describe and to teach. Observation of an experienced anesthesiologist is perhaps the best way to learn the technique. A proposed modification of the technique, the so-called plumb-bob approach, may decrease complications and may simplify the vertical concept of this block.[31]

Technique

Several anatomic points are important in the performance of the supraclavicular approach. The three trunks are clustered vertically over the first rib cephaloposterior to the subclavian artery, which can often be palpated in a slender, relaxed patient. The neurovascular bundle lies inferior to the clavicle at about its midpoint. The first rib acts as a medial barrier to the needle's reaching the pleural dome and is short, broad, and flat, with an anteroposterior orientation at the site of the plexus.

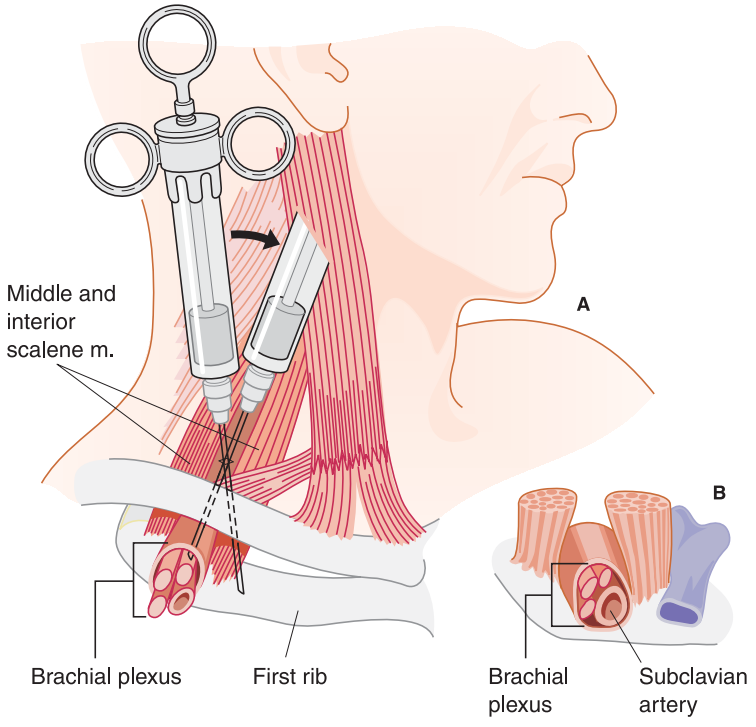

FIGURE 48–6. A. Supraclavicular block. The needle is systematically walked anteriorly and posteriorly along the rib until the plexus is located. **B.** The three trunks are compactly arranged at the level of the first rib. (Reprinted from Wedel DJ, Horlocker TT. Nerve blocks. In: Miller RD, ed. Anesthesia. 6th ed. Philadelphia: Churchill Livingston, 2005:1686–1717, with permission from Elsevier.)

The patient is placed in a supine position, with the head turned away from the side to be blocked. The arm to be anesthetized should be adducted and the hand should be extended along the side toward the ipsilateral knee as far as possible. In the classic technique, the midpoint of the clavicle should be identified and marked. The posterior border of the sternocleidomastoid can be easily palpated when the patient raises the head slightly. The palpating fingers can then roll over the belly of the anterior scalene muscle into the interscalene groove, where a mark should be made approximately 1.5–2.0 cm posterior to the midpoint of the clavicle. Palpation of the subclavian artery at this site confirms the landmark.

After appropriate preparation and injection of a skin wheal, the anesthesiologist stands at the side of the patient facing the patient's head. A 22-gauge, 4-cm needle is directed in a caudad, slightly lateral and posterior direction until either a paresthesia or motor response is elicited or the first rib is encountered. If a syringe is attached, this orientation causes the needle shaft and syringe to lie almost parallel to a line joining the skin entry and the patient's ear. If the first rib is encountered without elicitation of a paresthesia, the needle can be systematically walked anteriorly and posteriorly along the rib until the plexus or the subclavian artery is located (Fig. 48–6). Location of the artery provides a useful landmark; the needle can be withdrawn and reinserted in a more posterolateral direction that will usually result in a paresthesia or motor response. Upon localization of the brachial plexus, aspiration for blood should be performed prior to incremental injections of a total volume of 20–30 mL of solution.

Usually, the rib is contacted at a needle depth of 3–4 cm; however, in an obese patient or in the presence of tissue distortion resulting from hematoma or injection of solution, the depth may exceed the needle length. Nonetheless, gentle probing in the anterior and posterior directions should be done at the 2–3-cm depth if paresthesias are not obtained before the needle is advanced farther. Multiple injections may improve the quality or may shorten the onset of blockade.

The modified vertical (plumb-bob) approach uses similar patient positioning, although the needle entry site is at the point at which the lateral border of the sternocleidomastoid muscle inserts into the clavicle. After preparation and injection of a skin wheal, a 22-gauge, 4-cm needle is inserted while mimicking a plumb-bob suspended over the needle entry site. Often, a paresthesia or motor response is elicited prior to contacting the first rib or artery. If no paresthesia or motor response is elicited, the needle is reinserted while angling the tip of the needle cephalad, and finally caudad in small steps until the first rib is contacted (Fig. 48–7).

Side Effects/Complications

The prevalence of pneumothorax following supraclavicular block ranges from 0.5–6% and diminishes with experience. The onset of symptoms is usually delayed and may take up to 24 hours. Consequently, routine chest radiography after the block is not justified. The supraclavicular approach is best avoided when the patient is uncooperative or cannot tolerate any degree of respiratory compromise because of underlying disease. Other complications include frequent phrenic nerve block (40–60%), Horner syndrome, and neuropathy. The presence of phrenic or cervical sympathetic nerve block usually requires only reassurance. Although nerve damage can occur, it is uncommon and usually is self-limited.

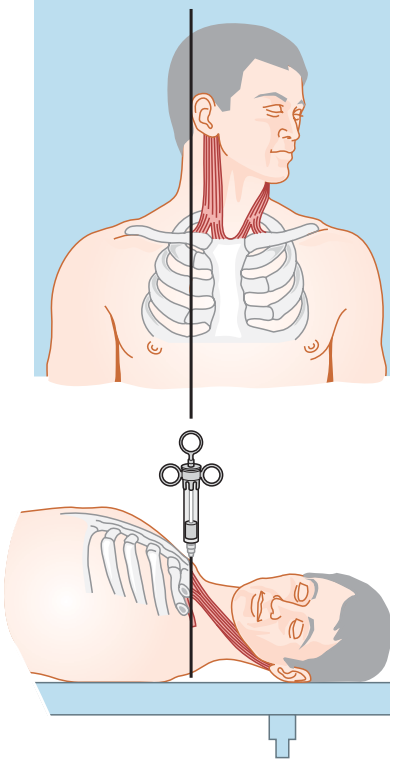

FIGURE 48–7. Supraclavicular block. Plumb-bob approach. (Reprinted from Wedel DJ, Horlocker TT. Nerve blocks. In: Miller RD, ed. Anesthesia. 6th ed. Philadelphia: Churchill Livingston, 2005:1686–1717, with permission from Elsevier.)

Infraclavicular Block

Clinical Applications

Infraclavicular block provides anesthesia to the arm and hand. Blockade occurs at the level of the cords and offers the theoretic advantages of avoiding pneumothorax while affording block of the musculocutaneous and axillary nerves. No special arm positioning is required. A nerve stimulator is required because there are no palpable vascular landmarks to aid in directing the needle. Historically, this approach was considered to be more painful than blockade at the axillary level. However, this has been refuted by recent investigations.[32] In addition, this approach is optimal for indwelling brachial plexus catheters because of the ease of site maintenance.

Technique

The needle is inserted 2 cm below the midpoint of the inferior clavicular border and is advanced laterally, using a nerve stimulator to identify the plexus.[33] Marking a line between the C6 tubercle and the axillary artery with the arm abducted is helpful in visualizing the course of the plexus. An incremental injection of 20–30 mL of solution is sufficient once the needle is correctly placed. Stimulation of the posterior cord or a multiple injection technique improves success rate.[34,35]

A coracoid technique, with the needle insertion site 2 cm medial and 2 cm caudal to the coracoid process, has also been described.[36] However, the more lateral insertion site may result in the absence of blockade of the musculocutaneous nerve, removing the major advantage of this approach over the simpler axillary block.

Side Effects/Complications

Because of the necessarily blind approach to the plexus, the risk of intravascular injection may be increased. Exaggerated medial needle direction may result in pneumothorax. A 30% reduction in pulmonary function as a consequence of diaphragmatic paresis is noted in the majority of patients; this could result in respiratory failure. These effects should be considered when evaluating a patient for this technique.[37,38] Other rare complications, such as infection and hematoma, are theoretically possible.

Axillary Block

Clinical Applications

The axillary approach to the brachial plexus is the most popular because of ease of block, reliability, and safety.[39] Blockade occurs at the level of the terminal nerves. Although blockade of the musculocutaneous nerve is not always produced with this approach, it can be supplemented at the level of the axilla or at the elbow. Indications for axillary block include surgery to the forearm and hand. Elbow procedures are also successfully performed using the axillary approach.[40] This block is ideally suited for outpatients and is easily adapted to the pediatric population.[41,42] However, axillary block is unsuitable for surgical procedures on the upper arm or shoulder and the patient must be able to abduct the arm to perform the block.

Technique

Anatomic concepts that should be considered prior to performing an axillary block include the following:

1. The neurovascular bundle is multicompartmental (Fig. 48–8).[43]
2. The axillary artery is the most important landmark; the nerves maintain a predictable orientation to the artery.
3. The median nerve is found superior to the artery, the ulnar nerve is inferior, and the radial nerve is posterior and somewhat lateral (Fig. 48–9).
4. At this level, the musculocutaneous nerve has already left the sheath and lies in the substance of the coracobrachialis muscle.
5. The intercostobrachial nerve, a branch of the T2 intercostal nerve, is usually blocked by the skin wheal overlying the artery; however, adequate anesthesia for the tourniquet can be ensured by extending the wheal 1–2 cm caudad and cephalad.

The patient should be in the supine position with the arm to be blocked placed at a right angle to the body, with the elbow flexed to 90°. The dorsum of the hand rests on the bed or

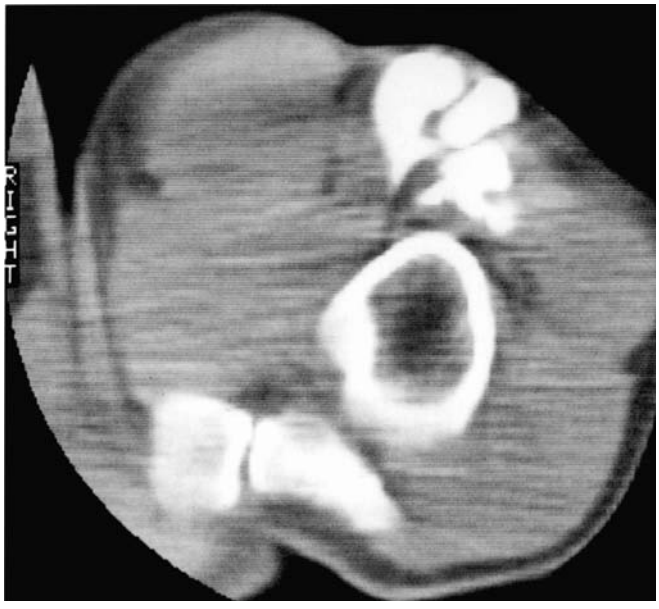

FIGURE 48–8. Axillary block. Computed tomogram after axillary block with bupivacaine 0.5% and iodothalamate. Separate injections of 10-mL solution were made after obtaining median and radial nerve paresthesia and transarterially. Contrast medium appears to remain in three separate compartments. (Reprinted from Wedel DJ, Horlocker TT. Nerve blocks. In: Miller RD, ed. Anesthesia. 6th ed. Philadelphia: Churchill Livingston, 2005:1686–1717, with permission from Elsevier.)

pillow; hyperabduction of the arm with placement of the hand beneath the patient's head is not recommended because this position frequently obliterates the pulse.

The axillary artery is palpated, and a line is drawn tracing its course from the lower axilla as far proximally as possible. The artery is then fixed against the patient's humerus by the index and middle fingers of the left hand, and a skin wheal is raised directly over the artery at a point in the axilla approximating the skin crease. Proximal needle placement and maintenance of distal pressure facilitate proximal spread of the solution.

Method of Needle Localization

Several methods of identifying the axillary sheath have been described, all with reportedly good results. Overall, paresthesia is unnecessary. However, multiple injections may shorten the onset and may improve the reliability of blockade.

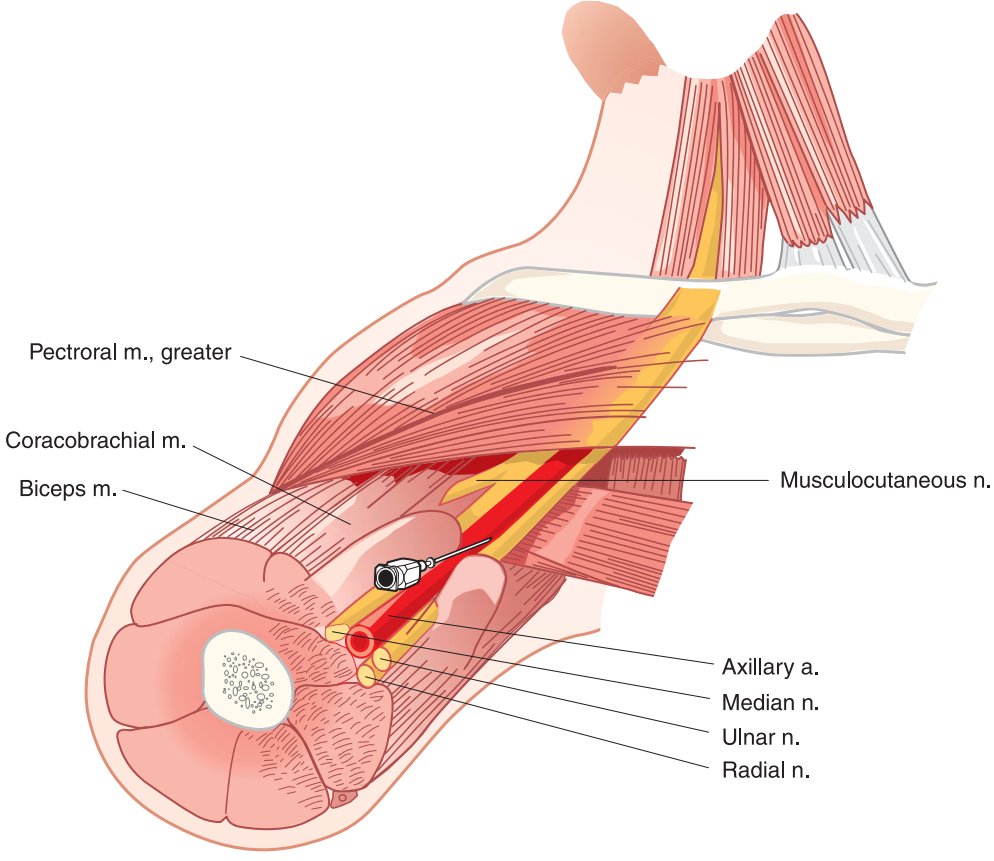

FIGURE 48–9. Axillary block. The arm is abducted at right angles to the body. Distal digital pressure is maintained during needle placement and injection of local anesthetic. (Reprinted from Wedel DJ, Horlocker TT. Nerve blocks. In: Miller RD, ed. Anesthesia. 6th ed. Philadelphia: Churchill Livingston, 2005:1686–1717, with permission from Elsevier.)

1. Paresthesias can be sought with a 25-gauge, 2-cm needle, beginning either deep (radial nerve) or with the nerves supplying the surgical site. Needles longer than 2 cm are rarely needed to reach the neurovascular bundle; smaller needles and a short-bevel needle may be associated with a lower risk of nerve damage.[41,44] Ten milliliters of local anesthetic is injected at each paresthesia.
2. A nerve stimulator can also be employed with an insulated needle to locate the nerves. This technique obviates the need for paresthesia. However, this has not been proven to lower the risk of nerve damage.[45,46]
3. A short-bevel needle can be advanced until the "axillary sheath" is entered, as evidenced by a "fascial click," whereupon 40–50 mL of solution is injected after negative aspiration.[39,47]
4. A transarterial technique can be employed, whereby the needle pierces the artery and 40–50 mL of solution is injected posterior to the artery; or, alternatively, half the solution is injected posterior and half anterior to the artery. Great care must be taken to avoid intravascular injection with this technique, particularly because the pressure of injection within the compartments of the axillary sheath may move anatomic structures in relation to the immobile needle. Some practitioners avoid intentional arterial puncture in the belief that it is unnecessarily traumatic.
5. Field block of the brachial plexus with a fanwise injection of 10–15 mL of local anesthetic solution on each side of the artery is a variation of the sheath technique. Paresthesias, although not sought, are often encountered in this technique and provide evidence of correct placement.

When the injection is completed, the arm should be adducted and returned to the patient's side. This prevents the humeral head from obstructing proximal flow of the solution; distal pressure and massage may also help. Vester-Andersen et al.[48] were unable to consistently block the musculocutaneous nerve with volumes up to 80 mL. Thus, if the musculocutaneous nerve is not blocked by the axillary approach, it can be blocked by injection within the body of the coracobrachialis muscle or at the elbow superficially at the lateral aspect of the antecubital fossa just above the interepicondylar line.

Success Rate with Axillary Block Techniques

Success rate for axillary block depends on how a successful block is defined (surgical anesthesia vs. blockade of all four terminal nerves of the upper extremity), the technique used to localize the brachial plexus, and the number of injections. Success rates with single-injection techniques are variable.[49,50] Thompson and Rorie[43] concluded that the presence of multiple compartments limits diffusion of the solution (and the success of single-shot techniques). Although Partridge et al.[51] confirmed the presence of these compartments, they concluded that the "septa" dividing them were incomplete on the basis of injections of methylene blue and latex solutions into cadavers.

Eliciting a paresthesia is as efficacious as peripheral nerve stimulation (with a motor response of 0.5–0.8 mA). In addition, most studies suggest that two-injection transarterial techniques are equivalent to single paresthesia or single nerve stimulation approaches. In general, the efficacy of paresthesia and peripheral nerve stimulator techniques increases when multiple injections are employed. Conversely, success rates with perivascular or fascial click approaches are variously reliable.[7] Familiarity with a variety of techniques for axillary block of the brachial plexus allows the anesthesiologist maximal flexibility in tailoring the anesthetic approach to the clinical situation.

Side Effects/Complications

Nerve injury and systemic toxicity are the most significant complications associated with the axillary approach. The assertion that neuropathies are more common with the paresthesia technique may be valid, but it is not supported by the available data. In addition, even when paresthesias are not sought, they often occur unintentionally.[52] Injection of large volumes of local anesthetic, particularly with the transarterial approach, increases the risk of intravascular injection and systemic local anesthetic toxicity. Hematoma and infection are rare complications. Central neural blockade and pneumothorax are not complications, as in other approaches to the brachial plexus.

Peripheral Blocks at the Midhumeral Level, Elbow, and Wrist

Clinical Applications

As techniques for brachial plexus blockade have gained popularity, indications for peripheral nerve blockade at the wrist and elbow have diminished. However, these techniques can be useful when limited anesthesia is required, when contraindications to brachial plexus block (infection, bilateral surgery, coagulation abnormalities, bleeding diathesis, difficult anatomy) exist, and when brachial plexus blockade is incomplete. Only the midhumeral approach provides anesthesia for the use of a tourniquet. Most patients tolerate an inflated tourniquet for only a brief period.

Midhumeral Block

A midhumeral approach to the brachial plexus has been described. This novel approach involves blocking each of the four nerves of the brachial plexus separately in the humeral canal at the level of the proximal one-third and distal two-thirds of the humerus. At this level, the median and ulnar nerves are located on the lateral and medial aspects of the brachial artery, respectively. The musculocutaneous nerve is identified within the body of the biceps muscle, while the radial nerve lies adjacent to the humerus. Eight to 10 mL of local anesthetic is injected after localization of each nerve with a nerve stimulator. Midhumeral block is reported to have a higher success rate than traditional (defined as stimulation of two nerves) axillary brachial plexus block.[53] In this study, time to complete the block did not differ between the two techniques; however, onset of complete sensory block was shorter in the axillary approach, whereas the success rate of blockade of all four major nerves was higher in the midhumeral group. This technique may have applications when anatomic difficulties preclude a traditional approach or when the surgical procedure requires a dense block of all four major nerves.

Median Nerve Block

Block of the median nerve provides anesthesia of the palmar aspects of the thumb and index finger, middle finger, and radial half of the ring finger, and the nail beds of the same digits. Motor block includes the muscles of the thenar eminence, lumbrical muscles of

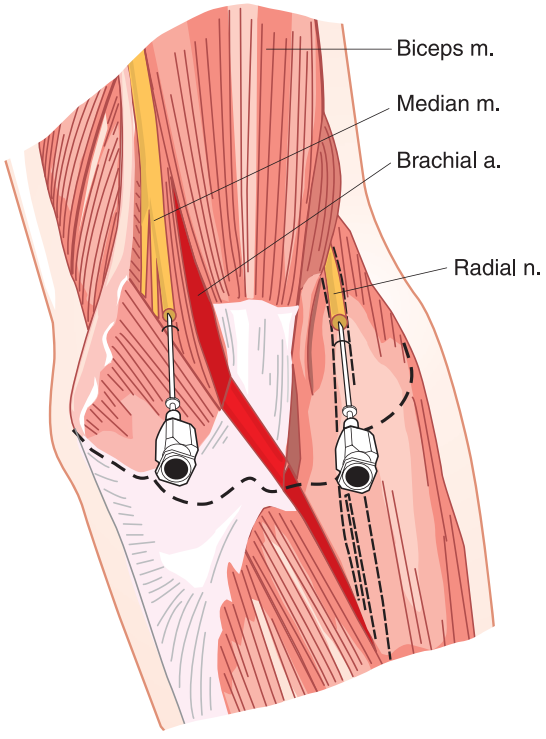

FIGURE 48–10. Anatomic landmarks for median and radial nerve block at the elbow. (Reprinted from Wedel DJ, Horlocker TT. Nerve blocks. In: Miller RD, ed. Anesthesia. 6th ed. Philadelphia: Churchill Livingston, 2005:1686–1717, with permission from Elsevier.)

the first and second digits, and, in the case of the block at the elbow, median-innervated wrist flexor muscles of the forearm.

Technique at the Elbow With the patient's arm placed in the anatomic position (palm up), a line is drawn connecting the medial and lateral epicondyles of the humerus. The major landmark for this technique is the brachial artery, which is found medial to the biceps tendon at the intercondylar line. The median nerve lies medial to the artery (Fig. 48–10) and can be blocked with 3–5 mL of solution after eliciting a paresthesia. If no paresthesia is obtained, the solution can be injected fanwise medial to the palpated artery.

Technique at the Wrist The median nerve is located between the flexor carpi radialis and palmaris longus tendons and can be blocked at a point 2–3 cm proximal to the wrist crease (Fig. 48–11). (The palmaris longus tendon is congenitally or postsurgically absent from some patients.) A loss of resistance is felt as the needle passes through the flexor retinaculum, at which point 2–4 mL of solution should be injected. A superficial palmar branch supplying the skin of the thenar eminence can be blocked by injecting 0.5–1 mL of solution subcutaneously above the retinaculum. Paresthesia should not be sought because of the confinement of this nerve within the carpal tunnel.

Radial Nerve Block

Block of the radial nerve provides anesthesia to the lateral aspect of the dorsum of the hand (thumb side) and the proximal portion of the thumb, index, middle, and lateral half of the ring fingers.

Technique at the Elbow The radial nerve can be blocked at the elbow as it passes over the anterior aspect of the lateral epicondyle. The intercondylar line and lateral edge of the biceps tendon are marked. A 22-gauge, 3–4-cm needle is inserted at a point 2 cm lateral to the biceps tendon and is advanced until bone is encountered (Fig. 48–12). A fanwise injection is made using 3–5 mL of solution.

Technique at the Wrist The radial nerve block at the wrist is a field block of the multiple peripheral branches descending along the dorsum and radial side of the wrist. The extensor pollicis longus tendon can be identified when the patient extends the thumb. The needle insertion is over this tendon at the base of the first metacarpal; the injection is superficial to the tendon. Two milliliters of local anesthetic is injected proximally along the tendon, and an additional 1 mL is injected as the needle passes at a right angle across the "anatomic snuffbox" (Fig. 48–12).

Ulnar Nerve Block

Blockade of the ulnar nerve provides anesthesia of the ulnar side of the hand, the little finger, and the ring finger and all the small muscles of the hand, except those of the thenar eminence and the first and second lumbrical muscles.

Technique at the Elbow Although the ulnar nerve is easily accessible at its subcutaneous position posterior to the medial epicondyle, blockade at this site is associated with a high incidence of neuritis. The nerve is surrounded by fibrous tissue at this point, requiring an intraneural injection for successful blockade. Use of a very fine needle along with a small volume of solution (1 mL) diminishes the risk; however, the nerve can be satisfactorily blocked with 5–10 mL of solution at a site 3–5 cm proximal to the elbow. The local anesthetic should be injected in a fanwise fashion without elicitation of a paresthesia.

Technique at the Wrist At the wrist, the ulnar nerve lies beneath the flexor carpi ulnaris tendon between the ulnar artery and the pisiform bone. At this point, it has already given off its palmar cutaneous and dorsal branches. The nerve can be approached by directing the needle medially from the radial side of the tendon or, alternatively, by directing the needle radially from the ulnar side of the tendon (Fig. 48–11). After eliciting a paresthesia, 3–5 mL of solution is injected or spread in a fanwise fashion.

Musculocutaneous Nerve Block

The musculocutaneous nerve terminates as the lateral cutaneous nerve of the forearm. This nerve provides sensory innervation to the skin on the radial side of the forearm up to the radiocarpal joint. This block is usually performed to supplement the axillary approach to brachial plexus anesthesia.

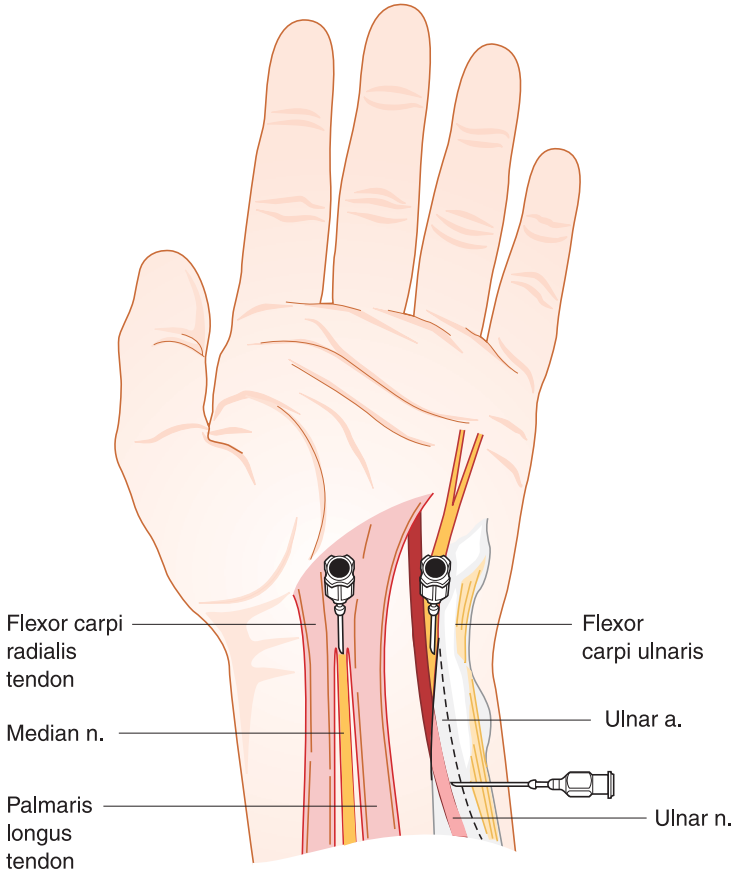

FIGURE 48–11. Anatomic landmarks for median and ulnar nerve block at the wrist. An alternative method for ulnar nerve block, from the ulnar side of the wrist, is shown. (Reprinted from Wedel DJ, Horlocker TT. Nerve blocks. In: Miller RD, ed. Anesthesia. 6th ed. Philadelphia: Churchill Livingston, 2005:1686–1717, with permission from Elsevier.)

Technique at the Elbow The lateral cutaneous nerve of the forearm can be blocked 1 cm proximal to the intercondylar line immediately lateral to the biceps tendon. Fanwise infiltration of 3–5 mL of solution subcutaneously at this site provides excellent anesthesia of this nerve.

Peripheral Blockade at the Elbow versus the Wrist

The forearm cutaneous nerves arise in the upper arm and are not anesthetized by block of the peripheral nerves at the elbow. Hence, there is no advantage of block of the peripheral nerves of the upper extremity when comparing elbow with wrist techniques; both provide sensory anesthesia of the hand.

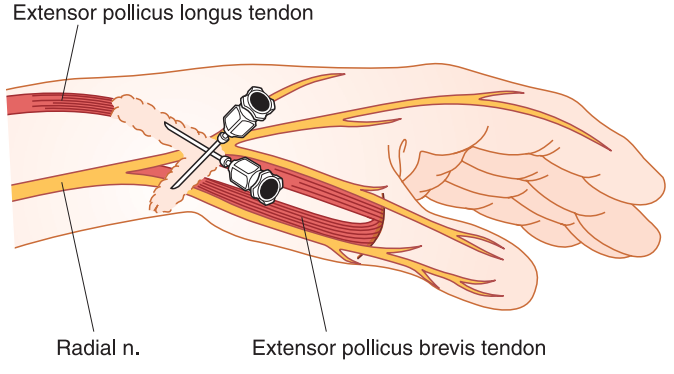

FIGURE 48–12. Anatomic landmarks and method of needle insertion for radial nerve block at the wrist. (Reprinted from Wedel DJ, Horlocker TT. Nerve blocks. In: Miller RD, ed. Anesthesia. 6th ed. Philadelphia: Churchill Livingston, 2005:1686–1717, with permission from Elsevier.)

Side Effects/Complications

In general, distal peripheral blocks are associated with a lower risk of complications. However, intravascular injection can occur, and the usual precautions of incremental injection after aspiration are recommended. The risk of nerve injury is theorized to be higher when more distal peripheral blocks are performed. This may be a result of superficial nerve placement between bony and ligamentous structures, thereby offering ready access to the probing needle point.

Intravenous Regional Blocks

Intravenous regional blocks were first described by August Bier, a German surgeon, in 1908.[54] Early methods involved two tourniquets and the first synthetic local anesthetic, procaine. The technique lost popularity as more reliable methods of blocking the brachial plexus evolved.

Clinical Applications

The Bier block has multiple advantages, including ease of administration, rapidity of recovery, rapid onset, muscular relaxation, and controllable extent of anesthesia. It is an excellent technique for short (≤ 90 minutes) open surgical procedures and for closed reductions of bony fractures.

Technique

An intravenous cannula is placed in the upper extremity to be blocked as distally as possible (the patient should also have an intravenous cannula in the nonoperative upper extremity for administration of fluids and other drugs). Traditionally, a double tourniquet is placed on the operative side; both cuffs should have secure closures and reliable pressure gauges. After exsanguination of the arm, the proximal cuff is inflated to approximately 150 mm Hg more than the systolic pressure (absence of a radial pulse confirms adequate tourniquet pressure). Total dose of local anesthetic is based on the patient's weight and is injected slowly (4–6 mg/kg of 0.5% prilocaine or lidocaine—without epinephrine). The onset of anesthesia is usually within 5 minutes. When the patient complains of tourniquet pain, the distal tourniquet, which overlies anesthetized skin, is inflated, and the proximal tourniquet is released. There are

data suggesting that the use of a single wide cuff allows use of lower inflation pressures during intravenous regional anesthesia. The postulated advantage is that the lower pressures will decrease the incidence of neurologic complications related to high inflation pressures with the narrow double cuffs.[55] The tourniquet may be safely released after 25 minutes, but the patient should be closely observed for local anesthetic toxicity for several minutes after the tourniquet release. Slow injection of local anesthetic solutions at a distal site has been shown to lower the risk of toxicity.[56]

Side Effects/Complications

Technical problems with this block include tourniquet discomfort, rapidity of recovery leading to postoperative pain, difficulty in providing a bloodless field, and the necessity of exsanguination in the case of a painful injury. Accidental or early deflation of the tourniquet or use of excessive doses of local anesthetics can result in toxic reactions. Injection of the drug as distally as possible at a slow rate decreases blood levels of anesthetic and theoretically increases safety.[56] The use of bupivacaine for intravenous regional anesthesia is associated with local anesthetic toxicity and death[57] and is not recommended. Cyclic deflation of the tourniquet at 10-second intervals increases the time to peak arterial lidocaine levels that may decrease potential toxicity.[58] Other rare complications associated with this technique include phlebitis (2-chloroprocaine), development of compartment syndrome, and loss of limb.

Upper Extremity Continuous Catheter Techniques

The advantages cited for continuous nerve blockade include prolongation of surgical anesthesia, decreased risk of toxicity because of lower incremental doses, and postoperative pain relief and sympathectomy. Catheter placement using both over- and through-needle methods have been described. Advances in equipment technology, including the development of stimulating needles and catheters and portable pumps allowing local anesthetic infusion after hospital dismissal, have increased the success rate and popularity of continuous peripheral blockade (Fig. 48–13).[59,60] Although concern regarding accurate catheter placement and maintenance still exists, the use of stimulating catheters and radiographic confirmation may further improve the functionality.[61,62] Risks of infection, inadequate anesthesia/analgesia, and accumulation of local anesthetic (systemic toxicity) are the major disadvantages. Catheter migration, catheter kinking or coiling, and nerve damage also rarely may occur.[63]

Methods of providing continuous brachial plexus anesthesia have been described since at least the 1940s,[64] and frequently offer ingenious solutions for the placement and securing of the needle or catheter. Longer catheters may be easier to secure and provide superior blockade if the tip lies more proximal in the plexus.[65] This technique is especially applicable to patients with upper extremity or digit replantation, total elbow arthroplasty, or reflex sympathetic dystrophies, for which prolonged pain relief and sympathectomy are advantageous.[66] Despite increased use, few studies have critically analyzed the benefits and outcomes of brachial plexus catheters to single injection or conventional methods of postoperative analgesia. Overall, superior analgesia is consistently reported, with lower opioid use and decreased pain scores. Other benefits include fewer sleep disturbances and increased patient satisfaction.[7,67] However, substantial improvements in surgical outcomes and economics have not been noted. This may be because of the relatively minor nature of upper-extremity procedures (and the associated decreased analgesic requirements) compared to neuraxial or lower-extremity operations.

LOWER-EXTREMITY BLOCKS

Knowledge of the anatomy of the lumbosacral plexus and peripheral nerves of the lower extremity enables anesthesiologists to provide more comprehensive anesthetic care. These blocks are safe and have certain advantages, such as postoperative pain relief and lack of complete sympathectomy, which make them ideal for selected patients.

Lower-extremity blocks are less popular than those routinely employed for surgical procedures of the upper extremity. In part, this is a result of the widespread acceptance and safety of spinal and epidural anesthesia. Furthermore, unlike the brachial plexus, the nerves supplying the lower extremity are not anatomically clustered where they can be easily blocked with a relatively superficial injection of local anesthetic. Because of the anatomic

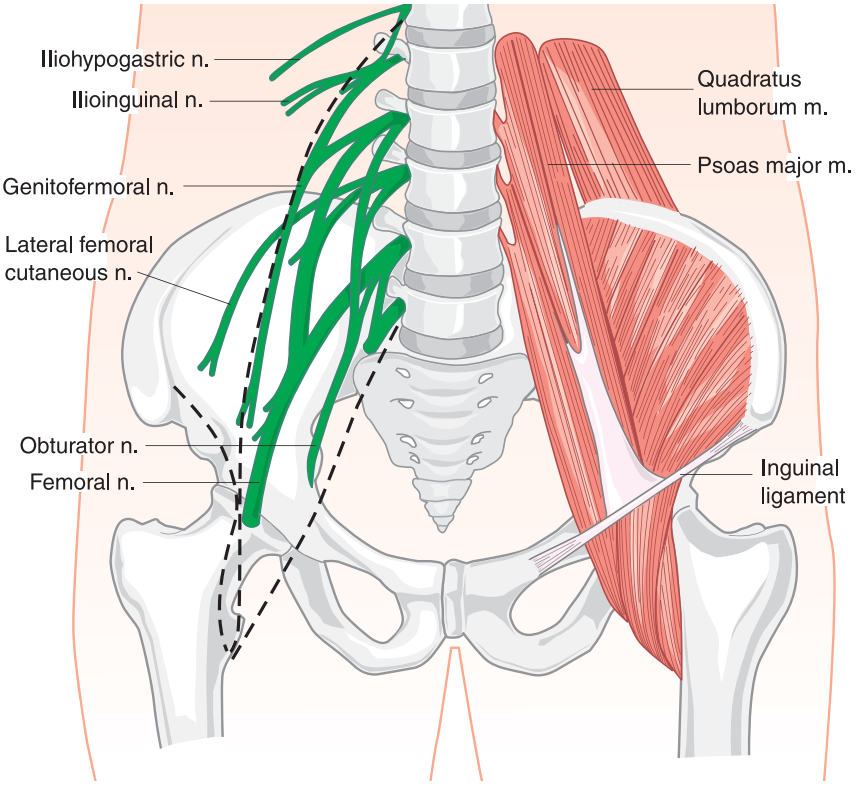

FIGURE 48–14. The lumbar plexus lies in the psoas compartment between the psoas major and quadratus lumborum muscles. (Reprinted from Wedel DJ, Horlocker TT. Nerve blocks. In: Miller RD, ed. Anesthesia. 6th ed. Philadelphia: Churchill Livingston, 2005:1686–1717, with permission from Elsevier.)

considerations, lower-extremity blocks are technically more difficult and require more training and practice before expertise is acquired. Many of these blocks were classically performed using paresthesia, loss of resistance, or field block technique; success was variable. Advances in needles, catheters and nerve stimulator technology have facilitated localization of neural structures and improved success rate. Recent applications have focused on prolonged postoperative analgesia to assist rehabilitation and hospital dismissal.

Anatomy

The nerve supply to the lower extremity is derived from the lumbar and sacral plexuses. The lumbar plexus is formed by the anterior rami of the first four lumbar nerves, frequently including a branch from T12 and occasionally from L5 (Fig. 48–14). The plexus lies between the psoas major and quadratus lumborum muscles, in the psoas compartment.

The lower components of the plexus, L2, L3, and L4, primarily innervate the anterior and medial thigh. The anterior divisions of L2, L3, and L4 form the obturator nerve; the posterior divisions of the same components form the femoral nerve; and the lateral femoral cutaneous nerve is formed from posterior divisions of L2 and L3.

The posterior cutaneous nerve of the thigh and the sciatic nerve are derived from the first, second, and third sacral nerves plus branches from the anterior rami of L4 and L5, respectively. These nerves pass together through the pelvis and the greater sciatic foramen and are blocked by the same technique. The sciatic nerve is actually a combination of two major nerve trunks, the tibial (ventral branches of the anterior rami of L4, L5, S1, S2, and S3) and the common peroneal (dorsal branches of the anterior rami of L4, L5, S1, S2, and S3), which form the sciatic nerve. At or above the popliteal fossa they separate, the tibial nerve passing medially and the common peroneal laterally. Figure 48–15 shows the cutaneous distributions of the lumbosacral and peripheral nerves.

Lumbar Plexus Block

Clinical Applications

The lumbar plexus can be blocked by three distinct approaches. Block of the full lumbar plexus (femoral, lateral femoral cutaneous, obturator) is accomplished with the psoas block.[14,68,69] In comparison, the fascia iliaca and femoral approaches will reliably block the femoral but not the lateral femoral, cutaneous, and obturator nerves.[68–70] Lumbar plexus block is often used to provide postoperative analgesia for patients undergoing major knee and hip surgery. Selection of regional analgesic technique is dependent on the surgical site. For example, the psoas compartment approach to the lumbar plexus is preferable for surgery to the hip because it is the most proximal lumbar plexus technique. Conversely, for surgery to the knee, the more distal femoral and fascia iliaca approaches are sufficient. Importantly, although differences in frequency of complete lumbar plexus blockade exists between techniques, no clinical differences in pain

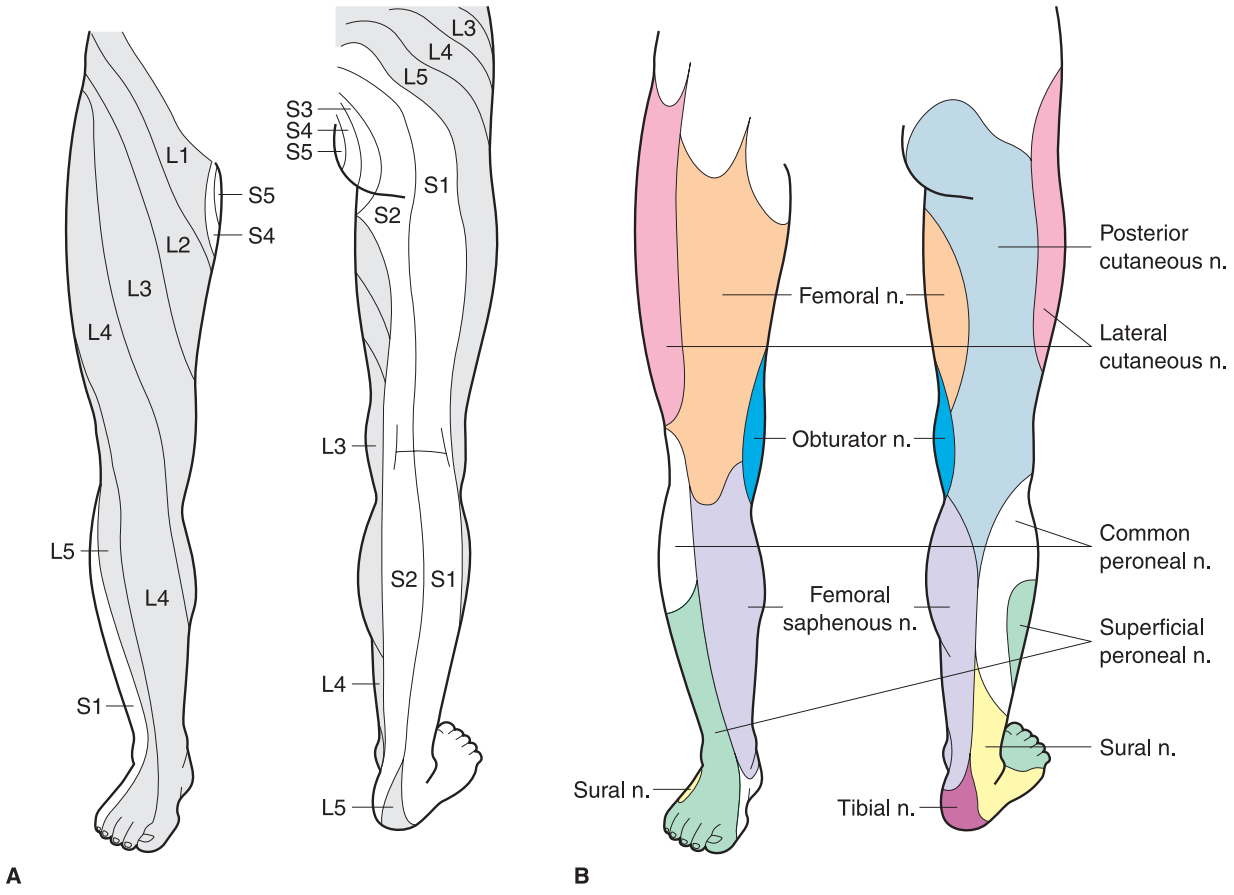

FIGURE 48–15. A. Cutaneous distribution of the lumbosacral nerves. **B.** Cutaneous distribution of the peripheral nerves of the lower extremity. (Reprinted from Wedel DJ, Horlocker TT. Nerve blocks. In: Miller RD, ed. Anesthesia. 6th ed. Philadelphia: Churchill Livingston, 2005:1686–1717, with permission from Elsevier.)

scores or supplemental opioid requirements has been noted. For example, femoral and psoas compartment block appear to provide equivalent analgesia following total knee replacement.[14,68] Supplemental sciatic[71–73] or obturator[74] block is required to obtain adequate analgesia following total knee (but not hip) arthroplasty.

Technique

Psoas Compartment Approach The psoas compartment block offers a single injection rather than three separate needle insertions for anesthesia of the lumbar plexus and involves needle placement into the space between the psoas major and quadratus lumborum muscles. A large volume of injected solution anesthetizes the hip and anterolateral thigh.[75]

The patient is placed in the lateral position, hips flexed, and operative extremity uppermost. A line is drawn to connect the iliac crests (intercristal line) identifying the fourth lumbar spine. After skin preparation, a skin wheal is raised 3 cm caudad and 5 cm lateral to the midline on the side to be blocked. A 21-gauge, 10-cm stimulating needle is then advanced perpendicular to the skin entry site until it contacts the fifth lumbar transverse process. The needle is redirected cephalad until it slides off the transverse process. The lumbar plexus is identified by elicitation of a quadriceps motor response. When the needle is in place, 30 mL of solution is injected (Fig. 48–16).

Based on anatomic imaging studies, Capdevila et al.[76] modified the classic psoas technique. Needle insertion site is the junction of the lateral third and medial two thirds of a line between the spinous process of L4 and a line parallel to the spinal column passing through the posterior superior iliac spine. (The spinous process of L4 was estimated to be approximately 1 cm cephalad to the upper edge of the iliac crests.) The needle is advanced perpendicularly to the plane of the back until contact with the transverse process of L4 is obtained and advanced under the transverse process until quadriceps femoris muscle twitches are elicited. Despite a difference between men and women in the depth of the lumbar plexus (median values: 8.5 and 7.0 cm, respectively), the distance from the L4 transverse process to the lumbar plexus was comparable (median value: 2 cm) in both sexes. Thus the authors stressed the importance of achieving contact with the L4 transverse process to establish appropriate needle depth and position.

Perivascular Approach ("3-in-1 Block") The perivascular approach to the psoas compartment is based on the premise that injection of a large volume of local anesthetic within the femoral canal while maintaining distal

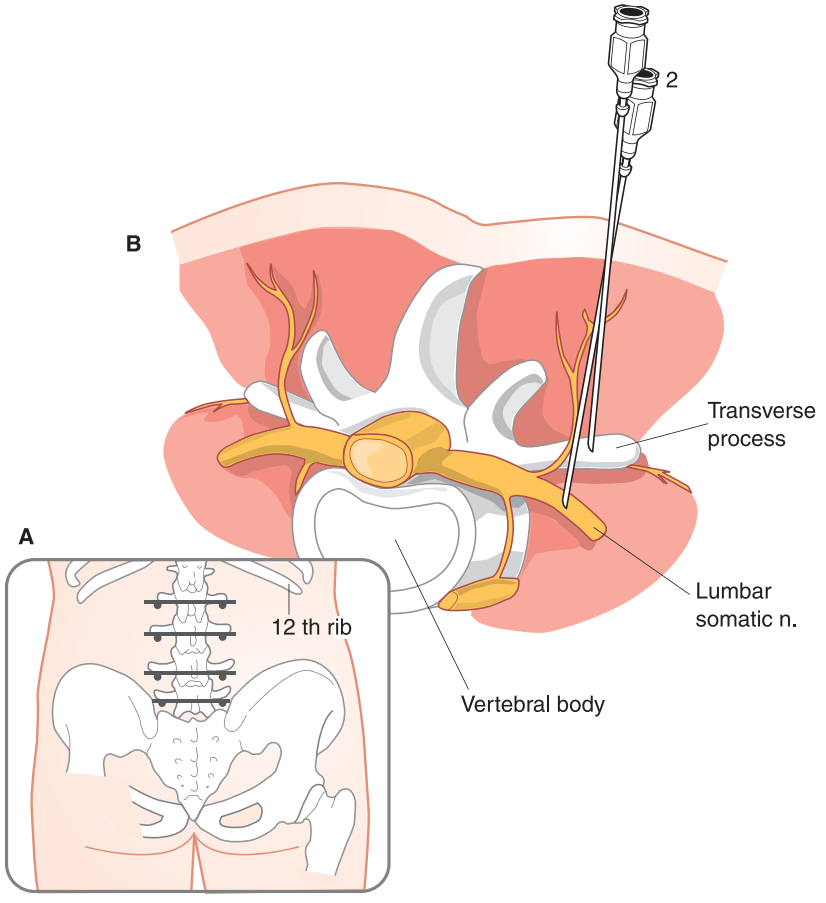

FIGURE 48–16. A. Lumbar plexus block, psoas compartment approach: patient position and surface landmarks. **B.** The needle is advanced perpendicularly until it contacts the transverse process. It is redirected to walk off the caudad surface of the transverse process and advanced 1–2 cm. (Reprinted from Wedel DJ, Horlocker TT. Nerve blocks. In: Miller RD, ed. Anesthesia. 6th ed. Philadelphia: Churchill Livingston, 2005:1686–1717, with permission from Elsevier.)

pressure will result in proximal spread of the solution into the psoas compartment and consequent lumbar plexus block.[77] The key anatomic assumption is that the fascial sheath surrounding the lumbar roots extends into the femoral canal and acts as an enclosed conduit for the spread of local anesthetic solutions. However, despite many efforts to consistently produce a 3-in-1 block, the femoral nerve is the only nerve consistently blocked with this approach.[78] In addition, blockade of the lateral femoral cutaneous and obturator nerves occurs through lateral and medial diffusion of local anesthetic, respectively (and not through proximal spread to the lumbar plexus).

The patient lies in the supine position. The inguinal ligament is marked as a line connecting the pubic tubercle and the anterior superior iliac spine. The femoral artery is marked. A 22-gauge, 5- cm needle is advanced lateral to the artery in a cephalad direction until a paresthesia or nerve stimulator response is obtained. The needle is held immobile while distal pressure is applied digitally to the femoral sheath. A total of 20–40 mL of solution is injected incrementally after negative aspiration. Reliable anesthesia of the femoral and lateral femoral cutaneous nerves can be predicted with 20 mL. However, obturator nerve block may not occur even with volumes greater than 30 mL (Fig. 48–17A).

Fascia Iliaca Approach The more lateral needle insertion site with this approach to the lumbar plexus increases the likelihood of successful lateral femoral cutaneous block and decreases the frequency of obturator blockade.[14,70] However, proximal catheter advancement is often associated with sciatic spread and improved analgesia.[79] An additional advantage of this approach is the simplicity; because neural structures are not specifically identified, elicitation of a paresthesia or motor response is not required. Rather, successful needle position is determined by a double "pop."

The patient is positioned supine and the inguinal ligament is identified and divided into thirds. The junction of the lateral one-third and medial two-thirds is determined. A 17-gauge Tuohy needle is inserted 1 cm below this point. An initial loss of resistance is noted as the needle penetrates the fascia lata. The second loss of resistance is felt as the needle penetrates the fascia iliaca and 30 mL of local anesthetic in incrementally injected (Fig. 48–18).

Side Effects/Complications

The deep needle placement with the posterior (psoas compartment) approach increases the risk of possible epidural, subarachnoid, or intravascular injection. Peripheral nerve damage is also a potential risk with this technique. Cardiac arrest caused by

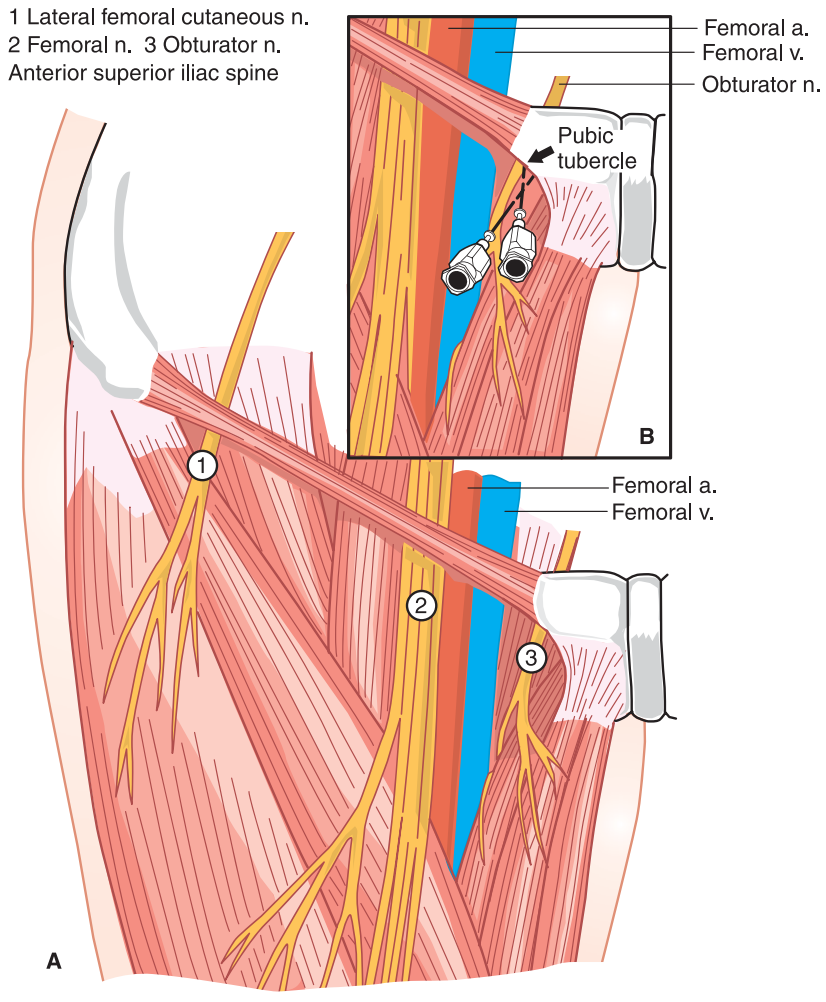

FIGURE 48–17. A. Anatomic landmarks for lateral femoral cutaneous, femoral, and obturator nerve blocks. **B.** Obturator nerve block. The needle is walked off the inferior pubic ramus in a medial and cephalad direction until it passes into the obturator canal. (Reprinted from Wedel DJ, Horlocker TT. Nerve blocks. In: Miller RD, ed. Anesthesia. 6th ed. Philadelphia: Churchill Livingston, 2005:1686–1717, with permission from Elsevier.)

total spinal anesthesia has been reported.[80] Thus, the depth of the neural structures and potential for serious side effects associated with the psoas compartment approach to the lumbar plexus (compared to more superficial fascia iliaca and femoral techniques) warrant consideration. Several authors have advocated use of the psoas compartment block only when more distal approaches are not indicated/efficacious.[68] An additional side effect of the psoas compartment block is the development of a sympathetic block secondary to extravasation of local anesthetic. This unilateral sympathectomy is usually of little consequence. Although one reason for choosing a lower-extremity block over spinal or epidural blockade is prevention of sympathectomy, the advantage of a psoas compartment block is diminished should this effect occur.

Intravascular injection and hematoma are possible with femoral perivascular and fascia iliaca techniques because of the close proximity of the femoral artery. The presence of femoral vascular grafts is a relative contraindication. Nerve damage is rare with these techniques. The lateral needle insertion site with the fascia iliaca approach overlies the hip joint; a third "pop" may signify advancement into the articular space.

Femoral Nerve Block

The femoral nerve is formed within the psoas major muscle by posterior divisions of the second, third, and fourth lumbar nerves. It emerges from the lateral border of the psoas muscle to descend in the groove between the psoas and iliacus muscles and enters the thigh by passing beneath the inguinal ligament lateral to the femoral artery. At this point, the nerve divides into multiple terminal branches, which have been classified as anterior and posterior. The anterior branches are primarily cutaneous, the deep branches chiefly motor.

The femoral nerve supplies the anterior compartment muscles of the thigh (quadriceps, sartorius) and the skin of the anterior thigh from the inguinal ligament to the knee. Its terminal branch is the saphenous nerve, which supplies an area of skin along the medial side of the leg from the knee to the big toe.

Clinical Applications

The femoral block is primarily used in concert with other peripheral blocks. However, it can be used alone for muscle biopsies of the quadriceps muscle or other surgical procedures limited to the anterior thigh, and it is reported effective for anesthetic management of knee arthroscopy and surgical repair of midfemoral shaft fractures.[81,82]

Technique

The patient is placed in the supine position. A line is drawn between the anterior superior iliac spine and the pubic tubercle, identifying the inguinal ligament. The femoral artery is marked. A 22-gauge, 4-cm needle is advanced lateral to this line (Fig. 48–17A). When the needle reaches the depth of the artery, a pulsation of the hub is visible. Elicitation of a paresthesia or motor response verifies correct needle position. Commonly, the anterior branch of the femoral nerve will be identified first. Stimulation of this branch leads to contraction of the sartorius muscle on the medial aspect of the thigh and should not be accepted. The needle should be redirected slightly laterally and with a deeper direction to encounter the posterior branch of the femoral nerve. Stimulation of this branch is identified by patellar ascension as the quadriceps

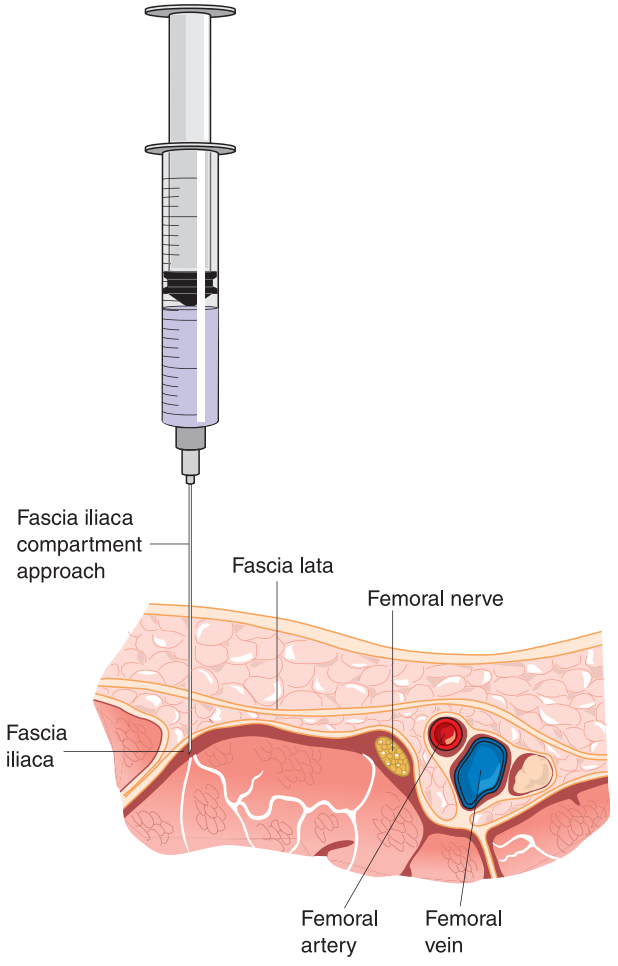

FIGURE 48–18. Lumbar plexus block: fascia iliaca approach. A discernable "pop" is noted as the needle traverses the fascia lata and then the fascia iliaca. Rochester, MN: Mayo Clinic Scientific Press, 2005:45.)

contract. Local anesthetic, 20 mL, is injected fanwise, lateral to the artery. If a paresthesia/nerve stimulator response is obtained, 7–10 mL of solution should be injected at that site.

Side Effects/Complications

Intravascular injection and hematoma are possible because of the close proximity of the femoral artery. However, anatomically, the nerve and artery are located in separate sheaths approximately 1 cm apart. In most patients with normal anatomy, the femoral artery can be easily palpated, allowing correct, safe needle positioning lateral to the pulsation. The presence of femoral vascular grafts is a relative contraindication to this block. Nerve damage is rare.

Lateral Femoral Cutaneous Nerve Block

The lateral femoral cutaneous nerve (L2 and L3) emerges at the lateral border of the psoas muscle immediately caudad to the ilioinguinal nerve. It descends under the iliac fascia to enter the thigh deep to the inguinal ligament 1–2 cm medial to the anterior superior iliac spine. The nerve emerges from the fascia lata 7–10 cm below the spine and divides into anterior and posterior branches. The skin of the lateral portion of the thigh from the hip to midthigh is supplied by the posterior branch; the anterior branch supplies the anterolateral thigh to the knee.

Clinical Applications

This block is useful for skin graft harvesting and can be used in concert with other peripheral nerve blocks for complete anesthesia of the lower extremity.

Technique

A point is marked 2 cm medial and 2 cm caudad to the anterior superior iliac spine. A 22-gauge, 4-cm needle is advanced perpendicular to the skin entry site until a sudden release indicates passage through the fascia lata. As the needle is moved fanwise laterally and medially, 10–15 mL of solution is injected, depositing local anesthetic above and below the fascia (Fig. 48–17A).

The nerve can also be blocked just medial and posterior to the anterior superior iliac crest with 10 mL of solution. Combining the two techniques increases the success rate, but the total volume of solution used may be limiting.

Side Effects/Complications

The extent of anesthesia is quite limited with this block, but there is a low risk of associated complications. Neuritis of this nerve secondary to needle trauma or drug toxicity is a potential but unlikely complication. Because there are no large blood vessels in the vicinity of this nerve, the likelihood of rapid uptake or intravascular injection is very small.

Obturator Nerve Block

The obturator nerve is derived primarily from the third and fourth lumbar nerves with an occasional minor contribution from L2. The nerve lies deep in the obturator canal, having descended from the medial border of the psoas muscle. As the nerve leaves the obturator canal, it divides into anterior and posterior branches. The anterior branch supplies an articular branch to the hip and the anterior adductor muscles and a variable cutaneous branch to the lower medial thigh. The posterior branch innervates the deep adductor muscles and may send an articular branch to the knee.

Clinical Applications

Usually, the obturator nerve is blocked as part of regional anesthesia for knee surgery. Because it is primarily a motor nerve, it is rarely blocked on its own; however, obturator nerve block can be useful in treating or diagnosing the extent of adductor spasm in patients with cerebral palsy and other muscle or neurologic diseases affecting the lower extremities prior to surgical intervention, such as adductor tenotomy.

Technique

The patient is placed in the supine position, and a mark is made 1–2 cm lateral and 1–2 cm caudad to the pubic tubercle. A skin wheal is raised, and a 22-gauge, 8–10-cm needle is advanced perpendicular to the skin entry site with a slight medial direction. The

inferior pubic ramus is encountered at a depth of 2–4 cm, and the needle is walked in a lateral and caudad direction, until it passes into the obturator canal. The obturator nerve is located 2–3 cm past the initial point of contact with the pubic ramus (Fig. 48–17B). After negative aspiration, 10–15 mL of local anesthetic is injected. A nerve stimulator is helpful in locating the obturator nerve; correct needle position is evidenced by contraction of the adductor muscles of the medial thigh.

The classic approach to obturator nerve block involves painful periosteal contact and multiple needle redirections. An alternate interadductor approach was described by Wasseff.[83] In this technique, the needle is inserted behind the adductor tendon, near its pubic insertion, and is directed laterally toward a mark on the skin 1–2 cm medial to the femoral artery and immediately below the inguinal ligament representing the obturator canal. The nerve is identified by a motor response to peripheral nerve stimulation in the adductor muscle.

Side Effects/Complications

Although complications are rare, this block is technically more difficult than other lower-extremity blocks. Because the obturator canal contains vascular and neural structures, there is a theoretical risk of intravascular injection, hematoma, and nerve damage. Absence of anesthesia in the obturator nerve distribution can render an otherwise perfect lower-extremity block inadequate for surgical procedures on the knee.

Sciatic Nerve Block

The sciatic nerve (L4 and L5, S1 through S3) is the largest of the four peripheral nerves of the lower extremity, with a width of 2 cm as it leaves the pelvis with the posterior cutaneous nerve of the thigh. The sciatic nerve is actually two nerves bound by a common sheath of connective tissue; the tibial component is medial and anterior, whereas the common peroneal component is lateral and slightly posterior. After passing through the sacrosciatic foramen beneath the piriformis muscle, it lies between the greater trochanter of the femur and the ischial tuberosity. The nerve becomes superficial at the lower border of the gluteus maximus muscle, where it begins its descent down the posterior aspect of the thigh to the popliteal fossa. It supplies cutaneous innervation to the posterior thigh and all of the leg and foot below the knee, except for a thin medial strip supplied by the saphenous nerve.

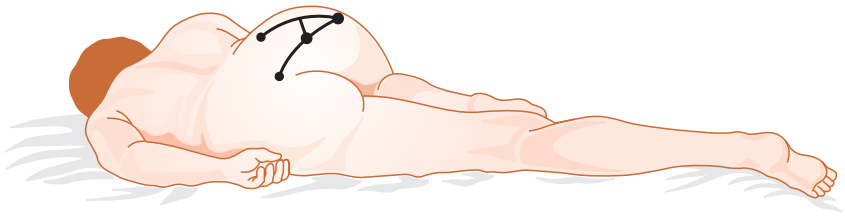

FIGURE 48–19. Posterior approach to the sciatic nerve: patient positioning. (Rerprinted from Wedel DJ, Horlocker TT. Nerve blocks. In: Miller RD, ed. Anesthesia. 6th ed. Philadelphia: Churchill Livingston, 2005:1686–1717, with permission from Elsevier.)

Clinical Applications

Because of its wide sensory distribution, the sciatic nerve block can be used, together with a saphenous or femoral nerve block, for any surgical procedure below the knee that does not require a thigh tourniquet. It can also be combined with other peripheral nerve blocks to provide anesthesia for surgical procedures involving the thigh and knee. The sciatic nerve may also be blocked at several sites in the hip and thigh. However, the more proximal approaches are necessary to achieve blockade of the posterior femoral cutaneous nerve, which is important in decreasing the posterior knee pain that knee replacement patients often experience in the early postoperative period.[14]

Because this form of anesthesia avoids the sympathectomy associated with neuraxial blocks, it may be advantageous when any shift in hemodynamics could be deleterious, such as in patients with significant aortic stenosis.

Technique

Classic Approach of Labat (Posterior) The patient is positioned laterally, with the leg to be blocked rolled forward onto the flexed knee as the heel rests on the knee of the dependent (nonoperative) leg (Fig. 48–19). A line is drawn to connect the posterior superior iliac spine to the greater trochanter of the femur. A perpendicular line is drawn bisecting this line and extending 5 cm caudad. A second line is drawn from the greater trochanter to the sacral hiatus. The intersection of this line with the perpendicular line indicates the point of needle entry and is located 3–5 cm along the line. A 22-gauge, 10–12-cm needle is advanced until a paresthesia or nerve stimulator response is elicited or bone is contacted (Fig. 48–20). If bone is encountered, the needle is redirected systematically in a lateral or medial direction. Once the needle is properly placed, a total of 20–30 mL of solution is injected.

Anterior Approach This technique is useful when the patient cannot be positioned for the classic posterior approach because of pain or lack of cooperation.[84] Blockade of the femoral nerve can be accomplished with the same needle insertion site.

With the patient in the supine position, a line drawn along the inguinal ligament from the anterior superior iliac crest to the pubic tubercle is trisected. A second line parallel to the inguinal ligament is drawn, beginning at the tuberosity of the greater trochanter. A 22-gauge, 10.5–12-cm needle is inserted perpendicularly with a slightly lateral angulation at the point where the line representing the juncture of the middle and medial thirds crosses the second line. This needle is advanced until it contacts bone, the lesser trochanter of the femur (Fig. 48–21). The needle is redirected medially past the femur, and a paresthesia/nerve stimulator response is sought at a depth of about 5 cm past bone. A total of 20–25 mL of solution is injected incrementally after careful aspiration.

Other Approaches The sciatic nerve can also be blocked with the patient in the lateral[85] and lithotomy positions,[86] although these are rarely employed clinically. A subgluteal approach, with needle insertion occurring at the midpoint of a line drawn between the greater trochanter of the femur and the ischial tuberosity has been described.[87] However identifying these bony landmarks in very obese patients is sometimes difficult and the patient position requires additional personnel to maintain. Furthermore, when using

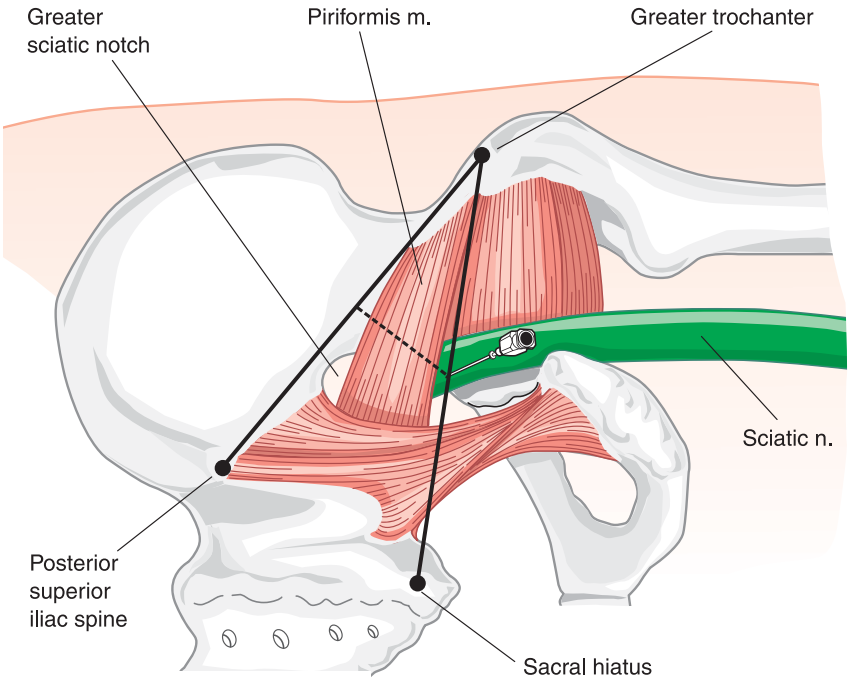

FIGURE 48–20. Anatomic landmarks for the posterior approach to sciatic nerve block. (Reprinted from Wedel DJ, Horlocker TT. Nerve blocks. In: Miller RD, ed. Anesthesia. 6th ed. Philadelphia: Churchill Livingston, 2005:1686–1717, with permission from Elsevier.)

more distal approaches to the sciatic nerve, the posterior femoral cutaneous nerve of the thigh will remain unblocked in a significant number of patients and result in pain as a consequence of surgery and/or tourniquet ischemia.

Techniques to Improve Success Rate Many methods have been tried to improve success with sciatic nerve blockade. Attempts to place the needle in the middle of the sciatic nerve by identifying a specific motor end point (foot inversion) might increase success rates.[88] Another method is the concept of multiple injections where the two major components of the sciatic nerve are separately identified and blocked.[46] Some experts recommend that sciatic nerve blocks be initiated well before the scheduled time of surgery to allow for long latencies.

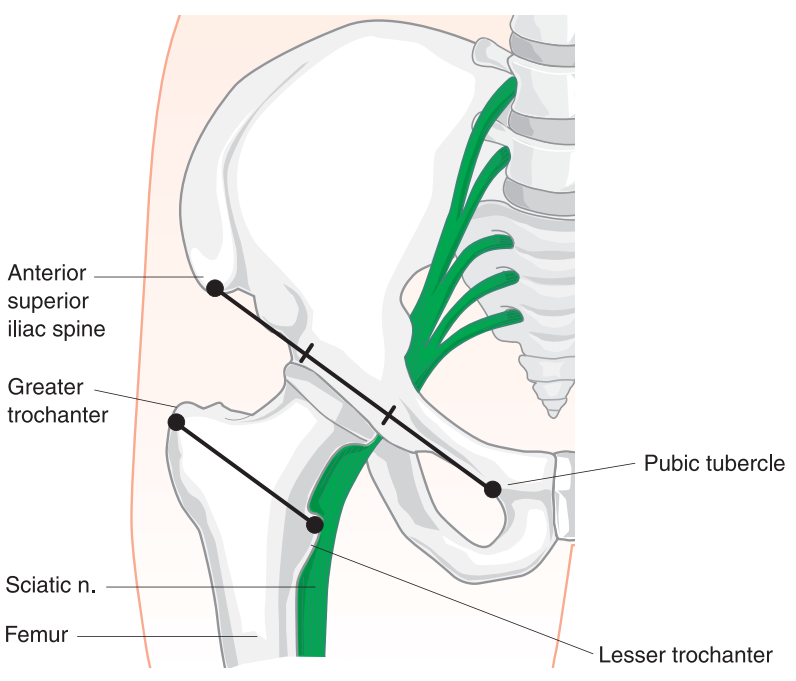

FIGURE 48–21. Anatomic landmarks for the anterior approach to the sciatic nerve block. (Reprinted from Wedel DJ, Horlocker TT. Nerve blocks. In: Miller RD, ed. Anesthesia. 6th ed. Philadelphia: Churchill Livingston, 2005:1686–1717, with permission from Elsevier.)

Side Effects/Complications

The block is technically difficult to perform and can be quite painful.[46] Hematoma formation is possible; the risk of nerve damage is also reported, although persistent paresthesias are usually self-limited. A minimal degree of vasodilatation may occur with sciatic nerve block.

Popliteal Fossa Block

The posterior muscles of the thigh are the biceps femoris, the semimembranosus, semitendinosus, and the posterior portion of the adductor magnus. As these muscles are traced distally from their origin on the ischial tuberosity, they separate into medial (semimembranosus, semitendinosus) and lateral (biceps) musculature, and form the upper border of the popliteal fossa. The lower border of the popliteal fossa is defined by the two heads of the gastrocnemius. In the upper part of the popliteal fossa, the sciatic nerve lies posterolateral to the popliteal vessels. Specifically, the popliteal vein is medial to the nerve, while the

popliteal artery is most anterior, lying on the popliteal surface of the femur. Near the upper border of the popliteal fossa, the two components of the sciatic nerve separate. The peroneal nerve diverges laterally and the larger tibial branch descends almost straight down through the fossa. The tibial nerve and popliteal vessels then disappear deep to the converging heads of the gastrocnemius muscle.

Clinical Applications

This block is chiefly used for foot and ankle surgery. The block has also been successfully used in the pediatric population. Popliteal fossa block is preferable to ankle block for surgical procedures requiring the use of a calf tourniquet. The components of the sciatic nerve may be blocked at the level of the popliteal fossa through posterior or lateral approaches. Supplemental block of the saphenous nerve is required for surgical procedures to the medial aspect of the leg, or when a calf tourniquet/Esmarch bandage is used.

Technique

Posterior Approach The classic approach to the popliteal fossa is posteriorly, with the patient positioned prone. However, access may also occur with the patient in the lateral (operative side nondependent) or supine (with leg flexed at the hip and knee) positions.

The borders of the popliteal fossa are identified by flexing the knee joint. A triangle is constructed, with the base consisting of the skin crease behind the knee, and the two sides composed of the semimembranosus (medially) and the biceps (laterally). A bisecting line is drawn from the apex to the base of the triangle, and a 5-cm needle is inserted at a site 5–10 cm above the skin fold and 0.5–1 cm lateral to the bisecting line (Fig. 48–22A). Classically, the 5-cm distance was described.[89] However, in an attempt to block the sciatic nerve prior to its division, a 7–10-cm distance has been recommended.[90] The needle is advanced at a 45° angle until either a paresthesia or nerve stimulator response is elicited. With a nerve stimulator technique, inversion is the motor response that best predicts complete neural block of the foot.[91] Injection of approximately 30-mL of local anesthetic solution is sufficient.

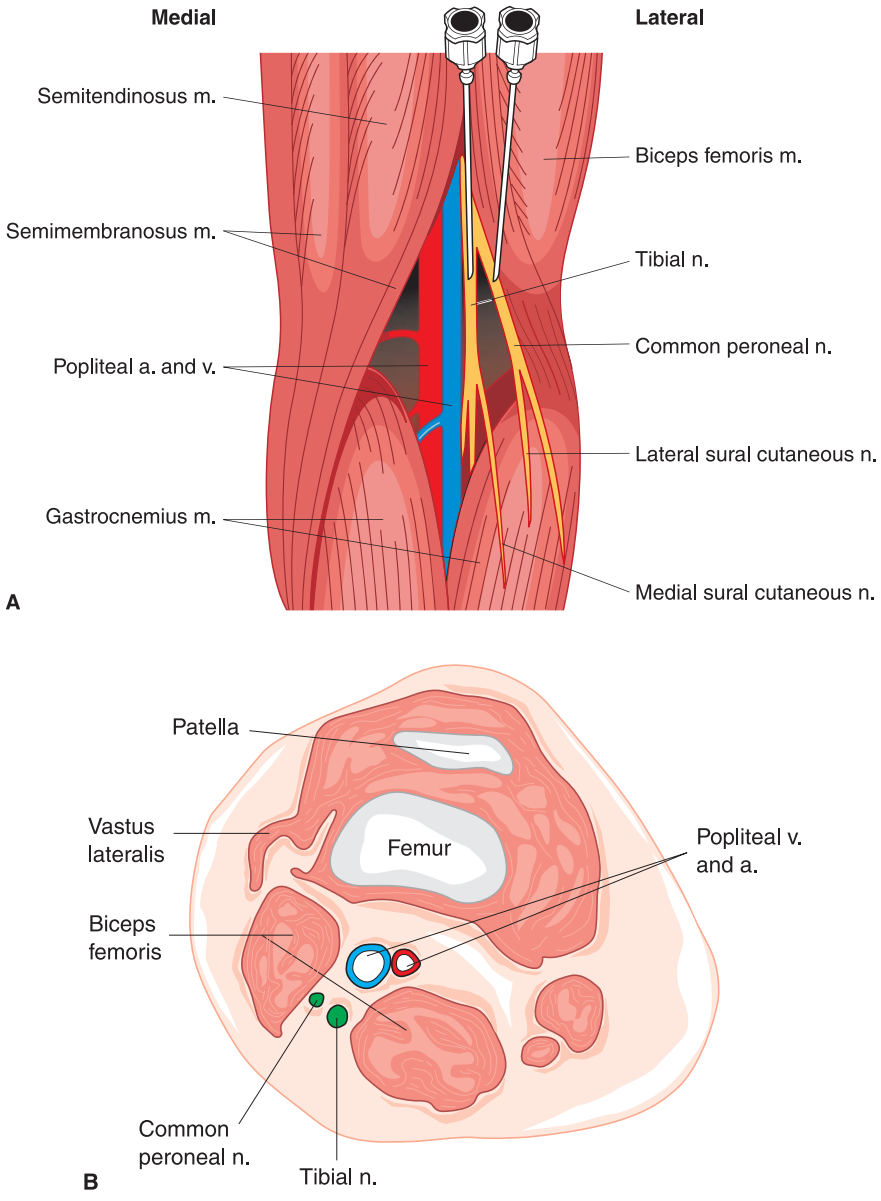

FIGURE 48–22. **A.** Anatomic landmarks for posterior approach to the sciatic nerve in the popliteal fossa. **B.** Anatomic landmarks for lateral approach to the sciatic nerve in the popliteal fossa. (Reprinted from Wedel DJ, Horlocker TT. Nerve blocks. In: Miller RD, ed. Anesthesia. 6th ed. Philadelphia: Churchill Livingston, 2005:1686–1717, with permission from Elsevier.)

Success rate is typically 90–95%.[89,91] No formal comparison between paresthesia and nerve stimulator techniques has been performed to assess efficacy and complications. It is believed that incomplete block is the result of poor diffusion (because of the size of the sciatic nerve), the separate fascial coverings of the tibial and peroneal nerves, or to blockade of only a single component of the sciatic nerve. Identification of both tibial and peroneal components decreases onset time and improves success rate.[92]

Lateral Approach A lateral approach to blockade of the sciatic nerve in the popliteal fossa has been described.[93] Although block time is somewhat longer, onset and quality of block are similar to the posterior approach.[94] The lateral approach allows the patient to be positioned supine and eliminates the need for repositioning. The patient's leg is extended, with the long axis of the foot at a 90° angle to the table. The site of insertion is the intersection of the vertical line drawn from the upper edge of the patella and the

groove between the lateral border of the biceps femoris and vastus lateralis. A 10-cm needle is advanced at a 30° angle posterior to the horizontal plane (Fig. 48–22B). Because the common peroneal nerve is located lateral to the tibial nerve, the stimulating needle encounters the common peroneal nerve first with the lateral approach. As with the classic posterior approach, an elicited inversion response is sought.[91] If a response associated with common peroneal nerve stimulation (such as eversion) is elicited, the needle is redirected more posteriorly.

Side Effects/Complications

As with other peripheral nerve blocks, neuropathy is the most common complication. Intravascular injection may occur as a result of the presence of vascular structures within the popliteal fossa. Performance of popliteal fossa block in patients with previous total knee arthroplasty or vascular bypass (femoral–popliteal) should be done with care. To date, however, there are no cases of graft disruption or joint infections relating to needle placement in these patients.

Nerve Blocks at the Ankle

Four of the five individual nerves that can be blocked at the ankle to provide anesthesia of the foot are terminal branches of the sciatic nerve: the posterior tibial, sural, superficial peroneal, and deep peroneal branches. The sciatic nerve divides at or above the apex of the popliteal fossa to form the common peroneal and tibial nerves. The common peroneal nerve descends laterally around the head of the fibula, where it divides into the superficial and deep peroneal nerves.

The tibial nerve divides into the posterior tibial and sural nerves in the lower leg. The posterior tibial nerve becomes superficial at the medial border of the Achilles tendon near the artery of the same name, and the sural nerve emerges lateral to the Achilles tendon.

Clinical Applications

Ankle blocks are simple to perform and offer adequate anesthesia for surgical procedures of the foot not requiring a tourniquet above the ankle. When a thigh tourniquet is required, a more proximal approach to the sciatic nerve (with supplemental saphenous nerve block) or spinal anesthetic is performed.[87]

Technique

Posterior Tibial Nerve The posterior tibial nerve can be blocked with the patient in either the prone or the supine position. The posterior tibial artery is palpated, and a 25-gauge, 3-cm needle is inserted posterolateral to the artery at the level of the medial malleolus (Fig. 48–23A and B). A paresthesia is often elicited; however, it is not necessary for a successful block. If a paresthesia is obtained, 3–5 mL of local anesthetic should be injected. Otherwise, 7–10 mL of solution should be injected as the needle is slowly withdrawn back from the posterior aspect of the tibia. Blockade of the posterior tibial nerve provides anesthesia of the heel, plantar portion of the toes, and the sole of the foot, as well as some motor branches in the same area.

Sural Nerve The sural nerve is located superficially between the lateral malleolus and the Achilles tendon. A 25-gauge, 3-cm needle is inserted lateral to the tendon and is directed toward the malleolus as 5–10 mL of solution is injected subcutaneously (Fig. 48–23A and C). This block provides anesthesia of the lateral foot and the lateral aspects of the proximal sole of the foot.

Deep Peroneal, Superficial Peroneal, and Saphenous Nerves The deep peroneal, superficial peroneal, and saphenous nerves can be blocked through a single needle entry site (Fig. 48–24). A line is drawn across the dorsum of the foot connecting the malleoli. The extensor hallucis longus tendon is identified by having the patient dorsiflex the big toe. The anterior tibial artery lies between this structure and the tendon of the extensor digitorum longus muscle and is palpable at this level. A skin wheal is raised just lateral to the pulsation between the two tendons on the intermalleolar line. A 25-gauge, 3-cm needle is advanced perpendicular to skin entry site, and 3–5 mL of local anesthetic injected deep to the extensor retinaculum to block the deep peroneal nerve. This technique anesthetizes the skin between the first and second toes and the short extensors of the toes.

The needle is now directed laterally through the same skin wheal while injecting 3–5 mL of solution subcutaneously, thus blocking the superficial peroneal nerve and resulting in anesthesia of the dorsum of the foot, excluding the first interdigital cleft. The same maneuver can now be performed in the medial direction, thereby anesthetizing the saphenous nerve, a terminal branch of the femoral nerve that supplies a strip along the medial aspect of the foot.

Side Effects/Complications

Multiple injections are required for some techniques, resulting in discomfort for the patient. Persisting paresthesia may occur, but it is self-limited. The presence of edema or induration in the area of the ankle block can make palpation of landmarks difficult. Intravascular injection is possible but unlikely if aspiration for blood is negative. The volume of local anesthetic used is small, thereby decreasing the risk of local anesthetic toxicity.

Continuous Catheter Techniques

Continuous lower-extremity techniques were described decades ago, but remained underused compared to continuous upper-extremity and neuraxial approaches. For example, Brands and Callanan[95] placed psoas compartment catheters to provide analgesia for femoral neck fractures in 1978. Reliable (and improved) success rates and the risk of spinal hematoma following neuraxial techniques lead clinicians to again consider continuous lower-extremity blocks. Contemporary applications for continuous psoas compartment, sciatic, femoral, and popliteal fossa blockade have been reported.[60,76,96] Compared to conventional systemic and neuraxial analgesic methods, continuous lower-extremity blocks provide superior analgesia with fewer side effects, improve perioperative outcomes, and accelerate hospital dismissal following major joint replacement.[76,96,97]

Perioperative Outcomes with Lower-Extremity Peripheral Regional Techniques

The unilateral nature of lower-extremity peripheral techniques makes them ideal for the patient undergoing total

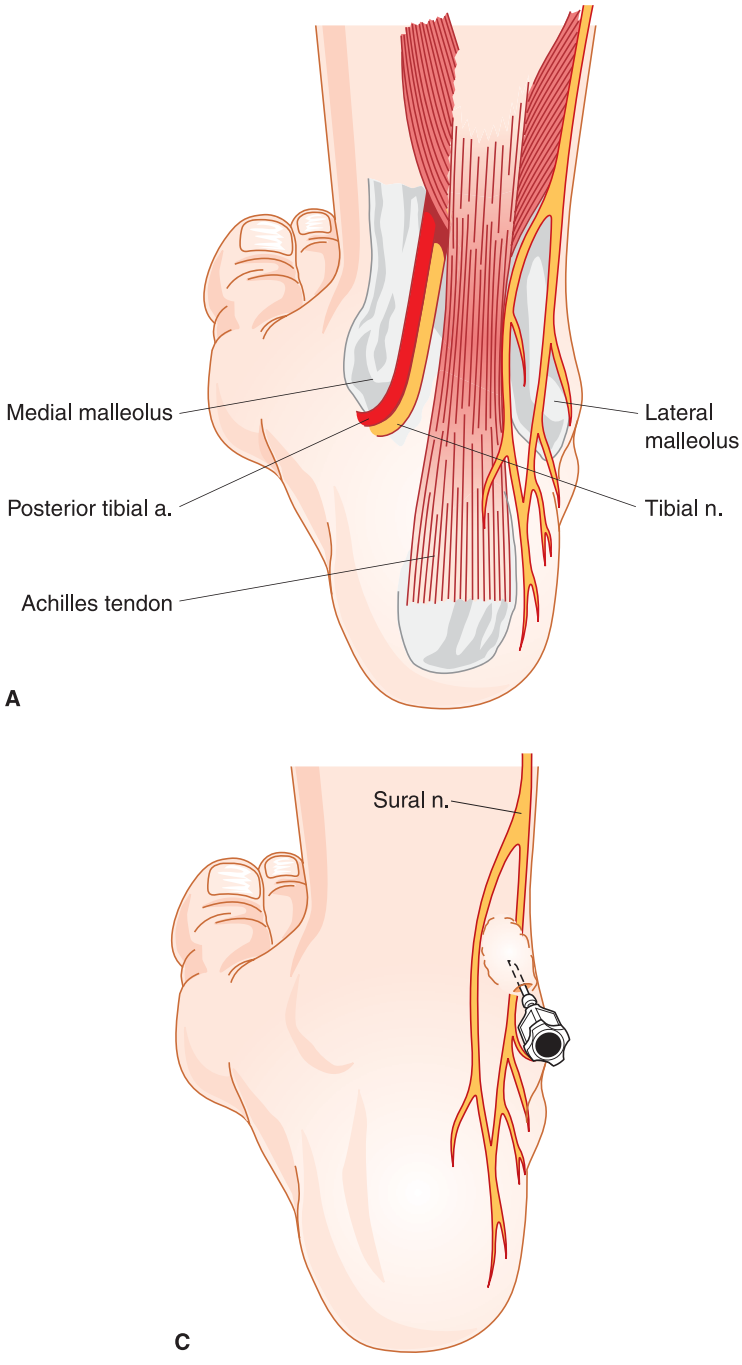

FIGURE 48–23. **A.** Anatomic landmarks for block of the posterior tibial and sural nerves at the ankle. **B.** Posterior tibial nerve. hip or knee arthroplasty, as the contralateral limb is immediately available to assist with early ambulation. Although single-injection techniques have been used, the duration of effect after a single injection is insufficient to result in major improvements in analgesia or outcome.[68,98,99]

Studies demonstrate that peripheral techniques are equally effective as epidural analgesia (and both are superior to intravenous morphine) in providing analgesia and facilitating rehabilitation after total joint replacement. For example, after total knee arthroplasty, patients receiving epidural analgesia or continuous femoral block reported lower pain scores, better knee flexion, faster ambulation, and shorter hospital stays than did patients who received intravenous morphine.[96,97,100] However, continuous femoral block was the preferred analgesic technique in each study because there were fewer technical problems and fewer side effects noted compared to epidural and systemic approaches. Similar results were reported for patients undergoing total hip arthroplasty who received a continuous psoas block rather than epidural analgesia or intravenous morphine.[76]

Recent innovations emphasize continuous peripheral nerve blocks combined with multiple scheduled analgesics (OxyContin, acetaminophen) and oral analgesics (e.g., oxycodone); no intravenous opioids are administered. Using strict criteria, 90% of patients undergoing minimally invasive prima-

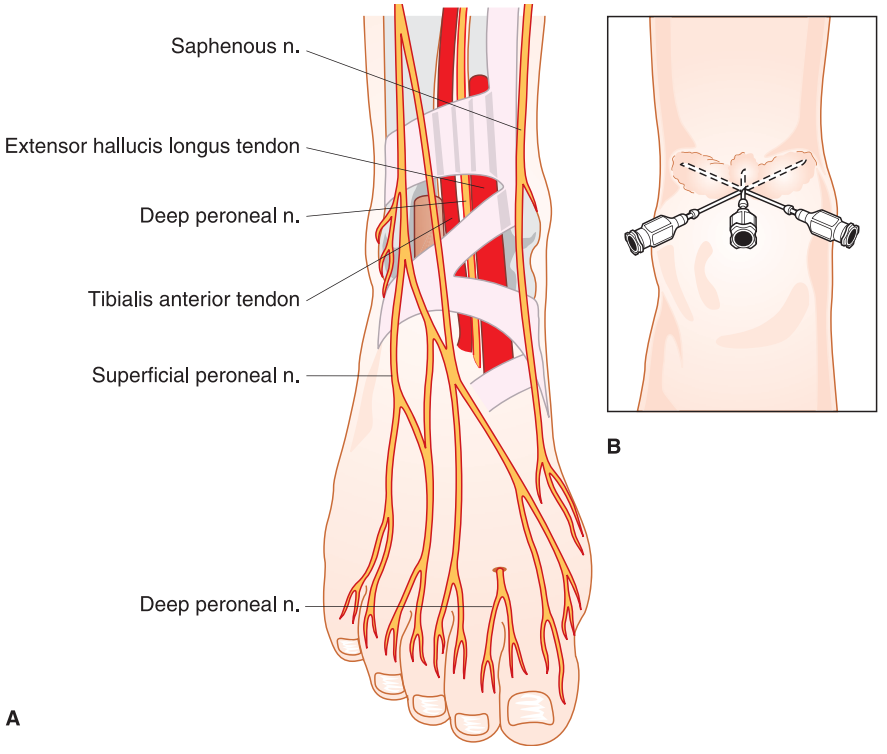

FIGURE 48–24. **A.** Anatomic landmarks for block of the deep peroneal, superficial peroneal, and saphenous nerves at the ankle. **B.** Method of needle placement for block of the deep peroneal, superficial peroneal, and saphenous nerves through a single needle entry site. ry hip or knee replacement achieved readiness for hospital discharge within 48 hours.[101] These studies support the movement toward continuous peripheral technique as the optimal analgesic method following total knee and hip arthroplasty. Additional information is needed to determine the effectiveness of these techniques in conventional primary and revision joint arthroplasty.

NEUROLOGIC COMPLICATIONS

Nerve injury is a recognized complication of peripheral regional techniques. In a series involving more than 100,000 regional anesthetics, the frequency of neurologic complications following peripheral blockade was less than that associated with neuraxial techniques, and was associated with pain on needle placement or injection of local anesthetic.[102] Risk factors contributing to neurologic deficit after regional anesthesia include neural ischemia, traumatic injury to the nerves during needle or catheter placement, infection, and choice of local anesthetic solution. However, postoperative neurologic injury as a result of pressure from improper patient positioning, tightly applied casts/surgical dressings, and surgical trauma are often attributed to the regional anesthetic. Patient factors, such as body habitus or a preexisting neurologic dysfunction, can also contribute to postoperative neurologic injury.

Although needle gauge, type (short vs. long bevel), and bevel configuration can influence the degree of nerve injury following peripheral nerve block, the findings are conflicting and there are no confirmatory human studies. Theoretically, localization of neural structures with a nerve stimulator would allow a high success rate without increasing the risk of neurologic complications, but this has not been established. Indeed, serious neurologic injury has been reported following uneventful brachial plexus block using a nerve stimulator technique.[30] Likewise, prolonged exposure, high dose and/or high concentrations of local anesthetic solutions also can result in permanent neurologic deficits. In laboratory models, the addition of epinephrine increases the neurotoxicity of local anesthetic solutions and decreases nerve blood flow. However, the clinical relevance of these findings in humans remains unclear. Finally, nerve damage caused by traumatic needle placement, local anesthetic neurotoxicity and neural ischemia during the performance of a regional anesthetic may worsen neurologic outcome in the presence of an additional patient factor or surgical injury.[7]

Prevention of neurologic complications begins during the preoperative visit with a careful evaluation of the patient's medical history and appropriate preoperative discussion of the risks and benefits of the available anesthetic techniques. It is imperative that all preoperative neurologic deficits are documented to allow early diagnosis of new or worsening neurologic dysfunction postoperatively. Postoperative sensory or motor deficits must also be distinguished from residual (prolonged) local anesthetic effect. Imaging techniques, such as CT and MRI are useful in identifying infectious processes as well as expanding hematomas. Although most neurologic complications resolve completely within several days or weeks, significant neural injuries necessitate neurologic consultation to document the degree of involvement and coordinate further workup. Neurophysiologic testing, such as nerve conduction studies, evoked potentials, and electromyography are often useful in establishing a diagnosis and prognosis.

HEMORRHAGIC COMPLICATIONS

Although spinal hematoma is the most significant hemorrhagic complication of regional anesthesia because of the catastrophic nature of bleeding into a fixed and noncompressible space, the associated risk following plexus and peripheral techniques remains undefined. No investigation has examined the frequency and severity of hemorrhagic complications following plexus or peripheral blockade in anticoagulated patients.

Several cases of vascular injury with (or without resultant nerve dysfunction) have been described following plexus or peripheral techniques in patients with normal and abnormal hemostasis. In all patients with neurologic deficits, neurologic recovery was

complete within 6–12 months. Thus, while bleeding into a neurovascular sheath may result in significant decreases in hematocrit, the expandable nature of peripheral site may decrease the chance of irreversible neural ischemia.[103]

Importantly, all cases of major bleeding associated with nonneuraxial techniques occurred after psoas compartment or lumbar sympathetic blockade. Anticoagulants implicated included warfarin, low-molecular-weight and standard heparin, and thienopyridine derivatives (clopidogrel and ticlopidine). These cases suggest that significant blood loss, rather than neural deficits may be the most serious complication of nonneuraxial regional techniques in the anticoagulated patient. Additional information is needed to make definitive recommendations. Conservatively, the Consensus Statements on Neuraxial Anesthesia and Anticoagulation may be applied to plexus and peripheral techniques.[103] However, this may be more restrictive than necessary. Rather, consideration of the degree and duration of anticoagulation as well as the specific site of needle/catheter placement are paramount in optimal management. In general, the authors recommend management of perineuraxial techniques (psoas compartment, lumbar sympathetic) similar to that of neuraxial techniques, whereas more blockade/catheter placement at more superficial and compressible sites (femoral, axillary) may be managed more liberally.

INFECTIOUS COMPLICATIONS OF PERIPHERAL REGIONAL TECHNIQUES

Although meningitis and epidural abscess are the most significant infectious complications of regional anesthesia, the associate risk following plexus and peripheral techniques remain undefined. Auroy et al.[102] reported no infectious complications in 21,278 single-injection peripheral nerve blocks. The more frequent placement of catheters for peripheral nerve blockade, often for prolonged periods, might be expected to increase the risk of infectious complications; however, few data are available to support this theoretical assumption. Two studies look more specifically at the infectious risk in continuous peripheral nerve blocks. Capdevila et al.[104] prospectively studied 1416 patients in 10 centers undergoing continuous peripheral nerve blocks for orthopedic procedures. A total of 969 (68%) catheters were cultured when removed, and patients were actively monitored for signs of localized infection or sepsis. A positive bacterial colonization was found in 278 (29%) catheters, most commonly *Staphylococcus epidermidis*. Local inflammation was present in 3% of patients. In these patients, 44% of the catheters were colonized, whereas only 19% of catheters were colonized in patients without inflammatory signs. There was no correlation between colonization and the presence of fever. Risk factors for local infection/inflammation were admission to an intensive care unit, male gender, catheter duration exceeding 48 hours and lack of antibiotic prophylaxis. Cuvillon et al.[105] investigated the incidence of infectious complications in 211 continuous femoral catheters. Colonization of the 208 catheters examined after 48 hours showed a rate of 57%, with the most common organism again being *S. epidermidis* (71%). Echography was performed in each instance of positive catheter colonization. Although no cellulitis or abscess was noted, three transitory bacteremias were attributed to the presence of the femoral catheters. There were no long-term sequelae in these two series as a consequence of infectious causes. Although the necessity of antibiotic prophylaxis during placement of permanent epidural catheters and implantable devices to treat chronic pain is well defined, the importance of antibiotic prophylaxis during placement and maintenance of neuraxial or peripheral catheters is less clear. In a series of 405 axillary catheters, the single infectious complication occurred in a nonsurgical patient who did not receive the "usual" perioperative antibiotic prophylaxis.[63] Until additional information is available, observance of aseptic technique and daily monitoring of catheter site (with appropriate removal if signs of infection are present) are the only evidence-based recommendations possible at this time.

SUMMARY

Although it is possible to perform all surgical procedures while the patient is under general anesthesia, the addition of peripheral nerve block techniques to the anesthesiologist's armamentarium adds flexibility and skills that benefit the patient both intraoperatively and postoperatively. Successfully mastering these techniques and applying them to the appropriate clinical situations add valuable options to the anesthetic care. Finally, for the anesthesiologist, knowledge of regional anesthesia is essential for the diagnosis and treatment of acute and chronic pain syndromes.

CHAPTER 49

Managing Adverse Outcomes during Regional Anesthesia

Ban C.H. Tsui, MSc, MD, FRCPC, and Brendan T. Finucane, MBBCh, FRCPC

No matter how skillful an anesthesiologist may be, adverse perioperative events are inevitable during regional anesthesia practice. Adverse events have been associated with regional anesthesia since local anesthetics were first introduced by Koller in 1884,[1] and will continue no matter how skillful we become. Because it is difficult to thoroughly address all regional anesthesia complications in this chapter, we focus our attention on those areas that have the most relevance to today's practice. This chapter addresses the principles involved in managing complications that are common to all regional anesthesia techniques. Subsequently, we address specific management of complications associated with the most commonly used regional anesthesia techniques.

GENERAL PRINCIPLES

Importance of Prevention

The time-honored statement that "an ounce of prevention is worth a pound of cure" is essential to remember[2] when considering the management of adverse outcomes in regional anesthesia practice. The most effective way to manage regional anesthesia complications is to prevent or minimize the risk of these complications occurring in the first place. Neurologic injury is one of the most dreaded complications associated with all anesthesia techniques, including regional anesthesia, and it is important to realize that once a serious neurologic injury occurs the chances of full recovery are unlikely.

Safe regional anesthesia begins with the first encounter with the patient. The first task at hand is to perform a thorough preoperative assessment of the patient. Good results are obtained when a *skilled* anesthesiologist uses appropriate equipment and technique. Careful intraoperative sedation and monitoring are vital to the practice of safe regional anesthesia. Resuscitation drugs and equipment must always be immediately available in the event of a problem or if general anesthesia is required. Last but not least, patients must be carefully observed during the postoperative period when most of the serious complications become evident. Early intervention is of the utmost importance in preventing permanent neurologic injury. The anesthesiologist should also be familiar with and aware of the legal implications of adverse events should they occur.

Poor outcomes and serious complications are *not* prima facie evidence of negligence. However, the risk of litigation in contemporary anesthesia practice is closely associated with the severity of patient injury rather than the occurrence of negligence; this is particularly true of regional anesthesia injuries. The Closed Claims study in the United States reported a high incidence of successful suits against anesthesiologists involved in regional anesthesia cases, even though the standard of care was met. The importance of effective communication and truthful disclosure with the patient and the patient's family cannot be overemphasized. Litigation generally results from the combination of an adverse event and a poor physician–patient relationship. A patient who feels that the physician has the patient's best interests at heart is less likely to pursue litigation than is a patient who does not respect or trust the physician; thus, the anesthesiologist should pay particular attention toward developing a good rapport with the patient in the limited time allotted. Table 49–1 summarizes basic recommendations for maintaining a

KEY POINTS

1. Safe regional anesthesia begins with a thorough knowledge of anatomy. In Labat's words, "anatomy is the foundation upon which the entire concept of regional anesthesia is built." Studying the anatomy of the major plexuses and peripheral nerves is critical for learning regional anesthesia and avoiding its complications.
2. Prior to performing regional anesthesia, it is imperative to thoroughly discuss the techniques, and their limitations, with the patient. Assessing which patients are most appropriate for performing these techniques on is important, as some are not suitable candidates (e.g., those with major anatomic distortion or serious mental illness).
3. One of the most important principles for safe regional anesthesia is provision of a comfortable patient environment. If a patient suffers as a result of one's intervention, a basic principle of the practice of anesthesia has been violated.
4. Resuscitation equipment must be immediately available when performing regional anesthesia and one must be prepared, at all times, to anesthetize and resuscitate the patient when necessary.
5. Knowing when to stop performing regional anesthesia techniques is crucial. Dogged persistence in the face of failure is inadvisable. Do not hesitate to seek assistance when faced with difficulties and be prepared to change to an alternative route of anesthesia if persistent failure (more than 3 attempts or 20 minutes) occurs.
6. Do not perform regional anesthesia procedures in anesthetized adult patients unless the benefits far outweigh the risks. If this principle is violated, the reasoning must be documented in the patient's file.
7. Always be accompanied by a skilled assistant when performing regional anesthesia.
8. Always ensure adequate patient monitoring during regional anesthesia performance and continuing until the block has completely worn off.
9. If neurologic injury is suspected following regional anesthesia, the cause should be determined quickly so as to prevent permanent injury.
10. One must not assume that all patient injury is from regional anesthesia, as other possibilities exist. Do not hesitate to involve other disciplines in the quest to determine the cause of injury.

TABLE 49–1.

Maintaining a Standard of Care during Regional Anesthetic Practice

- Preoperative patient selection
- Appropriate consent
- Using appropriate equipment and technique
- Monitoring regional anesthesia practice
- Accurate and meticulous anesthesia documentation
- Physician–patient communication
- Postoperative followup visit

standard of care in regional anesthesia practice. Maintaining a standard of care at all times does not guarantee against legal action, but it certainly will minimize the risk and is to be encouraged at all times.[3] Legal issues involving anesthesiology practice are discussed in detail in Chap. 95.

The following is a simple guide detailing how to minimize the risk of an adverse legal event by maintaining accepted standards of care during the practice of regional anesthesia.

Patient Selection

Proper patient selection is a critical consideration for the safe and successful performance of regional anesthesia, as not all patients are suitable candidates for regional anesthesia. Some patients are not psychologically suitable for regional anesthesia. A number of patients suffer from needle phobias and faint at the least provocation. Patients with schizophrenia are not suitable candidates for regional anesthesia unless it is combined with general anesthesia. Gross anatomic distortion may preclude the performance of regional anesthesia in some patients. Neuraxial techniques are frequently associated with hemodynamic disturbances such as bradycardia and hypotension; therefore they are contraindicated in hemodynamically unstable patients and in those with fixed cardiac outputs. Regional anesthesia should be used cautiously in patients with preexisting neurologic disease and if these techniques are employed in these patients, neurologic deficits must be clearly documented prior to the performance of regional anesthesia. Some patients are rigidly opposed to regional anesthesia and it is important not to badger them into accepting these techniques if they are reluctant to participate in the first place. If it is clearly evident that a patient will benefit from regional anesthesia, it is reasonable to explain in detail the rationale behind the procedure; however, the decision to undergo regional anesthesia must be finally left to the discretion of the patient. It is very important to discuss the options of anesthesia with patients even if they are undergoing minor operative procedures. It is imperative to follow national and international guidelines pertaining to regional anesthesia practice (i.e., American Society of Anesthesiologists [ASA] monitoring, American Society of Regional Anesthesia and Pain Medicine [ASRA] guidelines for anticoagulated patients), and if there is any deviation it is important to specify the reasons and to document them. Table 49–2 summarizes the important factors involved in selecting suitable patients for regional anesthesia.

Consent

Potentially serious complications associated with regional anesthesia should be disclosed to patients, including convulsions and the risk of cardiac toxicity from systemic injections of local anesthetics, spinal cord/nerve injury leading to paralysis or neurologic deficit, pneumothorax, hematoma, infection, cardiac arrest, and death. Any common unpleasant side effects specific to certain procedures such as the failure to achieve surgical anesthesia, patient awareness during conscious sedation, nausea, pruritus, headache, shivering, backache, dizziness, and urinary retention should also be discussed. Howev-

TABLE 49–2.

Patient Selection Factors

Factors Involved in Patient Selection	Relative Contraindications	Absolute Contraindications
Patient cooperation	Anxiety states; needle phobias; poorly controlled psychiatric disease; language barriers; pediatric patients	Patient refusal
Anatomic and physiologic considerations	Anatomical anomalies; technical challenges: obesity, severe arthritis, degenerative joint disease	
Anesthetic considerations		Lack of experience and skills; lack of appropriate equipment for performing the block (e.g., nerve stimulator, ultrasonogram); lack of appropriate equipment for resuscitation and monitoring (e.g., oxygen, mask, drugs)
Coexisting diseases	Preexisting progressive neurologic disease; comatose states; sepsis; coagulopathy	Infection at the site of injection; allergy to local anesthetics; coagulopathy (although an International Normalized Ratio [INR] of <2 is acceptable for ophthalmic procedures)
Surgical procedures	Lengthy procedures that outlast the duration of action of the local anesthetic (single-injection techniques; uncomfortable positioning for an extended period of time)	

er, anesthesiologists should bear in mind that even with informed consent, proper disclosure, effective communication, and an appropriate ethical approach, there is no guarantee that they will be legally protected.[4]

Informed consent and an explanation of the risks and alternatives to regional anesthesia must be provided to the patient (the anesthesiologist should never coerce a patient to accept or reject any anesthetic plan).

Use of Appropriate Equipment and Technique

As advances in regional anesthesia continue, techniques used must be continuously revised in light of any new, clinically relevant information and developments. For years, we have been percutaneously inserting needles toward neural targets and have relied solely on our knowledge of anatomy and our somewhat primitive techniques (i.e., paresthesia and the loss-of-resistance [LOR] technique). The introduction of nerve stimulation was an important advance in regional anesthesia because it provided some objective evidence that the needle tip was close to the neural target. Although it did take a long time to convince the artisans of regional anesthesia that the application of nerve stimulation in regional anesthesia was useful, most anesthesiologists currently use nerve stimulation techniques in regional anesthesia. Although nerve stimulation techniques have been used in regional anesthesia for more than 30 years, the science of this technique has not been studied in any great detail.

Nerve stimulation was the first step in the conversion of regional anesthesia from an art to a science. One of the most exciting new advances in regional anesthesia in recent years has been the introduction of ultrasonography as a method to accurately place needles in close proximity to neural targets. Ultrasonography allows real-time visualization of anatomical structures and offers the potential to guide needle and catheter placement in regional anesthesia. This section highlights recent advances in nerve stimulation and ultrasonography that may play an important role in preventing complications during regional anesthesia practice.

Nerve Stimulation in Regional Anesthesia: Peripheral Nerve Blockade Despite years of clinical use, the electrophysiologic effect of injectates on nerve stimulation has never been fully explained. The classical unanswered question concerning electrical stimulation is why is it that one may not be able to consistently stimulate a nerve with a current of less than 0.5 mA, even after eliciting a paresthesia in that nerve? Another phenomenon that is poorly understood is the "Raj test." The following is a brief description of the Raj test: when nerve stimulation is being used to locate a nerve, a twitch is observed when the needle tip is close to the neural target. Ideally, the twitch is required to persist at a current of 0.5 mA. The clinician then injects a small volume of local anesthetic or normal saline through the needle. If the needle tip is in the correct location, the muscle twitch immediately disappears.[5] Until very recently the disappearance of the twitch was thought to be caused by physical displacement of the nerve by the injectate.[6] We recently learned that this mechanism is best explained in electrical terms and is not entirely a result of the physical displacement of the nerve.[7] In a porcine model, the injection of 0.9% sodium chloride solution (NaCl) abolished the motor response, and a subsequent injection of 5% dextrose reestablished a motor response during peripheral nerve stimulation.[7] An accompanying in vitro experiment showed that injections of solutions, such as 0.9% NaCl, cause a change in the electrical field at the needle–tissue interface. It was concluded that the injection of electrically conducting solutions (saline or local anesthetic) increases the conductive area surrounding the stimulating needle tip, leading to a decrease in the current density surrounding the target nerve. The current density surrounding the needle tip is then no longer sufficient to stimulate the desired nerve.[7] This observation suggests that effective nerve stimulation is sensitive to changes that occur at the needle–tissue interface, such as the angle of the needle or the injection of the local anesthetic. The net effect of these changes is to alter the current density at the tip of the needle or the path of the electric current, ultimately resulting in a change in the quality of the motor response.[8] This phenomenon has also recently been reported in a clinical setting (Fig. 49–1).[9,10] In a clinical study, the mean current required to stimulate the supraclavicular, axillary, femoral, and sciatic nerves when using an insulated needle was 0.6, 0.5, 0.7, and 0.5 mA, respectively.[11] In contrast, the mean current required to stimulate these same nerves when using a stimulating catheter following the injection of normal saline, was

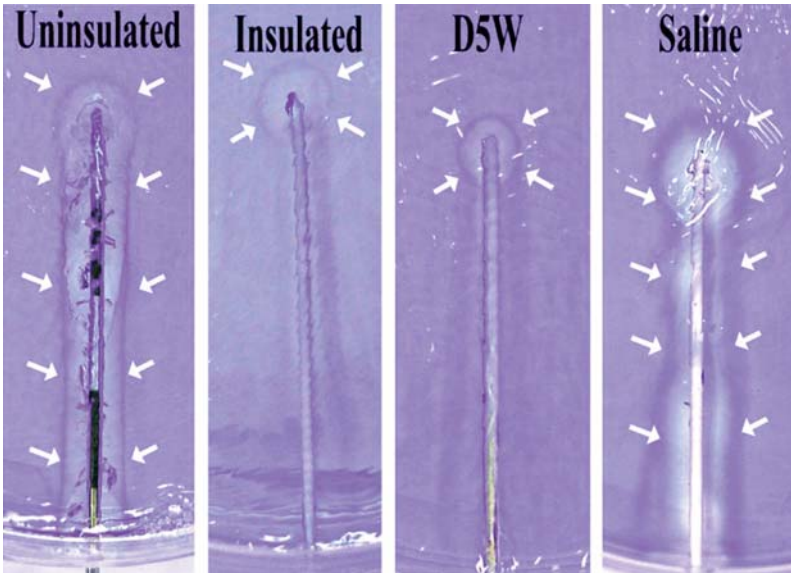

FIGURE 49–1. Gel electrophoresis: changes in the electrical field with uninsulated and insulated needles after 5% dextrose in water (D_5W) and saline injection. Arrows show the margin of the clear zone/electric field. *Far left*: Diffuse electric field with an uninsulated needle; *center left*: narrow electric field with an uninsulated needle; (*center right*): electric field with an insulated needle after D_5W injection remains narrow; *far right*: diffuse electric field with an insulated needle after normal saline injection. (Reprinted and adapted from Tsui BC, Wagner A, Finucane B. Electrophysiologic effect of injectates on peripheral nerve stimulation. Reg Anesth Pain Med 2004;29(3):189–193. Copyright May 2004, with permission from American Society of Regional Anesthesia and Pain Medicine.[7])

much higher (1.5, 1.5, 2, and 3 mA, respectively).[11] Those findings had important clinical implications as:

- One may potentially use a nonconducting solution, such as 5% dextrose in water (D_5W), rather than saline to dilate the perineural space.[7]
- Initial reports of the use of nonconducting injectates (e.g., D_5W) in peripheral nerve block are promising and appear to provide stability when using electrical stimulation techniques.[9,10]
- Another possible use of D_5W is to inject a small amount to highlight the needle tip and observe the spread of injectate without inhibiting the ability to use nerve stimulation[12] when using ultrasonography. However, future studies are warranted to determine the merit of this technique.

TABLE 49–3.

Comparison of the Standard Test Dose with the Epidural Stimulation (Tsui) Test for Confirming Epidural Catheter Location

Catheter Location	Test Dose	Epidural Stimulation Test
Subarachnoid	Hypotension/total spinal	Positive unilateral/bilateral motor response (< 1 mA)
Subdural	?	Diffuse motor response in many segments (< 1 mA)
Epidural space close to the nerve root	?	Unilateral motor response (<1 mA)
	?	Positive motor response (1–10 mA); threshold current increased after local anesthetic injection
Not intravascular	↑ Heart rate	Remain or return to baseline positive motor response (1–10 mA) even after local anesthetic injection
Intravascular	↑ Blood pressure	Electrocardiogram changes
Subcutaneous	?	Negative response

Nerve Stimulation in Regional Anesthesia: Neuraxial Blockade

Epidural stimulation has recently been used to confirm and guide catheter placement in the epidural space. The epidural stimulation test confirms catheter placement through stimulation of the spinal nerve roots (not the spinal cord) with a low-amplitude electrical current conducted through normal saline via an electrically conducting catheter.[13] Correct placement of the epidural catheter tip (1–2 cm from the nerve roots) is indicated by a motor response elicited with a current between 1–10 mA.[13,14] Any motor response observed with a significantly lower threshold current (< 1 mA) suggests that the catheter is in the subarachnoid or subdural space, or is in close proximity to a nerve root[15,16]; in these rare cases, a motor response is elicited with a significantly lower threshold current because the stimulating catheter may be very close (< 1 cm) to the nerve roots or because it may be in direct contact with highly conductive cerebrospinal fluid (CSF) (Table 49–3).

Electrical stimulation has been applied to neural structures for neurophysiologic evaluation and pain control for many years,[17–20] and has proven to be safe. The safety of the epidural stimulation test is not completely known, but it is anticipated that the risk of a brief intermittent electrical stimulation used in this setting would be lower than the risk of chronic epidural stimulation (4–30 mA) used in long-term pain management and during intraoperative monitoring for spinal surgery (2–40 mA).[21–24] Although no known complication or patient discomfort has resulted from the epidural stimulation test, it has been recommended to keep the current below 15 mA and the stimulation time as brief (less than a few minutes) as possible.[13,14,25,26] In particular, the current output must be carefully increased from zero and stopped once motor activity is visible to ensure that all motor responses, even those elicited with a low current (< 1 mA), are detected. The nerve stimulator must be sensitive enough to allow a gradual increase in current output to at least 10 mA.

Table 49–3 compares features of the epidural "test dose" (lidocaine with 1:200,000 epinephrine) and the epidural stimulation test. Epidural stimulation is a new tool for clinician use that may have a significant impact on three of the most significant complications associated with epidural anesthesia: systemic toxicity, accidental subarachnoid or subdural injections of local anesthetics, and neural damage.

Ultrasound Usage in Regional Anesthesia

The application of ultrasound in regional anesthesia was first published in 1989 by Ting et al.[28] Since then there has been an increasing number of reports in the world literature on this exciting application in regional anesthesia. It is only a matter of time before this technology will become a mainstream technique in regional anesthesia practice.

Ultrasound Usage in Regional Anesthesia: Peripheral Nerve Blocking

Brachial plexus anesthesia is one of the most challenging techniques in regional anesthesia; therefore, ultrasound has a great potential to improve success rates with this technique. The reason that the classic approach to the brachial plexus (the supraclavicular approach) has not withstood the test of time is because of the risk of pneumothorax. The application of ultrasound in regional anesthesia may renew interest in the classic approach to the brachial plexus (Fig. 49–2). With advances in this technology, we will be better able to see nerve trunks, blood vessels, pleura, and the approaching needle.[29,30]

To maximize the safety of regional anesthesia, one may potentially combine ultrasonography and nerve stimulation techniques when performing regional anesthesia.

- Ultrasonography allows the clinician to see the advancing needle approaching what appears to be the target nerve or trunk.
- Nerve stimulation allows one to identify which nerve is being approached and if indeed what is being approached is a neural structure.

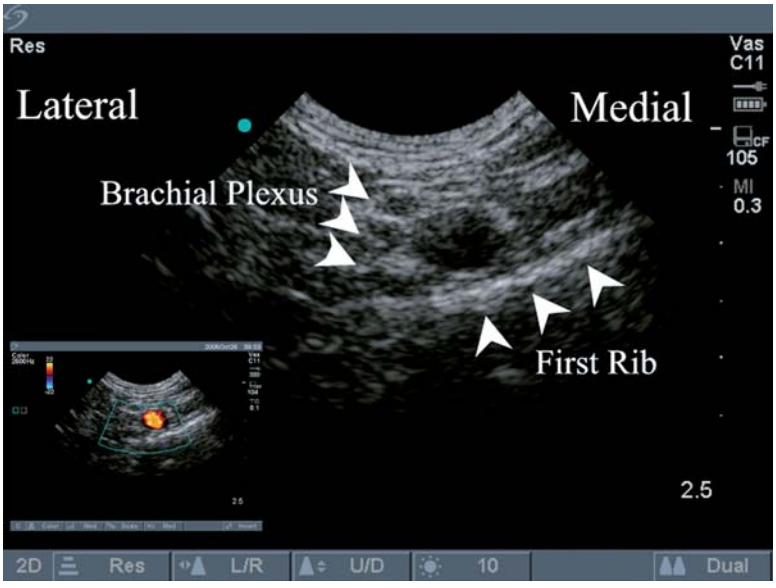

FIGURE 49–2. Ultrasonogram of supraclavicular region. The trunks of the brachial plexus can be identified as a cluster of circles (i.e., a honeycomb shape) positioned lateral and superior to the subclavian artery. If the identity of the hollow structure was in doubt, the color-flow Doppler provided further verification (*left bottom*).

Ultrasonograph technology is undeniably a great advance in regional anesthesia; however, it does not completely eliminate difficulty in accurately identifying structures and observing the advancing needle in detail in all cases. A number of regional anesthesia experts practicing ultrasonography, have already abandoned neurostimulation, upon discovering the value of ultrasound, yet it is essential to take a deliberate approach when considering the absolute use of ultrasound technology.

- Individually, ultrasonography (anatomic locating tool) and nerve stimulation techniques (physiologic response aid) have their limitations, but when used in combination, these techniques may serve to compensate for each other's weaknesses and may facilitate optimal needle placement for peripheral nerve blocks.
- With the use of ultrasonography, one can observe neural targets, vascular structures, the advancing needle, and the actual spread of the local anesthetic solution, following the injection of the local anesthetic, in real time.
- When one uses D_5W as a preinjectate, in conjunction with nerve stimulation, accurate needle/catheter-tip visibility is enhanced. The motor response resulting from electrical stimulation is augmented following an injection of D_5W in a very high percentage of cases (96%). This new observation allows one to increase the accuracy of placement of continuous catheters.[10]
- By using ultrasonography, one can observe the pattern of spread of D_5W before committing to the injection of local anesthetic

Ultrasound Usage in Regional Anesthesia: Neuraxial Blockade

Ultrasonography is useful for guiding peripheral nerve block placement in adult patients;[31,32] however its application for guiding neuraxial blockade in adults and children remains limited, and its use is not as yet widespread.

- Real-time ultrasound imaging of the lumbar spine is a simple procedure. Ultrasound aids the placement of lumbar epidural catheters and enhances the performance of combined spinal–epidural anesthesia.[33,34]
- Ultrasonography use improves the learning curve of obstetric lumbar epidural catheter placement for anesthesia trainees.[35]
- In patients with anticipated difficult epidural localization, this technology is helpful for estimating lumbar epidural depth; it also facilitates ease of placement.[36,37]
- Although ultrasound imaging has been used to guide lumbar epidural needle placement, it may be of limited value in the thoracic region, particularly in older children and adults, when visualization of the spinal cord and relevant structures is sought.[38,39] Calcification of the posterior vertebral bodies in children older than 6 months of age prevents reliable imaging of the spinal cord.[38]

At the present time, ultrasonography guidance is helpful for viewing the lumbar region of most patients, although its use for thoracic epidural placement is of value only in infants and small children, as their vertebrae are not fully ossified.

Monitoring Regional Anesthesia

It is very important to have an assistant observe and aid the patient at all times during the performance of regional anesthesia. As many as 15% of patients have a great fear of needles and vasovagal episodes occur when performing regional anesthesia.[40]

- Standard electrocardiogram and pulse oximetry are essential monitors while performing regional anesthesia.
- Before performing the neural block, a baseline blood pressure reading should be obtained. Once the regional anesthesia procedure is complete, the monitors should remain attached. In conscious patients, end tidal carbon dioxide monitoring is not used; however, there are special nasal prongs available for monitoring awake patients.
- Evidence of regressing sensory and motor blockade and stable vital signs must be present so as to fulfill the criteria for discharge from the recovery area.
- Local anesthetic infusions are now routinely used in many medical centers around the world. Patients receiving local anesthetic infusions should be visited regularly by a qualified physician postoperatively (i.e., Acute Pain Service).

Record Keeping/Documentation

Accurate and meticulous recording of anesthesia information is essential for maintaining the quality of care in regional anesthesia, and this will also benefit the clinician if involved in litigation.

- Detailed documentation of patient consent and the clinical procedure is very important.
- Open and honest communication with the patient is essential for providing good quality patient care.

Physician–Patient Communication

Effective communication with each patient is essential for the prevention and early diagnosis of any potential complications. Discussing the procedures, including their benefits and any significant risks involved, is the medicolegal and professional responsibility of all anesthesiologists. Equally important, maintaining good patient rapport respective of how to recognize and minimize potential risks during the postoperative period will help ensure that the maximum outcome is achieved following regional anesthesia.

- A telephone call to the patient on the first postoperative day is a reasonable and practical alternative to a visit.
- Specific common risks for certain blocks should be discussed with the patient prior to discharge. For instance, patients undergoing supraclavicular blocks should be warned about the risk of pneumothorax and be informed about potential symptoms and what to do if they develop.
- Caution patients about the risk of burns (i.e., from radiators), or the consequences of applying pressure to desensitized areas when sensory anesthesia continues after discharge.
- Warn patients about lying on paralyzed extremities for any length of time.
- Patients should receive written instructions and information about when to seek medical attention prior to discharge from the hospital.

COMPLICATIONS INVOLVED WITH LOCAL ANESTHETIC ADMINISTRATION IN REGIONAL ANESTHESIA

Local Anesthetic

Allergic Reactions

Although allergies to local anesthetics are rare, a full array of allergic symptoms and signs ranging from mild skin irritation to full-blown anaphylaxis have been described. These signs and symptoms are almost always associated with amino ester preparations or preservatives (e.g., methylparaben). Allergic reactions are more common following exposure to ester compounds than amides.[41]

Systemic Toxic Reactions

Systemic toxic reactions to local anesthetic drugs occur more commonly as a result of unintentional intravascular injection and rarely follow the injection of an excessive quantity of local anesthetic into an appropriate site. The incidence of systemic toxicity has substantially decreased within the past 30 years. In 1969, Massey Dawkins[42] reported the incidence of seizures following local anesthetic injections to be 0.2% following epidural anesthesia. A recent study from France reported an incidence of seizures of 0.01%, which represents a 20-fold decline in a 30-year period.[42,43] A higher occurrence of systemic reactions occurs following peripheral nerve blocks, especially brachial plexus and caudal blocks in adults.[44] The maximum plasma concentration of local anesthetic (C_{max}) resulting from an unintentional intravascular injection depends on a number of factors,[45] including the total dose of local anesthetic injected, the speed and site of injection, and whether the injection is administered intravenously or intraarterially. The lungs are an important repository for local anesthetic drugs; plasma concentrations of these drugs will be substantially higher if the lungs are bypassed (e.g., an accidental intraarterial injection in the head, face, or neck region).[46] Plasma concentrations of local anesthetics are also influenced by the tension of carbon dioxide (CO_2) and the pH. An elevated arterial CO_2 tension increases cerebral blood flow, and an acidotic state increases intracellular ion trapping and the amount of free drug available. This combination of factors has a synergistic effect on the seizure threshold.[47]

Systemic toxic reactions occur much less frequently when local anesthetics are administered in peripheral sites. A number of factors influence the degree of absorption taking place from the periphery to the central circulation. The most important factor influencing absorption is the site of injection—absorption is more rapid in highly vascular tissues and less so in poorly perfused tissue. Rapid absorption also occurs from intrapleural injections and very slow absorption occurs from the bladder and skin. Consequently, local anesthetic absorption increases from the highest to the lowest rates in the following

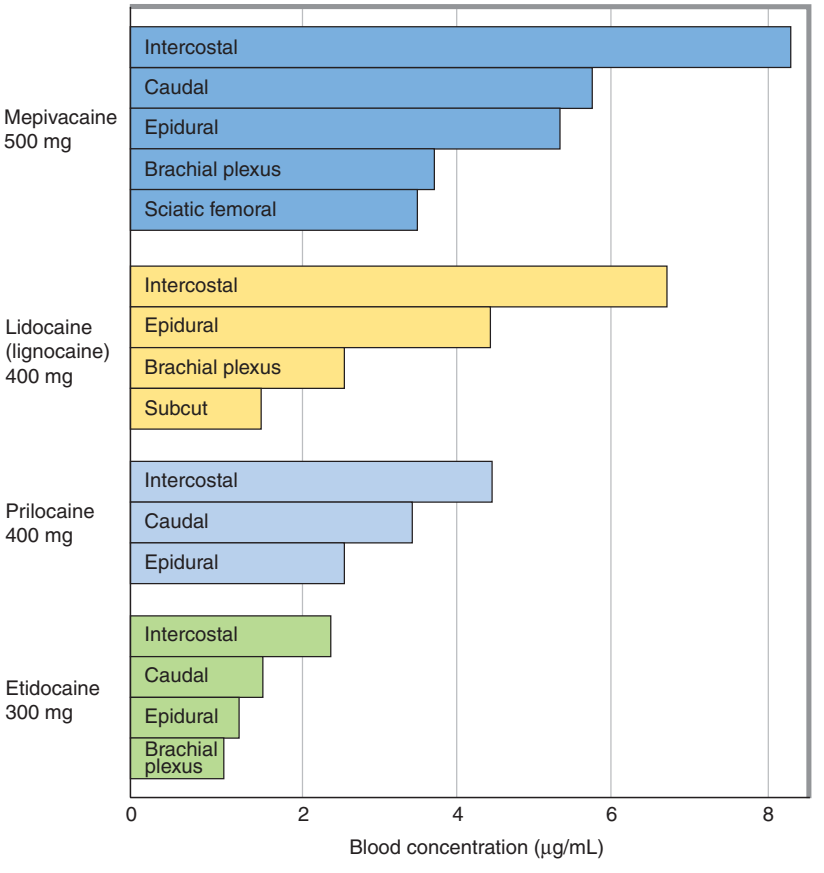

FIGURE 49–3. Comparative peak blood concentrations of several local anesthetic agents following administration into various anatomical sites. Subcut, subcutaneous. Neural Blockade in Clinical Anesthesia and Management of Pain. 3rd ed. Baltimore: Lippincott Williams & Wilkins, 1998:107.)

anatomic sites: intercostal, epidural, brachial plexus, lower extremity, and subcutaneous tissue (Fig. 49–3).

The rate of absorption is reduced by the addition of epinephrine to local anesthetic drugs, but this also depends on the local anesthetic used. Furthermore, the addition of epinephrine itself may lead to other complications (see Complications of Peripheral Nerve Blocks below). As the plasma concentration of lidocaine increases, there is a typical progression of effects on the CNS and the cardiovascular system. This pattern of symptomatology is not typically seen with the more potent local anesthetics (Fig. 49–4).[48] Central nervous system excitation and cardiovascular manifestations of systemic toxic responses following epidural anesthesia almost always arise as a result of unintentional intravascular injections. Local anesthetics are amphiphilic molecules, having both lipophilic and hydrophilic properties; these drugs enter a variety of cellular compartments, and have the potential to interact with a wide variety of molecules including inotropic signaling pathways (sodium, potassium and calcium ion channels), and also influence adrenergic and lysophosphatide signaling systems, cardiac bioenergetics, and mitochondrial dynamics.[49] Symptoms and signs of an unintentional intravascular injection must be closely monitored. As plasma concentrations of local anesthetic increase, signs of local anesthetic toxicity increase in severity. Concurrent treatment with CNS depressant medications may modify the typical clinical signs of a toxic reaction, and can mask some of the early warning signs (Table 49–4).

The cardiovascular system is more resistant to the toxic effects of local anesthetics than the CNS, especially following toxic doses of lidocaine. Local anesthetics affect both electrical and mechanical cardiac activity. Tachycardia and hypertension are early signs of cardiac toxicity and with increasing doses patients develop bradycardia and hypotension; however, this pattern of symptomatology may not be seen when the patient receives a rapid intravascular injection and this pattern of symptoms and signs is not evident with potent local anesthetics.

Prevention

Early recognition of an intravascular injection is the key to prevention. Methods investigated for detecting intravascular injection include the following:

- Careful aspiration
- The injection of dye (detected by pulse oximetry)[50]
- The administration of epinephrine and isoproterenol[51]
- Injections of lidocaine

Increased heart rate and systolic blood pressure in addition to T-wave changes are considered sensitive and specific end points in response to an intravascular injection of a test dose containing epinephrine. A single injection of 15 μg of epinephrine produces a heart rate increase of greater than 10 beats/min, a blood pressure increase greater than 15 mm Hg, and a decrease in T-wave amplitude of 25%.[52] In the sedated patient, changes in heart rate may not be as reliable as T-wave and blood pressure changes.[53] Elderly patients (> 60 years old) and those on β-blockers and anesthetized patients are also less sensitive to β-adrenergic stimulation.

In summary, sensible precautions should be undertaken to minimize the impact of accidental intravascular injection. These precautions include the following:

- Incremental administration of the local anesthetic
- Frequent aspiration
- Close observation of heart rate, systolic blood pressure, and T-wave changes
- Close observation of the patient

Signs of Early Accidental Intravascular Injection

Early Signs	Late Signs
Light-headedness	Muscle twitching
Tinnitus	Drowsiness
Blurred vision	Generalized tonic-clonic convulsions
Perioral numbness	

Management of Local Anesthetic Toxicity

The initial treatment recommended for the management of patients with systemic toxicity is very similar to that used for any resuscitation. The following mnemonic can be used when dealing with allergic reactions and systemic toxicity to local anesthetics [54]:

Stop injection

Airway

Ventilation

Evaluation of the circulation

Drugs

Because hypoxia, hypercapnia, and acidosis exacerbate all local anesthetic toxic reactions,[55,56] control of the airway and ventilation is of paramount importance in the treatment of local anesthetic toxicity. Recent studies dem-

onstrate improved hemodynamics and survival in animal models of bupivacaine toxicity with the administration of intravenous lipid emulsion.[57,58] Although the mechanism by which this occurs is unclear, it is suggested that lipid emulsion may remove local anesthetic molecules from binding sites that are responsible for the profound cardiovascular depression that is part of bupivacaine toxicity. Propofol, which is formulated in lipid, may reduce susceptibility to local anesthetic toxicity, however its negative inotropic effects may mitigate against its use as an antidote in the face of cardiovascular collapse.[59] Before either lipid or propofol become recommended elements of the resuscitation paradigm, further evaluation needs to be done. Anticonvulsant medications such as thiopental and the benzodiazepines should be used with caution and in greatly reduced dosage as they themselves may precipitate cardiovascular collapse. The following are the most current (as of this writing) recommendations for the management of significant local anesthetic systemic toxicity:

- Bronchospasm and generalized edema, sometimes associated with allergic reactions may require use of bronchodilators, antihistamines, and corticosteroids.
- Endotracheal intubation and ventilation are required to correct acidosis and hypoxia and hypercarbia.
- Chest compressions, cardioversion may be defibrillation are required to restore organ perfusion and should be instituted as necessary.
- Profound hypotension can occur in both allergic reactions and systemic toxicity, and usually responds well to vasopressors (e.g., epinephrine and vasopressin); hypotension occurring in allergic reactions and systemic toxicity respond well to plasma "expansion."
- As reduced cardiac contractility is a core element in this condition, it is thought that the maintenance of coronary perfusion with the administration of epinephrine and norepinephrine improves outcome.[60]
- However, malignant dysrhythmias, which particularly occur with bupivacaine systemic toxicity, should be controlled in a timely fashion as epinephrine can exacerbate these dysrhythmias.
- Therapeutic agents that are less arrhythmogenic have been investigated, including the use of vasopressin,[61,62] and phosphodiesterase inhibitors such as milrinone and amrinone.[63]
- Effective resuscitation in this setting is difficult, and atrioventricular pacing and cardiopulmonary bypass are additional options in refractory cases.[64]

COMPLICATIONS OF PERIPHERAL NERVE BLOCKS

Direct Needle Trauma to the Nerve

Most of the complications resulting from peripheral nerve blocks (PNBs) are similar to those of neuraxial blocks with the exception of those resulting from ophthalmic, brachial, and intercostal/paravertebral blocks, each of which has its own unique complications. The incidence of minor neural injury following PNBs is in the range of 1–2%; most of these injuries are transient neurapraxias, which represent axonal disruption. Typically neurapraxia injuries are observed postoperatively when patients complain of persistent numbness in the distribution of a peripheral nerve. One cannot simply assume that all neurapraxia injuries are anesthesia related, as patient positioning, surgical trauma, and tourniquet application can all give rise to these symptoms. Numbness gradually regresses over a period of weeks and is rarely observed beyond 3 months, which is the amount of time required for axonal regeneration to occur. Regional anesthesia related injuries are usually the result of needle trauma, injection pressure or the toxic effects of local anesthetics or additives. Auroy et al.[43] reported an incidence of serious nerve injury (permanent sensory and/or motor loss) following PNBs as 1.9 per 10,000 nerve block cases; in this study, all patients with serious injury experienced either pain on injection, or paresthesia, or both during the performance of the block.

Prevention

Most neural injuries are associated with either paresthesia or pain on injection. Needle damage or pressure generated during injection of local anesthetics account for most of these injuries.[43,65] Needle insertion without injection is a routine technique used during micronеurography and surgical repair procedures, which results in insignificant nerve damage.[66] Considerable nerve damage is more likely to be caused or worsened by both mechanical and chemical injury during intraneural injections of neurotoxic substances (i.e., local anesthetics). High-pressure injections cause mechanical destruction of the neural fascicular architecture, pathophysiologic damage, and neural scarring.[67] Chemically induced damage is also possible from high concentrations of local anesthetics, vasoconstrictors, preservatives, and other additives.

There is an ongoing debate among anesthesiologists about the safety of deliberately seeking paresthesia in regional anesthesia.[68] There is also concern about performing regional anesthesia in comatose/anesthetized patients because of the inability to detect paresthesia.[69,70] However, there is no substantial evidence that performing nerve blocks in awake patients is any safer than performing them in anesthetized patients.

With advances in the technology used for regional anesthesia such as nerve stimulation and ultrasonography, the need to use paraesthesia as a method to identify the location of a given nerve should diminish. Despite the recent advances in technology in regional anesthesia, there is no proof that any one method is safer or better in terms of success achieved. Intuitively, one might expect more success and fewer complications if one could observe a needle advancing toward a neural structure as opposed to the "conventional" blind insertion of needles.

Common sense dictates that small-gauge needles are less likely to damage nerves than larger-gauge ones. More than 30 years ago Selander[71] recommended using blunt needles when performing regional anesthesia, as it was thought that blunt needles were less likely to penetrate neural structures, and resultant intraneural injections would be less likely to occur; this recommendation was based on information derived from animal experiments. Selander's influence on this topic persists to this very day. Even though subsequent studies show that blunt needles, although far less likely to penetrate neural structures, are far more disruptive to neural tissue than sharp needles.[66] Nevertheless, there are no clinical trials supporting any recommendations as to what type of needle is

best for regional anesthesia procedures. Most clinicians prefer small-gauge, short, blunt needles.

Injection pressures may influence the amount of damage inflicted on a nerve. One study suggested that persistent motor deficits were observed in animals injected with pressures ≥ 20 psi.[72] Clinicians should avoid rapid and high-pressure injections.

Sterilizing agents, skin cleansing substances, detergents, and certain preservatives (e.g., metabisulfite) all cause neurotoxicity and should be carefully avoided when introduced into perineuronal spaces.

The neurotoxicity of a local anesthetic is related to its potency and its concentration.[73] High concentration local anesthetics such as 2% lidocaine and 0.75% bupivacaine should be avoided in peripheral nerve blocks. The addition of vasoconstrictors (e.g., epinephrine) to local anesthetics may enhance the damage caused by an intraneural injection.[74–76]

Generally, neural damage resulting from peripheral nerve blocks is rare; consequently, it may be difficult to clearly demonstrate the safest equipment and techniques to be used. However, Table 49–5 lists several measures that have been suggested to prevent nerve injuries.

Management

Because most regional anesthesia procedures involve the percutaneous insertion of needles toward neural, the burden often lies with the anesthesiologist to prove that damage was not caused as a result of improper technique and unsafe practice. Clinicians are obliged to maintain a very open mind when dealing with such challenging cases. When a neurologic injury is suspected postoperatively, a thorough history must be taken, and a complete physical examination must be performed. The anesthesiologist should play a major role in determining the cause of the injury, as anesthesiologists have far more information concerning preoperative and intraoperative events than do most neurologists. Symptoms and signs of compression of the spinal cord must be dealt with urgently (within 6–8 hours); otherwise permanent paraplegia or quadriplegia may result. The anesthesiologist, neurologist, neurosurgeon, and radiologist must work as a team and strive to arrive at a diagnosis before serious permanent injury occurs. Diagnostic tools should be used judiciously to support the team of clinicians in arriving at a correct diagnosis; this is when we must rely on our neurology and radiology colleagues to guide us. Electrodiagnostic and imaging techniques can often take the guesswork out of many diagnostic dilemmas and allow for quick and precise diagnoses. Table 49–6 summarizes the key steps involved in determining neurologic injury.

Diagnostic Tools for the Determination of Nerve Injury Direct injury to the spinal cord, nerve roots, or peripheral nerves is best evaluated using imaging techniques, especially in the early stages of an injury. Electrophysiologic techniques are more useful in the later phases of an injury. The most common imaging modalities used are computerized tomography (CT) and magnetic resonance imaging (MRI). Electrodiagnostic techniques include evoked potentials, nerve conduction studies, and needle electrode examination of muscles (electromyography [EMG]). The use of these tools should complement the clinical examination, rather than replace an examination. Choosing the best tools/technologies for diagnosis should be a joint decision made with the neurologist, surgeon, and radiologist.

- CT is best suited for evaluating bony abnormalities.
- MRI is ideally suited for the examination of soft-tissue abnormalities, especially the spinal cord.
- For peripheral nerve, nerve plexus, and peripheral nerve complications, imaging is less likely to be useful for the demonstration of nerve injury.
- MRI may demonstrate the accumulation of blood and edema fluid, which can lead to compartment syndrome; MRI may also indicate neural compression caused by injury from the needle and local anesthetic injection. Thus, electrodiagnostic techniques can complement imaging, especially for peripheral nerve complications. Nerve conduction studies test the function of large sensory and motor nerve fibers. Evaluating nerve conduction can reveal axonal loss or demyelination of the nerve; however, nerve conduction is less useful in timing lesions when the injury occurs.
- EMG is preferentially used for evaluating smaller motor units. EMG can be useful for the diagnosis of axonal injury and is also useful for quantitating the severity of the neurologic injury and for identifying the actual site of injury.

TABLE 49–5.

Suggested Methods/Equipment for Preventing Peripheral Nerve Injuries When Performing Regional Anesthesia

- Needle type: small gauge, short beveled
- Patient: awake with appropriate level of sedation
- Nerve stimulation: use accurate nerve stimulators and insulated nerve needles (current at least >0.2 mA)
- Ultrasonography: direct visualization of nerves ad surrounding structures by using high-resolution ultrasound equipment if available
- Paresthesia: injection should be stopped and needle repositioned if persistent
- High injection pressure: avoid rapid and high-pressure injections (pressure <20 psi)
- Local anesthetic: avoid high concentrations (i.e., lidocaine 2% or bupivacaine 0.75%)

The only effective way to manage neurologic complications is to prevent any mishaps from occurring in the first place, as there is limited chance of recovery once the damage has occurred. Currently, there are no reliable standards or guidelines for the management of neurologic injury. Neurologic consultation and testing should be considered if there are any persistent symptoms or signs following a procedure. If symptoms are mild and are not interfering with the patient's daily activities, reassurance can be offered after evaluating the extent and severity of the patient's symptoms. It is of prime importance to continue to follow patients suffering from nerve injury following discharge from the hospital; it is also necessary to instruct patients to seek medical attention if their symptoms worsen or do not improve. Most residual dysthesias or hypesthesias resolve in 4–6 weeks, and the majority are resolved (>99%) within 1 year.[77,78]

NEEDLE TRAUMA TO THE SURROUNDING ANATOMY

Surrounding tissues may be unintentionally injured during peripheral nerve

TABLE 49–6.

Key Steps in Determining Neurologic Injury

- Recognize and identify the neural dysfunction.
- The history of any new or intensifying neural dysfunction in the absence of further anesthetic injection must be considered as a warning sign of possible neural injury.
- When neural damage is suspected, a careful history assessment and a physical examination must be promptly carried out.
- The sequence and onset of the symptoms must be determined.
- The nature of pain, motor weakness, sensory deficit, and sphincter control should be compared to information obtained preoperatively about the patient's baseline neurologic status; such information may provide clues to the cause of injury and appropriate management.
- Symptoms/signs of spinal cord compression must be dealt with urgently (within 6–12 hours), otherwise permanent paraplegia or quadriplegia may occur.
- A thorough postoperative followup should be completed, even if a neurologic injury is not suspected.
- Consider surgical causes
  - Surgical trauma to neural structures from retractors, a scalpel blade, or tension within the surgical site may not have been mentioned to the anesthesiologist.
  - Long-acting local anesthetics may have been injected by the surgeon.
  - Compartment syndrome resulting from edema, or bleeding around the wound caused by dressings or casts, can compromise neural function.
  - Vascular injury during the surgery could result in nerve injury (e.g., spinal cord injury after thoracic aneurysm repair). Because of this, it is probably desirable to let the local anesthetic blockade abate after aortic surgery.
  - Patient positioning must be reviewed to rule out direct pressure (e.g., peroneal nerve at the fibular head) or tension on nerves (e.g., traction on the brachial plexus from hyperextension of the shoulder during thoracotomy); improper patient positioning may produce nerve injury that might otherwise be attributed to a regional anesthetic mishap.
- Consider anesthetic causes
  - The details of anesthesia management should be thoroughly reviewed, especially if portions of the anesthetic care were delivered by other anesthesiologists.
  - Drug choice, dose, and last time of administration should be recorded.
  - Duration of nerve blockade should be noted; a long duration of blockade can result in neural injury.
  - High concentrations of agents probably increase the risk of neural complications.
  - Multiple nerve-blocking attempts can increase the risk of injury.
  - The presence of parasthesia during needle insertion and the subsequent injection of local anesthetic can be a warning sign indicating neural injury.
  - The level of sedation must be appropriated without compromising the ability to observe a parasthesia.

blocks. Vascular injury can also occur during PNB as many peripheral nerves travel in parallel with vascular structures. Other injuries may be caused by direct needle trauma, including pneumothorax and direct spinal cord injury.

Spinal Cord Injury

Permanent spinal cord injury following brachial plexus block is the most severe complication resulting from PNB. There are a number of reported spinal injuries associated with peripheral nerve blocks: an interscalene block performed with an 8-cm needle resulted in a permanent neural deficit at the C8-T1 level.[79] In another instance, an anesthetized patient suffered permanent spinal cord injury following an interscalene block.[80] A patient has suffered from Brown-Séquard syndrome following an attempted interscalene block using a spinal needle.[81] Other peripheral blocks may also increase the risk of spinal cord injury. Permanent spinal cord injuries may occur following paravertebral blocks because the needles used for paravertebral blocks are inserted in close proximity to the spinal cord.

Prevention

It is important to note that most of the serious nerve injury cases reported involve deviations from the recommended anesthetic practice standards. Currently, it is recommended to perform these blocks in awake patients so as to detect paresthesia or pain on injection, which is a clear indicator of the risk of permanent damage. Ultrasonography may help to reduce the risk of spinal injury as needle advancement can be observed in real-time.

The best option for avoiding the risk of nerve injury is to select a blocking insertion site remote from the spinal cord. Axillary blocks appear to be safer than supraclavicular blocks; however, supraclavicular approaches to the brachial plexus are required in shoulder surgery. In most published cases of nerve injury involving the brachial plexus, the recommended standard of care was not followed.

Small-gauge needles and short needles are strongly recommended when performing brachial blocks in the supraclavicular region. Longer-than-usual needles were associated with many of the spinal cord injuries associated with brachial plexus blocks.

Management

There is no specific treatment for primary needle damage to the spinal cord. Nevertheless, the initial step in the management of spinal cord injury is the recognition and identification of neural dysfunction. Acute, potentially reversible causes of spinal cord injury, such as nerve compression from hematomas, must be identified and dealt with early (within 6–8 hours) otherwise permanent paraplegia or quadriplegia may result. The anesthesiologist, neurologist, and radiologist must work as a team to arrive at a correct diagnosis. Appropriate electrodiagnostic and imaging techniques must be used to make a quick and precise diagnosis.

Pneumothorax

Any regional technique requiring needle insertion toward the lung involves the risk of pneumothorax. Pneumothorax has been an unwelcome complication of supraclavicular techniques since Kulenkampff first described the classic supraclavicular approach in 1911.[82] The incidence of pneumothorax is difficult to determine and varies depending on the approach. Brand et al. reported an incidence of 6.1% in a large teaching hospital using the classic Kulenkampff technique.[83] DeJong found radiologic evidence of pneumo-

thorax in 25% of patients.[84] Phrenic nerve paresis is very common following supraclavicular blocks, yet patients do not usually become symptomatic.[85] The risk of pneumothorax has deterred many anesthesiologists from using the supraclavicular approach and is the most likely reason that axillary approaches are so popular. The risk of pneumothorax is much lower following the interscalene approach to the brachial plexus compared to the classic supraclavicular approach.[86] Ward et al. reported a 3% incidence of symptomatic pneumothorax following the interscalene technique.[87] The risk of pneumothorax is reduced following the vertical technique mainly because the needle is not directed toward the lung.[88]

Prevention

Anesthetic techniques requiring the insertion of a needle directed toward the lung in the supraclavicular region all carry the risk of pneumothorax. Extra care should be exercised in tall, thin patients as they appear to be at greater risk of pneumothorax. For all patients, a right-sided pneumothorax occurs more frequently because the cupola of the lung is higher on the right side. Patients should be warned in advance of this risk, and ambulatory patients should be given careful instructions on how to proceed should symptoms develop. Supraclavicular techniques should be used only when indicated.

Supraclavicular approaches should be avoided in patients with moderate or severe impairment of pulmonary function. Blocks should never be performed bilaterally. Intuitively, complications can be avoided or reduced if clinicians are able to visualize the advancing needle approaching the target nerve or trunk. Ultrasonograph technology facilitates this goal in real time. However, this technique requires significant training and much practical experience. Despite adequate training, it can be difficult to accurately identify structures using ultrasonography, and the advancing needle is not easily viewed in all cases. The clinician should pay attention to needle depth in relationship to the classical anatomical landmarks at all times, even when using ultrasonography.

Management

Because upper-extremity operations are carried out on ambulatory patients who are discharged within a few hours of surgery, it is imperative that patients be warned about the risk of pneumothorax before leaving the hospital. Patients who develop chest pain, dyspnea, or cyanosis following discharge should be instructed to go to the nearest emergency center. Symptoms and signs may not develop for hours, and patients may not become symptomatic until a 20% pneumothorax is present. A chest tube is usually required when the degree of lung collapse is 25% or greater. Positive pressure ventilation with N_2O/O_2 in the presence of a small pneumothorax may lead to tension pneumothorax with the rapid deterioration of vital signs. Consequently, a high index of suspicion should always be present when general anesthesia is required following a failed supraclavicular block, and nitrous oxide should be avoided in this situation.

TOXIC EFFECTS OF LOCAL ANESTHETICS ON THE NERVES AND SURROUNDING ANATOMY

Incidence of Toxic Effects of Local Anesthetics on the Nerves and Surrounding Anatomy

Neural Toxicity

Local anesthetics are considered harmless substances when injected perineurally in appropriate concentrations and quantities. High concentrations of local anesthetics can permanently damage neural tissue in some instances.[89] Preservatives in local anesthetic drugs may also damage nerves and other surrounding tissues. In the United States during the 1970s, it was noted that a change in the constitution of a sodium metabisulfite, a preservative found in chloroprocaine, resulted in several cases of cauda equina syndrome.[90] The addition of ethylenediaminetetraacetic acid (EDTA) to chloroprocaine is associated with severe back pain in some patients following epidural anesthesia.[91,92] Studies show that 5% hyperbaric lidocaine for spinal anesthesia is linked to the syndrome transient neurologic symptoms (TNS).[93]

Myotoxicity

Myotoxicity is a recognized complication of intramuscular injections of local anesthetics.[94]

Local anesthetics are proposed to cause a pathologic efflux of Ca^{2+} from the sarcoplasmic reticulum, resulting in contracture, cell destruction, and necrosis. Following this occurrence, the regeneration of fibrils occurs within a few weeks. Among the local anesthetics tested, bupivacaine caused the most damage, and procaine caused the least.[95] Injury was noted to be worse with repeated injections and when epinephrine was used.[96–98] All of these mentioned features are highlighted in a case in which a patient who received an interscalene block later developed intense neck pain and tenderness over the sternocleidomastoid muscle, which persisted for 2 months.[99] In clinical practice, myotoxicity is largely unnoticed except in ophthalmic regional anesthesia. Diplopia has been reported following retrobulbar blocks; however, this symptom is short-lived in most cases and permanent damage is rare. Ropivacaine was found to be less myotoxic than bupivacaine in an animal model.[100] The full implications of the effects of local anesthetics on muscle have not yet been evaluated.

Phrenic Nerve Paralysis

The incidence of hemidiaphragmatic paresis and decreased respiratory function following supraclavicular blocks in 8 healthy volunteers was noted; the overall incidence of paresis was 50% following the administration of 30 mL of lidocaine 1.5% with epinephrine; none of the volunteers reported respiratory symptoms.[101] However, anecdotal reports exist concerning patients who are devoid of respiratory disease, and who later became symptomatic following an interscalene block.[87,102–104]

Temporary phrenic nerve paralysis following interscalene brachial plexus block is expected in up to 100% of cases. Permanent phrenic nerve palsy has been observed following interscalene block,[105] but is extremely rare.[106]

The incidence of ipsilateral phrenic nerve paresis associated with all types of supraclavicular techniques is reported to vary between 36% and 40%, regardless of the technique chosen.[107] In another study, the effects of ipsilateral hemidiaphragmatic paralysis on respiratory function following continuous interscalene blocking showed that all patients had a 27% reduction in forced vital capacity (FVC), a reduced forced expiratory volume (FEV) of 26%, and a decreased peak expirato-

ry flow (PEF) rate.[108] In another small study, the effects of hemidiaphragmatic paralysis lead to a significant decrease in Pao_2, despite normal pulmonary function studies.

Thus, the use of supraclavicular techniques in certain groups of patients must be reevaluated. Supraclavicular techniques may need to be avoided in patients with advanced pulmonary disease. Bilateral supraclavicular techniques are *absolutely* contraindicated.

Prevention Until we have more data on this topic, it would be prudent to avoid all brachial plexus techniques above the clavicle (especially interscalene blocking) in patients with severe impairment of lung function. The majority of healthy patients do not experience any symptoms. The duration of action of this impairment depends on the dose and the individual properties of the local anesthetic used.[109] It has also been suggested that reducing the volume and quantity of local anesthetic chosen for supraclavicular blocks may influence the incidence of hemidiaphragmatic paresis.

Management Ipsilateral phrenic nerve paresis is quite common following all supraclavicular approaches to the brachial plexus. Such approaches to the brachial plexus should be avoided in patients with significant lung disease. Proper consent and information should be provided to the patients. For mild symptoms, reassurance given by the anesthesiologist to the patient and family is generally sufficient for management. For more severe symptoms and patient distress, appropriate monitoring and ventilatory support should be considered and employed until the phrenic nerve paralysis recovers.

Horner Syndrome

Horner syndrome (ipsilateral, miosis, ptosis, enophthalmos, loss of sweating) is frequently observed following supraclavicular approaches to the brachial plexus,[110] and patients and other caregivers should be informed of this temporary distortion to avoid diagnostic confusion.

Hoarseness

Hoarseness may occur if the local anesthetic spreads to the recurrent laryngeal nerve.

Other Complications of Brachial Plexus Blocks

There are a number of other, less common complications following brachial plexus blocks, including bronchospasm, hematoma formation, auditory impairment, total spinal/epidural block, and carotid compression.

Prevention/Management

The key to preventing complications associated with brachial plexus block is to increase the accuracy of needle placement and to use the minimum volume and concentration of local anesthetic required to successfully complete the block. With a better understanding of neural anatomy and distances between structures gained by using nerve stimulation, the accurate needle placement is a reality. The introduction of ultrasonography has revolutionized regional anesthesia, as ultrasonogram visualization makes it possible to directly visualize, in real time, the needle tip and the local anesthetic spread. With this technology, we believe regional anesthesiologists will have much greater success with regional anesthesia and fewer complications. As with other adverse effects, careful diagnosis of brachial plexus complications and the provision of supportive measures are essential for proper clinical management.

COMPLICATIONS OF NEURAXIAL BLOCKS (EPIDURAL/SPINAL)

Direct Needle Trauma

As a needle or catheter is advanced into the epidural space, direct trauma to the spinal cord, conus medullaris, and spinal nerve roots can occur. Sensory loss and, less commonly, motor deficits occur as a result of spinal cord trauma. Some patients recover completely from this unfortunate circumstance; however the injury persists in the majority of patients. The incidence of this complication is very low, and much of the data available comes from retrospective sources. In a prospective multicenter study Auroy[43] found 5 cases of radiculopathy following 30,413 epidurals. In each of these patients, pain or paresthesia was noted during needle insertion and drug administration, and the radiculopathy was observed in the distribution of the associated paresthesia. One of the most disturbing complications of neuraxial blockade is neurologic injury. Three well-known syndromes are associated with damage to the spinal cord, roots, and coverings: cauda equina syndrome, adhesive arachnoiditis, and anterior spinal artery syndrome. These syndromes are addressed in other chapters under specific complications.

Prevention

To avoid nerve trauma, a studied technique and accurate anatomic knowledge is advised.[111] Although epidural placement in the anesthetized child is considered safe, similar placement in the adult population remains controversial. Recent case reports highlight the potential for neurologic trauma when performing epidural anesthesia in the anesthetized patient.[69,112,113] The use of the epidural stimulation catheters allow pediatric anesthesiologists to place lumbar or thoracic epidurals from the caudal space, minimizing the risk of needle-mediated nerve injury.[26] When performing an epidural in an awake, cooperative adult, needle advancement should be halted if the patient complains of pain. In most adults, the spinal cord terminates at the lower portion of the body of L1; however, there are considerable variations among individuals. The ability of the clinician to correctly identify lumbar spinous interspaces has been questioned by Broadbent et al. using magnetic resonance imaging.[114] In this study, only 29% of the interspaces were correctly identified, whereas 51% of the time clinicians were at a higher vertebral level than anticipated; furthermore, the spinal cord terminated below L1 in 19% of subjects. Oblique lateral entry into the ligamentum flavum may direct the needle into the dural cuff region, resulting in potential nerve trauma with resultant unisegmental paresthesia; this is a warning sign in a conscious patient indicating that the needle or catheter is encroaching on a neural structure.[115]

Paresthesia associated with spinal cord injury can occur at the time of needle placement, yet it may also occur during the injection of the solution or as a secondary consequence of irritation, edema, or hematoma.[116,117] Pain is more commonly associated with extraaxial lesions affecting the nerve roots or blood vessels that are innervated by pain-mediating sensory neurons.[118] In contrast, because there are no pain receptors within the spinal cord (or the brain), intraaxial trauma may be painless[118]; this allows percutaneous cervical cordotomy to be performed in awake patients.[119,120] During

this procedure, the cervical cord is typically punctured multiple times with a 22-gauge needle electrode, yet the patient generally describes neither pain nor paresthesia.[121] In addition, pain following dural puncture is rare in clinical practice. Thus, anesthesiologists should be reminded that they should not simply assume that paresthesia will always be reported as the needle encroaches on the spinal cord.[122,123] However, one might expect a motor response if a needle encroaches on a motor tract during attempts at epidural anesthesia. Electrical stimulation during epidural needle advancement may provides an additional warning sign.[124,125] Despite all of the controversy on this topic, during thoracic epidural placement risk, minimization should be considered, while placing epidural needles and catheters at a site remote from the spinal cord (i.e., lower lumbar or caudal region) if at all possible.

Ischemic injuries are among the rarest complications reported following regional anesthesia procedures; however, when such injuries occur, several factors play a role, including hypotension, abnormal positioning, vascular disease, diabetes mellitus, and the clamping of major vessels.[65,126] The addition of epinephrine to local anesthetic solutions is controversial, as seen in an animal study where epinephrine and phenylephrine were administered with the result of a significant reduction in dural blood flow and no reduction in spinal cord blood flow.[127] It seems prudent, however, to avoid the use of large amounts of epinephrine in patients at greater risk of ischemia.

Management

The management of postoperative neurologic sequelae requires the cooperation of the anesthesiologist, surgeon, and neurologist. Advice may also be needed from the radiologist and neurosurgeon. Although it is easy to blame an adverse neurologic outcome on the presence of an epidural, it should be borne in mind that other factors can lead to demonstrable nerve injury, including undiagnosed preexisting neurologic disorders, ligation of nutrient spinal cord vessels during abdominal or thoracic surgery, injury to the femoral nerve during pelvic surgery, injury to the lateral cutaneous nerve of the thigh during retraction close to the inguinal ligament, and pressure on the fibular head leading to neurapraxia of the lateral popliteal nerve. If an adverse outcome occurs, the lesion should be localized by taking the patient's history and by performing a thorough neurologic examination.

- Bilateral symptoms associated with pain should alert one to the possibility of neuraxial pathology.
- Injury at the nerve roots affects both posterior and anterior rami.
- Preservation of sensation over the paraspinous muscles suggests a more distal injury.
- Investigations should include blood cultures and coagulation studies.
- Immediate MRI is the standard for evaluating neuraxial lesions.
- EMG can be used to determine the site of injury and the degree of axonal loss, although it may take up to 3 weeks for changes to appear on the electromyogram. It may be useful to perform this immediately upon recognition of neural dysfunction to establish the possibility of a preexisting lesion.

Hematoma

Epidural hematoma after neuraxial anesthesia is a rare event. Bleeding from an epidural vein may occur on needle or catheter insertion, but is usually self-limiting. Neurologic symptoms and signs caused by an epidural hematoma are atypical in the presence of normal coagulation; the true incidence is unknown, but is estimated to occur in less than 1 in 150,000 cases of neuraxial anesthesia.[128] Vandermeulen reviewed 61 case reports between 1906 and 1994 and found that two-thirds of the cases had a hemostatic abnormality.[129] Early diagnosis and intervention are essential to preventing any long-term adverse outcomes.

Prevention

In recent years, new anticoagulant and antiplatelet drugs have been introduced and have given rise to new challenges in the management of the anticoagulated patient undergoing neuraxial blockade. The American Society of Regional Anesthesia has released guidelines in response to this evolving shift in medical practice[128]; it is important to follow these guidelines to minimize the risk of hematoma.

Management

Similar to the peripheral nerve injury, the evaluation of neurologic injury following regional anesthesia is a vital part of adverse outcome management. Back pain with lower-limb weakness and sensory deficit should alert the clinician to the presence of a central compressing lesion.

- Bowel and bladder incontinence can be an associated finding.
- Painless evolution of this complication has been reported, and early warning signs may be masked by the administration of local anesthetic via an epidural catheter and the presence of a urinary catheter.
- If MRI confirms the diagnosis, then rapid surgical intervention within 6–8 hours is recommended.
- Epidural catheters containing metal elements should be avoided while undergoing MRI as it will not only generate artificial interference and inaccurate diagnoses, but other potential risks are possible albeit presently unknown.[130] Such catheters should be removed if it is safe to do so; if catheter removal is unsafe, a CT scan should be considered instead of an MRI.

Infection

Epidural abscess formation, although rare, is a serious, potentially devastating complication. Kane's retrospective review of 50,000 epidurals found no case of abscess formation,[131] whereas Moen et al. reported 12 cases of abscess formation from an estimated 250,000 patients following epidural insertion.[132] Of these patients, only 3 were healthy, while the others had infection risk factors. Six of the patients received their epidural for analgesia following trauma, and of these, 5 were thoracic epidurals for chest trauma. The authors speculated that the overrepresentation of thoracic trauma patients might in part be a result of a lesser hygienic standard being observed, where placement likely occurred outside the "cleaner" environment of the operating suite.

Although the immunocompromised patient may carry a greater risk of developing infective complications with epidural use, extensive experience using epidural analgesia and anesthesia with patients who have HIV has countered early fears surrounding regional anesthesia in this population. Regional anesthesia is particularly beneficial for the HIV carrier population, as it eliminates delayed metabo-

lism of systemic opioids caused by protease inhibitors.[133] Patients with AIDS often have neurologic manifestations of their disease, and the prevalence of peripheral neuropathy increases as the disease progresses.[134] Attention should be given to assessing preoperative neurologic status, as this allows the clinician to correctly attribute postblock neurologic sequelae to the true underlying cause.

Epidural abscess presentation can be variable, but the cardinal symptoms and signs involve back pain with localized tenderness and fever. With the presence of an epidurally induced abscess, a leucocytosis can be expected and may occur several days or months following needle and catheter insertion. Following the formation of an epidural abscess, the patient can develop progressive weakness and may develop paraplegia if untreated. Meningitis may develop if the patient has endured a lumbar puncture in this setting. The most common pathogen involved in abscess formation is *Staphylococcus aureus*; it should act as a standard for guiding antibiotic treatment until definitive culture results are available. As with an epidural hematoma, prompt surgical consultation is warranted for abscess development.

In pediatric patients, there is some concern regarding catheter infection with prolonged use of caudally placed catheters because of the proximity of the sacral hiatus to the anal region. Although studies have not found clinical evidence of greater infection rates with the caudal approach to catheter placement, increased bacterial colonization has been reported with this technique. *Staphylococcus epidermidis* was the predominant microorganism colonized on the skin and catheters of lumbar and caudal epidurals, and gram-negative bacteria were also found on tips of caudal catheters.[135] While the overall infection rate associated with caudal epidural catheters appears to be quite low, tunneling caudal catheters or simply fixing the catheter with occlusive dressing in an immediate cephalad direction has been recommended to reduce the risk of contamination by stool and urine.[26,136]

Prevention

Epidural abscesses can occur spontaneously (a reported incidence of 0.2–2 per 10,000 hospital admissions per year),[137] and lumbar puncture has been safely performed in potentially bacteremic patients.[138] Following is a list of guidelines for the prevention of epidural abscess formation:

- Factors that contribute to a lower incidence of epidural space infections involve, meticulous aseptic technique, monitoring of the infection site, antibiotic prophylaxis, and bacterial filter use.
- While both lidocaine and bupivacaine are bactericidal in high concentration, this property is much reduced at the concentrations commonly used in clinical practice.[139]
- The performance of neuraxial block should be avoided where local infection exists at the needle entry site.
- Debate continues as to whether systemic or localized infection distal to the entry site carries significant risk. Another concern is whether the catheter may act as a secondary focus for infection. The clinician must weigh the risks and benefits of neuraxial block.

Management

Following is a list of guidelines for the management of epidural abscess formation:

- Daily catheter site inspection is essential for the early prevention of epidural abscess formation.
- Prompt removal of the catheter is essential when erythema and local discharge are present.
- Carefully assess any symptoms or signs of back pain.
- If any neural dysfunction occurs, a diagnosis must be immediately made in order to evaluate infective causes.
- Once a diagnosis of epidural abscess is made, a combination of medical (antibiotic) and surgical (incision and drainage) treatment may be needed.

Total Spinal Anesthesia

Total spinal anesthesia occurs when an excessive dose of local anesthetic is injected into the subarachnoid space; this is usually the result of an unintentional injection of a dose of local anesthetic intended for the epidural space. A high spinal may be seen when a small epidural dose or a large spinal dose of local anesthetic enters the subarachnoid space. Obstetric patients are particularly vulnerable because the engorged epidural venous plexus reduces spinal CSF volume and predisposes this population to cephalad local anesthetic spread. Total spinal anesthesia is rarely seen in nonobstetric cases, as observed by Dawkins, who reported an incidence of 0.2% of total spinal anesthesia in 48,000 patients undergoing epidural anesthesia.[140]

Prevention

To prevent total spinal anesthesias from occurring, it is essential to use predictable technique when aspirating, and the epidural test dose should be used. The subsequent use of small incremental doses of local anesthetics may reduce the risk of this complication. The use of electrical stimulation is a useful and reliable real-time technique for confirming epidural catheter placement.[13,25,26,141,142] The advantage of the real-time electrical stimulation test is that intrathecal placement can be eliminated prior to the administration of a potentially large test dose. A test dose of lidocaine and epinephrine should still be administered to detect unintentional intravascular placement. However, when combined with the epidural stimulation test as described in the previous section, the test dose can be given with confidence as there is a reduced risk of developing total spinal anesthesia.[12]

Management

Total spinal anesthesia is a true medical emergency, as patients become profoundly hypotensive, apneic, and unconscious with pupillary dilation. Resuscitation with endotracheal intubation, mechanical ventilation and vasopressor therapy is frequently required, and recovery may take between 30 minutes and 6 hours, depending on the agent used and the type of dose administered. Cerebrospinal fluid lavage via an epidural catheter has been used to successfully treat a total spinal in a 14-year-old child; in this case, the patient recovered within 30 minutes.[143]

With a high spinal, the patient may complain of numbness in the hands or may have difficulty breathing; if this occurs, the situation can usually be managed with reassurance, careful use of sedation and treatment of hypotension. Respiratory function should be closely monitored with pulse oximetry, and measurements of adequate airflow should be made (i.e., determine the patient's ability to vocalize or to blow

out a match [the match test]).[144] The potency of sedative agents is increased in the presence of a high spinal,[145–147] and one should be prepared to intervene in the event of significant respiratory compromise.

Subdural Injections of Local Anesthetic Drugs

The subdural space is a potential space between the dura and the arachnoid that extends from the level of the second sacral vertebra up to the floor of the third ventricle; the subdural space differs from the epidural space in that it is both extra- and intracranial. This space envelops the cranial and spinal nerves for a short distance, and is widest in the cervical area. The incidence of subdural injections of local anesthetic drugs is reported to range from 0.1% to 0.8%,[148] and this occurs more frequently following epidural injections.[149] However, subdural injection may be an explanation for the occasional failed spinal anesthesia when pencil-point needles with side apertures are used. The design of a pencil-point needle with side apertures makes it possible for the opening to exist partially in both the subarachnoid and the subdural spaces.[150] The diagnosis of a subdural catheter placement is best achieved using an injection of radiopaque dye. A typical radiologic pattern is pathognomic of subdural catheter placement.

Prevention

Extra care should be exercised in patients who have had previous back surgery or a dural puncture at the same or adjoining interspace, as subdural injections are more likely to occur in these patients. The practice of rotating the Tuohy needle upon entering the epidural space has been implicated as a cause of subdural placement, yet there is no firm data to support this allegation. Clinically, the subdural injection of local anesthetic drugs should be suspected when motor or sensory changes do not follow the expected pattern. Subdural injections result in a very slow onset of motor and sensory anesthesia and extensive and/or patchy sensory blocking.[151] Patients may also complain of respiratory difficulties and may appear obtunded. The degree of cardiovascular depression may vary but hypotension is usually not severe; however, rapid onset of cardiovascular depression with concurrent loss of consciousness can result within 2 minutes, and cardiorespiratory arrest has been reported in the obstetric setting.[152] Based on cases reported, the epidural stimulation test appears to be a potential diagnostic test providing information about the location of the needle or catheter in the subdural space.[16,151]

Management

The treatment of subdural injections of local anesthetics is predominantly supportive. Patients sometimes require intubation, ventilation, and sedation and usually recover within 6 hours of the injection

Systemic and Local Toxicity

Unintentional intravascular catheter placement can go unrecognized and may lead to local anesthetic toxicity. There has been a dramatic decline in the incidence of systemic toxic reactions to local anesthetics following epidural anesthesia within the past 30 years. Dawkins reported a 0.2% incidence of toxicity in a retrospective analysis of 48,292 cases of epidural anesthesia in 1969[140]; this series included thoracic, lumbar, and sacral epidurals. More recently, Brown reported a 0.01% incidence of toxicity following lumbar epidural anesthesia in a retrospective study of 16,870 cases,[153] and a 0.69% incidence of toxicity following caudal epidural anesthesia in a series of 1295 cases. This 20-fold reduction in toxic reactions following epidural anesthesia during the past 30 years is in part explained by significant changes in regional anesthesia practice and by the influence of regional anesthesia societies in North America, Europe, Asia, Australia, and New Zealand. In the early 1980s, several deaths were reported in the United States following accidental intravascular injections of bupivacaine whilst performing epidural anesthesia. These deaths occurred as a result of cardiac toxicity which had not been previously reported with bupivacaine.[154] Several deaths were also reported in the United Kingdom when bupivacaine was used for intravenous regional anesthesia.[155] These tragedies led to a practice change in regional anesthesia. Single injection epidural techniques commonly practiced 30 years ago have been replaced by continuous techniques involving injections of small incremental doses of local anesthetics; subsequently, "test dosing" has become a standard when using local anesthetics in regional anesthesia. Bupivacaine was implicated in 50% of toxic reactions reported by Auroy and in a large percentage of cases in Brown's study.[43,153]

Prevention/Management

To avoid potential local toxicity, the use of local anesthetic free of preservatives in an appropriate concentration should be considered for use in the neuraxial space.

For epidural catheter anesthesia, using soft-tipped catheters (e.g., metal-reinforced catheter) may reduce the introduction of the catheter into the vessel.[156] The most important aspects of prevention were discussed in Local Anesthetic above but are summarized as follows:

- Aspiration
- Test dose
- Incremental dosing

The epidural stimulation test has the potential to detect intravascular catheter placement, and should not be overlooked.[15] In normal circumstances, repeated injections of local anesthetic into an appropriately placed epidural catheter results in the impairment of nerve conduction and requires a gradual increase in the amplitude of electrical current to produce a positive motor response to the stimulation test.[141] The absence of this trend after repeated doses of local anesthetic suggests that the injected local anesthetic may be rapidly disappearing from the epidural space, as is the case with intravascular placement. However, there have only been a few reported cases of intravascular catheter detection when using this technique. The general principles and treatment involved in managing unintentional intravascular toxicity from local anesthetic have been addressed earlier (see Management of Local Anesthesia Toxicity above).

Postdural Puncture Headache

Postdural puncture headache (PDPH) is a widely discussed and published topic in regional anesthesia; it is also one of the most common complications of epidural and spinal anesthesia. Advances in needle design and gauge, as well as a better understanding of the physiologic mechanism of PDPH have dramatically reduced the incidence of PDPH associated with spinal anesthesia, even in the obstetric

population.[157] However, the incidence of PDPH following epidural anesthesia in obstetric patients remains unchanged, with headaches ranging from 0 to 2.6% of cases.[157]

Prevention

Prevention of PDPH relies on the education of clinicians regarding the factors influencing the incidence of PDPH; such information is based on previous clinical case reports and studies. There is a strong link between onset of headache and needle gauge, age, gender, pregnancy, bevel design, and bevel orientation.

The dura consists of a mixture of elastic collagen and elastin fibers contained in a viscous intercellular ground substance[158]; it is primarily a longitudinally oriented structure, and its greatest tensile strength and stiffness exists in the longitudinal orientation. When a needle penetrates the dura, the size of the defect will be dependent on the number of elastin fibers cut, as well as by the tendency of those cut fibers to recoil in opposing directions, creating a crescent-shaped defect. As the gauge of the needle increases, more elastic fibers are cut. Fink examined the dura of elderly cadavers and found less viscoelastic material and more fibrous connective tissue.[159] Young patients are at greatest risk of PDPH as their greater dural elasticity maintains a patent defect compared to the less elastic dura of the elderly.

Norris[160] demonstrated the importance of bevel orientation in relation to the incidence of PDPH following penetration of the dura with an epidural needle. Lybecker[161] suggested that bevel orientation may be even more important than needle gauge and was unable to show any difference in PDPH when using 22- and 25-gauge needles, provided that the bevel was vertically oriented. Ready[162] suggested that the incidence of PDPH is reduced when the needle is placed in an oblique direction. The arachnoid is closely adherent to the dura, and when a needle is advanced perpendicularly, the holes made by the bevel in the dura and arachnoid regions are directly in line with one another. When a needle is directed obliquely, the dural puncture does not line up with that in the arachnoid layer, thus obstructing CSF leakage.

Needle design has been implicated as a factor in the development of PDPH. Blunt-pointed needles (e.g., Sprotte, Whitacre) are linked to a reduced incidence of PDPH as opposed to sharp cutting-point needles (e.g., Quincke). Blunt needles rather than sharp needles are the tool of choice, particularly in patients with a high risk of developing PDPH (e.g., adolescent and young adult patients). The most effective way to treat PDPH is to prevent this problem in the first place. The principal factor responsible for the development of PDPH is the size of the dural perforation. Thus, smaller, blunt needles should be used for spinal anesthesia. On the other hand, the most commonly used epidural needle used is the 16- or 17-gauge Tuohy needle for continuous epidural anesthesia.

Because sleep deprivation or continuous night work can be a confounding factor influencing the higher incidence of unintentional dural puncture, clinicians should be well rested when performing these techniques.

Treatment

Following unintentional dural puncture with a Tuohy needle during epidural catheter placement, some authors suggest that the epidural catheter should be advanced through the puncture hole in an effort to reduce the incidence of PDPH. Intrathecal placement of the epidural catheters following accidental dural puncture in the obstetric setting is common practice in some centers.[163] It is thought that the presence of the epidural catheter generates an inflammatory response, leading to early closure of the dural defect.[164] Because the epidural catheter is in the intrathecal space in this circumstance, extreme caution should be exercised to treat this catheter as a spinal catheter so as to avoid possible neurologic complications and infection.[157] Conservative measures, including bedrest and oral hydration remain popular therapies for PDPH, despite no evidence to support them. Bedrest may postpone the occurrence of the headache, yet it does not prevent the onset.[165] Obstetric patients should be encouraged to mobilize soon after delivery, so that PDPH, if present, can be diagnosed and treated while yet in the hospital.

Mild headaches can be treated with intravenous fluids, caffeine, and theophylline; methylxanthines may block cerebral adenosine receptors, leading to cerebral vasoconstriction. Camann demonstrated the efficacy of caffeine in 40 postpartum patients.[166] A single oral dose of caffeine is safe, less expensive than intravenous caffeine, and offers temporary relief. Caffeine is a potent CNS stimulant and should be avoided in women who have pregnancy-induced hypertension, as it may lower the seizure threshold.[167] When considering the usage of caffeine as treatment for mild headache, it is worth noting that the cerebral vasoconstrictive properties of caffeine are transient, and the headache may return after 48 hours.

Sumatriptan is a serotonin type 1-*d* receptor agonist, and has been used for cluster headaches and migraine and also as a treatment of PDPH.[168]

Cosyntropin, the synthetic form of adrenocorticotropic hormone (ACTH), has been used to treat PDPH; this pharmaceutical is thought to work by stimulating CSF production and β-endorphin output.[169]

Epidural Blood Patch The epidural blood patch (EBP), was introduced by Gormley in 1960, and is known to be the most effective treatment for PDPH. Gormley observed that patients who bled during myelography had a lower incidence of PDPH,[170] and when he himself subsequently developed PDPH, Gormley requested an injection of autologous blood into his epidural space with the positive result of the alleviation of his headache. In 1970, DiGiovanni and Dunbar's report of the successful use of epidural blood patching in 41 of 45 patients lead to its popularization.[171] This form of treatment is indicated when conservative measures have failed and the headache is severe or is likely to extend the hospital stay. The success rate for a first epidural blood patch is 85%, rising to 98% after a second patch.

DiGiovanni suggested that an epidural blood patch acts as a gelatinous tamponade and when injected, the blood generates sufficient pressure to lift the brain;[172] this author has suggested that blood acts as a sealant, plugging the hole created by the needle, thus preventing further CSF leakage. Magnetic resonance images displaying the lumbar region after blood patching shows a mass effect that compresses the thecal sac and conus. The blood spreads 3–5 spinal segments from the injection site, and spreads mostly in the cephalad direction. The mass effect persists beyond 3 hours, and clot resolution occurs in 7 hours.[173] Symptoms are frequently relieved within minutes of the proce-

dure, and this response supports the counterpressure theory.

Szeinfeld studied the dynamics of an epidural injection of blood using tagged red cells.[174] Blood was injected into the lumbar region until patients complained of discomfort in the back, buttocks, or legs. The mean volume of blood required to produce these symptoms was 14.8 mL. This study demonstrated that the blood injectate extended over 9 segments, in which 6 were in the cephalad direction, and 3 in the caudad direction.

When performing an EBP care should be taken to maintain a sterile field, and the epidural space should be identified in the usual manner.

To undergo EBP, an assistant draws 15–20 mL of autologous blood aseptically, which we believe should be further analyzed for cultures. The administration of blood should be done at a rate of 1 mL/3 sec. The end point of injection occurs when the patient complains of back, neck, or buttock pain. Much less blood is required for blood patches in the in the midthoracic region than in the lumbar region, usually in the order of 5–10 mL.

To ensure adequate healing, the patient should remain recumbent for 1–2 hours following a blood patch and may resume ambulation thereafter; the patient should refrain from any strenuous activity for several days.

Complications from EBP are rare, but can be serious. Transient bradycardia, lumbovertebral syndrome, and facial palsy have all been reported.[175–178] One case of cauda equina syndrome has been reported in a patient who was subjected to six blood patches; the patient made a full recovery following evacuation.[179]

EBP has also been successfully performed in children. A caudal blood patch has been performed in a 4-year-old child[180] and a lumbar EBP has been performed in a 7-year-old child.[181] The case reported by Kowbel involved a 4-year-old child who developed a subarachnoid cutaneous fistula following repeated lumbar punctures for chemotherapy.[180] In this situation, the epidural blood patch was performed by passing an epidural catheter via the caudal canal, and by injecting 8 mL of blood. Furthermore, there has been one case reported of cervical dural puncture treated successfully with a lumbar epidural blood patch.[182]

Blood patches have been safely performed in HIV-positive patients. HIV crosses the blood–brain barrier and infects the CNS early in the clinical course. EBP is unlikely to introduce HIV into the CNS.[165]

Prophylactic Epidural Blood Patching Prophylactic blood patches are controversial and have supporters and detractors.[183,184] The effectiveness of using EBP as a prophylactic depends on the proximity of the catheter tip to the dural tear. Although blood patching is a relatively safe procedure, there are some risks associated with its use, and patients do not always get a headache following dural puncture, even with a large-gauge needle. Aldrete describes a case of intrathecal hematoma and arachnoiditis after prophylactic blood patching through a catheter.[185]

Variations on the Epidural Blood Patch Epidural saline treatment has been used for PDPH, but is less effective than EBP. Successful use of prolonged saline infusion has been reported in patients with failed EBP.[186,187]

Fibrin glue, a pooled plasma product, has been used to treat CSF leak in cancer patients,[188] and in PDPH cases following spinal anesthesia where two EBPs had failed.[189]

Dextran-40 has also been used to treat PDPH as it undergoes delayed absorption from the epidural space because of its high viscosity and molecular weight.[190]

Failure of Spinal/Epidural Anesthesia

Failure of neuraxial blockade is more common with epidural rather than spinal anesthesia. Thus, this section will focus on discussing failed epidural anesthesia. Anesthesiologists recognize entry into the *subarachnoid space* by the tactile sensation produced and the visual element of CSF.

On the other hand, anesthesiologists recognize entry into the *epidural space* by the tactile sensation produced when using the LOR technique and the ease of epidural catheter insertion.

Thus, entry into the epidural space is purely tactile, and the end point of entry is subject to more misinterpretation than spinal anesthesia. In epidural anesthesia, false loss of resistance may occur and quite often the only proof that the needle is correctly positioned is that a successful block occurs. False losses of resistance are more frequently encountered in obese patients where anatomy may be ill-defined. Sharrock suggested that false loss of resistance may also occur in the elderly who have a high incidence of cyst formation within the interspinous ligaments.[191]

Prevention

An important distinction that should be made during epidural anesthesia is that of complete failure versus a partial blockade/failure. The inability to pass a catheter into the epidural space frequently indicates that the needle is not in the epidural space. Catheters may become occluded with blood, or the catheter may kink, take a unilateral course, break, or become knotted, all of which can contribute to the complete failure of epidural anesthesia.

The presence of a midline epidural band has been suggested[192] and may explain why difficulty may be encountered when threading the catheter through the Tuohy needle.

When epidural local anesthetic dosing for anesthesia approaches the maximum safe limit without noticeable analgesia, a failed epidural must be considered and should prompt the clinician to pursue an alternative course of anesthesia.

Careful matching of the dermatomal level of the catheter tip to that of the surgical site will yield greater success of epidural blockade. The epidural stimulation test has been used to verify accurate epidural tip placement,[26] ensuring that the dermatomes involved in the surgical procedure are selectively blocked.

Management

Effectively managing partially working and/or failed epidurals is very important in patient satisfaction and safety, particular in obstetric patients. The partially working epidural is commonly encountered when undergoing anesthesia for cesarean sections; reported failure rates are in the order of 2–13.1%.[193] A poorly functioning epidural or partially working spinal should be identified early before the decision to proceed to cesarean section is made. In an emergency situation, the anesthesiologist has a number of options available to rescue the situation; such options include converting to general anesthesia, supplemental epidural or caudal injections and local infiltration anesthesia. Intraoperative discomfort and visceral pain

may occur in up to 50% of cesarean patients.[194] A block to the T4 level is considered optimal in most cesarean patients, however debate exists concerning the best modality with which to test the upper level of the block. Loss of pinprick and cold sensation are popular testing options, but may have poor predictive value.[195,196] The loss of touch is considered by some to best equate with surgical anesthesia.[197]

Surgical factors increasing the likelihood of intraoperative discomfort include exteriorization of the uterus and round ligament stretching, both of which exceed the analgesia provided during an apparently adequately dense nerve block. Subdiaphragmatic blood or amniotic fluid may cause back, chest or shoulder discomfort.

Intervention by the clinician should involve direct communication with the patient. Pharmacologic management may be necessary depending on the level of distress. Intravenous ketamine in 10–20-mg increments and small doses of fentanyl or benzodiazepines are considered safe, although some advise waiting to administer these medications until the umbilical cord is clamped.[193] Nitrous oxide has been used in the treatment of patients with breakthrough pain, but this treatment is controversial in obstetrics anesthetics.[198] If rescue efforts fail, general anesthesia should be considered paying special attention to preoxygenation and potential airway difficulties.

For postoperative epidural analgesia, it is also important to confirm the working condition of epidural analgesia (sensory test, epidural stimulation test, low pain scores). If the epidural analgesia is not sufficient, an alternative mode of analgesia must be considered prior to discharge from the recovery room or as soon as possible.

Hypotension

Hypotension is a common physiologic change associated with neuraxial blockade. Its presence predicts block success, but as a side effect, if left untreated or poorly managed, hypotension can lead to serious morbidity or death. Hypotension results from preganglionic sympathetic blockade that leads to a reduction in systemic vascular resistance (SVR) and cardiac output if the venous return is not maintained. Systemic vascular resistance decreases as a result of a reduction in sympathetic tone, the extent of which is related to the number of spinal segments blocked. Cardiac output is altered by changes in heart rate and stroke volume. The reduction in stroke volume is a result of a fall in preload and contractility, which is load dependant. If the block involves the cardiac sympathetic nerve supply, bradycardia and reduced contractility can be expected.

Borghi et al. evaluated the frequency of hypotension and bradycardia during general anesthesia, combined epidural-general anesthesia, and in epidural anesthesia alone, in a population of 210 patients undergoing hip arthroplasty.[199] In this study, hypotension was observed in 18% of patients during the induction of the epidural block. The induction of general anesthesia in the presence of an epidural block was associated with a 4-fold increase in the odds of developing hypotension compared to general anesthesia without an epidural, and a 2-fold increase in these odds when compared to epidural anesthesia alone. One criticism of this study is that the local anesthetic dose administered was the same whether the patient received a general anesthetic or not. Many practitioners would discriminate between epidural analgesia with general anesthesia and epidural anesthesia, and would adjust the dosing regimen accordingly.

High thoracic epidural anesthesia has the potential to block cardiac afferent and efferent fibers originating at the first to fifth thoracic levels. Interest has evolved concerning the potential positive effects of cardiac sympathetic blockade in patients with coronary artery disease: dilation of coronary vessels, reduced heart rate, and decreased myocardial oxygen demand.[200]

Prevention

The effect of prophylactic administration of intravenous fluid, ephedrine, and methoxamine on cardiovascular responses to both epidural and combined epidural and general isoflurane anesthesia in 45 adult patients undergoing knee arthroplasty has been examined.[201] In Wright's study, systolic blood pressure was significantly greater after ephedrine administration than after fluid preloading or methoxamine administration. An increase in plasma volume triggered by epidural-induced hypotension has been observed as a result of fluid movement from the interstitial to the intravascular space.[202] A larger percentage of fluid administered is retained by hypotensive than normotensive patients,[203] resulting in hemodilution. Holte's recent study[204] showed that it was not the epidural that leads to changes in blood volume, but rather the infusion of fluid that effects blood volume. Hydroxyethyl starch and ephedrine have similar hemodynamic effects; ephedrine may be the preferred option for patients when excess fluid administration is undesirable. Fluid administration prior to induction of spinal and epidural analgesia usually can reduce the risk of hypotension. Patient position is crucial in preventing low cardiac output states in patients undergoing epidural anesthesia. If severe hypotension occurs during the course of epidural anesthesia, the most likely cause is inadequate venous return as a result of blood loss, an unfavorable patient position, or surgical obstruction.

Management

The first step in the management of hypotension is making sure that there is no interference with venous return. Place the patient in 5° of Trendelenburg and in a slightly head-down position. The presence of hypotension prompts the clinician to intervene with fluid or pressor administration to restore the systemic blood pressure to acceptable levels.

Significant changes in blood pressure are uncommon in pediatric patients after the proper administration of epidural analgesia. A high sympathetic single-shot caudal block to T6 caused no significant changes in heart rate, cardiac index, or blood pressure in children.[205,206] Even when thoracic epidural blockade is combined with general anesthesia, cardiovascular stability is usually maintained in otherwise healthy pediatric patients.

Hypotension should prompt anesthesiologists to immediately eliminate a total spinal and/or intravascular injection leading to local anesthetic toxicity and cardiovascular collapse.

Respiratory Complications

Several studies have examined high thoracic epidurals in both healthy people and in those with chronic obstructive airway disease. Peak expiratory flows, forced vital capacity, forced expiratory volume in 1 second (FEV_1), and maximum expiratory pressures are reduced[207,208] in those suffering from this disorder. Kochi investigated the

effect of high thoracic epidural anesthesia on the hypercapnic ventilatory response and ventilation pattern;[209] duration of inspiration, rib cage excursion, and its contribution to tidal volume decreased significantly, whereas mean inspiratory flow rate and minute ventilation increased. Furthermore, end-tidal PCO_2 and the tidal excursion of the abdomen remained unchanged, whereas hypercapnic ventilatory response decreased significantly. Lumbar and high-thoracic-region-induced epidurals do not interfere with the ventilatory response to hypoxemia.[210] Gruber demonstrated the safety of thoracic epidural anesthesia with bupivacaine 0.25% in patients with severe chronic obstructive pulmonary disease.[211] The potential for phrenic (C3-C5) palsy is low with an epidural block, except during unintentional blockade following an interscalene brachial plexus block.[212] Cervical epidural anesthesia has been used for upper limb, parathyroid and carotid operations.[213–215]

Bonnet reported respiratory difficulties in 3 of 394 patient undergoing carotid endarterectomy using 15 mL 0.5% bupivacaine or 0.37–0.40% bupivacaine plus fentanyl (50–100 μg).[213] Many case series, although smaller in number than this study published by Bonnet, have not reported respiratory difficulties to be a significant problem.[214,215]

Capdevila reported that both 0.25% and 0.375% cervical epidural bupivacaine impaired diaphragmatic excursion, tidal volume, forced vital capacity, and hand grip strength in patients having postoperative hand rehabilitation, and did not recommend the technique for this purpose.[216]

The incidence of respiratory depression is closely associated with the use of neuraxial opioids. The rate of incidence of respiratory depression requiring intervention after conventional opioid dosing is approximately 1%.[217]

Prevention

To prevent respiratory complications do the following:

- Avoid the use of high doses of opioids.
- Limit opioid dosages, especially in the intrathecal space.
- Avoid the concomitant use of parenteral opioids or sedatives.
- Avoid or limit doses in the patient with advanced age (> 60 years old), sleep apnea and other coexisting diseases
- Use hydrophilic drugs (e.g., morphine) with caution.

Management

To manage respiratory complications do the following:

- Treat mild respiratory depression with oxygen.
- If an infusion is used, then reduce the rate.
- Depending on the severity of respiratory complications, consider ventilatory support, the administration of narcotic antagonists, and the discontinuation of the opioid infusion.
- Carefully monitor during the central nerve blocking period—this cannot be overemphasized.

Nausea and Pruritus

Nausea and pruritus are common side effects seen with the administration of neuraxial opioids. The reported incidence of postoperative nausea and vomiting (PONV) with opioid administration is 30–65%,[218–220] and 80% for pruritus.[221] Pruritus is thought to be multifactorial in nature, and is speculated to operate via an "itch center" in the CNS via medullary dorsal horn activation, and antagonism of inhibitory transmitters.[222] Pruritus is a dose-dependant phenomenon, where its onset involves possible mediators including C fibers in the skin, serotonin ($5\text{-}HT_3$) receptors, and prostaglandins. The obstetric population seems to be at greater risk for developing pruritus.

PONV is a complex, multifactorial problem:

- Epidural administration of local anesthetics alone carries a low risk of causing the occurrence of PONV.[223]
- Factors such as surgery, age, and gender influence the reported incidence of PONV associated with epidural anesthesia.[224]
- Within 5–15 minutes of epidural administration, peak plasma opioid concentrations can reach levels similar to those seen following an intramuscular injection.[225]
- In patients receiving epidural morphine, there have been no differences in PONV onset or duration when different doses up to 5mg were administered,[226] whereas higher doses have been shown to lead to both an increase and a decrease in reported PONV.[224]
- Epidural fentanyl and meperidine do not appear to influence PONV in the same way that morphine does; as reported, fewer PONV cases have been documented with the use of fentanyl and meperidine after orthopedic surgery when compared with morphine.[227]

Prevention/Management

To prevent and/or manage PONV do the following:

- Reduce the dose administration and avoid neuraxial opioid administration. Doing so is effective in reducing the incidence of nausea and pruritus.
- Use antihistamines, opioid antagonists (naloxone and nalbuphine), propofol, nonsteroidal antiinflammatory drugs (NSAIDs), and $5\text{-}HT_3$ receptor antagonists as both preventative and therapeutic measures. Dexamethasone has been shown to be a superior antiemetic for PONV-associated epidural morphine when compared to metoclopramide[228] and $5\text{-}HT_3$ receptor antagonists.[229]

Postoperative Urinary Retention

Postoperative urinary retention (POUR) is common following major surgery and occurs in:

- 20–68% of patients after abdominoperineal resection.
- 16–80% of patients after radical hysterectomy.
- 20–25% of patients after anterior resection.
- 10–20% of patients after proctocolectomy.[230]

POUR is a multifactorial problem and involves factors such as age, pain, bladder outlet obstruction, detrusor-inhibiting medication, pelvic autonomic nerve damage, and the inhibition of sympathetic reflexes. A single episode of bladder overdistension can result in significant POUR morbidity. Overfilling of the bladder can stretch and damage the detrusor muscle, leading to atony of the bladder wall, so that recovery of micturition may not occur when the bladder is emptied. On the other hand, the excessive use of an indwelling catheter can lead to urinary tract infection, urethral stricture, prolonged hospital stay, or death.[231,232] Epidural use for postoperative pain management is usually reserved for patients undergoing major surgery,

where urinary catheter placement may be performed for reasons other than anticipated postoperative urinary retention. Stenseth et al. found an incidence of 42% for POUR in 1085 uncatheterized patients having epidural morphine for a variety of major operations.[233] Epidural morphine relaxes the detrusor muscle with a corresponding increase in the maximal bladder capacity; epidurally injecting morphine gives a localized effect, whereas intramuscular and intravenous morphine have no effect on detrusor contraction. This is further supported by the fact that detrusor changes occur 15–30 minutes following epidural morphine administration, and are reversed by intravenous naloxone, suggesting that spinal opioid receptors have an important role.[234]

Prevention/Management

Other epidural opioids such as fentanyl, meperidine, and methadone may also contribute to POUR, but contribute to a lesser degree than that observed with morphine.[227,235] In addition to bladder catheterization, treatment options for opioid-mediated POUR may include intravenous naloxone administration.[236] Nalbuphine is an opioid-mixed agonist–antagonist and has been used to restore detrusor function without reversing the analgesic effects of epidural morphine.[237] Short-term (24 hours) urinary catheterization for major surgery involving morphine epidural analgesia may help prevent the morbidities associated with both POUR and longer-term epidural catheterization.[238]

Backache

Backache is a common complaint following epidural anesthesia and its incidence ranges between 2% and 30% of patients.[140,239] The causal relationship between epidural anesthesia and backache has been suggested by some studies,[240,241] and refuted by others.[242,243]

The etiology of backache is multifactorial in nature. Drug use, abnormal posture, muscle relaxation, and in obstetric cases, exaggerated lumbar lordosis and the process of undergoing labor have been implicated as causes.[165]

In a retrospective study Macarthur et al. looked at 11,701 patients.[240] Of the 1634 women who reported backache, 1132 (69%) had experienced it for more than 1 year. In this study, a significant association was found between backache and epidural anesthesia (relative risk: 1.8); 903 of 4766 women (18.9%) who had had epidural anesthesia reported this symptom, compared with 731 of the 6935 women (10.5%) who had not undergone epidural anesthesia. However, prospective data refutes the findings of Macarthur, as noted by Breen who interviewed 1185 women and found that of the 1042 (88%) for which followup data was available, the incidence of postpartum back pain in those who received epidural anesthesia was equivalent to those who did not (44% vs. 45%).[242] Multiple logistic regressions revealed postpartum back pain was associated with a history of back pain, younger age, and greater weight. Russell and coworkers demonstrated that new-onset postpartum back pain was not associated with regional anesthesia.[196] Among the women in Russell's study who received either 0.125% bupivacaine or 0.0625% bupivacaine, the incidence of new long-term back pain was 7.6% when compared to controls, and there was no difference found between the groups. Women who are seeking analgesia for labor should be reassured that back pain following epidural analgesia is minimal and is usually limited to the early postpartum period.

In 1987, 2-chloroprocaine was marketed by Astra Zeneca in a new formulation (Nesacaine-MPF) involving disodium EDTA as a chelating agent, for epidural and caudal use. Reports linking this new formulation with backache emerged,[92,244] and gave way to a possible explanation that the EDTA could cause hypocalcemic tetany of the paraspinous muscles. The drug now comes preservative-free, and is prepared in dark-glass bottles to prevent light-induced disintegration. Despite the elimination of EDTA from this medication, backache continues to be reported with its use.[245]

Prevention/Management

Backache following epidural placement should not be ignored, as it can be a cardinal symptom of a space-occupying lesion within the spinal canal. Complications such as an epidural hematoma and abscess, although rare, can have catastrophic outcomes if unrecognized and untreated.

COMPLICATIONS OF INTRAVENOUS REGIONAL ANESTHESIA

Intravenous regional anesthesia (IVRA) is one of the oldest techniques used in anesthesia practice today; Bier first described IVRA in 1908.[246] The technique was not widely practiced for the first 50 years of its inception because it was not practical to perform a venous cut down on patients undergoing relatively minor extremity procedures. Holmes made a very simple adjustment to the technique in 1963, and demonstrated that Bier's technique could be performed using a percutaneous intravenous approach.[247] IVRA is now widely used for minor upper- and lower-extremity procedures all over the world[247] because of its ease to perform and association with a very high success rate. There are a number of recognizable risks associated with this procedure, the most serious being compartment syndrome and local anesthetic toxicity. A primary limitation of the technique is the duration of tolerability of the tourniquet, which, without opioid supplementation, is about 45 minutes. The addition of ketamine in very low doses (0.1 mg/kg) greatly extends the time that patients can tolerate the tourniquet. Clonidine and Ketoralac have also been recommended for this purpose. Fortunately systemic toxicity and compartment syndrome are rare complications when IVRA is properly administered.

Complications of IVRA

Compartment Syndrome

Compartment syndrome has been reported following IVRA of the upper and lower extremities.[248,249] In one reported case, hypertonic saline was mistakenly used as a diluent for the local anesthetic. Long bone fractures of the forearm or leg increase the risk of compartment syndrome and IVRA should not be used in this circumstance. Severe ischemia of the upper extremity has been reported in at least one case following IVRA in an otherwise healthy young female, where the etiology was unclear.[250] Table 49–7 lists some of the possible causes of compartment syndrome.

Venous thrombosis is a recognized complication of tourniquet application. There are some anecdotal reports of subclavian steal syndrome following sudden loss of resistance in the upper extremity, leading to transient cortical blindness.[251]

Local Anesthetic Toxicity

The risk of local anesthetic toxicity is quite low following IVRA. Auroy et al. reported an incidence of 2.7 seizures

TABLE 49–7.

Causes of Compartment Syndrome

- Excessive tourniquet pressures
- Allergic reactions
- Undiagnosed Raynaud disease
- Sickle cell disease
- Intraarterial injection
- Drug administration error

per 10,000 cases following IVRA in their study.[43] Deaths have been reported when increased amounts of toxic cardiac drugs (e.g., bupivacaine) have been used for IVRA.[155] The main cause of this complication is faulty tourniquet technique as noted.

Inadequate exsanguination before the inflation of the tourniquet allows the operator to exceed the tourniquet inflation pressure during the injection, thereby allowing local anesthetic solution to escape into the circulation. Interosseous escape of the local anesthetic can occur during injection. Accidental or premature deflation of the tourniquet (within 20 minutes) allows the local anesthetic to enter the circulation in toxic concentrations. When an excessive dose of local anesthetic is injected, toxicity may occur on release of the tourniquet, even when following appropriate recommendations.

Prevention

Intravenous regional anesthesia is easy to perform yet one must pay particular attention to the details surrounding the procedure. Preventing complications begins with appropriate patient selection and a positive surgical indication. Good intravenous access is important as is proper exsanguination of the limb. Table 49–8 lists points to consider for proper patient and surgical selection.

Proper techniques for effective and safe IVRA essential to prevent complications are as follows:

- Place the tourniquet above the elbow (tourniquet application is less reliable in the distal portion of the extremity).
- Thorough exsanguinations should take place prior to injection of the local anesthetic. Appropriate doses of preservative-free local anesthetic should be administered.
- Lidocaine free of preservatives is one of the most frequently used local anesthetics for IVRA; the recommended dose is 3 mg/kg. Other drugs, such as prilocaine, have been used because of their favorable pharmacokinetic profile; however, some of these drugs, such as prilocaine, are no longer available in many countries. A preservative-free form of chloroprocaine was recently introduced in Europe and has many potential benefits, especially with regard to toxicity.[252]
- Ropivacaine has also been studied as a potential local anesthetic for IVRA.
- Bupivacaine is contraindicated in IVRA.

Management

The management of local anesthetic toxicity is the same as that discussed in the previous section. The clinician must have dedicated intravenous access to inject other medications if required. Proper equipment and personnel must be available for emergency cardiopulmonary support (airway, breathing, circulation).

COMPLICATIONS OF OPTHALMIC REGIONAL ANESTHESIA

Like other types of nerve blocks, there are some serious risks associated with the use of ophthalmic regional anesthesia. Common complications include hemorrhage, brainstem anesthesia, and myotoxicity. However, the clinician should be aware of other less-frequently occurring complications of ophthalmic regional anesthesia that include globe ischemia, perforation of the globe, optic nerve and facial nerve damage, and elicitation of the oculocardiac reflex.

Hemorrhage

The reported risk of retrobulbar hemorrhage varies substantially in anesthetic literature.[253] In one of the largest reported series, Hamilton reported an incidence of 0.44% hemorrhages in 12,500 ophthalmic regional anesthesia cases.[254] The severity of retrobulbar hemorrhage varies depending upon the origin of the bleeding. Arterial bleeding is the most dangerous complication of retrobulbar injections because tamponade can occur, which leads to ischemia of the globe. In this situation, lateral canthotomy may be required to relieve the pressure. The site of injection is also important to consider in avoiding hemorrhage.

TABLE 49–8.

Factors for Proper Patient/Surgical Selection

- The upper-limb surgical procedure should not last longer than 1 hour. Surgical procedures lasting longer than 1 hour are not recommended because patients become very intolerant of the tourniquet.
- Failed IVRA occurs more frequently in lower-extremity procedures.
- The risk of toxicity is much greater in lower-limb surgery where larger quantities of drug are required.
- In addition to the usual contraindications of regional anesthesia, physicians should avoid admitting patients for IVRA who have the following: sickle cell disease, Raynaud disease, sickle cell anemia, or allergies to local anesthetics.
- Patients with gaping venous wounds, those with infected lesions, and those patients with long bone fractures of the extremities should not be recognized as patients suitable for IVRA.
- IVRA is generally not recommended in lengthy procedure.

IVRA, intravenous regional anesthesia.

Prevention of Complications Resultant of Ophthalmic Regional Anesthesia

To prevent complication as a result of ophthalmic regional anesthesia, do the following:

- Consider only selected patients who are taking anticoagulant medication with the current INR (< 2) levels not exceeding twice the normal value as candidates for ophthalmic regional blocking.[255]
- Carefully weigh the benefits and risks of performing ophthalmic regional anesthesia in patients who have discontinued their anticoagulant medication.
- Consider alternative methods of applying ophthalmic anesthesia if there is risk of thrombotic complications following discontinuation of anticoagulant medication.[256,257]
- Let patients on antiplatelet therapy continue their medications if medically indicated.[258]

- Postpone surgery in severely hypertensive patients.

The use of small-gauge disposable needles (25 gauge), less than 31 mm in length is recommended for use in ophthalmic regional anesthetic procedures.[259,260] The site of anesthetic injection should be carefully considered. Vascular structures are larger in the apex of the orbit, and also the upper nasal area is particularly vascular. Areas with increased vascular architecture should be avoided to prevent complications during the induction of ophthalmic regional anesthesia.

Management

As with other nerve blocks, once damage has occurred as a result of ophthalmic regional anesthesia it is difficult to reverse. If complications do occur, supportive measures are recommended for patient care.

Brainstem Anesthesia

When local anesthetic spreads directly into the brain from the orbit, brainstem anesthesia occurs. The incidence of brainstem anesthesia is 1 case for every 350–1500 ophthalmic cases[259] and symptoms may appear within 2 minutes of the injection. Maximum effects usually occur within 20 minutes and recovery occurs in 2–3 hours. Symptoms and signs can vary greatly and include the following (Table 49–9).

TABLE 49–9.

Signs and Symptoms of Brainstem Anesthesia, Prevention, and Management

Brainstem anesthesia	• Confusion • Shivering • Convulsions • Paralysis • Loss of consciousness • Apnea • Hypotension • Bradycardia • Nausea/vomiting
Prevention	• Use short needles <31 mm) and small doses of local anesthetics.
Management	• Surgery should be postponed and the patient should be observed and treated appropriately if symptoms of brainstem anesthesia develop. The treatment varies depending upon the symptoms and is mostly supportive in nature.

Globe Perforation

Blindly inserting a needle into the orbit is associated with the risk of globe perforation. The site of injection and the axial length of the globe must be carefully considered before needle insertion so as to prevent damaging the globe. In one reported series, there were no globe perforations in 2000 cases of ophthalmic regional anesthesia,[261] whereas another study reported an incidence of 1 case of globe perforation per 12,000 ophthalmic cases.[262]

Prevention

Globe perforation can be prevented by presurgically assessing the axial length of the patient's eye. Patients susceptible to perforation of the globe include those with elongated globes (>26 mm), which occur in myopic patients, in those with retinal detachment, and in those who require refractive surgery. Myopic patients with staphyloma are particularly vulnerable to globe perforation.[263]

The clinician should attempt to visualize in the "mind's eye" the equator of the globe and to avoid repositioning the needle until it is located past the equator. All needles should be directed tangentially with the bevel facing the globe. Pain or resistance to needle advancement is a warning sign of perforation of the sclera. Some experts suggest aiming the needle midway between the inferior and lateral rectus muscles to allow a clear point of entry to the intraconal space. The inferior rectus muscle should be carefully avoided to prevent diplopia.

Management

The key to successful management of globe perforation is early diagnosis and treatment. The patient may report paresthesia at the time of needle insertion. Funduscopic examination by an ophthalmologist may confirm the diagnosis of globe perforation. Depending on the severity of damage, globe perforation can be managed by laser photocoagulation therapy, cryotherapy, and other prompt surgical procedures. Because the appropriate management of globe perforation is complex, careful consultation should take place with the ophthalmologist.

Myotoxicity

Myotoxic effects of local anesthetic drugs were discussed in Toxic Effects of Local Anesthetics on the Nerves and Surrounding Anatomy above. Typically, diplopia and ptosis can occur for up to 48 hours when using long-acting local anesthetics. However, direct injection of these drugs into the highly sensitive eye muscles can permanently damage them. The inferior rectus muscle appears to be particularly vulnerable to injury.[104,264]

Miscellaneous Complications Resulting from Ophthalmic Regional Anesthesia

Globe ischemia, optic nerve and facial nerve damage and oculocardiac reflex are less-frequent complications of ophthalmic regional anesthesia.

SUMMARY

This chapter provides a comprehensive review of the management of complications following regional anesthesia.

- Although the overall incidence of complications following brachial plexus anesthesia is low, the proportion of complications following supraclavicular methods is higher than that reported following axillary blocks (i.e., the incidence of seizure activity following interscalene or subclavian perivascular methods is at least 6 times that of the axillary approach).
- Many of the complications of supraclavicular methods have an impact on pulmonary function; consequently, supraclavicular methods should be avoided in patients with significant pulmonary dysfunction. In a sense, there should always be a clear-cut indication for selecting supraclavicular methods because of the risk of pulmonary complications.
- Local anesthetic drugs must be injected slowly and incrementally,

and patients must be observed carefully for signs of local anesthetic toxicity. The addition of epinephrine to local anesthetics is a useful marker for detecting accidental intravascular injections.

- Persistent pain on injection of local anesthetics is a potential sign of intraneural injection.
- Large-gauge and long needles should be avoided, and brachial blocks should be avoided in comatose adult patients.

Finally, brachial plexus anesthesia is not yet an exact science. Ultrasonogram-guided needle insertion is rapidly converting regional anesthesia from an art to a science. There has been renewed interest in regional anesthesia as a result of this advance. Brachial plexus block has been a great challenge to anesthesiologists for more than 100 years. We can expect success rates close to 100% in the near future. However, complications will still occur. Important facts for consideration regarding managing adverse outcomes during regional anesthesia are:

- As professionals, we must select our patients carefully.
- We must provide informed consent.
- The safest approach must be selected.
- The appropriate dose of local anesthetic should be given.
- Patient discomfort must be minimized.

Drug delivery via neuraxial block is an effective method for providing analgesia for lower-extremity, abdominal, and thoracic procedures, as well as for managing labor pain. In the perioperative setting, epidural analgesia has numerous benefits in addition to providing effective pain relief. These benefits include earlier ambulation, rapid weaning from mechanical ventilation, reduced time spent in a catabolic state, and lowered circulating stress hormone levels.[265] While serious complications are uncommon, patients should be informed about common side effects, such as urinary retention and pruritus, and should be counseled concerning the risks of major neurologic complication such as paralysis. Newer technologies such as the use of ultrasonography, and the stimulating epidural catheter may increase the safety and ease of catheter placement. For the individual patient, the risks and benefits of epidural analgesia should be carefully considered, and prevention of patient injury is the highest priority.

SPECIALTY AREAS OF ANESTHESIA PRACTICE

CHAPTER 50

Neuroanesthesia

Michael M. Todd, MD,
David S. Warner, MD, PhD,
Mazen A. Maktabi, MD, and
Kamila Vagnerova, MD

The idea that there is something different about anesthesia for neurosurgery is relatively new, despite occasional observations as early as the mid-1800s about the effect of anesthetics on the condition of the brain; the subspecialty of neuroanesthesia arose in only the late 1960s and early 1970s. It developed because of the newfound ability to measure parameters such as intracranial pressure (ICP), cerebral blood flow (CBF), and cerebral metabolic rate (CMR). The relevance of such measurements was supported by the finding that volatile anesthetics could alter ICP in patients, a change apparently related to an increase in CBF. This was reinforced by the discovery that the barbiturates might be therapeutic in some patients. The result was a rapid growth in research and a simultaneous effort to use this information to guide clinical practice. The discipline has since grown to encompass many areas of neurophysiology as they apply to anesthesia, and to many areas of the basic neurosciences that have no immediate application to clinical care.

Despite scientific expertise, neuroanesthesia is plagued by one difficulty. Most of the physiologic parameters that we regard as important (and which we enjoy measuring under experimental conditions) are extremely difficult to record in patients; that is, it is impossible to *routinely* "monitor" the effects of drugs on CBF, CMR, or ICP. There is no neuroanesthetic equivalent of the pulmonary artery catheter or the transesophageal echocardiograph that permits a wide range of cerebral physiologic and pharmacologic effects to be followed easily in large number of patients. We can monitor the electroen-

KEY POINTS

1. Most of the physiologic parameters neuroanesthesiologists want to measure are not easy to record in the clinical setting, such as the effect of drugs on cerebral blood flow, cerebral metabolic rate, or intracranial pressure (ICP).
2. To understand ICP, the anesthesiologist should remember the analogy of the brain as a "closed box," out of which something must leave if something else goes in.
3. Although blood is the smallest of the four kinds of tissues located in the brain, its importance lies in the fact that the cerebral blood volume—and hence ICP—can be changed very rapidly.
4. The five factors that control cerebral flow, cerebral blood volume, and intracranial pressure are $Paco_2$, Pao_2 plus arterial content, autoregulation, cerebral flow-metabolism coupling, and autonomic nervous system control.
5. While the mechanism(s) controlling flow-metabolism coupling are unknown, it is important to recognize that anesthetics do not "uncouple" flow and metabolism.
6. Different anesthetics (e.g., barbiturates, propofol, etomidate, the volatile agents, and narcotics) all have somewhat different effects on cerebral blood flow (CBF) and cerebral metabolic rate (CMR). In general, intravenous drugs reduce CBF, whereas volatile agents are vasodilators. Essentially all agents, except perhaps ketamine, reduce CMR.
7. All volatile anesthetics can increase cerebral blood flow and ICP, in some cases dramatically. Nonetheless, these drug-induced ICP increases have never been demonstrated to be detrimental (at least during elective surgery) and are relatively easily counteracted by other ICP control measures, including hyperventilation.
8. Nitrous oxide is not benign in its effects on the brain. It can considerably increase cerebral blood flow.
9. In a patient who is severely hypertensive because of intracranial hypertension, it is probably unwise to aggressively lower blood pressure.
10. The sitting position, although accompanied by hazards of air embolism and other problems, is still in use in neurosurgery. In spite of the problems, it is not clear that alternative positions are better.
11. The concept of cerebrovasospasm, its diagnosis and treatment, should occupy the attention of the neuroanesthesiologist. The most recent work in the field has centered on the calcium antagonists, specifically nimodipine.
12. Continued reduction of brain swelling, even though the cranium is open, is a key to successful neuroanesthesia. "Relaxation" of the brain during the neurosurgical procedure itself may require not only hyperventilation but also osmotic diuretics, such as mannitol.
13. During cerebral aneurysm surgery, there must be a plan for dealing with a sudden rupture and the blood loss that can occur from such a tiny operative site.

cephalogram (EEG), but we have so far been unable to quantitatively link EEG patterns with changes in the other parameters. We can insolate the cerebral vasculature with a transcranial Doppler, but we still don't know what the numbers really mean. We can do wonderful science with magnetic resonance imaging (MRI) or positron emission tomography, but we can't routinely bring these into the operating room. We are thus forced to extrapolate from findings made in the animal or clinical laboratory. This approach is potentially fraught with error. In particular, it is unclear whether the findings made in the laboratory can be easily extrapolated to the clinical setting. Because relatively few neurosurgical patients do poorly after routine surgery, regardless of the management methods used, a huge number of patients would be needed to carry out any valid study relating a drug-mediated change in a hard-to-measure physiologic parameter to outcome. Such studies have never been done and may never be. As a result, we can, for example, show that halothane increases cortical CBF to a greater degree than does isoflurane. However, because the relationships between CBF and ICP are complex, it is not clear whether this means that halothane will produce a greater increase in ICP than will isoflurane. Furthermore, because the relationship between a drug-induced change in ICP and outcome is also unknown, it is even less clear whether the CBF and ICP effects of halothane, isoflurane, N_2O, barbiturates, narcotics, and other drugs have any real effect on our patients.

These comments are not meant to deprecate the efforts of researchers who have devoted their lives to understanding the cerebrovascular, metabolic, or electrophysiologic effects of anesthetics, nor to criticize those who have attempted to use such data to improve clinical care. We believe that an understanding of cerebrovascular physiology and pharmacology is important to anesthesiologists. As our knowledge grows, the connections between physiology and clinical management will become stronger, although some cherished beliefs will be discarded. We ask only that the reader realize these limitations, refrain from making (or believing) dogmatic statements (including ours), and avoid carelessly translating physiologic and pharmacologic observations into clinical practice.

TABLE 50–1.

"Normal" Human Values

Parameter	Whole Brain	"Gray"	"White"
CBF (mL/100 g/min)	50	80	20
CBV (mL/100g)	4	4–6	1.5–2.5
$CMRO_2$			
mL/100 g/min	2.7–3.6	3.4–4.3	0.7–1.1
μmol/g/min	1.2–1.6	1.5–1.9	0.3–0.5
CMRGlu			
mg/100 g/min	4.9	6.5–8.5	1.2–2.2
μmol/g/min	0.3–0.4	0.36–0.47	0.07–0.12
CMRLact			
mg/100 g/min	−0.32	—	—
μmol/g/min	−0.035	—	—

CBF, cerebral blood flow; CBV, cerebral blood volume; CMRGlu, cerebral metabolic rate of glucose; CMRLact, cerebral metabolic rate of lactate; $CMRO_2$, cerebral metabolic rate of oxygen. All values represent the authors' best estimates based on many sources. In PET measurements (which are used to derive regional data), an exact separation of gray and pure white matter is not possible. As a result, most of the gray matter values above might more accurately be described as "cortical," whereas white matter values are typically obtained from areas such as the internal capsule. Note that CMRLact is a negative number, which reflects the fact that lactate is usually produced by the brain rather than consumed (and hence the venous concentration is greater than arterial).

It is impossible to review the entire discipline of "neuroanesthesia." Several books have been written in an attempt to do just this.[151,155,470] We have chosen not to deal with EEGs, evoked potentials, and other forms of clinical monitoring except very briefly. Throughout this chapter we endeavor to exercise the skepticism we have asked of the reader and distinguish between matters of academic/scientific interest and the realities of the neurosurgical operating room.

BASIC PHYSIOLOGY

Cerebral Blood Flow, Cerebral Blood Volume, and Cerebral Metabolic Rate

Although we have cautioned about the careless extrapolation of CBF, cerebral blood volume (CBV), and CMR measurements to the clinical setting, we also believe that some understanding of what is and is not known about this subject is important. Specifically, one needs some understanding of the methods used to obtain information, and the specific limitations of these methods.

Measurement of CBF

Table 50–1 shows normal whole-brain and gray/white CBF values. However, these values remain somewhat abstract—and can be misinterpreted—unless one knows how they are obtained. This might be untrue if CBF could be measured "mechanically," that is, with a flowmeter around the carotid arteries, or with a technique as simple as thermodilution cardiac outputs. Unfortunately, with few exceptions, such methods do not work. Venous outflow from the dog brain can be diverted through a flowmeter to allow continuous "mechanical" measurements, but this technique is not applicable to humans. Retrograde thermodilution catheters[767] or Doppler ultrasound probes[545] have been placed in the jugular vein of patients and research subjects, but none of these methods has been widely accepted (although they can be extremely useful in selected circumstances). Consequently, we begin with a review of those methods that have been widely used in either the operating room or intensive care unit (ICU), with some later comments on laboratory techniques or more complex clinical methods.

CBF and CMR Methods for the Operating Room

There are basically 5 methods that have been widely used for CBF studies in the operating room/ICU setting: (a) the Kety-Schmidt method; (b) intracarotid

^{133}Xe injection; (c) intravenous/inhaled ^{133}Xe; (d) intraaortic ^{133}Xe; and (e) transcranial Doppler sonography. The resultant CBF values can, with major limitations (Table 50–2), be used to calculate CMR. We also briefly discuss the use of a sixth method, jugular venous O_2 sampling as a measure of flow–metabolism balance.

Kety-Schmidt Method Human CBF was first measured in 1945 by Seymour Kety and Carl Schmidt, using a variation of the Fick principal.[366] Catheters were inserted into a peripheral artery and into the jugular bulb (the internal jugular vein just as it exits the skull). A diffusible tracer (10–15% N_2O) was given by inhalation, and paired samples of blood entering and leaving the brain were obtained over the next 15–20 minutes. The arterial concentration of N_2O rises quickly, but, because the tracer is being taken up by brain tissue, the cerebral *venous* concentration rises more slowly (Fig. 50–1). The rate at which tissue saturation is reached (i.e., when arterial and venous concentrations equilibrate) is a reflection of the rate of tracer delivery. If CBF is high, equilibrium will occur quickly; if flow is low, equilibration will be slow.

Even after 50 years, many investigators consider this method to be the gold standard for whole-brain CBF measurements, and it has been widely used in the study of anesthetics. However, it is invasive, it provides only whole-brain CBF information, and it is "blind" to areas of near-zero flow (as areas that do not take up tracer do not contribute to the venous saturation curve). It is also time-consuming, requiring 10–20 minutes to complete a single measurement. For these reasons, a number of other techniques have been developed.

The Kety-Schmidt technique lends itself almost ideally to the calculation of cerebral metabolic rate (CMR), which is the rate at which the brain consumes or produces metabolic substrates or byproducts, e.g., oxygen ($CMRO_2$), glucose (CMRGlu), or lactate (CMRLact). CMR plays a major role in the control of CBF and is dramatically altered by anesthetics. The standard method for its determination is based on the Fick principle: CBF is multiplied by the arteriovenous concentration difference of the compound of interest. Because the Kety-Schmidt method requires both arterial and jugular venous sampling, obtaining the needed samples for CMR determinations is trivial. For example, if CBF is 50 mL/100 g/min, arterial O_2 content is 20 mL/100 mL (0.20 mL O_2/mL blood), and cerebral venous O_2 content is 12 mL/100 mL (0.12 mL O_2/mL blood), then:

$$CMRO_2 = CBF\ (A\ VO_2) = 50\ (0.20 - 0.12) = 4\ mL\ O_2/100\ g/min\ (or\ 1.54\ \mu mol/g/min)$$

where A is arterial O_2 content and VO_2 is venous O_2 volume. Similar calculations yield the other CMR values shown in the first column of Table 50–1. Note that these have also been expressed as μmol/g/min, which is useful when attempting to examine the stoichiometry of energy metabolism. For example, if you wish to calculate the relative amount of glucose being converted in the brain to CO_2 and H_2O via oxidative metabolism:

$$CMRO_2/CMRGlu = (1.54\ \mu mol/g/min)/(0.27\ \mu mol/g/min) = 5.7$$

TABLE 50–2.

Limitations of Various Flow Measurement Methods

Human and laboratory methods	
Kety-Schmidt	Invasive
	No regional data
	Slow (10–20-minute data acquisition)
	Blind to very-low-flow regions
	Invasive
	One hemisphere only
	Looks primarily at superficial cortex
	Looks primarily at superficial cortex
	Extracranial tracer delivery
	Computationally complex
	Tracer recirculation
	Looks primarily at superficial cortex
	Extracranial tracer delivery
	Underestimates CBF?
Transcranial Doppler sonography	Measures velocity only
	Accurately measures CBF changes—but not absolute CBF
	"Distorted" values if vessel diameter changes
Single-photon emission computed tomography	Typically single measurement
	Not usable in the operating room or intensive care unit
Positron emission topography	Extremely expensive and technically complex
	Not usable in the operating room or intensive care unit
Magnetic resonance imaging	Under development
	Not usable in operating room or intensive care unit
Laboratory methods	
	Tissue injury?
	Requires craniectomy
Venous outflow	No regional information
	Forebrain only
	Deterioration with time
	Requires craniectomy
Radioactive microspheres	Limited number of flows (6–8)
	Requires complex surgery
Autoradiography	One measurement only
	Complex processing needed

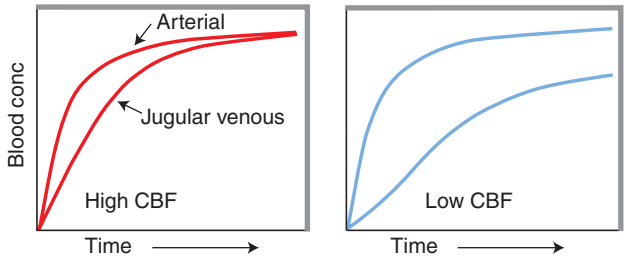

FIGURE 50–1. Cerebral blood flow (CBF) as measured by the Kety-Schmidt method. Catheters are placed into an artery and into the jugular bulb. A diffusible tracer (e.g., N_2O) is then given by inhalation, and pair arterial and jugular venous samples are drawn over time (usually 15–20 minutes). Note that in both of the two sets of curves, the shape of the blood concentration versus time for the arterial curve is essentially the same. However, the time to arteriovenous equilibrium is much longer in the low CBF curve (*right*) than on the *left* (in fact, equilibrium is never achieved on the left). Actual CBF is proportional to the area between the arterial and venous curves.

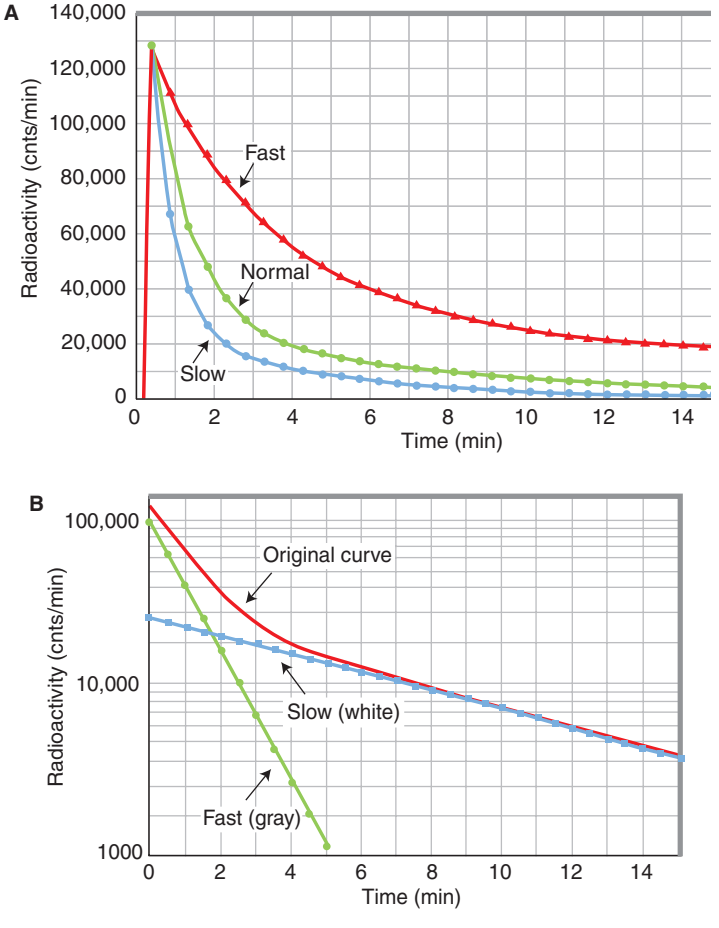

FIGURE 50–2. Single-channel curves showing the washout of radioactivity from the brain after the bolus injection of radioactive ^{133}Xenon into the internal carotid artery. **A.** The curves represent "raw data" plotted on a linear scale (counts vs. time). Injection was made just slightly before time zero. There are three curves, each with different slopes: the top representing a slow flow (low CBF), the middle a normal flow, and the bottom typical of a high flow state. **B.** The middle (normal) curve has been replotted on a log scale and is separated into monoexponential "fast" and "slow" components. Note that although these compartments are labeled as "gray" and "white," their exact anatomical nature is not defined. The fast compartment has a flow of 80 mL/100g/min, while that for the slow compartment is 20 mL/100g/min. (Reproduced with permission from Hoedt-Rasmussen K. Regional cerebral blood flow. Acta Neurol Scand 1967; 43(Suppl 27):13.)

This indicates that for every 5.7 mol of oxygen consumed, 1 mol of glucose is used. Because complete glucose oxidation uses 6 mol of oxygen per mole of glucose, this indicates that all of the glucose being consumed is not being oxidized but is being used in other processes. One can similarly calculate a respiratory quotient, lactate/glucose ratios, and other measures.

Radioactive Tracer Washout Methods: Intraarterial ^{133}Xe To obtain regional data, a diffusible radioactive tracer (e.g., ^{133}Xe in saline) can be injected as a bolus into the internal carotid artery. The rate at which radioactivity disappears from the head can then be monitored using extracranial radiation detectors.[541] If CBF is high, the slope of the washout curve will be steep; if slow, the rate of washout will be slow (Fig. 50–2A). If multiple collimated detectors are used, separate washout curves can be recorded from different regions of the hemisphere ipsilateral to the injection. The individual washout curves can be mathematically separated into two components, one representing ^{133}Xe clearance from a high-flow compartment (gray matter), and one representing a slow-flow compartment (white matter) (Fig. 50–2B). The calculations needed to separate the fast and slow components of the washout curve are identical to those used when distinguishing the early redistribution phase of a drug from its terminal clearance (i.e., $t_{1/2\alpha}$ vs. $t_{1/2\beta}$).

Unlike the Kety-Schmidt method, this technique can provide very-high-resolution regional CBF (rCBF) data from the hemisphere ipsilateral to the injection, and several mathematical processes have been developed to make it possible to compute flow indices in as little as 2 minutes after isotope injection (although a second flow cannot be measured until more isotope is cleared). Unfortunately, it requires direct carotid puncture (or transfemoral cannulation of the internal carotid). Nevertheless, its technical simplicity has resulted in its widespread use for flow measurements during carotid surgery, and essentially everything known about the effects of anesthetics during carotid endarterectomies and the cerebral hemodynamic effects of carotid occlusion has been obtained with this method.

Radioactive Tracer Washout Methods: Inhaled/IV ^{133}Xe Methods Intraarterial ^{133}Xe injection is invasive and provides data from only one

hemisphere. These limitations could be eliminated if an externally detectable tracer could be given IV or by inhalation (which would then be delivered to both hemispheres). Although at first glance this may seem simple, it is much more complex because of two problems.[541] First, an inhaled/IV tracer is delivered to *both* the brain and scalp (unlike tracer injected into the internal carotid artery). Hence the brain washout curve is "contaminated" by another curve representing flow in extracranial tissues. Second, the shape of the arterial wash-in and wash-out curves are much more complex, depending on redistribution of the tracer throughout the body and clearance of the tracer from the lungs. These problems have been solved but require extensive computations (which can now be handled by a desktop PC). Although these calculations require some assumptions, the advantages of relative noninvasiveness and bilateral distribution appear to outweigh them, and hence this method is used by a limited number of centers for anesthesia-related studies.[11,554]

Radioactive Tracer Washout Methods: Intraaortic ^{133}Xe Injection

One variation on the intraarterial and intravenous ^{133}Xe method is used during cardiac surgery.[641] A bolus of ^{133}Xe in saline is injected into the aortic root or into the aortic cannula. As with the intracarotid method, radioactivity is delivered to the brain as a bolus, and the washout mathematics are relatively simple. However, tracer is also delivered to extracranial tissues, and "contamination" remains a problem. During normothermia, CBF is much higher than scalp flow, making this a minor nuisance. However, during hypothermia, CBF falls and the contaminating influence of extracranial flow may become more of a problem. A study by Cook et al. comparing this method with the traditional Kety-Schmidt technique suggests that serious underestimates of actual CBF may occur.[143]
