In fact, the extreme variability of signs, symptoms, and physical presentation common among older patients is an essential characteristic of geriatric medicine.[15] This is not surprising, given that human aging represents the interaction of many factors, some universal and some idiosyncratic (Fig. 20–3). In all healthy geriatric patients, however, maximal organ system function remains greater than basal demand at all ages. The difference between maximal organ system capacity and basal function defines organ system "functional reserve." Aging is also inevitably associated with a decrease in functional reserve, which also is considered a defining physiologic characteristic of human aging (Fig. 20–4).

Clinically, decreased functional reserve implies a universal and predictable increase in the susceptibility of elderly patients to stress- and disease-induced organ system dysfunction. Organ system functional reserve is the "safety margin" that is available to meet, for example, the additional demands for cardiac output, carbon dioxide excretion, or protein synthesis imposed on the patient by trauma or disease or by surgery, healing, and con-

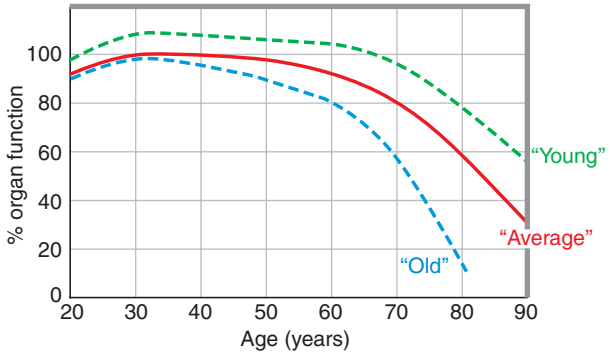

FIGURE 20–2. Differences in the rate at which maximal organ system functions decline with increasing age and differences in initial functional levels explain the inevitable variability seen in geriatric patients, clinically recognized as physiologically "younger" or "older" than average.

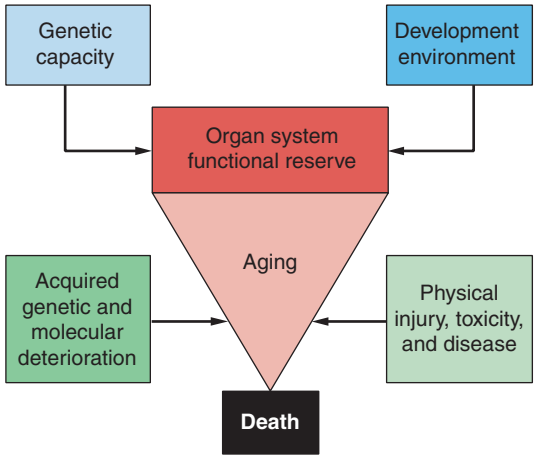

FIGURE 20–3. One concept of organ system functional reserve describes a "wedge" that is broadest at birth but then declines progressively after maturity (Reprinted with permission from Jazwinski SM. Longevity, genes, and aging. Science 1996;273:54–59[197] Copyright, 1996 AAAS). Genetically determined organ system functional reserve may determine life *span*, but life *expectancy* reflects "real-world" estimates of human longevity given extrinsic environmental factors. Actual observed life expectancy for a population of individuals is a measure of typical or average longevity and includes those with a "poor" genetic profile as well as those individuals who die of external, nongenetic causes.

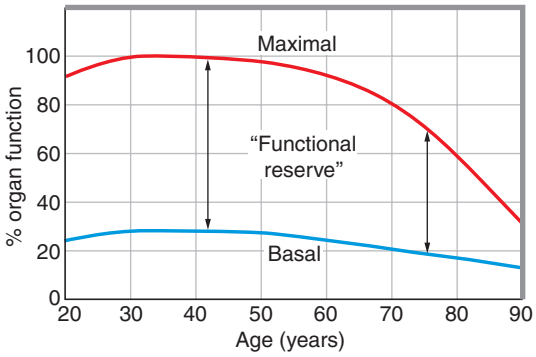

FIGURE 20–4. For any organ system, "functional reserve" represents the difference between basal (minimal) and maximal organ system function. The age-related decline in functional reserve may not be clinically apparent until demands made on the organ system are increased by stress, disease, polypharmacy, or surgical intervention.

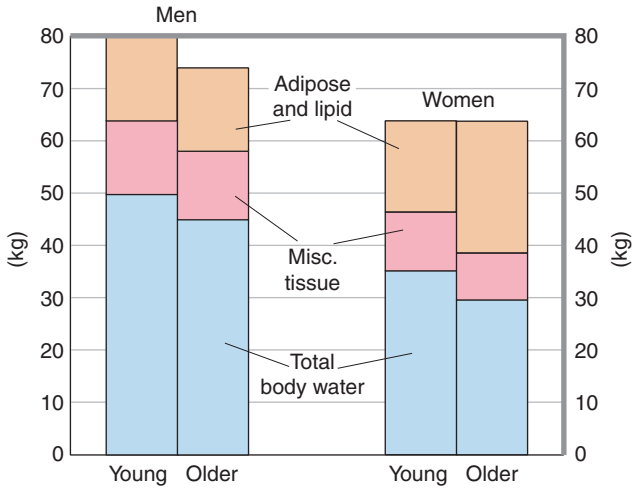

FIGURE 20–5. Age-related changes in body composition are gender specific. In women, total body mass remains constant because increases in body fat (*upper shaded segment*) offset bone loss (*middle segment*) and intracellular dehydration (*lower shaded segment*). In men, body mass decreases despite maintenance of body lipid and skeletal tissue elements because accelerating loss of skeletal muscle and other components of lean tissue mass produces marked contraction of intracellular water (*lower shaded segment*).

valescence. It is therefore of great importance to the anesthesiologist, and preoperative testing in the elderly patient is most effective when it provides the anesthesiologist with a quantifiable assessment of functional reserve. Testing should be clinically directed according to symptoms and complaints referable to age-related disease or to functional decline suggesting erosion of physiologic homeostasis.[16] However, although cardiopulmonary functional reserve can be assessed clinically using various exercise or aerobic stress tests, there are no comparable techniques for assessment of hepatic, immune, or nervous system functional reserve, at least at the present time. These require subjective clinical assessment and detailed clinical history and physical examination, with particular focus on activity levels and the ability to participate fully in the normal activities of daily life.

Aging, Metabolism, and Body Composition

Despite the assumptions of many physicians that elderly patients are often malnourished, surveys do not suggest that the elderly and aged commonly live in a state of poor nutrition. Dietary inadequacy, if anything, is related to income, not to age, and probably affects less than 10% of the elderly population.[17] The well-nourished normal elderly also do not appear to have altered requirements for vitamins or dietary supplements. Nevertheless, older adults of both sexes undergo significant atrophy of most metabolically active tissues, especially brain, liver, and kidney. In addition, normal aging, particularly in men, is associated with a progressive loss of skeletal muscle mass. In aged men, continuing loss of muscle and central organ atrophy eventually produces a significant decline in total body weight, often to levels less than those of young adulthood. In women, however, muscle and bone loss due to osteoporosis are largely offset by increasing body fat, and therefore total body weight usually returns toward, but rarely falls below, young adult values (Fig. 20–5).

Skeletal muscle and large, well-perfused organs comprise the lean tissue mass (LTM) component of total body weight. Age-related loss of LTM plays a powerful role in altering perioperative metabolism, cardiopulmonary function, and the pharmacokinetics of anesthetic agents. The linear correlation between basal metabolic rate (BMR) and creatinine excretion suggests that decreased muscle mass is largely responsible for the age-related decline in BMR,[18] although middle-aged subjects have a slightly lower BMR than younger subjects even when they are comparable in body size, body composition, or activity.[19] BMR decreases in parallel with the contraction of total body water (TBW) throughout most of adulthood, but a more accelerated decline in energy expenditure at rest occurs later in senescence, with kcal/d in the tenth decade only one-half that of young adults. There do not appear to be any gender-specific differences in the effects of age on BMR that are not related to body composition or activity. Nevertheless, because BMR for both men and women eventually decreases somewhat faster than can be explained from the decrease in LTM, lessened thyroid hormone activity may eventually limit the level of metabolic activity, as well as the mass, of lean tissue components.[20]

After the young adult years, TBW falls 10–20%. Virtually all of the age-related changes in body water content are limited to the intracellular compartments. Decreases in circulating blood volume, once believed to be inevitable, actually reflect deconditioning and dehydration and are typical only in bedridden elderly or those with essential hypertension.[21] Plasma volume, red cell mass, and extracellular fluid volumes are well maintained in nonhypertensive elderly individuals who maintain reasonable levels of daily physical activity.

Decreasing LTM reduces the capacity for body heat production, and impairment of thermoregulatory vasoconstriction places elderly surgical patients at increased risk for inadvertent intraoperative hypothermia.[22] In fact, intraoperative core temperature decreases at a rate twice as great as that observed in young adults under comparable conditions, and the time needed for spontaneous postoperative

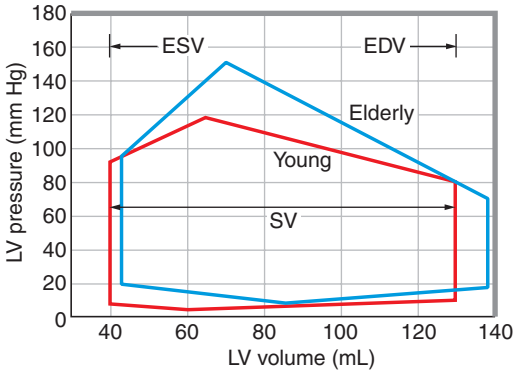

FIGURE 20–6. Left ventricular (*LV*) cardiac pressure-volume loops for fit young (*solid line*) and elderly (*broken line*) subjects. Older subjects have a slightly higher end-diastolic ventricular volume (*EDV*) and larger stroke volume (*SV*), as well as elevated pressures throughout the cardiac cycle, because of increased myocardial stiffness and delayed active relaxation during diastole, delaying the passive phase of ventricular filling. Consequently, aging alters ventricular hemodynamics by increasing dependence on atrial contraction for the maintenance of normal stroke volume.

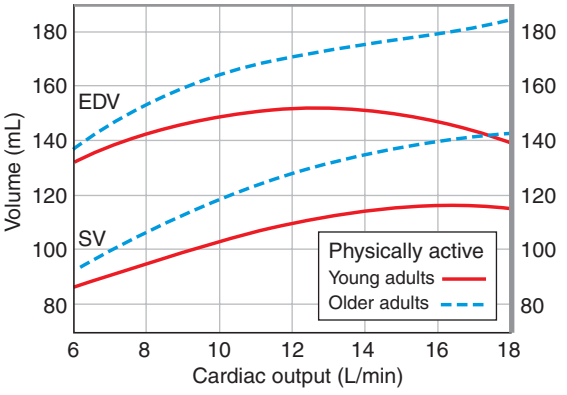

FIGURE 20–7. In healthy older adults (*broken lines*), maximal heart rate is less than can be achieved by young adults (*solid lines*). Consequently, increases in cardiac output during aerobic metabolic stress are achieved by augmentation of stroke volume (*SV*) caused by generalized ventricular dilation and increased end-diastolic volume (*EDV*), with ejection fraction maintained at constant levels.

rewarming increases in direct proportion to patient age.[23,24] Because muscle, liver, and other components of LTM provide storage for carbohydrates, aging limits the ability to handle a glucose challenge even though the timing and the magnitude of insulin release is normal in the elderly. Consequently, aging may be associated with a loss of pancreatic islet cell sensitivity to hyperglycemia, the so-called glucoreceptor defect.[25] Alternatively, age-related glucose intolerance may reflect antagonism of insulin's effect on target tissues.[26] Thus fluid replacement with glucose-containing solutions should be limited to environments that permit frequent measurement of blood sugar levels in elderly patients.

Cardiovascular Function

The heart, unlike other major organs, does not atrophy with age. The aging left ventricle is actually thicker and less elastic than its younger counterpart, exhibiting the physical characteristics of *presbycardia*.[27] This is caused by, at least in part, an increase in collagen cross-linking in the myocardial cytoskeleton to which the myocytes are attached.[28] Cross-linking may reflect the buildup of advanced glycation end products produced by the chemical transformation of sugar moieties normally found in tissues.[29] Mitochondrial dysfunction has also been invoked as an explanation for the age-related changes in ventricular dynamics.[30]

Whatever the precise mechanism, the stiffer ventricle and atrium do not permit complete chamber relaxation until relatively late in diastole. Consequently, passive ventricular filling, which occurs during the early phase of diastole, is significantly reduced in older adults, producing a form of diastolic dysfunction (Fig. 20–6). As a result, the elderly are particularly dependent on the synchronous atrial contraction of sinus rhythm for complete ventricular filling and may experience significant increases in pulmonary blood volume during exercise.[31,32] Small decreases in venous return, such as those produced by positive pressure ventilation, surgical hemorrhage, or venodilator drugs, can significantly compromise stroke volume if even minor cardiac dysrhythmias are present.

Resting cardiac index in healthy elderly subjects decreases slightly throughout adulthood and into senescence, but this is not evidence of degenerative cardiovascular change.[33,34] To the contrary, reduced cardiac output at rest is an appropriate integrated cardiovascular response to the reduced metabolic activity that occurs because of age-related loss of LTM. Normal aging simply produces a smaller "aerobic machine" with reduced perfusion requirements. Under conditions of submaximal demand, myocardial contractility is well maintained, at least until the eighth decade of life.[35] Short-term demands for increased cardiac output are first met by moderate increases in heart rate and then by increasing left ventricular end-diastolic volumes and pressures.

During vigorous aerobic exercise, the aging but well-conditioned heart can increase cardiac output to levels near those of younger adults by generating progressively larger stroke volumes through the Starling mechanism, a nonpathologic adaptation unique to older adults (Fig. 20–7).[36] Nevertheless, although many aged individuals compete successfully in a variety of strenuous athletic events, aging does ultimately impose significant limitations of maximal aerobic power generation (maximal oxygen consumption: VO_2max) by reducing both the inotropic and chronotropic responses to β-agonists and to autonomic reflex pathways.[37,38] In general, however, peripheral factors, such as lactate production and musculoskeletal stiffness, and not cardiac reserve actually limit VO_2max during strenuous physical exercise in older adults.[33]

Systolic hypertension with widening of arterial pulse pressure is a major cardiovascular risk factor.[39] It is common in the geriatric population and reflects a gradual increase in large artery stiffness caused by fibrotic replacement of elastic tissues during the adult years.[40] This reduces the ability of the aorta and large arteries to store hydraulic energy and increases vascular impedance to ejection of stroke volume. The end result of these changes is a progressive and sustained increase in left ventricular wall tension and myocardial workload that produces symmetrical ventricular hypertrophy and increased ventricular mass. Impedance to the ejection of stroke volume in-

creases in older adults, even when systemic vascular resistance (SVR) is unchanged.[41] Increased vascular stiffness and loss of arterial cross-sectional area also increase the reflection of arterial pressure waves that produces the familiar "ringing" characteristics of radial artery waveform tracings in geriatric patients.

Pulmonary Function

Loss of tissue elasticity occurs in the lungs as well as in the cardiovascular system, and all elderly individuals eventually demonstrate some degree of emphysema-like increases in lung compliance. However, calcification and stiffening of the costochondral joints of the thorax reduce chest wall compliance, so net pulmonary compliance does not increase but is usually unchanged.[42] Within the lung parenchyma, fibrous connective tissue proliferates and there is degeneration and cross-linking of lung elastin.[43] Breakdown of alveolar septae also reduces total alveolar surface area, increasing both anatomic and alveolar dead space.

Loss of lung elastic recoil is the primary anatomic mechanism by which aging degrades the efficiency of pulmonary gas exchange.[44] Small airway patency, normally maintained by elastic recoil, is compromised, and closing capacity increases to the point at which it becomes greater than the volume of the lung at rest.[45] The elderly individual probably experiences closure of some small airways even before the end of exhalation, and chronic airway obstruction is increasingly common but often undiagnosed in senescence.[46] Vital capacity is significantly and progressively compromised because residual lung volume increases at the expense of inspiratory and expiratory reserve volumes (Fig. 20–8).[47] Because the changes in elasticity are nonuniform, they severely disrupt the normal matching of ventilation and perfusion within the lungs, increasing both shunting and physiologic dead space.

Overall, pulmonary function in older adults during general anesthesia is best characterized as decreased efficiency of gas exchange as a consequence of significant ventilation–perfusion mismatch, primarily because of the deterioration of intrinsic recoil, disruption of alveolar architecture, and increased sensitivity to anesthetic-induced depression of active hypoxic pulmonary vasoconstriction.[48] As a result, total venous admixture during anesthesia increases steadily with advancing age (Fig. 20–9).[49] Although the strength and endurance of the ventilatory apparatus remain adequate to meet moderate demands, skeletal calcification and rising airway resistance increase the work of breathing in elderly subjects, predisposing them to acute postoperative ventilatory failure.[50,51]

The cardiovascular and ventilatory responses to imposed hypoxia or hypercarbia are also delayed in onset and are of smaller magnitude in geriatric patients.[52] However, the moment-to-moment neural control of ventilation and the responses to changes in pH and respiratory gases appear to be essentially unchanged. Informal but clinically valuable assessment of pulmonary function may be possible by questioning the elderly with regard to ability to climb stairs, provided that other causes for stopping, such as claudication, can be excluded. Inability to climb 2 flights of stairs correlates with a forced expiratory volume (FEV) that is less than 70% of predicted value, and failure to achieve 3 flights of stairs may predict severe pulmonary complications after thoracic surgery.[53,54]

Hepatic, Endocrine, and Immune Systems

The age-related changes in hepatosplanchnic function are predominantly quantitative rather than qualitative.[55] Liver tissue mass decreases approximately 40% by age 80 years, and hepatic blood flow is proportionally reduced, primarily because of decreasing portal perfusion.[56] Hepatic enzyme activities are comparable to those of young adults, but there is great variability of metabolic function that may reflect loss of hepatocyte density.[57] Plasma concentrations of transaminase and other hepatocyte-derived enzymes are similar to those of young adults, but the bromsulfophthalein (BSP) retention test is prolonged with increasing age, approaching the upper limit of normal in the seventh decade of life.[58] Functional capacity for nitrogen clearance is also progressively reduced in aging adults, as is galactose elimination—both to an extent somewhat greater than can be accounted for based on changes in liver blood flow alone.[59,60] As a result, hepatic biotransformation and protein synthesis, although adequate to

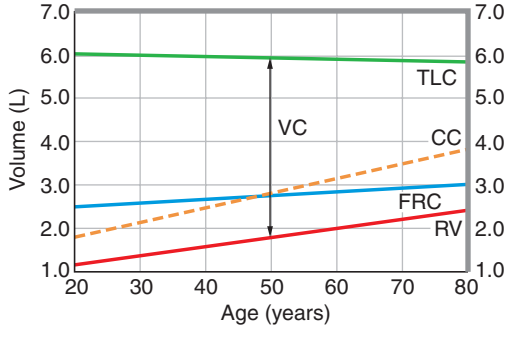

FIGURE 20–8. Total lung capacity (TLC)—the sum of vital capacity (VC) and residual volume (RV)—decreases slowly in older adults of either gender. However, VC, which represents exchangeable intrathoracic gas volume, is markedly compromised by increases in thoracic rigidity and loss of ventilatory muscle power. RV increases because intrinsic lung elastic recoil is progressively reduced. Closing capacity (CC, *dotted line*) increases to a value greater than that of functional residual capacity (FRC). CC greater than FRC implies that there is persistent closure of small airways when the lung is at rest in the neutral state.

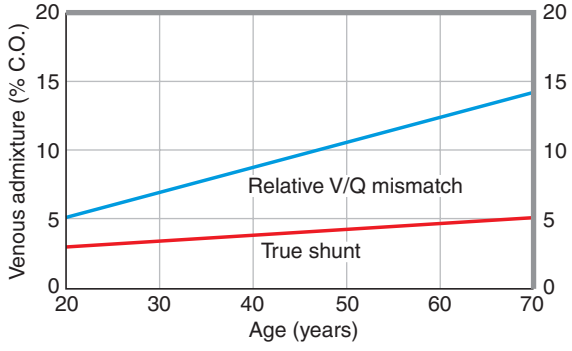

FIGURE 20–9. During anesthesia, total venous admixture (expressed as percentage of cardiac output [CO]) increases with increasing age largely because of a progressively greater amount of diffuse ventilation–perfusion (V/Q) mismatching, with only minimal increases in true intrapulmonary shunting.

meet modest increases in metabolic demand, may easily be overwhelmed by the metabolic demands of trauma, disease, or surgical intervention, especially if associated with arterial hypotension, low cardiac output, hypothermia, or direct hepatic injury.[61] Loss of hepatic functional reserve also explains the reduced rates of plasma clearance and prolonged clinical effects of narcotics and many other xenobiotics in geriatric subjects.[62] Overt hepatic dysfunction and failure appear in approximately 4% of elderly surgical patients, but more subtle degrees of hepatic compromise and limited hepatic functional reserve produce many postoperative complications and may require supportive therapy and intensive care.[63]

Aging appears to have little effect on macrophage and other aspects of phagocytic activity, but even fit elderly subjects exhibit subtle evidence of decreased immune responsiveness and specificity. As people age, the ability of the immune system to distinguish "self" from "nonself" antigens is reduced, increasing the prevalence of autoimmune phenomena and decreasing resistance to infection.[64,65] The effects of aging on mitochondrial function and control of apoptosis may play an important role in this process.[66] Thymic involution at sexual maturity is associated with marked changes in lymphocytic balance that progresses through senescence. Older adults have decreased B- and T-cell lymphocyte activity and depressed serum titers of immunoglobulin E, depressed skin response to exogenous allergens, and impaired delayed hypersensitivity.[67] Older adults are particularly predisposed to streptococcal pneumonia, meningitis, and septicemia. Sepsis is second only to respiratory failure as a cause of morbidity and mortality in elderly trauma patients.[68]

Adrenal tissues also show evidence of age-related atrophy, and cortisol secretion declines at least 15% by 80 years of age, although plasma levels of cortisol remain similar to those of younger adults because of reduced rates of degradation. Similarly, in the pituitary–thyroid axis, thyroxine levels are relatively unchanged, but there is a damped pituitary response to thyrotropin-releasing factor (TRF) and decline of thyroid-stimulating hormone (TSH) levels, although the end-organ cellular response to TSH is not affected by age.[25,69] However, plasma concentrations of norepinephrine are 2–4-fold higher in elderly subjects than in younger adults during sleep, at rest, and even in response to exercise-induced physical stress.[70] These are rarely apparent clinically in elderly patients because aging markedly and progressively depresses β-adrenergic end-organ responsiveness, producing, in effect, endogenous β-blockade.[71] In contrast, there appears to be little change in α-adrenoceptor or cholinoreceptor activity.[72]

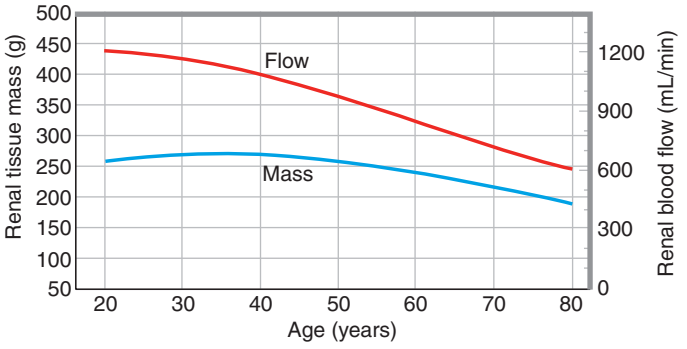

FIGURE 20–10. Renal blood flow decreases more rapidly than does renal tissue mass with increasing age. Glomerular filtration rate (not shown) decreases somewhat more slowly than plasma flow because filtration fraction actually increases in some elderly individuals.

Renal System

As people age, there is a progressive reduction in renal tissue mass and renal blood flow (Fig. 20–10). Renal plasma flow, glomerular filtration rate, and, most important, creatinine clearance decline significantly.[73] These deficits are further exacerbated by decreased perfusion caused by cardiovascular system aging and superimposed disease.[74] One must be wary of perioperative fluid balance, potential electrolyte imbalance, and the potential for impaired renal metabolism of perioperatively administered medications. Of note, a "normal" plasma creatinine concentration may not indicate normal renal functional reserve in the elderly patient because creatinine load is greatly reduced by atrophy of skeletal muscle mass. Calculated creatinine clearance remains the most sensitive marker of renal function in the elderly.[73]

Pharmacology of Aging

The high prevalence of disease in an elderly surgical patient population exposes them not only to the stigmata of the disorders themselves, but also to the risks of polypharmacy from the drugs used for medical therapy.[75] One-half of all adults age 75 years or older take at least 2 different types of medication for the purpose of treating an age-related disease. Elderly patients account for 30% of all drug prescriptions, approximately twice the rate expected from their representation in the general population, and they consume 40% of all over-the-counter medications.[76] Adverse drug interactions occur more often in older than in younger patients because polypharmacy is more common in older adults and the reduced hepatic and renal functional reserve of the elderly patient prolongs both the desired and the unwanted effects of their medications. Although it is appropriate to maintain elderly patients perioperatively on all medications needed to effectively control the symptoms of their disorders, especially cardiovascular, neurologic, and metabolic disease, some drug interactions may complicate perioperative management or make the pharmacokinetics of drugs used perioperatively less predictable.[77]

The effect of nervous system aging on requirements for general anesthesia is well established.[78] Between young adulthood and the geriatric era, relative minimum alveolar concentration (MAC) values for the newer inhalational agents decline by approximately 30%, the same decrement seen with older anesthetics such as cyclopropane (Fig. 20–11).[79,80] However, the mechanisms producing this age-related increase in pharmacodynamic sensitivity to anesthetic agents remain unknown. Declining neuronal bioenergetics as a consequence of mitochondrial genetic mutation or because of age-related oxidative stress reduce anesthetic requirement, but it is not yet established that this, in fact, explains the reduced anesthetic requirement in the elderly.[81,82] Given this empirical

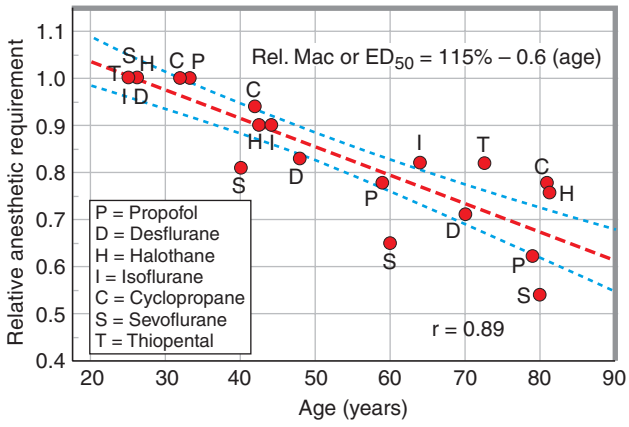

FIGURE 20–11. The age-related decline in relative anesthetic requirement (MAC or median effective dose [ED_{50}]) in unsedated human subjects is a consistent characteristic reported for a wide variety of inhaled and injected anesthetic agents.

phenomenon, however, agedness itself may be an indication for additional monitoring of anesthetic depth using a processed electroencephalogram (EEG) or similar device.[83]

Clinical experience also suggests that there are significant age-related reductions in the dose requirements for thiopental as well as virtually all other agents that depress consciousness.[84,85] Nevertheless, pharmacologic data for the effect of aging on the dose requirements for opioids, barbiturates, and benzodiazepines are less consistent than those for inhalational anesthetics. Most studies suggest that aging increases brain sensitivity to narcotics, but the effects of aging on the pharmacodynamics of barbiturates or etomidate are less impressive.[86–89] Plasma drug concentrations immediately after intravenous injection are usually higher in elderly than in young adults.[90] Consequently, there remains considerable controversy as to whether the clinically apparent age-related increase in the potency of these drugs is truly a pharmacodynamic phenomenon or whether it simply reflects age-related changes in the "alpha" or early phase redistribution pharmacokinetics of injected agents.

In any case, the concentrations of short-acting IV agents in plasma change so rapidly and in such a complex manner that the two-compartment pharmacokinetic model used in traditional pharmacokinetic studies may be of little value for studying the early or "alpha-phase" behavior of these drugs and their subsequent redistribution in elderly subjects.[91] Because the interaction between subtle changes in both pharmacodynamics and redistribution pharmacokinetics is sufficiently complex and unpredictable, some researchers believe that it must be characterized for each drug to predict the implications of aging on intravenous drug dosage.[92]

The net effect of age-related structural and functional changes within the nervous system on pain-related neurologic function remains controversial. The study of the amplification, modulation, and selectivity of afferent input within the spinal cord, thalamus, and other locations within the aging nervous system does not yet permit broad generalizations regarding aging and perception of pain.[93,94] In addition, optimizing postoperative pain management in older adults may be further complicated by cognitive impairment and by unrealistic fear of opioid side effects.[95] Perceived intensity of perioperative pain also appears to be far more dependent on anxiety, personality, and the prospect of long-term debility or disfigurement than on age itself.[96] Nevertheless, the classic observation that opiate requirements are inversely related to patient age and essentially independent of body weight remains a useful and valid general guideline.[97] When a fixed dose and volume of local anesthetic is used, higher levels of sensory blockade are also achieved in elderly patients undergoing spinal anesthesia.[98] Segmental dose requirements for epidural analgesia are similarly reduced with increasing age, although the differences because of aging may be clinically insignificant.[99,100]

Although the elderly have reduced skeletal muscle mass, disseminated neurogenic atrophy at the neuromuscular junction allows proliferation of extrajunctional cholinoreceptors. An increased density of cholinoreceptors at the muscle endplate implies that increased concentrations of neuromuscular blocking drugs are needed to produce competitive blockade. In fact, the median effective dose (ED_{50}) and steady-state plasma concentration required for half-maximal neuromuscular blocking effect (median effective concentration [EC_{50}]) remain virtually unchanged, or may actually increase slightly, in the elderly patient.[101] Maximal relaxant effect is delayed in onset relative to that produced in young adults, and duration of blockade is prolonged for relaxants with hepatic or renal elimination because plasma clearance declines with increasing age.[102–105] Relaxants, such as cisatracurium, that do not require organ-based elimination may provide more consistent duration of clinical effects in older patients.[106,107] However, antagonism of the effects of neuromuscular blocking drugs and recovery of neuromuscular transmission is unchanged if the pharmacokinetics of relaxant elimination are favorable.[108]

COMMON COMORBID DISEASE STATES

The functional capacity of organs reduces with age, resulting in decreased reserve, decreased compensation for stress, and increased incidence of coexisting diseases.[109] Coexisting diseases further depress organ function, leading to even greater risk with surgical procedures.[109] It is useful to review the common diseases encountered in the elderly.

Cardiovascular Disease

The elderly patient is likely to suffer from altered cardiovascular function. Common disease states include coronary artery disease, cardiac valvular disease, congestive heart failure and diastolic dysfunction, abnormal heart rhythm, systolic hypertension, and peripheral vascular disease.

Coronary Artery Disease

The presence of coronary artery disease (CAD) increases with age. Anatomic coronary artery disease can be detected in more than 50% of people older than 70 years of age (Fig. 20–12).[110] CAD in the aged is more severe and

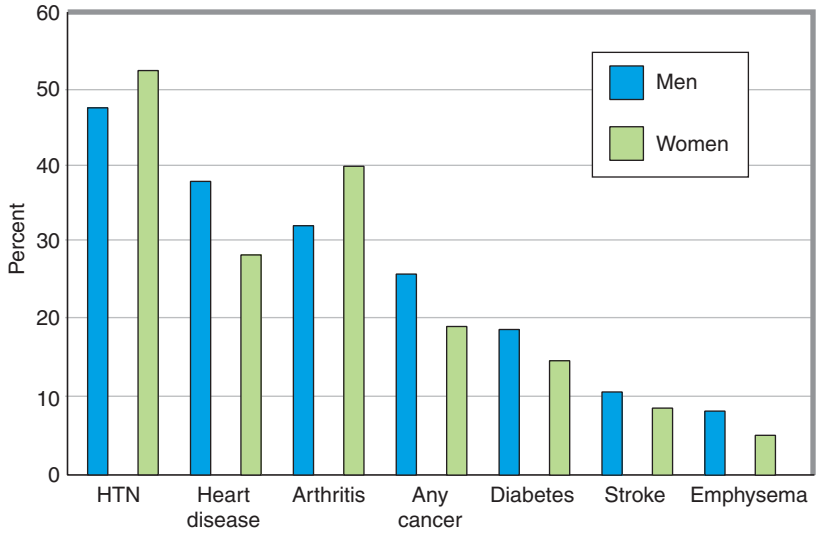

FIGURE 20–12. The percentage of chronic disease in a non-institutionalized adult population older than 65 years of age (data averaged from 2000–2002). (Adapted from Centers for Disease Control and Prevention, National Center for Health Statistics, National Health Interview Survey. Available at: http://www.agingstats.gov/chartbook2004/healthstatus.html. Last accessed June 19, 2006.)

diffuse than in younger patients.[111–113] There are differences in prevalence by gender: at 65 years of age, CAD is more prevalent in men than in women; by age 80, the prevalence of symptomatic congestive heart disease is nearly equivalent in men and women.[113,114] Despite the high prevalence of anatomic CAD, only 10–20% of people older than 65 years of age carry a diagnosis of active CAD.[113] This may be a result of misdiagnosis, lack of clinical symptoms because of inactivity, or lack of recognition of risk factors leading to diagnosis. One study reported that 37% of elderly patients had subclinical CAD, making it as common as clinically overt CAD in older adults.[115] Furthermore, in this study, the presence of subclinical CAD was significant as it strongly predicted overt CAD, stroke, and mortality, even after adjustment for traditional cardiovascular risk factors.[15] Despite the high prevalence of CAD, over the last 30 years in the United States, the CAD mortality rate has decreased significantly. This includes reduced recurrent myocardial infarction and increased postmyocardial infarction survival.[116]

Cardiac Valvular Disease

Aortic Valve Fibrotic thickening and increased opacity of the mitral and aortic valves occurs with age. Furthermore, one-third of patients older than 70 years of age have calcium deposits in the mitral or aortic valve.[116] Common causes of valvular heart disease in the elderly are degenerative calcification, myxomatous degeneration, papillary muscle dysfunction, and infective endocarditis.[116]

The most frequent valvular lesion in the elderly is degenerative calcified aortic stenosis, with a prevalence of 2.5% at the age of 75 years and of almost 8% at 85 years.[117] Aortic regurgitation, mostly mild, was found in 29% of the entire study cohort.[117] The severity of aortic stenosis in the elderly is often underestimated because its progression is so gradual and because symptoms may be attributed to normal aging. Common causes of aortic valve stenosis are calcification of a congenital bicuspid aortic valve and degenerative aortic stenosis. Rheumatic heart disease is the cause in 20%; mitral valve disease often coexists.

Mitral Valve Mitral valve disorders are common in the elderly, but the symptoms of mitral valve disease may be masked or exacerbated by coexistent coronary artery disease, pulmonary disease, hypertension, and other systemic disorders that commonly occur in older adults.[118] Chronic mitral regurgitation is the most common type of mitral valve disease in the elderly. Rarely, isolated chronic mitral regurgitation occurs as a consequence of papillary muscle dysfunction after myocardial infarction. Chronic mitral regurgitation may also be a result of mitral annular calcification, myxomatous valve degeneration (with mitral valve prolapse), chordal rupture, and rheumatic heart disease. Mitral annular calcification occurs in approximately 6% of people older than 60 years of age, predominantly in women. The incidence of myxomatous valvular degeneration increases with age.

Mitral stenosis is a disease of younger patients because severe mitral stenosis usually leads to surgery or death before 65 years of age.[116] If present, mitral stenosis is usually a result of rheumatic heart disease, a common condition when the current elderly population was young. Less commonly, mitral stenosis develops because of progressive mitral annular calcification.

Tricuspid Valve Tricuspid regurgitation is usually a result of annular dilation caused by right ventricular failure (usually resulting from left-sided heart failure) or pulmonary hypertension. Unlike in younger patients, infective endocarditis is a less-common cause. Tricuspid stenosis is rare in the elderly.

Pulmonic Valve Pulmonic valve disease as a consequence of primary valve dysfunction is rare but is usually secondary to pulmonary hypertension.

Concurrent Valvular Disease Concomitant mitral and aortic valve disease is common in the elderly. About one-half of patients with rheumatic mitral regurgitation have associated aortic valve disease, usually aortic regurgitation. In one study, concurrent mitral regurgitation found in elderly patients undergoing isolated aortic valve replacement (AVR) was found to be an independent risk factor for long-term survival.[119]

Systolic Hypertension, Diastolic Dysfunction, and Congestive Heart Failure

As reviewed earlier, diastolic dysfunction and systolic hypertension are common and increase with aging. Ninety percent of Americans still having a healthy blood pressure at 55 years of age have hypertension when they reach 75 years of age.[120,121] Another common problem in the elderly is chronic heart failure, which can be divided into two broad categories: systolic heart failure and diastolic heart failure.[122] Diastolic heart failure occurs more frequently in the elderly, in women, and in those with systolic hypertension, but is less associated with concurrent CAD than systolic heart failure.[122]

Peripheral Vascular Disease

Peripheral vascular disease is not a normal consequence of aging but is associated with systemic atherosclerosis and other risk factors for CAD, many of which are commonly found in the aging patient. The prevalence of peripheral arterial disease increases with age and has a variable presentation: asymptomatic, associated with intermittent claudication, or associated with critical limb ischemia.[123]

Abnormal Heart Rhythm

Age-related changes in atrial chamber size and pressure, in left ventricular mass, and in catecholamine levels, in addition to increased incidence of CAD, contribute to a higher incidence of arrhythmias and conduction disturbances in the elderly. Common arrhythmias are atrial fibrillation, ectopic beats, and heart block.

Atrial Fibrillation Atrial fibrillation is among the most common arrhythmias seen in the general population.[124] The prevalence of this condition is increasing and increases with age; it occurs in 5.9% of people older than 65 years of age as compared with its occurring in 2.3% of people between 40 and 65 years of age.[125] In all age groups, men are more affected than women. It is believed that by 2050, more than 5.6 million people will suffer atrial fibrillation and that more than 50% of those older than 85 years of age will have this condition.[126] There are multiple conditions that predispose to atrial fibrillation, most commonly structural heart disease. Other contributory conditions include hypertension, coronary artery disease, heart failure thyrotoxicosis, sick sinus syndrome, and amyloidosis.

Heart Block There is a striking increase in the incidence of bradydysrhythmias and conduction abnormalities associated with progressive fibrosis in both the sinus node and atrioventricular conduction system in the elderly; sinoatrial pacemaker cells decrease progressively from 60 years of age such that approximately 10% of the cells are still present at age 75.[116,127] The sinoatrial node is also subject to fat accumulation, which may serve to separate nodal tissue from the atria musculature.[116] Bradydysrhythmias may be present preoperatively but can initially present as unexpected heart block under general anesthesia.[128]

Pulmonary Disease

Pulmonary emphysema and chronic pulmonary obstructive disease are not associated with normal aging but are the consequences of exposure to environmental toxins, such as tobacco, which may vary among populations. One study from Norway estimated that in people older than 70 years of age, 11% reported having at least one current obstructive pulmonary disease, 8% reported daily wheezing, and 12% reported significant dyspnea.[129] However, they noted that the only respiratory symptom or disorder to show any clear age-related pattern was dyspnea, which increased through 89 years of age before decreasing.

As noted, because of declines in immunologic function, the elderly person is more prone to pneumonia than is a younger person. Furthermore, there may be an increased risk of aspiration pneumonia as a result of other conditions such as gastrointestinal sphincter malfunction or altered mental status.

As is expected in an aging population, the absolute number of patients with lung cancer is increasing.[130] Historically, there has been a reluctance to aggressively treat elderly lung cancer patients because of a lack of supportive data and concern for potential toxicity. However, the bulk of evidence suggests that healthy elderly patients can benefit from therapy in all stages of non–small cell lung cancer and that the decision to offer therapy should be based on comorbidities and performance status rather than age.[130]

Gastrointestinal Disease

Although most gastroenterologic disorders that develop in younger people may also develop in the elderly, the presentation, treatment, and prognosis may be different.[131] Disorders that may have a higher incidence in the elderly include peptic ulcer, ischemic complications of vascular abnormalities, drug-induced disorders, malignancies, and passive reflux. Important to consider in the perioperative patient is the high likelihood of a gastrointestinal side effect of a medication such as a nonsteroidal antiinflammatory agent.[132] Furthermore, there may be an increased risk of constipation and bowel obstruction with opioids in the elderly.

Renal Disease

Known decreases in renal function and glomerular filtration rate lead to a high incidence of mild chronic renal insufficiency. Progression to chronic kidney disease is associated with a high risk of renal failure, cardiovascular disease, and death.[133] Many common comorbid disease states contribute to the increased incidence of renal dysfunction, including systemic hypertension, systemic arteriosclerotic disease, and chronic congestive heart failure. Regardless of the cause, the severity of chronic kidney disease can be classified by glomerular filtration rate (GFR): stage 1, kidney damage with a normal or increased GFR; stage 2, kidney damage with a mild decrease in GFR (60–100 mL/min/1.73 m^2); stage 3, a moderate decrease in GFR (30–59 mL/min/1.73 m^2); stage 4, a severe decrease in GFR (15–30 mL/min/1.73 m^2); and stage 5, kidney failure (<15 mL/min/1.73 m^2 or conditions requiring dialysis).[134] Albuminuria is also used for diagnosis of renal dysfunction. This is a common problem, as 18% of people older than 60 years of age have albuminuria, and 7% have an estimated GFR of less than 60 mL/min/1.73 m^2.[133,135] In people 70 years of age or older, those percentages increase to 30% and 26%, respectively.[133,135]

The diagnosis of renal dysfunction is indirect as GFR is estimated from the serum creatinine concentration or with creatinine-based estimations.[133,134] One should not rely on creatinine alone; equations for GFR estimation should incorporate additional demographic and clinical variables.[133]

Other problems to consider include urinary tract obstruction, common in elderly patients with an increased rate of benign prostatic hypertrophy, and urinary incontinence.

Musculoskeletal Disease

The known decreases in the musculoskeletal system lead to predictable disorders, including tears of stiffer tendons and ligaments, especially in the rotator cuff, biceps tendon, and quadriceps tendon insertion to the patella, Achilles tendon, and posterior tibial tendon.[136] A large study in the United Kingdom identified the odds ratio of an Achilles tendon rupture to be 6.4% in patients ages 60 to 70 years and 20.4% in patients age 80 years or older.[137] There is also an increased incidence of osteoarthritis with age.[138] Less clearly associated with aging but with a high incidence in the elderly patient is rheumatoid arthritis.[139] These

conditions are associated with known problems with airway manipulation and positioning. Spinal column intervertebral disc degeneration with disc herniation and osteophyte formation is progressive in the elderly and may lead to cauda equina or nerve root impingement and symptoms of spinal stenosis.[136,140,141] Other conditions include polymyalgia rheumatica, gout, and pseudogout.

Endocrine Disease

Most significant endocrine functions do not decline specifically with aging with a few exceptions. Among these are thyroid disorders, diabetes, and androgen deficiency.[142] Glucose intolerance is especially important to assess, and thyroid disease is an underappreciated cause of morbidity in the elderly patient. A study of 3233 individuals age 65 years or older showed an association between subclinical hyperthyroidism and development of atrial fibrillation.[143] However, this study did not support the hypothesis that unrecognized subclinical hyperthyroidism or subclinical hypothyroidism is associated with other cardiovascular disorders or mortality.

Neurologic and Mental Status Disease

Starting with middle age, there is a progressive decrease in learning and memory, a factor to consider when assessing the ability of an elderly person to cooperate with perioperative care. An interesting hypothesis is that this is not caused by loss of the ability to generate new neurons, but rather to a reduction in the decline of growth factors (fibroblast growth factor-2, insulin-like growth factor-1, and vascular endothelial growth factor) necessary for new neuron growth.[144] There is also an increased occurrence of all forms dementia, including Alzheimer dementia and neurologic disorders such as Parkinson disease.[145]

The risk of suffering a stroke increases linearly with age and is associated with other forms of cardiovascular disease, especially atrial fibrillation. For example, the proportion of strokes with atrial fibrillation in the United States is 6.2% for patients who are 50–59 years of age, 7.3% for patients 60–69 years of age, 16.5% for patients 70–79 years of age, and 30.8% for patients 80–89 years of age.[146,147] Other causes of stroke are hypertension, cerebrovascular disease, myocardial infarction, structural heart disease, and cardiomyopathy.

Depression is very common in the elderly, with fewer reported symptoms than in younger people.[148] Up to 35% of hospitalized elderly patients may suffer from depression.[149] Not only does depression lead to increased symptoms from medical illness and increased use of healthcare resources, but it may affect the patient's ability to cooperate with preoperative conditioning and postoperative rehabilitative care. Interestingly, depression may be related to disturbances in other systems, such as the hypothalamic–pituitary–adrenal axis, the cerebrovascular disease, inflammatory conditions, and nutrient deficiencies.[148,150] Another condition to be aware of is alcoholism in the elderly with implications for perioperative withdrawal and malnutrition.[151]

Ophthalmologic Disease

Visual impairment is common in elderly and aged patients.[152] The most common causes include presbyopia, macular degeneration, cataract formation, diabetic retinopathy, and glaucoma.[153] Untreated, visual impairment leads to physical handicap, increased incidence of falls, depression, social isolation, and dependency.[153] Visual diseases and the medications used to treat them must be considered with the choice of anesthetic agents. Furthermore, perioperative disorientation or delirium may be in partly a result of declines in visual stimuli.

Hearing Impairment

Hearing loss occurs linearly with age, but the variation in hearing thresholds is large. Possible explanations include precipitating medical conditions, coexisting diseases, prior environmental exposure (especially occupational), and undefined genetic contributions.[154,155] Hearing impairment may also contribute to postoperative delirium.

Oncologic Disorders

In developed countries, more than 50% of all cancers and approximately 70% of cancer deaths occur in patients age 70 years and older.[156,157] A contributing factor may be the known decreased immune responsiveness and specificity. Common cancers in the elderly include prostrate, breast, bladder, and colon, in addition to lymphoma. Treatment of this age group is complicated by age-related changes in cardiovascular, gastrointestinal, pulmonary, and renal physiology, all of which effect cancer treatment and chemotherapy toxicity in the elderly.[158] Furthermore, difficult decisions about treatment necessitate planning treatment only for those who will benefit with respect to quality or quantity of life.[159]

COMMON PROCEDURES IN THE ELDERLY

Currently, more than 20% of people older than 60 years of age undergo surgery and anesthesia as compared with only 12% of those ages 45–60 years. These proportions are expected to increase in the future.[160] Despite the higher numbers of elderly patients having surgery, mortality and morbidity rates have been declining.[160]

Because all types of surgical operations are being offered to increasingly older people, it is important to differentiate the effects of aging from the pathology of individual disease processes and to control for comorbid conditions.[161,162] In general, preoperative testing is not determined on the basis of age but in consideration of the procedure, the coexistent disease states, and the overall condition of the patient. However, it is reasonable to search for common, but perhaps asymptomatic, comorbid problems, such as subclinical cardiac disease or glucose intolerance. Common procedures in the elderly are briefly reviewed below.

Cardiac Surgery

All types of cardiac procedures, including coronary artery bypass grafting (CABG), valvular repair or replacement, and ventricular assist device placement, are being offered to patients older than 65 years of age, and increasingly to patients older 80 years of age. The morbidity and mortality of these procedures increase with age, but the benefits are a greater life expectancy as well as a better quality of life.

In-hospital mortality for CABG is approximately 8% for patients older than age 80 years and is similar in highly selected patients older than age 90 years.[163] Although there are limited studies, the data appear to suggest that elderly patients at higher risk have better outcomes with revascularization than with medical therapy alone.[163]

AVR combined procedures (AVR and CABG) and, to a lesser extent, mitral valve surgery are increasingly offered to the elderly. The risk appears to be similar to CABG alone, as two authors have reported in-hospital mortality rates of 7.9% and 8.5% for mitral and aortic valve surgery, respectively.[164,165] Certainly age and comorbid disease states play a role both in morbidity and mortality but also in the choice of valve repair versus the type of prosthetic valve used.[118]

Vascular Surgery

The prevalence of vascular disease is high in the elderly population, with major vascular procedures most commonly performed to treat the effects of peripheral vascular disease and carotid artery atherosclerosis. This means that many elderly patients undergo procedures such as aortic repair (open and endovascular), femoral-to-popliteal bypass grafting, and carotid endarterectomy. In general, the morbidity and mortality of many vascular operations are not different between a *healthy* elderly patient and a younger patient, but the elderly are often not diagnosed until late in the disease process, leading to higher-risk procedures with higher mortality rates.[166] Endovascular interventions have made vascular surgery less invasive; a recent comparison of aortic endovascular repair to open repair revealed a reduced incidence of perioperative complications compared with open vascular surgery.[167] However, long-term followup determined that the incidence of cardiac mortality and myocardial infarction was similar.

Cardiac Conduction Procedures

With the significant increase in conduction abnormalities, CAD, and congestive heart failure in the elderly, it is logical to anticipate an increased incidence of procedures to treat these abnormalities. In fact, one-half of all pacemakers implanted in the United States are for patients age 75 years and older.[168] Currently, the benefits of alternative pacing modes, the indications for biventricular pacing in heart failure, and the indications for cardioverter-defibrillator implantation are being investigated for the elderly.

Thoracic Procedures

The choice to undertake thoracic procedures must be carefully weighed against the risks and benefits in an elderly population. For example, an oncologic indication for a procedure may carry more weight than a quality-of-life indication (e.g., surgery for emphysema) in this higher-risk population. A study of 356 patients older than 70 years of age after lung resection found a 33–48% 30-day morbidity and a 4–69% 30-day mortality rate.[169] Independent predictors for postoperative complications included a low predicted postoperative forced expiratory volume in 1 second (FEV_1), concurrent CAD, and extended resection. Others have found that post-lung resection morbidity is predicted by a reduction in the ability to carry out activities of daily living, decreased cognition, and length of surgery.[170] Brunelli et al. suggested that a simple screening test for surgical fitness is the ability to climb stairs because it was determined that concomitant cardiac disease and a low stair height climbed preoperatively predicted cardiopulmonary complications in the elderly after lung resection.[171] The type of procedure contemplated may also affect the decision to offer a surgical intervention, in that a minimally invasive procedure may lead to less immediate morbidity, although the overall long-term mortality may be similar. There appear to be fewer age-related concerns for other types of smaller thoracic procedures such as bronchoscopies, mediastinoscopies, and esophagoscopies.

Orthopedic Procedures

As osteoarthritis and rheumatoid arthritis increase with age, so do the procedures to treat these conditions, primarily knee and hip replacements. Furthermore, the high prevalence of skeletal disease, combined with an increased predisposition to fall, leads to a high incidence of fractures (especially of the hips, the vertebrae, and the wrists) in older people who then present for treatment on an emergency basis (Fig. 20–13).[136]

Hip Replacement

Hip replacement and repair of hip fracture are exceedingly common operations in the elderly and aged populations. For example, in 2002–2003, the National Health Service in the United Kingdom admitted 78,554 hip fracture patients, 96% of whom were older than 65 years of age.[172] A Cochrane review of the treatment of evidence-based best practices for elderly hip fracture patients revealed that spinal anesthesia, pressure-relieving mattresses, perioperative antibiotics, and deep venous thromboses prophylaxes were beneficial, whereas preoperative traction was not beneficial, and types of surgical management, postoperative wound drainage, and even "multidisciplinary" care lacked sufficient evidence to determine either benefit or harm.[173] A large study of 2390 patients older than 60 years of age with hip fracture found a 9.6% 30-day mortality and a 33% 1-year mortality after hip fracture surgery; preoperative vari-

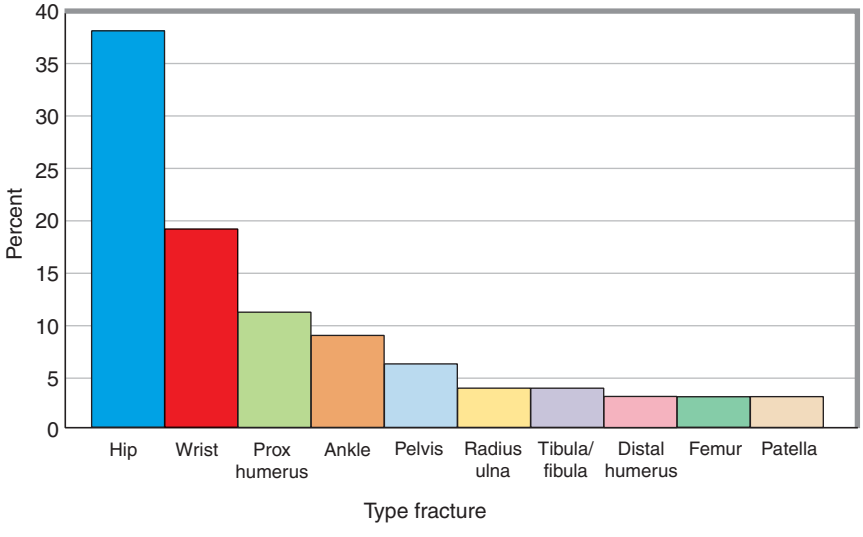

FIGURE 20–13. The most common types of fractures found in Medicare beneficiaries for the 1 year between July 1991 and June 1992. (Data from Grecula MJ, Caban ME. Common orthopaedic problems in the elderly patient. J Am Coll Surg 2005;200:774–783.)

ables that predicted mortality included 3 or more comorbid conditions, preexisting chest infection, and concurrent malignancy.[174]

Knee Replacement

Total knee replacement (TKR) is primarily a surgery for the elderly, with younger patients less likely to be referred for surgery than older patients.[175] As the population ages, TKR is now almost as common as total hip replacement. Long-term results in patients older than 70 years of age are excellent, but infection and loosening and malpositioning of the implants are common complications.[175,176]

Genitourinary Treatment

Elderly men are subject to abnormalities of the urethra primarily related to benign prostatic hypertrophy and prostate cancer; these conditions lead to the common need for a transurethral prostrate procedure. In contrast, elderly women are prone to bladder and vaginal relaxation with urinary incontinence and prolapse symptoms. Thus, many urethral and urethrovaginal procedures are performed on patients older than 65 years of age. In one study, preexisting cardiovascular disease increased the risk perioperative complications in elderly women undergoing urogynecologic surgery, but the overall perioperative morbidity rate was low.[177] Procedures to treat benign prostatic hypertrophy are commonly performed and usually well tolerated in the elderly. Older patients undergoing radical retropubic prostatectomy for prostate cancer have survival rates similar to those of younger counterparts, suggesting that surgical intervention is appropriate in the elderly.[178]

Abdominal Surgery

Abdominal procedures are undertaken in the elderly for a variety of reasons. As surgical and anesthesia techniques have developed, age is no longer considered a contraindication to an abdominal procedure. Furthermore, the increased use of minimally invasive techniques for abdominal procedures has led to low morbidity and mortality rates in older patients.[179]

Eye Surgery

As visual impairment conditions increase with age, so do corrective surgical procedures to restore sight; elderly patients represent the majority of the surgical population scheduled for ophthalmologic surgery.[180] Eye surgery is usually minimally invasive and is performed as day-case surgery despite the high comorbidity of these patients.[180]

Overall Surgical Risk

Overall surgical risk is related to physiologic organ system age, comorbid diseases, and the risks of the procedure to be undertaken. In general, an otherwise healthy elderly patient can expect a good outcome with continued quality of life. However, there are known overall risks for surgery in the elderly. Emergency procedures have especially high mortality in the elderly.[160] An example is a study of 48-hour emergency surgery mortality rates in 795 patients in which patients older than 90 years of age had a mortality of 7.8% as compared with a 0.6% for age-matched patients undergoing elective surgery.[181,182] These findings prompted one author to state that "if surgical condition is allowed to progress to the point of urgent or emergency status, elderly patients tolerate surgical treatment very poorly."[183] The risk of major cardiac complications (e.g., myocardial infarction, pulmonary edema, ventricular fibrillation) is relatively higher after abdominal, noncardiac thoracic, and suprainguinal vascular procedures in individuals 50 years of age or older.

The type and number of coexisting diseases are exceedingly important as it has been proposed that the effects from coexisting disease outweigh the effects of age alone on anesthesia outcome.[160] When age and severity of illness are compared, the number of coexisting diseases is more significant. Additionally, the albumin level may serve as a marker for preoperative health status of the elderly patient, as albumin level has been linked to perioperative mortality.[184]

Of elderly patients undergoing surgery, 10–40% develop a postoperative complication that can lead to serious adverse events.[185] According to a recent study, even seemingly mild initial complications may profoundly alter postoperative prognosis, beginning a cascade of other complications that result in death.[185] Silber et al. examined Pennsylvania Medicare claims and determined that the odds of an elderly patient dying within 60 days after surgery increased 3.4-fold in patients with complications compared with those without complications.[186] Certain complications increased the risk substantially, such as respiratory compromise, associated with a 7.2-fold increase in the risk of dying, and congestive heart failure, resulting in a 5-fold risk in the odds of dying compared with patients without any perioperative complications.

Altered Perioperative Mental Status

Perioperative delirium is common in high-risk surgery and is associated with age, education, preoperative cognitive functioning, preexisting medical conditions, and postoperative complications. In addition, the pathophysiology is poorly understood. As well as being linked to narcotics, sedatives, and anticholinergics, delirium is associated with urinary tract infection, pneumonia, hypoxia or hypercarbia, fever, blood loss, and electrolyte disturbances. For example, 102 patients between 41 and 88 years of age underwent elective open abdominal aortic aneurysm surgery. Delirium occurred in 33% of the patients during the first 6 days after surgery. With multivariate analysis, the most powerful preoperative predictors of delirium *were number of pack years smoked*, mental status scores, and number of perioperative psychoactive medications.[187] Longer duration of delirium was related to lower education, preoperative depression, and greater preoperative psychoactive medication use. Unrelated variables were characteristics of the surgery and hospital stay.

Others have sought to determine whether the type of anesthesia (general or regional) plays a role in the development of cognitive impairment in elderly patients during the immediate postoperative period. Forty-seven patients older than 60 years of age who were undergoing major surgery were randomly allocated to receive either regional or general anesthesia. Overall, elderly patients subjected to general anesthesia displayed more frequent cognitive impairment during the immediate postoperative period in comparison with those who received a regional technique.[188]

However, several studies have failed to demonstrate any long-term differences in postoperative cognitive function between general and regional anesthesia. Williams-Russo et al. examined 262

patients older than the age of 40 years who were undergoing total knee arthroplasty, randomly assigned to either epidural or general anesthesia.[189] No differences were found between the patients for either cognitive or cardiovascular outcome. Rather, at 1 week postoperatively, both anesthetic groups had significant decreases from their preoperative neurocognitive tests scores. At 6 months postoperatively, both groups improved, but the incidence of long-term postoperative cognitive deficit remained at 5% regardless of anesthesia group. Rasmussen and colleagues also examined patients older than 60 years of age randomly allocated to general or regional anesthesia for major noncardiac surgery.[190] They demonstrated that a substantial proportion of patients experienced postoperative cognitive dysfunction at 1 week and 3 months postsurgery (incidence: 10–20%). There was no significant difference in the incidence of postoperative cognitive dysfunction between the groups at 3 months after surgery. The authors concluded that the choice of anesthesia should be based on an open discussion of patients' preferences, general postoperative complications, and the experience of the anesthetist.

Pain Management

It is generally supported in the literature that the elderly have unique needs for analgesia compared with younger patients, including the problem of increased sensitivity to opioids.[191] However, this should not be interpreted to mean that elderly patients do not need pain medication, as some have withheld analgesics for fear of prolonged action or increased side effects.[192] To care for the elderly patient in pain, one must also consider the coexisting diseases and their effects on the distribution of analgesics, elimination of analgesics, and the potential for exacerbated or unique side effects from analgesic medications in the elderly. Furthermore, the high incidence of postoperative confusion, delirium, or altered mental status may complicate the assessment and communication of postoperative pain. Consideration should be given to the use of nonopioid analgesics, reduced doses of opioid analgesics, and alternate routes of analgesic administration. One solution is to use regional anesthetic techniques with local anesthetics so that opioids are avoided.

Type of Anesthetic

Multiple studies have demonstrated that the type of anesthesia (general vs. regional anesthesia) has no substantial effect on perioperative morbidity and mortality.[193] However, it intuitively makes sense that elderly patients benefit from an anesthesia technique that allows for minimal cognitive depression with excellent postoperative pain control.[193] It is essential to recognize that many factors influence the outcome; the quality of the anesthetic administered rather than the type of anesthetic is most important.[193]

Quality of Care

We know that improved quality of care (QOC) received by patients is strongly associated with better survival among community-dwelling vulnerable older adults.[194] Attention to the surgical QOC in elderly patients is of great importance because of the increasing number of older adults undergoing operations.[195] QOC indicators have been developed in 7 domains—comorbidity assessment (cardiopulmonary disease); elderly issues (cognition); medication use (polypharmacy); patient-to-provider discussions (life-sustaining preferences); intraoperative care (preventing hypothermia); postoperative management (preventing delirium); and discharge planning (home healthcare)—with the majority of indicators rated addressing processes of care not routinely performed in younger surgical populations.[195] However, to address these varied goals, interdisciplinary team care has been applied successfully in hospital, outpatient, home, and nursing-home settings.[196] It has been stated that the best outcomes are achieved in the elderly patient when clinical care is multidisciplinary and integrated beginning with preoperative assessment and continuing through to supportive care after discharge.[162]

SUMMARY

The elderly are the fastest-growing segment of the world's population and have unique medical and surgical needs. Decrements in organ function decline combined with increases in organ system disease lead to challenges in surgical and anesthetic care. Forethought about comorbid conditions and physiologic reserve with planning for the most efficacious approach to surgical care can lead to excellent outcomes from a variety of procedures in most elderly and aged patients.

ACKNOWLEDGMENT

Many thanks to Terri Monk, MD, Professor of Anesthesiology at the Durham Veteran's Administration Medical Center in North Carolina for manuscript review, collaborations, guidance, and bringing authors together!

CHAPTER 21

Evaluation of the Pregnant Patient

Robert Gaiser, MD

Caring for the pregnant patient is one of the most challenging and the most rewarding aspects of anesthesia because it involves two patients, the mother and the fetus. Both patients must be considered when making decisions. The mother is the primary patient, with the fetus secondary. Generally, optimal care of the mother provides good care of the fetus. Pregnancy alters maternal physiology. These changes must be considered when evaluating the pregnant patient.

PHYSIOLOGIC CHANGES OF PREGNANCY

Cardiac

Pregnancy results in an increase in cardiac output to meet the increased demands of oxygen consumption. Cardiac output increases 40% during pregnancy, with most of the increase occurring during the first trimester. The increase in cardiac output allows a 10- to 20-fold increase in uterine blood flow. The increase in cardiac output is multifactorial, resulting from increases in both stroke volume and heart rate (an increase of 10–20 beats/min).[1,2] Despite the increase in cardiac output, systolic, diastolic, and mean blood pressures decrease. Central venous pressure and pulmonary artery pressures do not change with pregnancy and are similar to the values in the nonpregnant state.

Maternal blood volume increases by 35% during pregnancy. The increase begins early in gestation and continues throughout pregnancy. Two theories exist for the increase in blood volume. In the overfill hypothesis, increased mineralocorticoid levels lead to sodium and water retention. The intravascular space expands to accommodate the increase in volume. In the underfill hypothesis, the intravascular space expands due to hormonal-induced vasodilatation. Fluid retention increases to accommodate the increased intravascular space. The increased blood volume during pregnancy allows parturients to tolerate normal blood loss of delivery (approximately 400 mL during vaginal delivery and 700 mL during cesarean section).[3] The uterus contracts at delivery, resulting in autotransfusion of approximately 500 mL. Blood volume returns to prepregnancy levels within 7–14 days after delivery. As blood volume increases, total peripheral vascular resistance decreases.

Normal parturients are less responsive to vasopressors and chronotropic agents.[4,5] This decrease in response may be related to downregulation of α- and β-receptors. As such, one may need to increase the amount of vasopressor administered to a parturient as compared to a non-pregnant individual.

In the supine position, up to 15% of pregnant patients develop nausea, hypotension, and vomiting (supine hypotension syndrome).[6] The supine position allows the gravid uterus to compress the inferior vena cava and aorta. Caval compression results in decreased venous return to the right atrium and, hence, cardiac output. Anesthetic drugs or techniques that cause venodilation further decrease venous return with caval obstruction. A decrease in blood pressure results in a decrease in uterine perfusion. Further decreases in uterine blood flow occur if the uterus compresses the aorta, because the uterine artery is a branch of the hypogastric artery, which emerges distal to the level of aortic compression. Studies performed with pregnant women in the lateral position have not noted major decreases in cardiac output.[7,8] By tilting the patient to the left, the uterus is displaced off the vena cava and the aorta. As such, pregnant women should not lie supine after 20 weeks of gestation; the uterus should be tilted to the left by placing a wedge underneath the right hip.

KEY POINTS

1. Unlike other operations wherein the patient is primarily concerned with him or herself, the pregnant woman usually is concerned for her baby's welfare.
2. The anesthesia provider must be aware of the various physiologic changes of pregnancy and incorporate them into the anesthetic plan.
3. These physiologic changes have implications for various diseases and must be considered.
4. The central nervous system effects of pregnancy include a reduced local anesthetic requirement when these agents are given intrathecally or epidurally.
5. Pregnant patients are at increased risk for aspiration during general anesthesia.
6. There is some suggestion that surgery during the first trimester is linked to central nervous defects during surgery.
7. Fetal heart rate monitoring is possible during some surgical procedures but is not universally used in the United States.
8. Preterm delivery remains the leading cause of perinatal morbidity and mortality in the United States. Preterm labor is difficult to control with medication; the most promising medications are the calcium channel-blocking drugs. Magnesium sulfate is frequently used and is associated with prolonged depolarizing and nondepolarizing neuromuscular blockade.
9. The etiology of preeclampsia remains to be elucidated but is believed to be triggered by a paternal antigen in a susceptible mother.
10. Magnesium sulfate is the most effective medication for the prevention of seizures in women with preeclampsia.
11. Labetalol is the preferred medication for the control of blood pressure in mothers with preeclampsia.
12. The two causes of antepartum hemorrhage are placenta previa and placental abruption. Associated with the increase in cesarean sections is a high risk of placenta accreta in patients with placenta previa.
13. Perinatal transmission of HIV is low if the viral load is <1,000 copies/mL, and patients with these levels do not require cesarean section. If the viral load is greater, cesarean section may decrease the risk of perinatal transmission.

Physical examination of pregnant women typically reveals a point of maximal cardiac impulse that is displaced cephalad and leftward from its location prepregnancy. Diaphragmatic elevation displaces the heart leftward so that it may appear enlarged on chest radiographs. The electrocardiogram shows left axis deviation. A small pericardial effusion may develop in healthy asymptomatic women during the third trimester of pregnancy.[9]

Respiratory System

Various changes occur in the maternal airway during gestation. Vascular engorgement of the airway results in edema of the oral and nasal pharynx, larynx, and trachea.[10] When airways of parturients were examined at 12 weeks of gestation and then again at 36 weeks of gestation, the percentage of patients with a Mallampati class IV airway had doubled.[11] This airway edema can make intubation of the trachea difficult. Of the maternal deaths in the United States, approximately half occur because of failed intubation.[12] For oral tracheal intubation, the likelihood of edema in the false cords mandates the use of smaller endotracheal tubes. A size 6.0 cuffed endotracheal tube should be ready and available for every case. Exacerbation of these changes may occur in patients with upper respiratory tract infections or preeclampsia. The mucous membranes are very friable. Manipulation, such as nasal intubation or insertion of a nasogastric tube, may result in excessive bleeding.

The gravid uterus results in a 4-cm elevation of the diaphragm. Despite this elevation, total lung capacity changes little as the chest expands in the anteroposterior and traverse diameters to compensate. The diaphragmatic elevation does cause a 20% decrease in functional residual capacity (FRC) at term. This decrease in FRC is a result of decreases in both residual volume and expiratory reserve volume. Oxygen consumption increases by 20% as a result of increased metabolism and increased work of breathing.[13] The parturient compensates for this increased oxygen consumption in two ways: (1) increasing alveolar ventilation and (2) shifting the oxyhemoglobin dissociation curve to the right, thus facilitating unloading of oxygen at the cellular level. The P_{50} increases from 26 to 30 mm Hg. The shift is caused by an increase in 2,3-diphosphoglycerate.

The decrease in FRC and increased oxygen consumption make parturients very vulnerable to hypoxia. After complete denitrogenation by breathing 100% oxygen, nonpregnant patients tolerate 9 minutes of apnea before oxygen saturation is $<90\%$, whereas parturients can tolerate only 2–3 minutes.

Alveolar ventilation increases by 70%. This increase results primarily from increased tidal volume and secondarily from a small increase in respiratory rate. $Paco_2$ decreases to 32 mm Hg as a result of increased ventilation, and Pao_2 increases 5–10 mm Hg. Decreased serum bicarbonate from 26 to 22 mm Hg results in a partially compensated respiratory alkalosis.

From 60–70% of healthy pregnant women have mild, intermittent dyspnea. The cause is not clear, but the dyspnea may be related to alterations in chest wall proprioceptors or progesterone-induced hyperventilation.[14] Diaphragmatic elevation may result in increased lung marking, mimicking mild congestive heart failure, on the chest radiographs of healthy pregnant women.

Gastrointestinal Changes

The enlarged gravid uterus displaces the stomach cephalad. This displacement changes the angle of gastroesophageal junction, decreasing competence of the gastroesophageal sphincter. The uterus also displaces the pylorus upward and posteriorly, resulting in delayed gastric emptying. Elevated concentrations of progesterone decrease gastrointestinal motility and food absorption. These changes facilitate the occurrence of gastric reflux and heartburn in as many as 70% of pregnant women.[15] These changes also place pregnant women at major risk for regurgitation and aspiration of gastric contents during induction or maintenance of general anesthesia or any other loss of consciousness. Given these changes, many anesthesia care providers believe that all pregnant women should be considered as having full stomachs and receive rapid sequence induction. It is prudent to use good clinical judgment, weighing the risks of rapid sequence induction (failed intubation, tachycardia, hypertension) against the risks of aspiration in an asymptomatic parturient.

Hepatic Changes

Little or no change in hepatic blood flow occurs during normal pregnancy. Healthy pregnant women frequently have increased levels of serum aspartate aminotransferase, lactic dehydrogenase, alkaline phosphatase, or cholesterol. Colloid oncotic pressure decreases as a result of decreased total protein and decreased albumin-to-globulin ratio. Colloid oncotic pressure decreases further after delivery, regardless of method of delivery or anesthesia administered.[16]

Pseudocholinesterase activity is decreased by 24% before delivery and by 33% on the third postpartum day.[16,17] It returns to normal 2–6 weeks postpartum. The decreased cholinesterase activity usually is not sufficient to result in clinically relevant prolonged paralysis after a single dose of succinylcholine.

Hematologic Changes

Plasma volume increases 45%, but the red cell mass increases only 20%, leading to the physiologic (dilutional) anemia of pregnancy. A maternal hemoglobin concentration <11 g/dL is abnormal. The most common cause of anemia during pregnancy is iron deficiency.

Platelet count usually is elevated, but a modest decrease can be seen without any other hematologic pathology. Gestational thrombocytopenia is believed to be an exaggerated normal response in which platelets are consumed.[18] Pregnancy produces a hypercoagulable state. All coagulation factors, except factors XI and XIII, increase in concentration. Fibrinolytic activity decreases during the third trimester as a result of decreased plasminogen activator concentrations. These changes, combined with rapid contraction of the uterus after placental separation, help protect women from major hemorrhage. Unfortunately, this hypercoagulability also predisposes pregnant women to thromboembolic complications. Parturients are at greatest risk for deep venous thrombosis and pulmonary embolism immediately after delivery.

Endocrine

Mean blood glucose concentration remains within the normal range, although in some women glucose concentrations may be lower than before pregnancy. Parturients become insu-

lin resistant as a result of human placental lactogen, which causes increased release of insulin.[19]

The thyroid gland enlarges 50–70% during pregnancy. Concentrations of thyroid-binding globulin and total thyroxine increase, but concentrations of free thyroxine and triiodothyronine do not change.

Renal

Renal plasma flow and glomerular filtration rate (GFR) increase during the first trimester to 50% above normal by the fourth month. During the third trimester, both slowly return to normal. The increases in renal plasma flow and GFR result in increased creatinine clearance, with decreased blood urea nitrogen (BUN) and creatinine (Cr) levels.[20] BUN decreases 40% to 8–9 mg/dL, and Cr decreases to 0.4–0.5 mg/dL. A BUN of 15 mg/dL, serum Cr level of 1.0 mg/dL, and Cr clearance of 100 mL/min suggest abnormal renal function in pregnant women who are near term. Glucosuria may occur in healthy pregnant women because tubular glucose reabsorption may not keep up with increased GFR. Proteinuria (up to 300 mg/d) is common.

Maternal progesterone, which is a smooth muscle relaxant, causes dilation of renal calyces, pelves, and ureters. After midpregnancy, the enlarged uterus compresses the ureters of the pelvic brim, exacerbating ureteral dilation. Urinary stasis predisposes pregnant women to urinary tract infections.

Central Nervous System

The minimum alveolar concentration (MAC) for inhaled anesthetics is decreased up to 40% in pregnancy.[21] This decrease also occurs with the newer inhalation agents sevoflurane and desflurane.[22,23] The mechanism is unclear but may be related to progesterone (which has sedative activity) and endorphins. A concentration of an inhalation agent that may not produce loss of consciousness in nonpregnant patients may render pregnant women unconscious, placing the parturient at risk for aspiration. For this reason, inhalation agents for labor analgesia are not desirable.

Pregnant women require less local anesthetic volume to produce the same level of epidural or spinal block.[24] In the epidural space, the lesser anesthetic volume required may be partly due to epidural vein engorgement, thus decreasing the volume of the epidural space. However, this decreased requirement is seen in the first trimester, well before significant mechanical changes have occurred. Acid–base changes in cerebrospinal fluid or hormonal changes of pregnancy may cause increased sensitivity to local anesthetics.[25]

Reproductive Tract

The uterus weighs 50–70 g in the nonpregnant state and increases to 1.0–1.5 kg in pregnant women at term. Total uterine blood flow increases from 50 mL/min in nonpregnant women to 700 mL/min in pregnant women at term, representing approximately 10% of the cardiac output. The majority of the uterine blood flow perfuses the intervillous space; the remainder of the blood flow perfuses the enlarged myometrium.

The uterine vasculature appears maximally dilated in healthy pregnant women; therefore, uterine blood flow decreases parallel with maternal arterial pressure. Little or no autoregulation of uterine blood flow occurs during pregnancy. Any factor that decreases venous return and cardiac output will decrease uterine blood flow. Uterine contractions also decrease uterine blood flow. No known drugs specifically or directly increase uterine blood flow.

MONITORING THE FETUS

Use of electronic fetal monitoring for assessing fetal well-being has become universal, used by both physicians and nurses.[26] Monitoring the fetal heart rate is used to determine adequate cerebral oxygenation of the fetus. As the brain modulates the heart, a decrease in fetal heart rate is believed to reflect inadequate fetal cerebral oxygenation. External fetal heart rate monitors use a Doppler detective device with computerized logic to interpret and count the Doppler signals, whereas internal fetal heart rate monitors involve placement of an electrode on the fetal scalp. The presence of fetal heart tones as well as their rate and rhythm are well-recognized indicators of fetal well-being.[27] A normal fetal heart rate tracing reveals a rate of 110–160 beats/min with minimal to moderate beat-to-beat variability with or without accelerations.[28] A preterm fetus is expected to have a more rapid rate with little or no beat-to-beat variability and no accelerations (an increase in fetal heart rate over baseline, usually occurring with fetal movement).[29] The goal of antepartum fetal surveillance is to document fetal well-being, allowing the pregnancy to continue without concern for fetal death. Several antepartum techniques in use include fetal movement, nonstress test, contraction stress test, biophysical profile, and umbilical artery Doppler flow velocimetry.

Fetal movement is the easiest means for documenting fetal well-being. The mother can perceive fetal movements, which serve as a basis for assessment. A diminution in the perception of fetal movement often precedes fetal death.[30] Perception of 10 distinct movements in a period of up to 2 hours is considered reassuring.

Heart rate reactivity is thought to be a good indicator of normal fetal autonomic function. Loss of reactivity is associated most commonly with fetal sleep but also may result from any central nervous system depression. A nonstress test involves connecting the mother to the fetal heart rate monitor and observing. Nonstress test results can be categorized as reactive or nonreactive. The nonstress test is considered *reactive* (normal) if two or more fetal heart rate accelerations are observed within a 20-minute period. The nonstress test is considered *nonreactive* when no accelerations are observed over a 40-minute period.[31]

The contraction stress test is based on the response of the fetal heart rate to uterine contractions. During a uterine contraction, fetal oxygenation worsens as a result of uterine artery compression. In the suboptimally oxygenated fetus, this further decrease in oxygenation is not tolerated, leading to the fetal heart rate pattern of late decelerations. Three contractions in a 10-minute period are required. Contractions are produced by either oxytocin infusion or nipple stimulation.[32] The contraction stress test is interpreted according to the presence or absence of late fetal heart rate decelerations, which are defined as decelerations that reach the nadir after the peak of the contraction and persist beyond the end of the contraction.[33] The presence of late decelerations suggests that the fetus is compromised and must be de-

TABLE 21–1.

Ultrasound Components of the Biophysical Profile

Fetal breathing movements (>1 episode of rhythmic fetal breathing movements of ≥30 sec within 30 min)
Fetal movement (≥3 discrete body or limb movements within 30 min)
Fetal tone (>1 episode of extension of a fetal extremity with return to flexion, or opening or closing of a hand)
Determination of the amniotic fluid volume (single vertical pocket of amniotic fluid exceeding 2 cm)

livered, usually by cesarean section. The results of the contraction stress test are negative if no late or significant variable decelerations occur after 50% or more of contractions.

The biophysical profile was developed as a method for integrating real-time observations of the fetus directly in its environment. It is used as an assessment tool for both acute and chronic fetal conditions in the antepartum period. The biophysical profile consists of a nonstress test combined with four observations made by ultrasonography (Table 21–1).[34] Each of the five components is assigned a score of either 2 (normal) or 0 (abnormal). A composite score of 8–10 is normal, a score of 6 is considered equivocal, and a score of 4 or less is abnormal. The biophysical profile is frequently performed in the labor suite, necessitating a basic understanding by the anesthesiologist. The ability of the biophysical profile to predict cesarean delivery or admission to the neonatal intensive care unit was studied prospectively in 100 normal singleton pregnancies. A biophysical profile of 6 or lower was highly predictive of cesarean delivery and admission to the neonatal ICU.[35]

Umbilical artery Doppler flow velocimetry is based on the observation that flow velocity waveforms in the umbilical artery of normally growing fetuses differ from those of growth-restricted fetuses. The umbilical flow velocity waveform of normally growing fetuses is characterized by high-velocity diastolic flow, whereas in fetuses with intrauterine growth restriction, umbilical artery diastolic flow is reduced.[36] When using Doppler, the angle between the beam and the vessel should be $<30^{\circ}$. Clearly, this angle is difficult to obtain accurately. As such, a variety of angle-independent indices have been developed to characterize flow velocity waveforms. Indices rely on systolic, diastolic, and mean velocities. These indices do not measure the volume of blood flow. Commonly measured flow indices based on peak systolic frequency shift (S), end-diastolic frequency shift (D), and mean peak frequency shift over the cardiac cycle (A). Systolic velocities are peak velocities that result from cardiac contraction. Diastolic velocities result from a combination of factors: peak flows, vessel compliance, heart rate, and vascular impedance. This allows for the following calculations to be obtained: systolic to diastolic ratio (S/D), resistance index (S-D/S), and pulsatility index (S-D/A). To maximize interpretability, multiple waveforms should be assessed, and the filter settings should be set low enough to avoid masking diastolic flow. Initial testing at 32–34 weeks of gestation is appropriate for most pregnancies at risk for stillbirth.

Future routine monitors may include the transabdominal fetal pulse oximeter. The depth of the fetal head from the maternal abdomen is determined on ultrasound; the distance between the optodes must be twice the depth of the fetus. Using this device, oxygen saturations between 50% and 74% have been obtained and are similar to those obtained transvaginally.[37] This monitor provides measures of both the fetal heart rate and the oxygen saturation of the fetal blood. The value of this monitor is evident because not all cases of decreased fetal heart rate variability are the result of decreased oxygenation. The transabdominal fetal pulse oximeter allows for differentiation between normal fetal sleep and decreased oxygen content.

PRETERM LABOR

Preterm birth is one of the major health problems in the United States. Approximately 11–12% of all births occur preterm (<37 weeks of gestation), and the rate has increased approximately 19% since 1990.[38] The concern with preterm labor and birth is its outcome: it accounts for approximately 70% of all neonatal deaths and 50% of the long-term neurologic disabilities.[39] Almost one fifth of all very preterm infants do not survive the first year of life. Of the smallest infants, handicaps occur in approximately half of survivors.[40] Healthcare costs resulting from preterm birth are staggering. The cost to the U.S. economy is estimated at $5 billion annually.[41] Risk factors for preterm labor are listed in Table 21–2.

The prediction and prevention of preterm labor and delivery continue to be a major focus of intense investigation. The major conclusion of the research is that preterm labor and birth are complex and multifactorial. In the last decade, it has become increasingly clear that infection has a prominent role in preterm birth. An estimated 80% of preterm births are associated with chorioamnionitis or organisms in the placental membrane.[42] For women at risk for preterm delivery based on their history and who have bacterial vaginosis, evidence supports that treatment with metronidazole decreases the risk of preterm birth by 25–75%.[43,44] The other major advance in the prediction of preterm birth comes from genomics. Genomics is the study of gene expression at the messenger RNA level to provide an integrated view of the relationship among the host genome, gene expression, and disease outcome. Several studies have demonstrated a link between nucleotide polymorphisms and preterm birth.[45,46]

Tocolysis has been a prominent component of efforts to prevent preterm labor and delivery. The premise behind tocolysis is that administration of medication will reduce uterine con-

TABLE 21–2.

Risk Factors for Preterm Labor and Birth

Current multifetal pregnancy
Infection
Diabetes mellitus
Hypertension
Asthma
Lack of prenatal care
Smoking
Alcohol
Cocaine
Stress
Long work hours with long periods of standing

tractility, thus allowing retention of the fetus in utero. However, consensus is increasing among obstetricians that only a minority of patients benefit from tocolysis. Literally, hundreds of trials have evaluated medications for the prevention of preterm birth. Acute tocolysis occurs at the initial presentation for preterm labor, which differs from maintenance after successful acute tocolysis.

The β-mimetics, such as terbutaline or ritodrine, have been increasingly falling from favor as a first-line tocolytic agent because of the high incidence of maternal adverse effects, such as hypokalemia, hyperglycemia, tachycardia, decreased systemic vascular resistance, and increased risk of pulmonary edema. In fact, β-mimetics have been linked to at least 25 maternal deaths from pulmonary edema.[47] A meta-analysis included nine trials of primary tocolytic agents compared to placebo.[48] For β-mimetics, only one trial found an increase in the length of pregnancy, one found a prolongation measured in days, and the rest found no benefit. In 2003, the American College of Obstetricians and Gynecologists (ACOG) concluded, "It would appear, on the basis of currently available evidence, very difficult to support the use of betamimetics, which have a high incidence of side effects. Although these drugs do delay delivery in the short term, there is no demonstrable benefit for the newborn."[49]

The use of magnesium sulfate as a tocolytic varies by location. It is rarely used in Europe but is widely used in the United States, where it continues to be used because of its high safety profile. Magnesium sulfate results in blurry vision and maternal weakness. It potentiates the nondepolarizing muscle relaxants, necessitating a major reduction in dose of these medications. A 2004 review found no benefit of magnesium for short- or long-term delay in delivery.[50] However, magnesium sulfate may be beneficial for neuroprotection in the preterm newborn when administered prior to delivery.[51]

Calcium channel blockers relax the myometrium. The most recent study included a total of 1024 patients and found that calcium channel blockers were more effective than β-mimetic agents in prolonging pregnancy for 7 days or longer, were much less likely to cause maternal side effects, and were associated with reduced neonatal morbidity.[52] The most commonly used drugs are nifedipine, followed by nicardipine. These drugs should not be used in women with cardiovascular disease or those who are hemodynamically unstable.

The discovery that prostaglandins play a role in the initiation of labor led to the study of prostaglandin synthetase inhibitors as agents for treating preterm labor and preventing preterm birth. Studies suggest that indomethacin is more effective than placebo in prolonging pregnancy.[53] The concern with the use of indomethacin is its fetal effects. Premature closure of the ductus arteriosus and oligohydramnios have been associated with maternal administration of indomethacin.

A recent development was the discovery of oxytocin antagonists. Labor is clearly accompanied by an increase in oxytocin receptors. It stood to reason that the administration of an antagonist to oxytocin would be beneficial. Atosiban is the only oxytocin antagonist to date that has undergone extensive studies. Atosiban has several advantages in that it is a specific inhibitor of myometrial contractility with little transplacental passage. A multicenter trial compared atosiban to placebo in 501 women with preterm labor. No difference in length of labor or neonatal outcome was noted.[54] A disadvantage of atosiban is that it must be administered intravenously. Furthermore, the agent is much more expensive than the calcium channel blockers.

Multiple studies have failed to show a benefit to maintenance of tocolysis for preventing the recurrence of preterm labor or improving neonatal outcome.[55] Because of its associated high neonatal morbidity and mortality, physicians feel obligated to do something when a parturient presents in preterm labor. At the present, most interventions fail to demonstrate benefits. The safest agent currently used for tocolysis appears to be nifedipine, although ACOG has not identified a tocolytic of choice.

PREECLAMPSIA

Preeclampsia is a multisystem disorder unique to human pregnancy. Because no good animal model exists, investigation of the etiology of preeclampsia has been difficult. It is characterized by an abnormal vascular response to the placenta that is associated with increased systemic vascular resistance, enhanced platelet aggregation, activation of the coagulation system, and endothelial cell dysfunction.[56] Parturients with preeclampsia develop edema, raised blood pressure, and proteinuria. Preeclampsia typically occurs after week 20 of gestation, except when associated with a hydatidiform mole, but rarely occurs before week 24 of gestation. ACOG has defined preeclampsia as a blood pressure of at least 140 mm Hg (systolic) or at least 90 mm Hg (diastolic) on at least two occasions at least 4–6 hours apart.[57] Table 21–3 lists the possible abnormal laboratory values in preeclampsia. In general, maternal and perinatal outcomes are good in patients with mild preeclampsia developing after 36 weeks of gestation. If preeclampsia develops in patients before 33 weeks of gestation or in patients with preexisting medical disorders, the outcome is less favorable.[58] Preeclampsia usually abates within 48 hours of termination of the pregnancy. Eclampsia is preeclampsia with central nervous system involvement leading to seizures or grand mal convulsions not related to other cerebral conditions. The diagnosis of severe preeclampsia requires the presence of end-organ disease (Table 21–4).

The incidence of preeclampsia ranges from 2–7% of nulliparous patients.[59] Higher frequency and greater severity occur in patients with multifetal gestations, previous preeclampsia, and chronic hypertension. Several risk factors for preeclampsia have been identified (Table 21–5). Preeclampsia tends to occur at both extremes of reproductive age. The greatest risk factor is a

TABLE 21–3.

Abnormal Laboratory Values in Preeclampsia

Proteinuria
Elevated hemoglobin level
Elevated creatinine level
Elevated blood urea nitrogen level
Thrombocytopenia
Elevated uric acid level
Elevated prothrombin time and partial thromboplastin time
Elevated liver enzyme levels
Microangiopathic hemolytic anemia

TABLE 21–4.

Clinical Criteria for Severe Preeclampsia

One of the following criteria will make the diagnosis of severe preeclampsia necessitating delivery in the preeclamptic parturient:
- Systolic blood pressure ≥160 mm Hg
- Diastolic blood pressure ≥110 mm Hg
- Proteinuria ≥5 g/24 h
- Oliguria ≤400 mL/24 h
- Cerebral visual disturbances
- Headache
- Pulmonary edema
- Hemolysis, elevated liver enzymes, low platelets (HELLP) syndrome
- Epigastric pain

first pregnancy. Long-term sperm exposure with the same partner has a protective effect. The risk of preeclampsia is increased in a multiparous parturient if she has a different partner.[60] The importance of the father in causing preeclampsia was highlighted in a study examining the Medical Birth Registry of Norway. If a woman becomes pregnant by a man who has already fathered a preeclamptic pregnancy in a different woman, her risk of developing preeclampsia is increased 1.8 (95% confidence interval [CI], 1.2–2.6). There is also a genetic component. Using the same birth registry, the authors demonstrated that daughters of women who had preeclampsia during pregnancy had double the risk of developing preeclampsia themselves. The same did not apply to the sons who fathered children.[61]

During pregnancy, the placenta exerts a significant influence on maternal blood pressure because of the interaction of its various hormones, vasoactive substances, and structure. In a normal pregnancy, peripheral vascular resistance decreases, resulting in a lower blood pressure. Maternal blood pressure decreases as early as 7 weeks of gestation. After 28 weeks of gestation, the blood pressure increases, reaching nonpregnant values toward the end of the third trimester. Also, in a normal pregnancy, all fluid compartments expand. In patients with preeclampsia, the exact opposite occurs, with an increase in blood pressure and a decrease in the fluid compartments.

TABLE 21–5.

Risk Factors for Preeclampsia

- Maternal age (<20 y or >40 y)
- Multiple births
- Hypertension before pregnancy
- First pregnancy
- Previous pregnancy with preeclampsia
- Diabetes mellitus
- Asthma
- Kidney disease
- Lupus
- Scleroderma
- Obesity

The cause of preeclampsia is unknown, but the disease seems to begin at implantation, well before the clinical manifestations allow the diagnosis to be made. The likely culprit in preeclampsia is the placenta. Preeclampsia is seen in patients with molar pregnancies (thus it cannot be a result of the fetus) and in patients with abdominal pregnancies (thus it cannot be a result of the uterus). There are two theories regarding the role of the placenta. One theory is that inadequate placental implantation results in placental ischemia leading to oxidative stress. The other theory is immunologic maladaptation to a paternal antigen.[62,63]

Anticonvulsants were introduced for women with preeclampsia in the belief that the drugs would prevent eclampsia and improve outcome. Predicting who is at risk for eclampsia is difficult, and only 1–2% of those with preeclampsia develop eclampsia. However, prophylactic anticonvulsants are used in all parturients with preeclampsia. A variety of anticonvulsants have been proposed and evaluated, but the most widely used drug is magnesium sulfate. Other agents used include diazepam and phenytoin. Evidence continues to support the use of magnesium sulfate for the prevention of seizures, and it appears to be superior to phenytoin or nimodipine.[64,65] The largest study that examined magnesium sulfate was a multicenter trial that included centers from the United Kingdom, South America, and South Africa. A total of 10,110 patients were randomized to receive magnesium sulfate (5055 patients) or placebo (5055 patients). A greater incidence of side effects, such as flushing, hot flashes, and blurry vision, was observed in the magnesium sulfate group. The magnesium sulfate group also had a 58% lower risk of eclampsia; this lower risk did not affect maternal mortality.[66] Magnesium does not prevent the progression of the disease to severe preeclampsia. In 222 women with mild preeclampsia, 109 patients received intravenous magnesium. There was no difference in the groups with regard to the progression to severe disease.[67] Magnesium sulfate does relax the uterus. The use of magnesium sulfate in parturients with preeclampsia does not slow labor, but the need for oxytocin is greater. There is no difference in the incidence of postpartum hemorrhage.[68]

It was hoped that low-dose aspirin would be beneficial in preventing preeclampsia. Low-dose aspirin reduces thromboxane production by selective inhibition of platelet thromboxane production without affecting prostacyclin production by the vascular endothelium. The largest study randomized 2539 women to receive either low-dose aspirin (60 mg) or placebo.[69] The use of low-dose aspirin did not affect the incidence of preeclampsia. A meta-analysis of aspirin studies identified 14 trials that met specific criteria. Aspirin was effective only in women with known risk factors. It was not beneficial for the general population.[70]

Treatment of acute hypertension is intended to prevent potential cerebrovascular complications (the most common cause of morbidity in patients with preeclampsia). It is important to note that antihypertensives prevent cerebrovascular problems; they do not alter the course of the disease. A Cochrane review supports this conclusion.[71] Intravenous hydralazine or labetalol or oral nifedipine are the most commonly used drugs. Originally hydralazine was believed to be the drug of choice because it preserves uterine blood flow. In a meta-analysis comparing hydralazine to labetalol or nifedipine, hydralazine was associated with more maternal hypotension, more cesarean sections, more adverse effects on the fetal heart rate, and lower 1-minute Apgar scores. It was also associated with less maternal bradycardia compared to labetalol.[72] This analysis supports the use of labetalol for the control on maternal hemodynamics.

In an earlier review of hypertension in pregnant women, Lindheimer and Katz[73] concluded: "Epidural block

should be avoided, since in preeclampsia it is associated with sudden falls of blood pressure and on occasion with vascular collapse." The literature does not support this stance.[74,75] Studies have demonstrated the stability of maternal cardiac output after administration of epidural anesthesia in patients with severe preeclampsia. Epidural anesthesia provides excellent analgesia during labor and allows patients to remain awake and alert during vaginal or cesarean delivery. Epidural anesthesia has at least three specific advantages in parturients with preeclampsia. It reduces circulating concentrations of catecholamines in laboring women, facilitating control of blood pressure and improving intervillous blood flow.[76,77] It allows better control of systemic and pulmonary arterial pressures during cesarean section.[78] Finally, epidural anesthesia does not require laryngoscopy and intubation, which might be hazardous or difficult because of pharyngeal edema.[79]

Platelet turnover and function are often altered in preeclampsia. Normal platelets are disk-shaped cells (2–4 μm in diameter) that lack a nucleus. Platelets are formed in the bone marrow from giant cells called megakaryocytes. At any moment, approximately 80% of the platelets are circulating and 20% are localized in the spleen. Platelets participate in coagulation factor reactions leading to thrombin formation by providing a lipoprotein surface on which coagulation enzymes and substrates interact. The bone marrow does not contain a substantial reserve of platelets. If circulating plates are rapidly destroyed or lost, thrombocytopenia persists for several days until enough platelets are formed to correct the condition.

Pitkin and Witte[80] measured platelet counts every 4 weeks in 23 pregnant women and found that platelet counts dropped from 322 × 1000/μL in the first trimester to 278 × 1000/μL in the third trimester. In a study of 30 women, O'Brien[81] found a progressive decline in platelet counts. This decrease is caused by increased destruction. Preeclampsia is accompanied by endothelial injury, leading to increased platelet activation with consumption in the microvasculature. Platelet consumption is a late finding in preeclampsia, but increased platelet turnover may be an early marker of preeclampsia. Thrombocytopenia is the most common hematologic abnormality in patients with preeclampsia. Its incidence depends upon the severity of the disease and the presence or absence of abruption placenta. A platelet count $< 150 \times 1000/\mu L$ was found in 50% of the women and a count $< 100 \times 1000/\mu L$ in 36% of women with preeclampsia.[82] Roberts et al.[83] retrospectively studied 292 patients with low platelet counts. Patients were divided into two groups: those with platelet counts $< 50 \times 1000/\mu L$ and those with platelet counts of $50–100 \times 1000/\mu L$. Bleeding was likely only if the platelet count was $< 40 \times 1000/\mu L$. The only therapy for the thrombocytopenia of preeclampsia is delivery. Epidural analgesia has been successfully placed in individuals with platelet counts $< 100 \times 1000/\mu L$ in the absence of any other existing coagulopathy.

ANTEPARTUM HEMORRHAGE

The two major causes of antepartum hemorrhage are placenta previa and placental abruption. Hemorrhage is the third leading cause of maternal mortality in the United States.[84] Hemorrhage can be quite severe, with uterine blood flow of 500–700 mL/min at term.

Placenta previa is present when the placenta overlies the cervical os. Placenta previa varies in degree and may be complete (37% of cases), partial (27%), or low-lying (46%). Risk factors for placenta previa are listed in Table 21–6. The main sign of placenta previa is painless vaginal bleeding. The bleeding usually stops spontaneously but may recur suddenly at any time. The recurrent bleeding usually is severe. If the diagnosis of placenta previa is suspected, ultrasonography is performed. The accuracy of this technique is 95%.[85] The double setup technique in which a cervical examination is performed in the operating room with preparation to perform an immediate cesarean section should bleeding occur is no longer performed. Before term gestation, the patient with placenta previa usually is managed conservatively with bedrest if the patient is not actively bleeding. If bleeding occurs, emergency cesarean section is required. Occasionally, the placenta implants directly to the myometrium, giving rise to three situations: placenta accreta (the placenta attaches to the myometrium), placenta increta (the placenta invades the myometrium but does not penetrate it fully), or placenta percreta (the placenta penetrates the entire thickness of the myometrium and may attach to other structures in the pelvis). In the general obstetric population, the incidence of placenta accreta is approximately 1:2,500. In patients with placenta previa and no prior cesarean section, the incidence is 5–7%. The risk of placenta accreta in patients with placenta previa who have undergone a prior cesarean section is much higher. With one prior uterine incision, the incidence of placenta accreta reportedly is between 24% and 31%; with two or more prior uterine incisions, the incidence rises to approximately 50%.[86] In patients with placenta previa and previous cesarean section, the anesthesia provider should be prepared for massive hemorrhage. Large-bore intravenous access and the immediate availability of blood products are mandatory.

Cocaine use
History of abortion

Placental abruption refers to separation of the placenta after 20 weeks of gestation but before the birth of the fetus. The incidence ranges from 0.2–2.4%, depending upon the population studied. From 1979–2001, the rate of placental abruption increased 92% among black women and 15% among white women.[87,88] A high infant mortality rate is associated with placental abruption. Risk factors for placental abruption are listed in Table 21–7. The primary etiology of placental abrup-

Smoking

tion is unknown. It begins with hemorrhage into the decidua basalis, causing a split in the decidua and subsequent hematoma formation. This expanding hematoma causes additional separation, compression, and ultimately destruction of the adjacent placental tissue. The classic signs of placental abruption are vaginal bleeding, abdominal pain, uterine tenderness, and contractions. Bleeding is either through the vagina or concealed in the uterus. If the blood is concealed, underestimating blood loss is common. Unlike placenta previa, abruption cannot be ruled out by a negative ultrasound examination, as ultrasound evidence of hemorrhage is present in only 50% of patients.[89] Anesthetic management of the parturient with placental abruption requires volume resuscitation. The anesthesia provider must also be prepared to manage a coagulopathic patient because placental abruption is associated with disseminated intravascular coagulation.

SURGERY DURING PREGNANCY

From 1–2% of pregnant women require anesthesia for surgery unrelated to delivery. The anesthesia provider should consider possible fetal effects of the maternal disease process. Protection of the mother is paramount, but other goals of anesthetic management include maintenance of uterine blood flow and fetal oxygenation, avoidance of teratogenic drugs, and prevention of preterm labor.

Perhaps the greatest concern of pregnant women is whether anesthetics or anesthesia may increase the risk of congenital anomalies. Shnider and Webster[90] evaluated the medical records of 9073 women who delivered infants between July 1959 and August 1964. Of these women, 147 (1.6%) had surgery during pregnancy. There was no increased incidence of congenital anomalies in the surgical group, but the authors noted that most of the patients received anesthetics during the second or third trimester, after organogenesis. Brodsky et al.[91] mailed questionnaires to 287 women who had surgery during pregnancy. Among the women, 187 had surgery during the first trimester. There was no major increase in congenital anomalies in infants born to women who had surgery during pregnancy compared with a control group of pregnant women who did not have surgery. Duncan et al.[92] used health insurance data from 1971 to 1978. They matched 2565 women undergoing surgery during pregnancy to women of similar height and weight who did not. There was no difference in the rate of congenital anomalies. There was an increased risk of spontaneous abortion in women undergoing surgery with general anesthesia in the first or second trimester, especially in those undergoing gynecologic surgery. Mazze and Kallen[93] obtained data from three Swedish healthcare registries to evaluate the risk of adverse reproductive outcomes after anesthesia administration and surgery in pregnant women between 1973 and 1981. They identified 5405 women who underwent surgery during the first trimester. Among these women, 65% received general anesthesia, and 35% received regional or local anesthesia. There was no increased incidence of congenital anomalies. Another approach to this question is to examine anomalies and see if there is a link to anesthesia and surgery.[94] Of the 20,830 pregnant women who had offspring with a congenital anomaly, 31 patients had operations with anesthesia. This fraction did not differ from the 35,727 women who had babies without defects and 73 who had surgery during pregnancy. There was no higher rate of surgery and anesthesia in any congenital anomaly group.

However, this finding is not universal. Mazze and Kallen[93] reexamined their database and noted six infants with neural tube defects (an expected incidence of 2.5). Of these six infants, the mothers of five of the infants had surgery during gestational weeks 4–5, the period of neural tube formation.[95] This group was not the only one to note a link. Infants born with central nervous system defects in Atlanta between 1968 and 1980 were matched to controls by race, birth hospital, and period of birth.[96] Of the 694 mothers of infants with central nervous system defects, 12 reported first trimester anesthesia exposure (34/2984 control mothers reported such exposure). There was an increased risk for hydrocephalus (odds ratio = 9.6, 95% CI, 3.8–24.6). The strongest association was for hydrocephalus and eye defects (odds ratio = 39.6, 95% CI, 7.5 – 209.2). In the past, anesthesia providers told patients that there was only a theoretical risk that exposure to anesthesia in the first trimester increased the risk of teratogenesis. These two studies suggest that a small risk may exist. When discussing the risk of anesthesia with pregnant women scheduled for surgery, the anesthesia care provider should remind the patient that there is a 3% baseline incidence of fetal anomalies among all pregnant women.

The use of fetal monitoring during maternal surgery is a hotly debated subject. After 18–20 weeks of gestation, the fetal heart rate can be monitored. The argument for intraoperative fetal monitoring is that it can improve fetal outcome. Changes in the fetal heart rate may signal fetal compromise, allowing the anesthesia care provider to take steps to improve uteroplacental perfusion and fetal oxygenation. These may include increasing left uterine displacement, higher concentration of inspired oxygen, adjustment of maternal ventilation, augmentation of maternal circulating blood volume, or pharmacologic management of hypotension. Despite these benefits, the use of fetal monitoring during surgery is not universally applied. Hospitals in the United States were surveyed regarding monitoring.[97] Of the 184 respondents, 60% routinely used fetal monitors, and 40% did not. ACOG recognized that there are no data regarding monitoring during surgery[98]: "It is important for physicians to obtain obstetric consultation before performing nonobstetric surgery because obstetricians are uniquely qualified to discuss aspects of maternal physiology and anatomy that may affect intraoperative maternal-fetal well-being. The decision to use fetal monitoring should be individualized and if used, may be based on gestational age, type of surgery, and facilities available. Ultimately, each case warrants a team approach for optimal safety of the woman and her baby." Anesthetic care of parturient requiring nonobstetric surgery is discussed in Chapter 61.

EVALUATING THE PARTURIENT WITH COEXISTING DISEASE

Cardiac Disease

The cardiovascular changes of pregnancy place a major stress on the maternal heart and circulatory system. These changes may even result in

death of the mother. In an attempt to quantify this risk, 562 pregnant women with cardiac disease (either congenital or acquired) were followed prospectively in 13 Canadian hospitals.[99] The study followed these women through pregnancy and for 6 months after delivery. Neonatal morbidity, preterm labor, and "small for gestational age" births occurred in 20% of these patients. Maternal complications included pulmonary edema, stroke, and tachyarrhythmia. The most significant predictor of morbidity and mortality was the presence of left ventricular dysfunction prior to the pregnancy, with an odds ratio of 11 (95% CI, 4–34). The best predictor of maternal outcome is the New York Heart Association functional class (Table 21–8). In a study of 482 pregnancies, cardiovascular morbidity was less in mothers with Class I as compared to other function classes.[100] The higher the functional class, the greater the incidence of morbidity and mortality.[101]

Valvular lesions in pregnant patients are decreasing because of the decrease in rheumatic heart disease. In general, the parturient with valvular incompetence does better than the parturient with stenotic lesions. The reduced systemic vascular resistance of pregnancy improves forward flow, thus limiting the effects of regurgitation. In contrast, stenotic valvular lesions create a fixed impediment to the required increase in cardiac output of pregnancy, precipitating heart failure. Mitral stenosis is the most common valvular lesion encountered in the parturient.[102] There is an increased incidence of atrial fibrillation, leading to heart failure. Balloon mitral commissurotomy is a nonsurgical option for treatment of mitral stenosis and is an option for parturients with mitral stenosis.[103] Aortic stenosis is infrequently encountered and usually is the result of a congenitally abnormal valve. Hypertrophic cardiomyopathy is a genetically transmitted cardiac disease characterized by left ventricular hypertrophy and reduced left ventricular size and compliance. Reduction of preload and afterload results in an increase in the outflow gradient and reduction of left ventricular filling. One hundred parturients with hypertrophic cardiomyopathy were compared with the general population. There were two pregnancy-related deaths, both in women with severe disease.[104] If the patient was asymptomatic prior to the pregnancy, the progression of symptoms, atrial fibrillation, and syncope were uncommon.

TABLE 21–8.

New York Heart Association Functional Classification of Cardiovascular Disease

Class I: No limitation of physical activity. Ordinary activity does not precipitate cardiovascular symptoms.
Class II: Slight limitation of physical activity. Ordinary physical activity will precipitate cardiovascular symptoms.
Class III: Less than ordinary physical activity precipitates symptoms that markedly limit physical activity. Patients are comfortable at rest.
Class IV: Patients are unable to perform any physical activity without discomfort. Cardiovascular symptoms may be present at rest.

Congenital heart disease is increasingly prevalent in women of childbearing age because of the advances in diagnosis and treatment of these conditions. In 74 patients with congenital heart disease, 144 pregnancies occurred.[105] Congenital heart disease was divided into two groups: those with acyanotic lesions and those with cyanotic lesions. Patients with cyanotic lesions developed significantly more congestive heart failure and deteriorated more often than those with acyanotic lesions. Women with obstructive lesions had a higher incidence of pregnancy-induced hypertension. In the cyanotic group, the mean birthweight was approximately 1 kg less than in the acyanotic group. Acyanotic conditions include atrial or ventricular septal defects or persistent ductus arteriosus with small or moderate left-to-right shunts. Cyanotic lesions include tetralogy of Fallot and transposition of the great vessels in women who underwent the Fontan procedure. In cyanotic lesions, the increase in cardiac output and decrease in systemic vascular resistance lead to greater right-to-left shunting, worsening the cyanosis and hypoxemia.

Peripartum cardiomyopathy is a rare form of heart failure with no identifiable cause that occurs within the last month of pregnancy or within 5 months after delivery. The incidence is 1:4000. Risk factors include advanced maternal age, multiparity, multiple gestation, black population, obesity, and preeclampsia. There is a high morbidity and mortality: approximately 20% of those who develop the condition die[106]; the rest recover partially or completely. The largest series of patients with the disorder and a subsequent pregnancy consisted of 44 women.[107] Twenty-eight pregnancies occurred in women who recovered completely, and 16 pregnancies occurred in women who had persistent left ventricular dysfunction. All deaths occurred in patients with persistent left ventricular dysfunction (19%), and these patients were also twice as likely to present with congestive heart failure (44% vs. 21%). These patients also had a greater frequency of premature deliveries.

Acute myocardial infarction is rare in pregnant patients, with an incidence of 1:10,000 pregnancies. However, the incidence is increasing, most likely reflecting the trend toward an older maternal age.[108] Mortality is approximately 40%, with the greatest risk occurring if the infarction occurs late in the pregnancy. Cardiac troponin is unaffected by pregnancy, allowing for the diagnosis of ischemic infarction.

Pulmonary hypertension is defined as a mean pulmonary artery pressure >25 mm Hg associated with a pulmonary capillary wedge pressure <12 mm Hg. Primary pulmonary hypertension is a rare disease that affects young women of childbearing age. Pulmonary hypertension may be secondary to other causes, such as congenital heart disease, thromboembolic disease, and connective tissue disorders. The most common cause on pulmonary hypertension in the parturient involves the late consequences of a large cardiac shunt (e.g., Eisenmenger syndrome). Pulmonary hypertension is tolerated poorly during pregnancy because of insufficient adaptation of the right heart to increases in cardiac output and a poorly compliant pulmonary vasculature. In a series of 14 parturients with severe pulmonary hypertension (4 primary and 10 secondary), two patients died before delivery and three died postpartum.[109] Because of the small sample size, it was not possible to determine whether parturients with primary pulmonary hypertension fared better than patients with secondary pulmonary hypertension.

TABLE 21–9.

Classification for Severity of Asthma

	Medication Use	Symptoms	FEV_1
Intermittent	No daily medications Bronchodilator PRN	≤2×/w	≥80%
Mild persistent	One medication	>2×/w but <1 ×/d	≥80%
Moderate persistent (no nocturnal symptoms)	Two medications	Daily	>60%
Severe (nocturnal symptoms)	Three medications	Daily	≤60%

FEV_1, forced capacity expiratory volume in 1 second.

Asthma

Asthma is a disease of chronic airway inflammation with acute episodes of bronchospasm. Asthma severity is classified according to its clinical features (Table 21–9). Approximately 7% of pregnant women are affected by asthma.[110] A number of physiologic changes of pregnancy affect the course of asthma in the parturient. Airway closure that results from decreased FRC during tidal breathing might lead to exacerbation of the disease.[111] To determine the effect of pregnancy and stage of pregnancy on asthma, six electronic databases were searched for prospective studies of asthmatic women during pregnancy.[112] This review demonstrated that asthma improves in 70% of parturients and worsens in 30%. This improvement peaked in the second trimester and reverted to baseline after delivery. Harirah et al.[113] studied the effect of gestational age on peak expiratory flow rate in normal parturients. The peak expiratory flow rated declined significantly throughout gestation, returning to normal at 6 weeks postpartum.

Parturients with asthma are at a higher risk for developing complications during pregnancy. Parturients with poorly controlled asthma had double the risk for spontaneous preterm labor.[114] Asthma is also associated with the development of preeclampsia.[115] Frequency of asthmatic symptoms during pregnancy was strongly associated with preeclampsia. Fetal hypoxia has been suggested as the mechanism for the association between asthma and preeclampsia as well as between asthma and intrauterine growth retardation.[116] Parturients with asthma have a greater risk of developing chorioamnionitis, most likely because of premature rupture of membranes coupled with immunosuppressive therapy of asthma.[117]

The treatment of asthma combines allergen avoidance, smoking cessation, pharmacotherapy, and education. Pregnancy is not considered a contraindication for treatment. In fact, the management in pregnant women should follow the same guidelines as for nonpregnant patients, with inhaled steroids being the first line of therapy.[118] Parturients are not treated with systemic glucocorticosteroids because of their teratogenetic effect (the increased risk of orofacial cleft).[119] Inhaled steroids are not associated with this risk. Further, treatment with inhaled steroids as compared to theophylline resulted in a greater improvement in forced expiratory volume in 1 second (FEV_1) in the parturient.[120] The mainstay for treatment of an acute attack is inhaled albuterol. Albuterol is a relatively selective β_2-adrenergic bronchodilator that has been shown to have no effect on maternal and fetal circulations.[121]

Back Pain

Back pain during pregnancy is a frequent problem. A cohort of 200 consecutive women was followed throughout pregnancy.[122] Of these participants, none reported back pain at the start of the study. However, at 12 weeks of gestation, 19% of the study population complained of a backache. The incidence increased to 47% at 24 weeks of gestation and peaked at 49% at 36 weeks of gestation. After delivery, the prevalence of back pain declined to 9.4%. Interestingly, despite a relatively high prevalence, it appears that only 32% of women with low back pain during pregnancy report this problem to their physician, and only 25% of providers recommend a specific therapy.[123]

The etiology of the back pain is multimodal. One popular theory is that the exaggerated lumbar lordosis to compensate for the enlarging uterus places significant mechanical strain on the lower back. There is also a hormonal component. Relaxin is a polypeptide hormone of ovarian origin of the insulin-like growth factor family. Relaxin is associated with remodeling of collagen fibers and pelvic connective tissue. The primary source of circulating relaxin is the corpus luteum. The placenta is another major source of relaxin. Serum levels of relaxin measured in parturients both with and without back pain best explained the differences in back pain.[124]

Patients who develop low back pain during pregnancy may avoid subsequent pregnancy to prevent recurrence of the back pain. Women with low back pain during pregnancy have an extremely high risk for experiencing a new episode during a subsequent pregnancy.[125]

The majority of patients with low back pain during pregnancy respond to activity and postural modification. Exercise to increase the strength of the abdominal and back muscles is helpful. Scheduled rest periods with elevation of the feet to flex the hips and decrease the lumbar lordosis help to relieve muscle spasm and pain.[126]

Diabetes Mellitus

Diabetes mellitus complicates 3–5% of all pregnancies.[127] Type 1 diabetes results from primary failure of endogenous insulin production, whereas type 2 diabetes represents a relative insulin deficiency. The precise etiology of type 1 diabetes is unknown. For an individual to develop type 1 diabetes mellitus, it appears that he or she must have genetic susceptibility and an environmental insult, which leads to an autoimmune attack against the insulin-producing pancreatic islet β cells.

During normal pregnancy, the parturient develops an insulin resistance that begins near midpregnancy and progresses through the third trimester. The insulin resistance appears to result from a combination of increased maternal adiposity and of hormones excreted by the placenta, such as human placental lactogen and progesterone. The fact

that insulin resistance rapidly abates following delivery (important to remember when managing diabetic parturients in the labor suite) suggests that the major contributor to this insulin resistance is placental hormones.

Glucose control is important for both maternal and fetal well-being during pregnancy. Studies have consistently shown a significant positive correlation between ambient serum glucose concentration during organogenesis and the incidence of spontaneous abortion.[128] When glycosylated hemoglobin levels were <8.5%, the fetal malformation rate (cardiac defects, sacral agenesis, renal agenesis, polycystic kidneys, anencephaly, meningomyelocele) was 3.4%, but when the glycosylated hemoglobin level was >9.5%, the rate of fetal malformations approached 22%.[129] Glucose crosses the placenta; fetal levels reflect maternal levels. Insulin does not cross the placenta. Maternal hyperglycemia produces fetal hyperglycemia, causing stimulation of fetal cells and fetal hyperinsulinemia. Insulin is the major fetal growth hormone and produces excessive fetal growth, especially in the fat. The fetus of a poorly controlled diabetic mother is likely to be large, especially in the shoulders and chest, increasing the risk of shoulder dystocia at delivery. Increased insulin levels in the fetus delay fetal lung maturity. Diabetic parturients also have an increased risk of developing preeclampsia. In 1949, White[130] proposed a system of classifying diabetes in obstetric patients. The White classification (Table 21–10) is still used today for predicting pregnancy outcome and as a means of conveying to others the severity of the disease process. Parturients in class A have less severe disease than those in class C or D. Classes R, F, H, and T imply end-organ damage. The more severe the disease, the poorer the outcome.

The management of diabetes in pregnancy includes a careful combination of diet, exercise, and insulin. Fasting glucose level should be maintained near 90 mg/dL, and 1-hour postprandial glucose level should be 140 mg/dL. During the night, glucose levels should not fall below 60 mg/dL. Glycosylated hemoglobin level should be no higher than 6%.[131]

Gestational diabetes mellitus is defined as glucose intolerance with the onset or first detection during pregnancy. Risk factors include advanced maternal age, family history of diabetes, and obesity. In low-risk populations, the incidence is approximately 2%, but the risk can be as high as 5–6% in the high-risk population.[132,133] In women with gestational diabetes, the insulin response to a glucose load is reduced compared to the response in a normal parturient. This occurs because of β-cell dysfunction in patients with chronic insulin resistance. Long-term followup of patients with gestational diabetes indicates that the majority progress to diabetes after pregnancy.[134] Very few have diabetes soon after delivery; the incidence appears to increase 10 or more years after delivery. The focus of treatment antepartum is to return glucose levels to normal. After pregnancy, the main focus of clinical care should be on reducing the risk of diabetes and treating it if it develops.

TABLE 21–10.

White Classification of Diabetes in Pregnancy

Class	Age at Onset	Duration	Complications	Insulin Requirement
Gestational Diabetes				
A1	Any	Any	—	No
A2	Any	Any	—	Yes
Pregestational Diabetes				
B	>20 y	<10 y	—	Yes
C	10–19 y	10–19 y	—	Yes
D	<10 y	>20 y	Benign retinopathy	Yes
F	Any	Any	Nephropathy	Yes
R	Any	Any	Proliferative retinopathy	Yes
T	Any	Any	Renal transplant	Yes
H	Any	Any	Cardiac	Yes

Much debate has focused on the role of oral hypoglycemic agents for the management of diabetes during pregnancy. These drugs are routinely used in nonpregnant adults with type 2 diabetes. They have recently been proposed for the treatment of gestational diabetes. The most promising agent is the second-generation sulfonylurea glyburide. It does not cross the placenta, thus avoiding possible teratogenicity. It has an onset of action of 4 hours and a duration of 10 hours. In a study of 404 women, glyburide was similar to insulin in regard to glucose control, with a lower incidence of hypoglycemia in the glyburide group.[135]

Thyroid Disease

Thyroid disease is more common in women, with a female-to-male ratio of 12:1. Thyroid autoimmunity is by far the most frequent cause of hypothyroidism in women of reproductive age.[136] The prevalence of hypothyroidism in the general population of reproductive age is 2%. The incidence of hyperthyroidism in pregnant women is estimated at 0.2%, with the most common cause being Graves disease (autoimmune-induced thyroxine overproduction). During pregnancy, normal thyroid activity undergoes significant changes, including a 2- to 3-fold increase in thyroxine-binding globulin concentrations, increased serum thyroglobulin levels, and increased renal iodide clearance. In addition, human chorionic gonadotropin (hCG) has mild thyroid stimulating activity.[137]

Hypothyroidism in women may cause infertility. This is not surprising because thyroid hormones have direct effects on granulose cells, luteal cells, and oocytes. With mild hypothyroidism, pregnancy may occur, but the resulting pregnancies often are associated with abortion, stillbirth, or prematurity.[138] For the fetus, maternal thyroid hormones are transferred across the placenta. This transfer is important in early gestation because the fetal thyroid gland becomes operational only after midgestation. Maternal hypothyroidism is associated with neurologic disorders in the newborn because thyroid hormonal levels are important for fetal brain development.[139] Systematic screening for hypothyroidism, administration of L-thyroxine in selected cases, and monitoring of thyroid function have proved to be helpful in the management of these patients.

Hyperthyroidism during pregnancy is less common than is hypothyroidism. Hyperthyroidism can cause miscarriage, neonatal death, preterm delivery, and intrauterine growth retardation. Two pregnancy-specific conditions, hyperemesis gravidarum and trophoblastic disease, can cause hyperthyroidism in the mother.[140,141] Hyperemesis gravidarum is characterized by severe vomiting that begins approximately at 6 weeks of gestation and usually resolves by 20 weeks of gestation. The etiology of transient hyperthyroidism in hyperemesis gravidarum is unclear. In trophoblastic disease, there is an increase in hCG that increases thyroid function. In select cases, propylthiouracil may be required.

Human Immunodeficiency Virus

AIDS was first reported in women in 1981. The percentage of AIDS cases involving women has increased thereafter, accounting for an estimated 26% of new AIDS diagnoses in 2002. Since 1998, deaths among women with AIDS have remained stable. Of the women with human immunodeficiency virus (HIV), 31% were of childbearing age.[142] Pregnancy does not affect HIV or disease progression; viral load is not increased by pregnancy but may rebound during the immediate postpartum period.[143] As such, the challenge with HIV in pregnant patients is preventing transmission of HIV to the child.

The first major discovery in the prevention of transmission of virus to the neonate was the demonstration that treatment of the mother with zidovudine during pregnancy and labor and of the neonate for the first 6 weeks after birth could reduce the transmission rate from 25% to 8%.[144] The introduction of this practice had a dramatic effect on perinatal transmission.[145] However, use of a single agent now is considered obsolete, and most patients receive combination therapy. Combination therapy generally consists of two nucleoside reverse transcriptase inhibitors and a nonnucleoside reverse transcriptase inhibitor or protease inhibitor. Combination antiretroviral therapy has proved effective in reducing maternal HIV-1 RNA levels to <500 copies/mL, which minimizes the risk of perinatal transmission and improves the health of the mother.[146]

Early studies suggested an association between vaginal delivery and fetal transmission of the virus, with a decreased likelihood of transmission with cesarean delivery.[147,148] In 1999, the International Perinatal HIV Group published a meta-analysis of 15 prospective cohort studies that examined the mode of delivery and the risk of vertical transmission.[149] This meta-analysis included only those studies of at least 100 mother–child pairs and defined elective cesarean section as that performed before the onset of labor. The number of patients in the final analysis was 7800 mother–child pairs. The study concluded that the likelihood of maternofetal transmission of HIV decreased by approximately 50% with elective cesarean section as compared with other modes of delivery. The addition of antiretroviral therapy during prenatal, intrapartum, and neonatal periods to women undergoing cesarean section reduced the risk of maternofetal transmission by approximately 87%. The problem with this analysis was that the majority of studies were performed prior to the use of highly active antiretroviral therapy and without any data concerning maternal viral load. Given these data, ACOG published a committee opinion, which can be summarized as follows:

1. In patients with HIV who did not take antiretroviral therapy, the risk of vertical transmission is 25%.
2. The addition of zidovudine decreases the risk to 5–8%.
3. If a cesarean section is performed, the risk is approximately 2%.
4. A similar risk of 2% or less is seen among women with viral loads <1000 copies/mL. Women whose viral loads are >1000 copies/mL should be counseled regarding the potential benefit of scheduled cesarean section.

Viral load should be measured to assist the obstetrician in planning the route of delivery.[150]

Cocaine Abuse

The consequences of acute and chronic cocaine abuse must be considered in the obstetric population because of the prevalence of abuse in women of childbearing age. Overall approaches to the perioperative management of substance abuse are provided in Chapter 23; this brief review focuses on the special concerns that affect the parturient and potentially her child. Cocaine is derived from the *Erythroxylon coca* plant. It is taken intravenously, intranasally, or orally. "Crack" is a form of cocaine that is smoked. Cocaine produces sympathetic stimulation by blocking the presynaptic reuptake of norepinephrine, dopamine, and serotonin. This pathophysiology explains the hypertension and tachycardia frequently seen following acute use. In fact, it is difficult to differentiate preeclampsia from acute cocaine used based upon physiologic variables.[151] Urine testing for protein differentiates the two. The reported use of cocaine in the United States is approximately 1% but may be as high as 10% in an inner-city population.[152] In addition to its cardiovascular effects, maternal ingestion of cocaine is associated with premature labor, placental abruption, nonreassuring fetal heart rate, and uterine rupture.[153] Cocaine rapidly crosses the placenta, resulting in a high incidence of fetal anomalies.[154] Cocaine use is associated with thrombocytopenia.[155] Propranolol is contraindicated in patients with hypertension from acute cocaine use because of unopposed α-adrenergic stimulation. Labetalol or hydralazine is acceptable.[156] The American Heart Association recommends nitroglycerin and benzodiazepines as first-line agents for patients experiencing cocaine-related myocardial ischemia.[157] For hypotension, ephedrine may not be effective because of depletion of catecholamines. Phenylephrine would be effective.[158]

PUTTING IT ALL TOGETHER

Unlike other patients, evaluation of the parturient involves two patients, the mother and the fetus. Optimal care of the mother provides the best care for the fetus. The parturient undergoes various physiologic changes that vary depending upon gestation. These changes must be considered when devising an anesthetic plan. These changes also must be considered when the parturient has an underlying disease. These diseases and conditions can worsen during pregnancy, ultimately resulting in deterioration of the mother's health. These changes also have implications in the pharmacologic management. The anesthesia provider must clearly understand that pregnant patients are at increased risk for aspiration of gastric contents. Preterm labor does not en-

tail increased risk to the mother; rather, it carries significant risk to the fetus. However, the use of tocolytic agents places the mother at risk. Magnesium sulfate remains the cornerstone of seizure prophylaxis in patients with preeclampsia. It potentiates depolarizing and nondepolarizing muscle relaxants. Although one of the most challenging aspects of anesthesia is the parturient, it is also one of the most rewarding.

CHAPTER 22

Evaluation of the Obese Patient

Babatunde O. Ogunnaike, MD, and Charles W. Whitten, MD

EVALUATION OF THE OBESE PATIENT

The worldwide epidemic of obesity is a key factor in the increased incidence of type 2 diabetes mellitus, and cardiovascular diseases, such as high blood pressure, and stroke.[1] Obesity is characterized by an abnormally high percentage of body weight as fat. Overweight is an increase in weight relative to a standard. Approximately 65% or two of every three adults in the United States is overweight or obese.[2]

The foundation for obesity usually is laid during childhood. At age 4, approximately 20% of obese adults probably were obese, and a morbidly obese adolescent has an up to 80% likelihood of being a morbidly obese adult.[3] Approximately 85% of the economic burden of obesity can be accounted for by obesity-related diseases (coronary artery disease, stroke, type 2 diabetes mellitus, hypertension, hyperlipidemia) and prescription drugs.[4] Obese people have a markedly decreased life expectancy.[5] Weight gain of more than 1 kg per year or more than 10 kg overall is associated with an increased risk to health.[6]

The anatomic distribution of body fat is associated with varying pathophysiologic consequences. Android (central) obesity is commonly seen in men and is associated with increased oxygen consumption and increased incidence of cardiovascular disease with a truncal or upper body distribution of the adipose tissue. Visceral fat is particularly associated with cardiovascular disease and ventricular dysfunction. Alcohol encourages deposition of central (android pattern) body fat. Gynecoid (peripheral) obesity, which typically is seen in women, locates adipose tissue predominantly in the hips, buttocks, and thighs. The adiposity of the gynecoid pattern is less closely associated with cardiovascular disease because it is less metabolically active. Waist circumference (WC), waist-to-stature ratio (WSR), and waist-to-hip ratio (WHR) are body circumference (anthropometric) indices that identify patterns of obesity and correlate strongly with mortality and the development of obesity-related diseases. Central adiposity contributes greatly to cardiovascular risk.[7] WC generally represents abdominal fat and is an independent predictor of disease. WC is best measured at either the umbilicus or at the narrowest circumference

KEY POINTS

1. Expiratory reserve volume is the most sensitive indicator of the effect of obesity on pulmonary function testing.
2. Obesity is an independent risk factor for ischemic heart disease and eventual heart failure. Cardiovascular disease is strongly associated with central (android) distribution of fat. Angina may actually be a direct symptom of obesity because a significant number of obese patients with angina do not have demonstrable coronary artery disease.
3. Plasminogen activator inhibitor-1 (PAI-1), which is secreted by the endothelium, vascular smooth muscle cells, hepatocytes, and adipocytes is associated with visceral obesity and inhibits the fibrinolytic system. PAI-1 decreases fibrinolysis and increases the risk of coronary artery disease.
4. Gastric emptying is delayed in obese patients because of increased abdominal mass that causes antral distension, gastrin release, and a decrease in pH with parietal cell hypersecretion. However, emptying has been documented to be faster with high-energy-content intake such as fat emulsions, but residual volume is increased because of their larger gastric volume (up to 75% larger).
5. Rhabdomyolysis has been documented in morbidly obese patients undergoing prolonged procedures. Elevations in serum creatinine and creatine phosphokinase levels unexplained by other reasons and complaints of buttock, hip, or shoulder pain in the postoperative period should raise the suspicion of rhabdomyolysis.
6. Postoperative polyneuropathy, known as acute post–gastric reduction surgery neuropathy, could result from vitamin and nutrient deficiencies. Patients present with protracted postoperative vomiting, hyporeflexia, and muscular weakness.
7. The magnitude of body mass index does not have much influence on the difficulty of laryngoscopy. Such difficulty correlates better with increased age, male sex, temporomandibular joint pathology, Mallampati classes 3 and 4, history of obstructive sleep apnea, and abnormal upper teeth. Neck circumference has been identified as the single biggest predictor of problematic intubation in morbidly obese patients.
8. Forearm blood pressure is a fairly good predictor of upper arm blood pressure in most patients; however, forearm measurements with a standard cuff may overestimate both systolic and diastolic blood pressures in obese patients.
9. Preoxygenation in the head-up or sitting position is more effective and provides the longest safe apnea period during induction of anesthesia in obese patients.
10. The head-elevated laryngoscopy position, or "ramped" position, significantly elevates the obese patient's head, neck, upper body, and shoulders above the chest to a point where an imaginary horizontal line can be drawn from the sternal notch to the external ear to better improve laryngoscopy and intubation.
11. Positive end-expiratory pressure is the only ventilatory parameter that has consistently been shown to improve respiratory function in obese subjects, but it decreases venous return, cardiac output, and subsequent oxygen delivery.
12. The 400 J of energy on regular defibrillators is sufficient for the morbidly obese because their chest wall usually is not much thicker, but the higher transthoracic impedance from the fat may obligate several attempts.

TABLE 22–1.

Disease Risk According to Waist Circumference

Body Mass Index (kg/m²)	Waist Circumference/Risk	
	Male: <102 cm Female: <88 cm	Male: ≥102 cm Female ≥ 88 cm
18.5–24.9	Average	Average
25.0–29.9	Increased	Increased
30.0–34.9	High	Very high
35.0–39.9	Very high	Very high
>40	Extremely high	Extremely high

seen anteriorly. WC >102 cm (40 in) in men and 88 cm (35 in) in women increases the risk of obesity-related diseases, including cardiovascular diseases, diabetes mellitus, and dyslipidemia (Table 22–1). WHR >0.9 in women and >1.0 in men is associated with a higher risk of morbidity and mortality than is a more peripheral pattern of body fat distribution (WHR <0.75 in women and <0.85 in men). WSR is a simple yet effective anthropometric index in predicting a wide range of cardiovascular risk factors and related health conditions. It is recommended that a person's WC not exceed half the stature to minimize the incidence of these diseases.[8]

Ideal body weight (IBW) is the weight associated with the lowest mortality rate for a given height and gender. It is estimated using the Broca index: IBW (kg) = height (cm) – x, where x = 100 for adult males and 105 for adult females. Body mass index (BMI) is more appropriate for clinical use. It estimates the degree of obesity using the following equation:

$$\text{BMI} = \frac{\text{Weight (kg)}}{\text{Height (m)} \times \text{Height (m)}}$$

or

$$\text{BMI} = \frac{\text{Weight (lb)}}{\text{Height (in)} \times \text{Height (in)} \times 703}$$

BMI of 18.5–24.9 is within the normal weight range, BMI of 25.0–29.9 is overweight, and BMI >30 and >40 kg/m² are considered obesity and extreme obesity, respectively (Table 22–2). BMI reliably measures body fat, but it cannot distinguish overweight from overfat because heavily muscled people can be easily classified as overweight using BMI. A simplified formula that reverses the BMI equation can be used to estimate IBW by relating the "normal" BMI average of 22 (normal = 18.5–24.9) to a known height. The equation can then be rearranged to read: IBW = 22 × Height². This equation yields weights that fall midway within the range of values obtained with other IBW formulae.[9]

PATHOPHYSIOLOGY OF OBESITY (TABLE 22–3)

Respiratory System

Morbidly obese patients have an increased work of breathing as a result of reduced chest wall compliance associated with accumulation of fat on the chest wall, diaphragm, and abdomen. There is some contribution from obesity-related respiratory muscle dysfunction. Decreases in functional residual capacity (FRC) and expiratory reserve volume (ERV) are the most commonly reported abnormalities of pulmonary function in obese subjects.[10] Decreased respiratory compliance leads to decreased FRC, vital capacity (VC), and total lung capacity (TLC). These parameters are significantly lower in individuals with upper body fat distribution (central obesity). The reduction in FRC is the result of decreased ERV. Reduction in ERV is the result of encroachment of abdominal contents on the diaphragm, decrease in respiratory system compliance by chest wall fat, and impairment of respiratory muscle strength. ERV is the most sensitive indicator of the effect of obesity on pulmonary function testing. Each kilogram of weight gained results in an approximately 26-mL reduction in VC.[11] Residual volume remains normal. Decreased FRC can result in lung volumes below closing capacity during normal tidal ventilation, leading to small airway closure, ventilation/perfusion mismatch, right-to-left shunting, and hypoxemia (Figure 22–1). Anesthesia worsens the situation such that up to a 50% reduction in FRC occurs in the obese anesthetized patient compared with 20% in the nonobese. Reduction in FRC impairs the ability of obese patient to tolerate even minimal periods of apnea, hence the rapid desaturation after induction of anesthesia despite adequate preoxygenation.

Obesity increases total oxygen consumption and carbon dioxide production even at rest. This is the result of metabolic activity of excess body fat and increased workload on supportive tissues. Minute ventilation needs to be increased to meet these requirements. The body increases cardiac output and alveolar ventilation in an attempt to meet these metabolic demands. Basal metabolic activity in relation to body surface area usually is within normal limits, and an increase in minute ventilation usually maintains normocapnia. The increase in minute ventilation requires an increase in oxygen consumption because most obese patients retain their normal response to hypoxemia and hypercapnia. Morbidly obese patients do extra work to maintain their augmented ventilation; therefore, they must dedicate a high percentage of their total oxygen utilization to perform respiratory work even during regular respiration.[12]

TABLE 22–2.

Classifications of Obesity

Body Mass Index (kg/m²)	Description	Obesity Class
<18.5	Underweight	
18.5–24.9	Normal	
25.0–29.9	Overweight	
30.0–34.9	Obesity	I
35.0–39.9	Morbid Obesity	II
>40	Extreme obesity	III

TABLE 22–3.

Medical Consequences of Obesity

System	Pathology
Respiratory	Obstructive sleep apnea, obesity hypoventilation syndrome, asthma, pulmonary hypertension
Cardiovascular	Arrhythmias, atherosclerosis, cardiac failure, coronary artery disease, peripheral vascular disease, sudden cardiac death, systemic hypertension, thromboembolism, varicose veins
Gastrointestinal	Colon cancer, gallbladder disease, gastroesophageal reflux disease, hernias, nonalcoholic fatty liver disease, nonalcoholic steatohepatitis
Endocrine/metabolic	Diabetes mellitus, dyslipidemia, hyperinsulinemia, hypothyroidism, insulin resistance, metabolic syndrome
Genitourinary	End-stage renal disease, macrosomia, menorrhagia, preeclampsia and eclampsia, prostate cancer, urinary incontinence
Neurologic	Carpal tunnel syndrome, pseudotumor cerebri, stroke
Hematology	Hypercoagulability, polycythemia
Musculoskeletal	Acanthosis nigricans, gout, osteoarthritis, rheumatoid arthritis
Psychology/psychiatry	Depression, reduced self-esteem, social stigma

Dynamic lung volumes, including the forced expiratory volume in 1 second (FEV_1) and the forced vital capacity (FVC), decline with increasing body mass, resulting in an unchanged ratio of FEV_1/FVC. Significant hypoxemia is attributed in part to closure of dependent airways within the range of normal tidal ventilation. Substantial weight loss results in gas exchange improvement as evidenced by an increase in Pao_2. Morbid obesity is associated with reductions in forced expiratory flow during midexpiratory phase ($FEF_{25–75\%}$) and maximum voluntary ventilation (MVV), whereas the diffusing capacity remains normal.[13] MVV, an index of respiratory muscle strength, is decreased in extreme obesity. Respiratory muscle efficiency is suboptimal in obese patients. Inefficiency is suggested by a sharper increase in oxygen consumption during exercise when compared to nonobese patients. Supine position reduces FRC because of cephalad displacement of the diaphragm. This effect is exaggerated in the obese, leading to a further reduction in FRC, further small airway closure, and increased work of breathing. Clinically significant increases in intrapulmonary shunting and oxygen consumption have been documented in obese patients while they are changing from the sitting to the supine position. Chest wall and lung compliance both are decreased by fat accumulation on the thorax and abdomen. Increased pulmonary blood volume, which is part of an overall increase in total blood volume, partially explains the decreased lung compliance. Chronic hypoxemia causes polycythemia, which contributes to the increased blood volume. Morbidly obese patients who are breathing room air have lower arterial oxygen tensions (Pao_2) than that predicted for similarly aged nonobese subjects in both sitting and supine positions. Chronic hypoxemia eventually can lead to pulmonary hypertension and cor pulmonale.

Obstructive Sleep Apnea

Many obese patients manifest the upper airway obstruction syndrome during sleep, which can be classified into three categories: obstructive sleep apnea, obstructive sleep hypopnea, and upper airway resistance. Features common to all three include disruption of sleep because of increased ventilatory effort in response to upper airway closure and daytime somnolence.

Obstructive sleep apnea (OSA) is defined as cessation of airflow for more than 10 seconds, five or more times per hour of sleep, despite continuous respiratory effort against a closed glottis, in combination with a decrease in arterial oxygen saturation of greater than 4% (Figure 22–2). Obstructive sleep hypopnea is a >50% decrease in airflow for >10 seconds, occurring ≥15 times per hour of sleep; it usually is associated with snoring and arterial oxygen desaturation >4%. The upper airway resistance syndrome is characterized by arousal in response to increased upper airway resistance without an elevated apnea–hypopnea index (AHI). AHI is the total number of apneas and hypopneas per hour and is used to quantify the severity of OSA.[14]

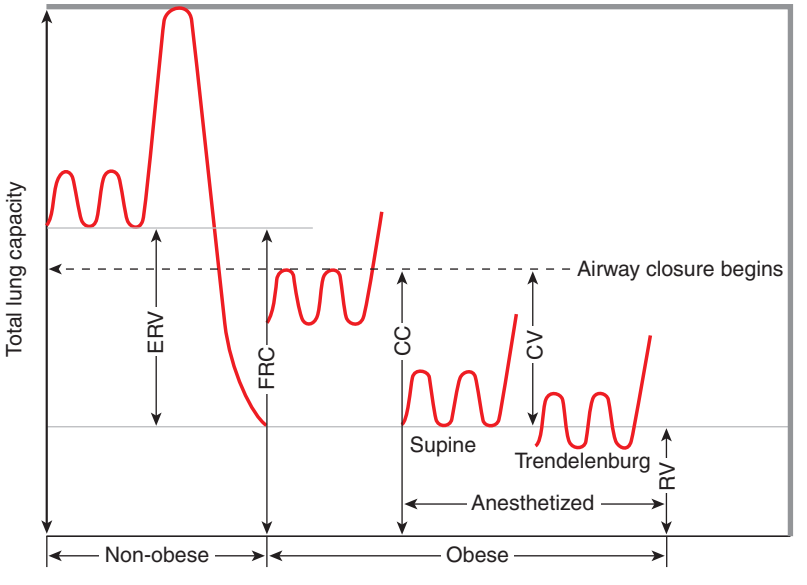

FIGURE 22–1. Effects of obesity, positioning, and anesthesia on lung volumes. CC, closing capacity; CV, closing volume; ERV, expiratory reserve volume; FRC, functional residual capacity; IRV, inspiratory reserve volume; RV, residual volume. (Modified from Ogunnaike and Whitten[97] with permission.)

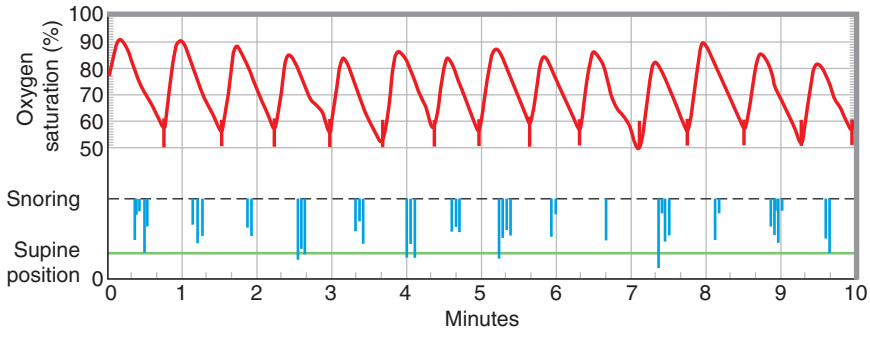

FIGURE 22–2. Pattern of oxygen saturation in a patient with severe sleep apnea. The vertical lines below the oxygen saturation values indicate respiratory disturbances. Episodes of snoring are shown. Patient is in the supine position. (Flemons WW. Obstructive sleep apnea. N Engl J Med 2002;347:498. Copyright 2002, Massachusetts Medical Society. All rights reserved.)

AHI >30 signifies severe OSA, AHI of 5–15 defines mild OSA, and AHI of 16–30 defines moderate OSA. The total arousal index (AI) is the total number of arousals per hour. The sum of AHI and total AI is known as the respiratory disturbance index (RDI).

OSA is characterized by frequent episodes of apnea or hypopnea during sleep, snoring, and daytime somnolence, fatigue, reduced cognition, reduced intellectual function, impaired concentration, memory problems, personality and behavioral problems, and morning headaches. Predisposing factors to OSA include male gender, middle age, and obesity. Alcohol consumption or night sedation worsens the situation. BMI >30 kg/m^2 and collar size >16.5 inches correlate with severe OSA. Resulting physiologic abnormalities include hypoxemia, hypercapnia, and generalized (pulmonary and systemic) vasoconstriction. Secondary polycythemia as a result of recurrent hypoxemia increases the risk of cerebrovascular and ischemic heart disease. Right ventricular failure is a potential consequence of chronic hypoxic pulmonary vasoconstriction. The electrocardiographic (ECG) pattern of right ventricular hypertrophy (RVH) or echocardiographic evidence of hypofunction may be seen. Initially, respiratory acidosis occurs only during sleep, with return to normal homeostasis when awake. Hypoxemia during apnea can lead to bradycardia, long sinus pauses, second-degree heart block, and ventricular dysrhythmias with markedly increased severity if arterial oxygenation decreases below 60%. The higher incidence of nocturnal angina and myocardial infarction in OSA patients may be explained by the increased incidence of arrhythmias in these patients. Up to 50% of OSA patients have diurnal systemic and pulmonary hypertension that likely is the result of repetitive increases in sympathetic tone accompanying each hypoxemic–hypercapnic arousal event which likely accounts for the high incidence of RVH and left ventricular hypertrophy (LVH) seen in OSA patients.[15] Activation of the sympathetic nervous system occurs in response to hypoxemia as a result of apneic and hypopneic events, which may explain the increased incidence of hypertension in obese OSA patients. Clinical diagnosis of OSA is made in a patient with obesity, snoring, apnea during sleep, periodic snorting, and apparent arousal (extremity movement, turning, and vocalization) and daytime somnolence or fatigue. Definitive diagnosis can be made only with a sleep study.

There is an inverse relationship between obesity and the pharyngeal area. The decreased pharyngeal area results from deposition of adipose tissue into pharyngeal tissues, including the uvula, tonsils, tonsillar pillars, tongue, aryepiglottic folds, and lateral pharyngeal walls (Figure 22–3). Fat deposition is most pronounced in the lateral pharyngeal walls, and its volume correlates with the severity of OSA. Weight loss improves the pharyngeal and glottic function of patients with OSA.[15] Decreased patency of the pharynx from increased fat deposition increases the likelihood that relaxation of the upper airway muscles will result in collapse of the soft-walled oropharynx between the uvula and the epiglottis. In obese patients, the upper airway can be compressed externally by superficially located fat masses, which increase the pharyngeal extraluminal pressure. This situation is evidenced by a significantly larger neck in the obese patient with OSA when compared to those without OSA and the fact that the severity of OSA correlates better with larger neck circumference than with general obesity. Weight loss significantly reduces the severity of OSA.

Central depressant anesthetic drugs (benzodiazepines, opioids, and induction agents such as thiopental and propofol) reduce the action of pharyngeal dilator muscles, causing severe pharyngeal collapse in obese patients. Small precurarizing doses of muscle relaxants and nitrous oxide also reduce their action. Addition of opioids will depress ventilation and result in poor response to the ensuing hypoxemia and hypercapnia. OSA is associated with difficult mask ventilation and difficult laryngoscopy, which, when combined with decreased FRC and reduced oxygen stores, requires anticipation and preparation for airway difficulty.

High leptin levels have been detected in patients with OSA independent of body fat content, which suggests that OSA may be associated with leptin resistance.[16] Leptin is a peptide secreted by white adipose tissue. It crosses the blood–brain barrier to reach the hypothalamus, where it modulates the neuroendocrine and autonomic nervous systems to decrease food intake and energy expenditure.

Obesity-Hypoventilation Syndrome

Obesity hypoventilation syndrome (OHS) is a combination of obesity and chronic hypoventilation that ultimately results in pulmonary hypertension and cor pulmonale.[17] It also can be defined as a combination of obesity (BMI >30 kg/m^2) and awake arterial hypercapnia ($Paco_2$ >45 mm Hg) in the absence of known causes of hypoventilation. OHS is seen in up to 10% of morbidly obese patients. Clinical features are similar to those seen with OSA and include excessive daytime somnolence, fatigue, and morning headaches. In addition, daytime hypercapnia and hypoxemia are associated with pulmonary hypertension and right-sided congestive heart failure (cor pulmonale), resulting in substantial morbidity and mortality.[18]

OHS patients have an increased sensitivity to the respiratory depressant effects of general anesthetics. Epi-

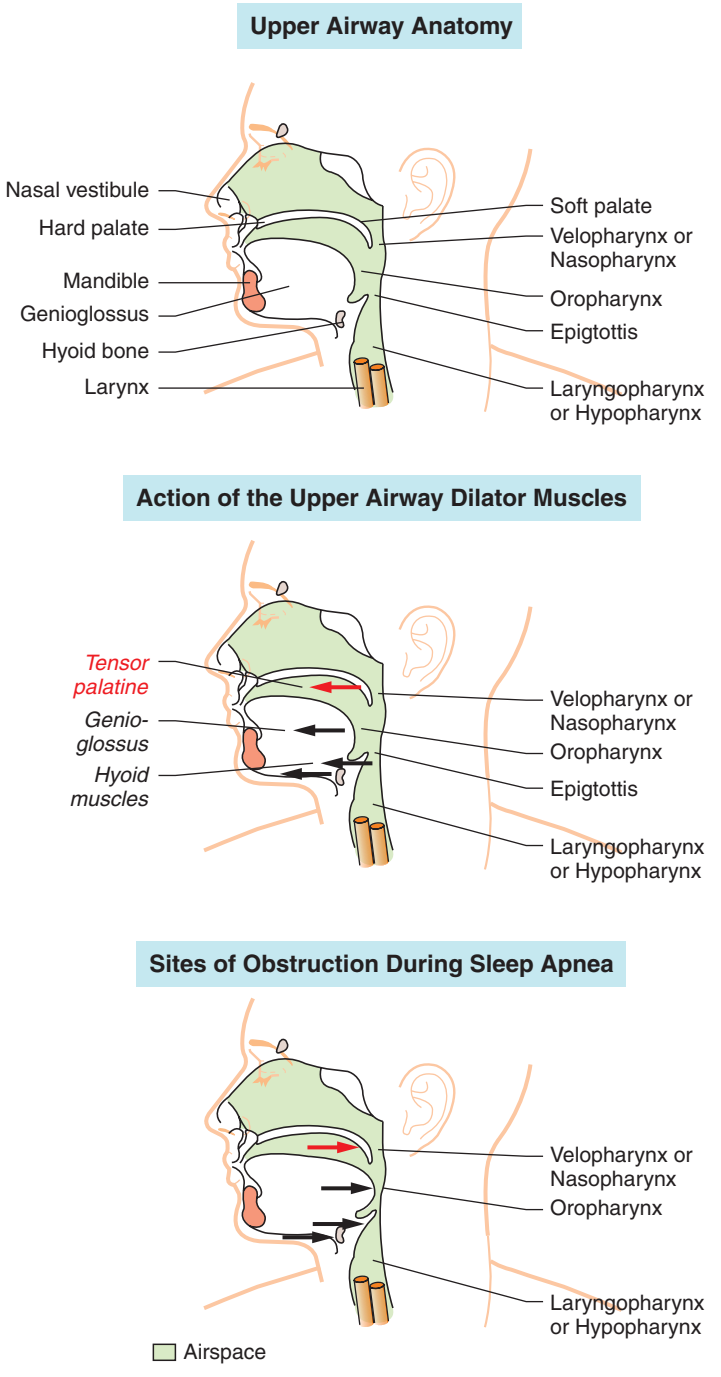

FIGURE 22–3. Airway obstruction during sleep apnea. (Reprinted from Benumof JL. Obstructive sleep apnea in the adult obese patient: implications for airway management. J Clin Anesth 2001; 13:144, with permission from Elsevier.)

sodes of central apnea from progressive desensitization of respiratory centers to hypercapnia initially are limited to sleep but eventually leads to a progressive reliance on hypoxic drive for ventilation. Pickwickian syndrome,[19] characterized by obesity, hypersomnolence, hypoxia, hypercapnia, right ventricular failure, and polycythemia, is the end result of OHS. Pulmonary, metabolic, neuromuscular, and genetic diseases should be excluded before making the diagnosis of OHS. Daytime hypoxemia and increased alveolar oxygen gradient found in these patients suggest that ventilation/perfusion inequalities as well as alveolar hypoventilation are an intrinsic part of this condition. Chronic daytime hypoxemia may be a better predictor of pulmonary hypertension and cor pulmonale than the presence and severity of OSA.[20] There is a strong correlation between increasing BMI >40 kg/m^2 and the likelihood of developing OHS.[21] Many obese patients with OHS also have OSA, but the reverse is not always true, suggesting that OHS is an autonomous disorder.[22]

Arterial blood gas (ABG) analysis should be obtained in any morbidly obese patient with unexplained hypoxemia or features of cor pulmonale, because pulse oximetry detects oxyhemoglobin desaturation without considering contribution from hypercapnia. This results in inappropriate treatment with supplemental oxygen alone that does not reverse the hypoventilation.[17] An ABG confirms the presence of daytime hypercapnia and usually reveals compensated respiratory acidosis and hypoxemia. Elevated bicarbonate level is consistent with chronic hypercapnia.

Treatment of OHS with weight reduction, tracheostomy, or nocturnal positive-pressure support improves daytime hypercapnia and hypoxia without changing the abnormal ventilatory responses.

Cardiovascular System

The increased morbidity and mortality of obesity largely result from cardiovascular problems, including hypertension, ischemic heart disease, cardiac failure, cardiomyopathy, arrhythmias, dyslipidemia, and sudden cardiac death.[23] Total blood volume is increased in the obese but is less than in nonobese individuals when compared on a volume-to-weight basis (50 mL/kg compared to 70 mL/kg). Most of the extra blood volume supplies adipose tissue. Excess adiposity requires an increase in cardiac output to parallel the increase in oxygen consumption, leading to a systemic arteriovenous oxygen difference that remains normal or slightly above normal. Cardiac output increases with increasing weight (20–30 mL/kg of excess adipose tissue) because of ventricular dilation and an increase in stroke volume. Left ventricular dilation results in increased left ventricular wall stress leading to eccentric hypertrophy that leads to reduced left ventricular compliance, impairment of left ventricular filling (diastolic dysfunction), elevation of left ventricular end-diastolic pressure (LVEDP), and eventual pulmonary edema. The dilated left ventricle has a limited capacity to hypertrophy so, when left ventricular wall thickening fails to keep pace with dilation, systolic dysfunction ("obe-

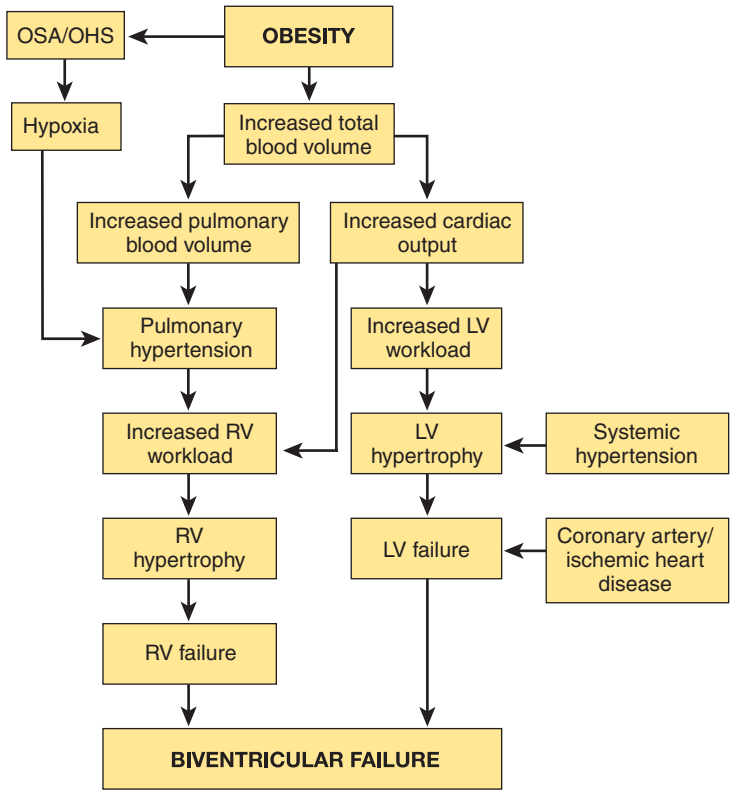

FIGURE 22–4. Interrelationship of cardiovascular and pulmonary sequelae of obesity. LV, left ventricle; OHS, obesity hypoventilation syndrome; OSA, obstructive sleep apnea; RV, right ventricle. (From Ogunnaike and Whitten[97] with permission.)

sity cardiomyopathy") results with eventual biventricular failure (Figure 22–4). Increased workload on the heart is suggested by an increase in cardiac weight with increasing BMI. The increased cardiac work may result in cardiomyopathy and cardiac failure, independent of other coexisting diseases such as hypertension, diabetes mellitus, or atherosclerosis. Cardiac weight decreases with weight loss. Obese subjects compensate for the increased workload by utilizing cardiac reserve, especially in the presence of hypertension. Systemic vascular resistance (SVR) usually is within normal limits in morbidly obese patients, suggesting that hypertension and obesity can coexist with a normal SVR.

Obesity accelerates atherosclerosis; however, because of reduced mobility, morbidly obese patients appear asymptomatic in the face of significant cardiovascular disease; symptoms such as angina and exertional dyspnea occur only during periods of significant physical activity.[24] Cardiac output rises faster in response to exercise in the morbidly obese and often is associated with a rise in LVEDP and pulmonary capillary wedge pressure. Increase in cardiac output during exercise is achieved by increases in heart rate without a concomitant increase in stroke volume or ejection fraction but with an increase in filling pressures. Similar changes occur during the perioperative period. The expanded blood volume of the obese patient is distributed between the peripheral and central circulations, with both ventricles distended at end-diastole leading to the increase in stroke volume. This situation accounts for the increased cardiac output and the consistent increase in left ventricular stroke work. With the exception of renal and splanchnic blood flows, which increase with obesity, organ blood flow does not change significantly because the additional cardiac output is diverted to perfuse excess fat. Blood volume and cardiac output are approximately twice the values predicted for those with IBW, but when they are normalized for body surface area, they are within normal limits or slightly below normal. The chronically elevated preload causes dilation and hypertrophy of the left ventricle (eccentric hypertrophy). Systolic performance as well as compliance will suffer as workload of the heart increases correspondingly. Chronically increased cardiac output and blood volume may cause SVR to increase over time. A high SVR and high preload combination may lead to early left ventricular dysfunction and congestive heart failure.

Obesity is an independent risk factor for ischemic heart disease (IHD) and eventual heart failure. Cardiovascular disease is strongly associated with central (android) distribution of fat. Angina may actually be a direct symptom of obesity given that a significant number of obese patients with angina do not have demonstrable coronary artery disease.[25] The risk of heart failure increases by 5% for men and 7% for women for every 1 kg/m^2 increment in BMI.[26] Coronary blood flow reserve in obese patients is limited because of ventricular mass and metabolic demands of the myocardium. Weight loss reduces left ventricular volume and diastolic pressures during exercise and at rest. Body oxygen consumption, blood volume, cardiac output, stroke volume, and blood pressure also decrease. Intraoperative cardiac failure can occur from rapid intravenous fluid administration (indicating left ventricular diastolic dysfunction), negative inotropy of anesthetic agents, or pulmonary hypertension precipitated by hypoxia or hypercapnia.

Cardiac arrhythmias can be precipitated by fatty infiltration of the conduction system, hypoxia, hypercapnia, electrolyte imbalance, coronary artery disease, increased circulating catecholamines, OSA, and myocardial hypertrophy. ECG findings frequently seen in morbidly obese patients include low QRS voltage, multiple criteria for LVH and left atrial enlargement, and T-wave flattening in the inferior and lateral leads.[27] In addition, there is a leftward shift of the P-wave, QRS complex, and T-wave axes, lengthening of the corrected QT interval, and prolonged QT interval duration. Substantial weight reduction can reverse many of these ECG abnormalities by shifting the mean P-wave, QRS, and T-wave axes rightward, significant reduction in the frequency of low QRS voltage, lower frequency of LVH, and marked decrease in T-wave flattening in the inferior and lateral leads.[28] Echocardiography usually shows increased cardiac output, increased LVEDP, and LVH in otherwise healthy obese subjects.

Mild to moderate hypertension is common in obese patients. Hyperten-

sion leads to a significant increase in cardiovascular mortality, especially in those with hypercholesterolemia or diabetes.[29] There is a 3–4 mm Hg increase in systolic arterial pressure and a 2 mm Hg increase in diastolic arterial pressure for every 10 kg of weight gained. Their expanded blood volume causes increased cardiac output with a lower calculated SVR for the same level of arterial blood pressure. The renin–angiotensin–aldosterone system (RAAS) has been implicated in the hypertension of obesity. Circulating levels of angiotensinogen, aldosterone, and angiotensin-converting enzyme (ACE) increase. As little as 5% reduction in body weight leads to a significant reduction in activity of the RAAS in both plasma and adipose tissue, contributing to a reduction in blood pressure.[30] With obesity, most tissues have a normal to increased level of sympathetic nervous system activity. An increased basal level of sympathetic activity predisposes to insulin resistance, dyslipidemia, and hypertension.[31] Obesity-induced insulin resistance enhances the pressor activity of norepinephrine and angiotensin II.[29] Hyperinsulinemia further activates the sympathetic nervous system causing sodium retention and contributing to the hypertension of obesity.[32] Hypertension causes concentric hypertrophy of the ventricle in normal-weight individuals but causes eccentric dilation in obese subjects.[33] It is associated with increased preload and stroke work. The combination of obesity and hypertension causes left ventricular wall thickening and a larger heart volume and, therefore, increased likelihood of cardiac failure (Figure 22–5).

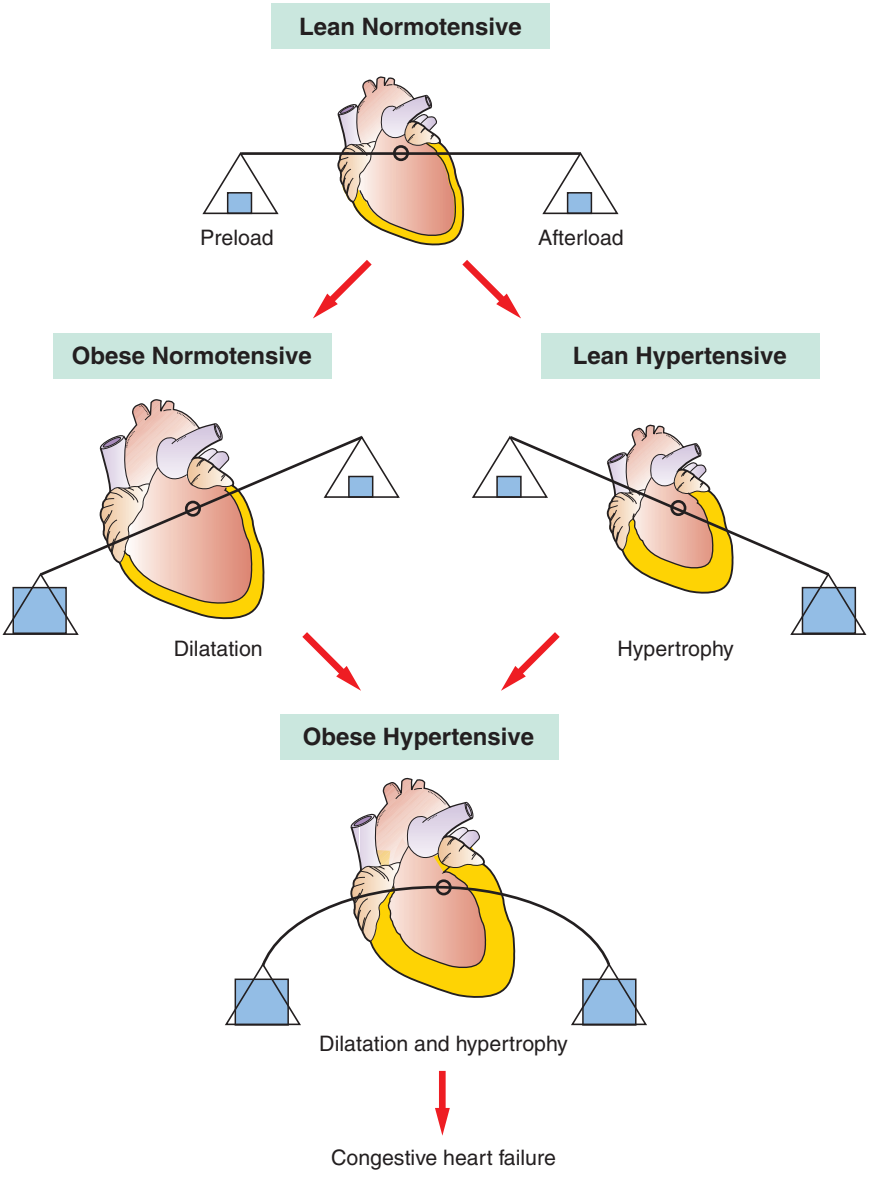

FIGURE 22–5. Adaptation of the heart to obesity and hypertension. (Reprinted from Messerli FH. Cardiovascular effects of obesity and hypertension. Lancet 1982;1:1165, with permission from Elsevier.)

A hypofibrinolytic and hypercoagulable state predisposes the obese patient to cardiovascular disease.[34] Obese patients have higher levels of fibrinogen (a marker for the inflammatory process of atherosclerosis), factor VII, factor VIII, von Willebrand factor, and plasminogen activator inhibitor-1 (PAI-1).[34] Increased fibrinogen, factor VII, and factor VIII levels and hypofibrinolysis as a result of increased PAI-1 levels are associated with hypercoagulability in obese patients. Significant decrease in fibrinogen concentration requires substantial (>40%) weight loss.[35] High factor VIII coagulant activity levels are associated with increased cardiovascular mortality. High fasting triglyceride levels also correlate with increased factor VII concentrations, whereas postprandial lipemia causes activation of factor VII. Factor VII levels are decreased by weight loss via a decrease in plasma triglyceride levels. Visceral (abdominal) fat is associated with increased levels of factor VIII and von Willebrand factor. Endothelial dysfunction induced by insulin increases von Willebrand factor and factor VIII levels, predisposing to fibrin formation. PAI-1 is secreted by the endothelium, vascular smooth muscle cells, hepatocytes, and adipocytes. Increased secretion of PAI-1 is associated with visceral obesity and inhibits the fibrinolytic system. PAI-1 is a significant cardiovascular risk factor because it decreases fibrinolysis and increases the risk of coronary artery disease.[36]

Gastrointestinal/ Hepatic System

Gastric volume and acidity are increased, hepatic function altered, and drug metabolism adversely affected by obesity. A significant number of fasted morbidly obese patients have gastric volumes >25 mL and gastric pH <2.5, which are the generally accepted volume and pH indicative of high risk for pneumonitis in the event of regurgitation and aspiration. Gastric emptying can be delayed in obese

patients because of increased abdominal mass that causes antral distension, gastrin release, and a decrease in pH with parietal cell hypersecretion; however, emptying has been documented to be faster with high-energy-content intake such as fat emulsions, but residual volume is increased because of their larger gastric volume (up to 75% larger). Both faster gastric emptying and larger gastric volume can be partially reversed by weight loss.[37] Accelerated gastric emptying induces hunger and frequent eating by reducing the negative feedback satiety signal produced by the presence of nutrients inside the stomach, thus precipitating a feeling of hunger and shortening the interval between consecutive meals.[38]

An increased incidence of hiatal hernia and gastroesophageal reflux increases aspiration risk. Fasting, nonpremedicated, nondiabetic obese surgical patients who have no significant gastroesophageal pathology are not more likely to have high-volume, low-pH gastric contents than are lean patients at the time of general anesthetic induction after routine preoperative fasting.[39] They should follow the same guidelines as those used for nonobese patients and be allowed to drink clear liquids (up to 300 mL) until 2 hours before elective surgery, a quantity that has been shown not to adversely affect gastric pH and volume at induction of anesthesia.[40] There is a positive correlation between obesity and frequent gastroesophageal reflux disease (GERD) symptoms and between obesity and esophageal erosions.[41] One mechanism by which obesity increases the risk of GERD is via mechanical factors whereby abdominal obesity increases intragastric pressure, increasing the frequency of transient lower esophageal sphincter relaxation and/or formation of hiatal hernia. The risk of GERD symptoms, erosive esophagitis, and esophageal adenocarcinoma is increased with obesity when compared with normal BMI.[42] The increased risk of GERD with obesity is such that a $>3.5\ kg/m^2$ increase in BMI is associated with a 2.7-fold increase in risk for developing new reflux symptoms.[43] Weight loss, including that through surgery, significantly improves GERD symptoms.[44] The combination of hiatal hernia, gastroesophageal reflux, and delayed gastric emptying, coupled with increased intraabdominal pressure and a high-volume, low-pH gastric content, puts the obese at risk for increased incidence of severe pneumonitis should aspiration occur.

Peculiar morphologic and biochemical abnormalities of the liver associated with obesity include fatty infiltration, inflammation, focal necrosis, and cirrhosis. Fatty infiltration reflects the duration rather than the degree of obesity. Histologic and liver function test abnormalities are relatively common in the obese, but clearance usually is not reduced. Abnormal liver function tests are seen in up to one third of obese patients who have no evidence of concomitant liver disease; increased alanine aminotransferase (ALT) is most frequently seen. Weight loss results in sustained improvement in liver enzymes in direct proportion to the extent of weight reduction.[45] Despite these histologic and enzymatic changes, no clear correlation exists between routine liver function tests and the capacity of the liver to metabolize drugs.[46] Hepatic decompensation can occur after Roux-en-Y gastric bypass, which necessitates careful assessment for preexisting liver disease in candidates scheduled to undergo this procedure because of a high prevalence (63%) of nonalcoholic fatty liver disease (NAFLD) and cirrhosis.[47] Obesity is a major risk factor for NAFLD and nonalcoholic steatohepatitis (NASH). NAFLD is a group of liver abnormalities associated with obesity and insulin resistance. Hepatomegaly, elevated liver enzyme levels, and abnormal liver histology (including steatosis, steatohepatitis, fibrosis, and cirrhosis) are intrinsic components of this disease.[48] NAFLD is the most common liver disease worldwide. The more progressive forms of NAFLD, NASH, and associated hepatic fibrosis are strongly associated with obesity and the metabolic syndrome.[49] Up to 95% of morbidly obese patients have NASH.[50] NASH is an aggressive form of NAFLD that can progress to cirrhosis or hepatocellular carcinoma. Insulin resistance and features of metabolic syndrome are good predictors of NASH.[51] Fatty liver disease often represents the hepatic component of the metabolic syndrome characterized by obesity, hyperinsulinemia, peripheral insulin resistance, diabetes mellitus, hypertriglyceridemia, and hypertension.[52] Massive weight loss in nondiabetic, nonalcoholic morbidly obese subjects leads to significant improvement in NASH and liver fibrosis.[53] Major improvements have been demonstrated in the biochemical and histologic features of liver disease associated with obesity and metabolic syndrome after surgical weight loss. Those with metabolic syndrome have greater initial histologic abnormalities and greater improvement with weight loss.[54]

The incidence of gallbladder disease, including cholelithiasis, is significantly increased in morbidly obese subjects; the relative risk appears to be positively correlated with increasing BMI.[55] Obesity, particularly in male patients, results in earlier onset of biliary disease and an increase in its prevalence.[55] After intestinal bypass surgery, patients have a particularly high prevalence of hepatic dysfunction and cholelithiasis; abnormal cholesterol metabolism is partially to blame.

Renal, Endocrine, and Metabolic Systems

Impaired glucose tolerance in the morbidly obese is reflected by a high prevalence of type 2 diabetes mellitus as a result of the resistance of peripheral fatty tissues to insulin. The severity of diabetes mellitus depends on the degree and duration of the obesity. A significant number of obese patients have an abnormal glucose tolerance that predisposes them to wound infection and an increased risk of myocardial infarction.[56] Exogenous insulin may be required perioperatively to oppose the catabolic response to the stress of surgery, even in obese patients on oral hypoglycemic agents. Abnormal serum lipid profiles may explain the high prevalence of ischemic heart disease. Gastric bypass surgery improves or even cures type 2 diabetes mellitus by substantially improving insulin resistance through an unknown mechanism. Marked improvement in insulin resistance or complete loss of insulin resistance has been seen as early as 6 days following gastric bypass surgery; suggesting that bypass of the stomach and duodenum results in physiologic changes that either inhibit the stress response to surgery, or more likely, alleviate insulin resistance to such an extent that postsurgical insulin resistance is not manifest.[57]

Subclinical hypothyroidism occurs in approximately 25% of all morbidly obese patients.[58] Thyroid-stimulating hormone (TSH) levels are frequently elevated, suggesting the possibility that

obesity leads to a state of thyroid hormone resistance in peripheral tissues.[59,60] Hypothyroidism should be considered in any obese patient who displays perioperative cardiovascular or respiratory instability. Hypoglycemia, hyponatremia, and impaired hepatic drug metabolism are other adverse consequences of hypothyroidism. Reduction of thyroxine requirements is seen with a decrease in BMI.[61]

Obesity is a major risk factor for end-stage renal disease (ESRD) and essential hypertension. It induces high blood pressure through increased renal tubular sodium reabsorption, impaired pressure natriuresis, volume expansion resulting from activation of the sympathetic nervous system and renin–angiotensin system, and physical compression of the kidneys, especially when visceral obesity is present. Renal vasodilatation and glomerular hyperfiltration initially serve as compensatory mechanisms to maintain sodium balance in the face of increased tubular reabsorption. These changes, plus the increased systemic arterial pressure, create a hemodynamic burden on the kidneys leading to glomerular injury.[62] Chronic obesity results in increasing urinary protein excretion and gradual loss of nephron function that worsens with time and exacerbates hypertension. Kidney disease progresses much faster when type 2 diabetes mellitus and other metabolic problems supervene. Weight loss is an essential first step in managing the hypertension and renal disease of obesity. Obesity-related glomerular hyperfiltration decreases after weight loss, which decreases the incidence of overt glomerulopathy.[63] Up to a 10-fold increase in the biopsy incidence of obesity-related glomerulopathy has been documented.[64] Obesity-related glomerulopathy is defined as focal segmental glomerulosclerosis and glomerulopathy or glomerulopathy alone. Increased BMI in men is associated with an increased risk of development of ESRD, independent of blood pressure and proteinuria; maintenance of optimal body weight reduces the risk of ESRD.[65] Despite the negative association of obesity and kidney disease, a "reverse epidemiology" model has been documented in obese patients undergoing maintenance hemodialysis for ESRD whereby the association of obesity and renal disease occurs in the opposite direction, with obesity conferring survival advantages to hemodialysis patients.[66]

The Metabolic Syndrome

Obesity plays a major role in the development of the metabolic syndrome, a clinical entity resulting from the interaction of genetic, hormonal, and lifestyle factors. Components of the syndrome include insulin resistance, diabetes mellitus (or impaired glucose tolerance), hypertension, coronary artery disease, peripheral vascular disease, stroke, and hyperlipidemia.[67] The metabolic syndrome can be perceived as a prediabetes state because it takes into account the two major outcomes: cardiovascular disease and type 2 diabetes mellitus.[68] According to the International Diabetes Federation, a person diagnosed with metabolic syndrome must have central obesity (defined as WC >94 cm for men and >80 cm for women) plus any two of the following four factors[69]:

1. Raised serum triglyceride level (≥ 1.7 mmol/L)
2. Reduced serum high-density lipoprotein (HDL) cholesterol level (<1.03 mmol/L in males and <1.29 mmol/L in females)
3. Raised blood pressure (systolic blood pressure ≥ 130 mm Hg or diastolic blood pressure ≥ 85 mm Hg) or treatment of previously diagnosed hypertension
4. Abnormal fasting plasma glucose level (fasting plasma glucose level ≥5.6 mmol/L) or previously diagnosed type 2 diabetes mellitus

The metabolic syndrome represents a cluster of the most dangerous heart attack risk factors, including diabetes (or prediabetes), abdominal obesity, changes in cholesterol level, and high blood pressure. People with this syndrome have up to a 5-fold greater risk of developing type 2 diabetes mellitus (if not already present). They are twice as likely to die from and three times more likely to have a heart attack or stroke compared to people without the syndrome.

Insulin resistance is associated with elevated plasma leptin levels independent of body fat mass. Leptin is a hormone secreted by the adipose tissue that binds to receptors in the hypothalamus to influence the normal regulation of body weight and energy expenditure. Obesity has been suggested to be a leptin-resistant state given that leptin levels are elevated in most obese individuals.[70]

PHARMACOLOGY

The pharmacokinetics of drugs in obese patients are significantly influenced by differences in tissue distribution, hemodynamics, and blood flow to adipose, splanchnic, and other tissues, plasma composition, or liver and kidney function.[71] The effect of obesity on the pharmacokinetic parameters of anesthetic drugs depends on lipid solubility and diffusion through body compartments and tissues. General pharmacokinetic principles dictate that drug dosing should take into consideration the volume of distribution (V_d) for administration of the loading dose and the clearance for the maintenance dose.[72] The loading dose for a drug that is mainly distributed to lean tissues should be calculated based on IBW, whereas dosing should be calculated based on total body weight (TBW) if the drug is equally distributed between adipose and lean tissues. For maintenance, the maintenance dose for a drug with similar clearance values in both obese and nonobese individuals should be calculated based on IBW, whereas the maintenance dose for a drug whose clearance increases with obesity should be calculated according to TBW.

Changes in V_d correlate well with drug lipophilicity. Drugs with a high affinity for fat have an increased V_d, whereas drugs with low partition coefficients do not have significant alteration in V_d. The volume of the central compartment in which drugs are first distributed remains unchanged in obese patients, but absolute body water content is decreased and lean body adipose tissue mass is increased, affecting lipophilic and polar drug distribution. The V_d in obese patients is affected by reduced total body water, increased total body fat, increased lean body mass (LBM), altered protein binding, increased blood volume, increased cardiac output, increased serum concentrations of free fatty acids, triglycerides, cholesterol, and α_1-acid glycoprotein, lipophilicity of the drug, and organomegaly.[73] Increased distribution of a drug prolongs its elimination half-life whether clearance remains the same or is increased. In general, more

lipophilic compounds are affected by obesity to a greater extent than are hydrophilic compounds. Lipophilic compounds are associated with increases in V_d with some exceptions, such as digoxin, procainamide, and cyclosporine, which are highly lipophilic substances but have comparable volumes of distribution in obese and nonobese subjects.[73]

Changes in concentration of plasma proteins or alterations in their affinity for substrate affect movement of drugs into tissue compartments.[73] The major plasma proteins are albumin (primarily responsible for binding acidic drugs), α_1-acid glycoprotein (primarily responsible for binding basic drugs), and lipoproteins. Plasma protein binding of acidic drugs may decrease in an obese patient because of the obesity-associated decrease in albumin levels and an increase in concentration of α_1-acid glycoprotein. Hyperlipidemia and an increased concentration of α_1-acid glycoprotein affect protein binding and lead to a reduction in free drug concentration. Drugs that are primarily bound to albumin (e.g., thiopentone, phenytoin) show no significant changes in protein binding in obese individuals, whereas binding of drugs to α_1-acid glycoprotein increases. Lipoprotein levels may be elevated in obese individuals because of higher triglyceride and cholesterol levels. Overall evidence suggests that plasma protein binding affinity may change in obesity without changes in protein concentrations.

As earlier mentioned, histologic and liver function abnormalities are common in the obese with concomitant deranged liver function tests; however, metabolism and clearance usually are not adversely affected. Drugs that undergo phase I metabolism (oxidation, reduction, hydrolysis) and acetylation (a phase II reaction) are generally unaffected by obesity-induced changes, whereas other phase II reactions (sulfation and glucuronidation) are enhanced. Renal clearance, glomerular filtration rate, and tubular secretion are increased, with tubular secretion disproportionately enhanced compared to glomerular filtration. Therefore, drugs that depend on the kidneys for elimination face consistently higher clearance rate in obese patients.[74] Orally administered medications are expected to have decreased bioavailability in obese patients because of increased splanchnic blood flow, but no evidence suggests a significant difference in the absorption and bioavailability of orally administered drugs when comparing obese to nonobese subjects. Hemodynamic and regional blood flow changes resulting from obesity impact drug pharmacokinetics. Reduced cardiac performance from obesity itself further compromises tissue perfusion.[72]

Increase in LBM accounts for approximately 20–40% of an obese patient's increase in TBW; therefore, adding 20% to the estimated IBW is sufficient to include the extra lean mass. Nondepolarizing muscle relaxants can be dosed in this manner. Increased blood volume in the obese patient decreases the plasma concentrations of rapidly injected intravenous drugs. Fat, however, has poor blood flow; therefore, doses calculated on actual body weight could lead to excessive plasma concentrations. A reasonable approach is to calculate the initial doses based on IBW and subsequent doses determined by pharmacologic response to the initial dose. Repeated injections accumulate in fat, leading to prolonged response as a result of subsequent release from this large fat depot.

SPECIFIC INTRAVENOUS AGENTS (TABLE 22–4)

Thiopental

Thiopental is highly lipophilic and has a larger V_d in obese patients; prolonged somnolence is expected. Increased blood volume, cardiac output, and muscle mass necessitate an increase in the initial induction dose. Thiopental pharmacokinetics are consistent, with easy and fast penetration through different tissue barriers and ultrashort-acting and high potency. The V_d is larger in obese than in nonobese patients, although elimination half-life is significantly longer in the obese. Obese patients require much less thiopental per body weight for induction than do nonobese patients. Both the terminal half-life and steady-state volume of distribution are increased. They are more sensitive to the effects of thiopental dosed according to TBW. Obese people should receive induction doses of thiopental adjusted to IBW.[75] Continuous infusion results in longer elimination half-life because of a larger V_d; however, clearance remains unaltered.

Propofol

Propofol rapidly redistributes into inactive tissue depots, such as fat and muscle, after its initial rapid crossover into the blood–brain barrier and redistribution to the central nervous system. Both the V_d and clearance of propofol in obese and nonobese subjects correlate well with TBW without signs of accumulation and prolongation of action because the half-life is similar in obese and nonobese subjects as a result of the increase in both V_d and clearance.[76] These properties and the pharmacokinetic behavior of propofol suggest that both the induction and maintenance dosing for propofol in both obese and nonobese individuals should be based on TBW. However, the negative cardiovascular effects of large doses of propofol combined with the negative physiologic effects of obesity on the cardiovascular system should prompt a somewhat reduced total dose.

Midazolam

Significant increase in both V_d and elimination half-life has been demonstrated in obese patients, with good correlation between lipid solubility and distribution profile in adipose tissue. Midazolam is relatively shorter acting compared to other benzodiazepines; therefore, the intensity and duration of its sedative side effects after a single intravenous dose correlate better with the extent of distribution of the drug than on the rate of elimination and clearance.[77] The total V_d and elimination half-life of midazolam in the obese is up to three times larger and three times prolonged than in nonobese subjects with no difference in the clearance rates, suggesting that adiposity per se does not alter the capacity of the liver to metabolize midazolam. A single intravenous dose of midazolam should therefore be administered based on TBW, but continuous infusion dosing should be adjusted according to IBW rather than TBW. Even though midazolam is considered short acting, it has the potential to accumulate and cause prolonged sedation in obese patients because larger initial doses are required to achieve adequate serum concentrations.

Neuromuscular Blocking Agents

Muscle relaxants are polar and hydrophilic drugs that are distributed poorly

TABLE 22–4.

Intravenous Drug Dosing in Obesity

Drug	Dosing	Comments
Thiopental	IBW (somewhat increased)	Increased V_d, increased blood volume, cardiac output, and muscle mass. Increased absolute dose. Prolonged duration of action. Longer elimination half-life. Adjust loading/induction dose accordingly.
Propofol	Induction: TBW (somewhat reduced) Maintenance: TBW	Highly lipophilic. Total clearance and V_d at steady state correlate well with TBW. Keep in mind negative cardiovascular effects. High affinity for well-perfused organs.
Midazolam	Loading dose: TBW (somewhat reduced) Maintenance infusion: IBW	Significant increase in V_d and elimination half-life. Sedative effect correlates better with distribution than elimination/clearance. Prolonged sedation because higher loading dose is needed to achieve adequate serum concentration.
Succinylcholine	TBW	Larger extracellular fluid compartment in the obese. Pseudocholinesterase activity increases with increasing weight.
Rocuronium	IBW	Faster onset and longer duration when dosed according to TBW. Pharmacokinetics and pharmacodynamics not altered in obese subjects.
Vecuronium	IBW	Prolonged action when dosed according to TBW. Obesity does not alter distribution or elimination of the drug.
Atracurium	TBW	V_d, absolute clearance, and elimination half-life unchanged by obesity. Unchanged dose per unit body weight prolongation of recovery because of organ-independent elimination.
Cisatracurium	IBW	Pharmacokinetics similar to atracurium but prolonged duration of action when dosed according to TBW.
Fentanyl	Derived "pharmacokinetic (PK) mass"	Measured total body clearance has a nonlinear relationship to TBW. Fentanyl dosing based on pharmacokinetic mass correlates better with clearance. Dosing based on TBW overestimates does requirements in the obese.
Sufentanil	Loading dose: TBW Maintenance: IBW	Increased V_d and prolonged elimination half-life, which correlates with degree of obesity. Clearance similar in obese and nonobese. Overestimation of plasma concentration occurs in the morbidly obese range (BMI >40 kg/m²).
Remifentanil	IBW	Pharmacokinetics similar in obese and nonobese subjects. Systemic clearance and V_d corrected per kg of TBW is significantly smaller in the obese. Consider age and lean body mass for dosing.
Dexmedetomidine	TBW	Lacks significant effect on respiration. Ideally suitable as an analgesic adjuvant in morbidly obese subjects in whom opioid-induced respiratory depression may be catastrophic.

BMI, body mass index; IBW, ideal body weight; TBW; total body weight; V_d, volume of distribution.

into excess adipose tissue. Obese individuals have a larger absolute LBM in conjunction with extra adipose tissue and a decreased proportion of muscle mass and body water when compared to nonobese subjects.[46] Drugs with weak or moderate lipophilicity have fairly predictable effects in obese patients because of their distribution mainly into lean tissues; therefore, they should be dosed based on IBW rather than TBW with the exception of succinylcholine.[78]

Succinylcholine

Succinylcholine should be dosed based on TBW. Larger extracellular fluid compartment and a linear increase in pseudocholinesterase activity with weight gain necessitate an increase in succinylcholine dosage in obese patients. The potency estimates for succinylcholine in obese adolescents with BMI >30 kg/m^2 are similar to those of nonobese adolescents in the same age group when calculated based on TBW.[79]

Nondepolarizing Muscle Relaxants

Nondepolarizing muscle relaxants should be administered according to LBM to prevent delayed recovery because of increased V_d and impaired hepatic clearance. The effects of obesity on the pharmacodynamics of nondepolarizing relaxants vary with the composition and distribution of body fat. There is no alteration in the pharmacokinetics of rocuronium in obese female patients when compared to normal weight patients; similarly, the V_d, distribution and elimination half-lives, plasma clearance, and mean residence are not different. Pharmacodynamic parameters of rocuronium, including onset time, duration, and recovery times, also are comparable.[78] The duration of action of rocuronium in obese patients is significantly longer when dosed according to TBW, prompting the recommendation that rocuronium be administered to morbidly obese patients on the basis of IBW.[80] Vecuronium pharmacokinetics and pharmacodynamics in obese patients are consistent with dosing on the basis of IBW because the V_d, plasma clearance, and elimination half-life of vecuronium are not different between obese and nonobese patients.[81] However, vecuronium action is prolonged when dosed according to TBW because of the excess dose administered; obesity does not alter the distribution or elimination of the drug. The

V_d, absolute clearance, and elimination half-life of atracurium are unchanged by obesity. However, if dosed according to TBW, atracurium concentrations are higher in obese patients than in the nonobese with no increase in recovery times. The median effective dose is higher; therefore, dosing can be based on TBW with some reduction in the total dose.[82] The duration of action of cisatracurium is prolonged in the morbidly obese when dosed according to TBW, suggesting that dosing based on IBW is optimal in this group of patients.[83]

Opioids

All synthetic opioids are highly lipophilic drugs. Application of non–weight-based pharmacokinetic models for fentanyl derived from normal-weight patients overestimates the plasma concentration of fentanyl as body weight increases from normal to morbid obesity. Fentanyl dosing based on a derived "pharmacokinetic mass" (derived pharmacokinetic body weight for dosing) is clinically more useful than that based on TBW because of the strong linear correlation between this derived mass and total body clearance.[84] Administration of fentanyl according to TBW overestimates fentanyl dose requirements in obese patients. Pharmacokinetic mass is the dosing weight for fentanyl that reflects the influence of TBW on clearance.[84] Fentanyl dosing for postoperative analgesia also correlates with pharmacokinetic mass.[85] Sufentanil is highly lipid soluble and distributes extensively in excess body fat as well as in lean tissues. It has an increased V_d and a prolonged elimination half-life that correlates positively with the degree of obesity. However, plasma clearance is similar in obese and nonobese patients; therefore, loading dose should account for total body mass, whereas maintenance and infusion dosing should be reduced and dosed according to IBW. Pharmacokinetic parameters derived from nonobese subjects accurately predict plasma sufentanil concentrations in morbidly obese subjects, but overestimation of plasma sufentanil concentration rises in patients with BMI >40 kg/m^2.[86] Remifentanil is a fentanyl congener that is hydrolyzed by blood and tissue esterases, leading to rapid metabolism and inactive products. No difference has been reported in the estimates of V_d of remifentanil between obese and nonobese subjects, but the V_d is less than expected for lipid-soluble molecules with only modest distribution into body tissues.[87] Remifentanil pharmacokinetics is more closely related to LBM than to TBW; therefore, dosing should be based on IBW.[87]

Dexmedetomidine

Dexmedetomidine is a highly specific α_2-adrenergic agonist with an eight times higher affinity than clonidine for the α_2-adrenoceptor.[88] It has sedative–hypnotic, anesthetic-sparing, analgesic, and sympatholytic properties. Dexmedetomidine lacks significant effects on respiration, making it ideally suitable as an analgesic adjuvant in morbidly obese subjects in whom opioid-induced respiratory depression may be catastrophic.[89] α_2-Agonists produce transient hypertension at higher doses; therefore, slow intravenous loading over 10–20 minutes is recommended to reduce these effects on heart rate and blood pressure. At infusion rates of 0.2–0.7 μg/kg/h, dexmedetomidine produces clinically effective sedation with decreased analgesic and anesthetic requirements.

MEDICAL AND SURGICAL THERAPY FOR OBESITY

Antiobesity medications are formulated to reduce energy intake, increase energy utilization, or decrease absorption of nutrients. Indications for drug treatment include BMI ≥30 kg/m^2 or BMI between 27 and 29.9 kg/m^2 in conjunction with an obesity-related medical complication. The combination of phentermine and fenfluramine (Phen-Fen) previously was popular for obesity treatment until evidence indicated its association with valvular heart disease and pulmonary hypertension. Sibutramine and orlistat are recently approved antiobesity medications for long-term use that have not yet been associated with such detrimental side effects. Sibutramine inhibits the reuptake of both serotonin and norepinephrine to increase satiety after the onset of eating rather than reduce appetite; it does not promote the release of serotonin, unlike fenfluramine and dexfenfluramine, which primarily increase the release of serotonin in brain synapses and also inhibits reuptake to produce anorexia. Sibutramine does not deplete the neural synapses of catecholamines; therefore, dangerous hypotension that is unresponsive to indirectly acting vasopressors, seen with fenfluramine and dexfenfluramine, does not occur. Orlistat blocks the absorption and digestion of dietary fat by binding lipases in the gastrointestinal tract. It improves cardiovascular risk factors associated with obesity, such as hypertension, WC, fasting blood glucose levels, and lipid profile.[90] Low-density lipoprotein (LDL) and total cholesterol levels also decrease. An increase in the anticoagulant effect of warfarin is seen with chronic dosing of orlistat because of its side effect of decreasing absorption of fat-soluble vitamins, including vitamin K.[91] This results in an abnormal plasma thromboplastin time (PTT) because of deficiency of clotting factors II, VII, IX, and X.

Obesity (bariatric) surgery is generally classified into malabsorptive, restrictive, or combined. Malabsorptive procedures, which include jejunoileal bypass and biliopancreatic diversion, are rarely used today. Restrictive procedures include the vertical banded gastroplasty and the adjustable gastric banding. The Roux-en-Y gastric bypass combines gastric restriction with a minimal degree of malabsorption. Roux-en-Y gastric bypass is the most commonly performed bariatric procedure in the United States today. It involves anastomoses of the proximal gastric pouch to a segment of the proximal jejunum, bypassing most of the stomach and the entire duodenum. It is the most effective bariatric procedure for achieving safe short- and long-term weight loss in morbidly obese patients. Patients who have undergone Roux-en-Y gastric bypass lose an average of 50–60% excess body weight and decrease their BMI by approximately 10 kg/m^2 during the first 12–24 postoperative months. Type 2 diabetes mellitus resolves in >90% of patients after Roux-en-Y gastric bypass.[92] Adjustable gastric banding requires placement of an adjustable inflatable band around the proximal stomach to limit stomach capacity. Adjustments can be made to meet a patient's individual needs by adding to or removing saline from the silicone band, making it tighter or looser. All of these procedures can be performed under laparoscopy.

Rhabdomyolysis has been documented in morbidly obese patients undergoing prolonged procedures such as laparoscopic bariatric surgery; the main risk factor is prolonged duration of surgery. Elevations in serum creatinine and creatine phosphokinase (CPK) levels unexplained by other reasons and complaints of buttock, hip, or shoulder pain in the postoperative period should raise the suspicion of rhabdomyolysis.[93]

PREOPERATIVE EVALUATION

Evaluation of the cardiovascular and pulmonary systems is important because obese patients have significant derangement of these systems. Previous experiences as detailed by the patient and anesthetic records are useful sources of information. Explanation of perioperative anesthetic problems associated with morbid obesity has a significant effect on the type of anesthesia chosen by most obese patients. The majority (>50%) of patients would chose to attempt to lose weight before elective surgery if given the choice, rather than be subjected to the increased risk of anesthesia.[94]

Obese patients should be evaluated for systemic and pulmonary hypertension, signs of right and/or left ventricular or congestive cardiac failure, and ischemic heart disease. Excess adiposity may make signs of congestive cardiac failure difficult to elucidate. The chronicity of pulmonary impairment, including OSA and OHS, makes pulmonary hypertension common in morbidly obese patients. Tricuspid regurgitation noted on echocardiography is the most useful confirmatory test of pulmonary hypertension but should be combined with clinical features such as exertional dyspnea, fatigue, and syncope, which reflect inability to increase cardiac output in response to activity.[95] Features of RVH, such as tall precordial R waves, right axis deviation, and right ventricular strain pattern may be seen on ECG. Sensitivity of the ECG features correlates well with the degree of pulmonary hypertension. Chest radiographs may show evidence of underlying lung disease and prominent pulmonary arteries.

Patients who have previously undergone bariatric surgery should be screened for long-term metabolic and nutritional abnormalities during their preoperative visit. Common deficiencies include vitamin B_{12}, iron, calcium, and folic acid. A collective form of postoperative polyneuropathy, known as acute post–gastric reduction surgery (APGARS) neuropathy, could result from these deficiencies.[96] Patients with APGARS neuropathy present with protracted postoperative vomiting, hyporeflexia, and muscular weakness. Differential diagnoses of this disorder include thiamine deficiency (Wernicke encephalopathy, beriberi), vitamin B_{12} deficiency, and Guillain-Barré syndrome. Because of the associated hyporeflexia and muscular weakness, close attention should be paid to dosing and monitoring of neuromuscular blocking agents.[97] Electrolyte and coagulation indices should be checked before surgery, particularly in patients who have been chronically taking diuretics and weight loss medications and in those who are acutely ill or poorly compliant with vitamin and nutritional supplements. Chronic vitamin K deficiency can result in coagulation abnormalities requiring vitamin K analogue or fresh-frozen plasma.

Evidence for OSA and OHS should be sought during the preoperative visit because these conditions are frequently associated with difficult laryngoscopy and intubation. Inquiry should be made about snoring or apnea during sleep, frequent arousals, and daytime somnolence. History of hypertension or neck circumference >40 cm correlates with an increased probability of OSA. OSA is a legitimate reason to delay elective surgery in order to obtain a proper workup.[15] A formal sleep study may be indicated for quantifying its severity. Patients requiring general anesthesia should be treated as having severe OSA. Regional anesthesia should be considered if it is technically feasible. OSA patients should generally be treated as inpatients; however, outpatient surgery can be considered in the following circumstances: mild OSA, local or regional anesthesia with minimal or no sedation, 23-hour observation in the postanesthesia care unit (PACU) following surgery, and patients taking oral medication at the time of discharge. Patients on continuous positive airway pressure device (CPAP) at home should be encouraged to bring the device to the hospital because it may be needed postoperatively. The possibility of invasive monitoring, prolonged endotracheal intubation, and postoperative mechanical ventilation should be discussed during the preoperative evaluation. Specialized tests such as pulmonary function tests and liver function tests need not be routinely obtained because they are not cost effective in asymptomatic morbidly obese patients. Blood glucose abnormalities should be corrected if present.

Preoperative Medications

All current medications should be continued until the time of surgery; with the possible exception of insulin and oral hypoglycemic agents. Antibiotic prophylaxis is important because of an increased incidence of wound infection in obese patients partly as a result of a decrease in tissue oxygenation.[98] Both bariatric and general elective surgeries carry an equivalent risk of postoperative wound infection in morbidly obese patients.[99] Oral benzodiazepines are reliable for anxiolysis and mild sedation; intravenous midazolam can be titrated in small doses during the immediate preoperative period. Prophylaxis against both aspiration pneumonitis and deep venous thrombosis (DVT) should be addressed during the preoperative period. H_2-receptor antagonists, nonparticulate antacids, and proton pump inhibitors all reduce gastric volume, acidity, or both, reducing the risk and severity of aspiration pneumonitis.

Obesity is a major independent risk factor for DVT and subsequent morbidity and mortality from postoperative pulmonary embolism.[100,101] Mini-dose subcutaneous heparin 5000 IU administered before surgery and repeated every 8–12 hours until the patient is fully mobile reduces this risk. The incidence of clinically evident DVT after laparoscopic Roux-en-Y gastric bypass is low when the procedure is accomplished in a relatively short time, with the initiation of calf-length pneumatic compression hose before induction of anesthesia and with routine early ambulation.[102] Meeting these conditions precludes any form of mandatory heparin anticoagulation except in patients with a history of prior DVT, those with a known hypercoagulable state, or with a significant family history of DVT. Preoperative inferior vena cava (IVC) filter placement is recommended for bariatric

surgery patients with prior pulmonary embolus, prior DVT, evidence of venous stasis, or hypercoagulable state.[103] Four important risk factors are significant in the development of postoperative venous thromboembolism: venous stasis disease, BMI ≥60, truncal obesity, and obesity hypoventilation/sleep apnea syndrome. If all of these factors are present, prophylactic IVC filter placement is highly recommended.[104] Many bariatric surgeons prefer low-dose unfractionated heparin as their primary method of thromboprophylaxis.[105] The use of a protocol for heparin dosing in gastric bypass patients as opposed to a fixed dose is the preferred method. Dose calculations based initially on height and weight and later adjusted according to peak anti–factor Xa activity result in better thromboprophylaxis and fewer side effects.[106] Low-molecular-weight heparins (LMWHs) have become popular for thromboembolism prophylaxis in bariatric surgery patients because of their bioavailability when injected subcutaneously. Subcutaneous enoxaparin, 40 mg every 12 hours, decreases the incidence of postoperative DVT without increasing bleeding complications.[107] Other authors have recommended that enoxaparin dosing in obese patients be varied according to age and LBM.[108]

AIRWAY

History obtained from the obese patient and examination of previous anesthetic records may divulge previous airway management difficulties. Anatomic changes of obesity that contribute to a potentially difficult airway include limitation of movement of the atlantoaxial joint and cervical spine by upper thoracic and low cervical fat pads, excessive tissue folds in the mouth and pharynx, short thick neck, suprasternal, presternal, and posterior cervical fat, and a very thick submental fat pad. Obese patients with OSA are significantly more difficult to intubate than patients without OSA; however, there is no relationship between the severity of sleep apnea and the occurrence of difficult intubation.[109] A short thick neck is significantly more related to difficult intubation, whereas obesity and a short thick neck are significantly related to each other, in addition to both being related to OSA. Patients with OSA have excess adipose tissue deposits in their pharyngeal area, including the tonsils, tonsillar pillars, uvula, tongue, aryepiglottic folds, and lateral pharyngeal walls.[15] This fat deposition is most pronounced in the lateral pharyngeal walls and may not be noticed during routine airway examination. Even with the presence of these anatomic changes and pathology, the magnitude of BMI does not correlate with the difficulty of laryngoscopy. Such difficulty correlates better with increased age, male sex, temporomandibular joint pathology, Mallampati classes 3 and 4, history of OSA, and abnormal upper teeth.[110] Neck circumference has been identified as the single biggest predictor of problematic intubation in morbidly obese patients.[111] A larger neck circumference is associated with the male sex, higher Mallampati score, grade 3 views at laryngoscopy, and OSA. The probability of a problematic intubation is approximately 5% with a 40-cm neck circumference compared with a 35% probability with a 60-cm neck circumference.[111]

PSYCHOLOGY OF THE OBESE

The general public often stigmatizes obesity. The belief that weight can be controlled and that obesity is a manifestation of character deficits makes the general public openly unkind to the obese. Obese people demonstrate poor well-being associated with psychological problems mainly because of discrimination. Increased anxiety, symptoms of depression, and a lower positive mental attitude toward life are some of the psychological problems. The health-related quality of life is worse in the severely obese than in other groups of patients with chronic diseases.[112]

Bariatric surgery is currently the most viable option for successful weight loss and maintenance; however, postsurgical drastic weight loss and alleviation of medical risks are accompanied by remarkable psychosocial changes.[113] Not all morbidly obese patients seeking surgery have elevated levels of psychopathology; however, postoperative improvements in mood have been consistently found despite the lack of preoperative psychopathology findings.[113] A positive correlation exists between presurgical severity of depression and 1-year success at weight loss after bariatric surgery.[114] More depressed individuals tend to lose more weight compared to less depressed individuals. Depression, anxiety, and poor self-esteem are prominent psychosocial symptoms that are part of the etiologic factors of obesity; however, the obese population generally does not manifest more severe psychopathology than does the nonobese population, and psychological symptoms are more likely a result of obesity rather than its cause.[115]

OBESITY AND AMBULATORY ANESTHESIA

The Royal College of Surgeons of England issued guidelines in 1992 that deemed patients with BMI >30 kg/m^2 unsuitable for ambulatory surgery.[116] Subsequent evaluation of adherence to these guidelines discovered that >85% of ambulatory surgery units in England and a significant number in other countries continued to routinely anesthetize patients with BMI >30 kg/m^2.[117,118] More than 75% of anesthesiologists responding to a survey believe that morbidly obese patients with comorbidities and no patient escort will be unsuitable for ambulatory anesthesia because many of them are in suboptimal health.[119] The presence of cardiovascular or respiratory comorbidity significantly reduces the willingness of anesthesiologists to provide ambulatory care to the obese.[119] An excess of adverse cardiovascular events has not been found in obese patients undergoing ambulatory surgery despite a prevalence of cardiovascular disease in this patient population; however, adverse intraoperative and postoperative respiratory events, including arterial oxygen desaturation and bronchospasm, are common.[120] Individual evaluation is the most prudent way to choose which obese patients can undergo ambulatory anesthesia and surgery. If an obese patient will require ambulatory anesthesia, the proper equipment and procedures for positioning and monitoring, including difficult airway and resuscitation equipment, should be readily available. Arrangements for transfer to a 23-hour observation unit or full admission unit should be in place. Ambulatory anesthesia for morbidly obese patients without significant comorbidities does

not increase risk. Obese patients do not have a higher incidence of contact with healthcare professionals after discharge from the ambulatory surgery unit; neither do they have a higher postambulatory surgery unplanned hospital admission rate than does the general population.[121] Although obesity is associated with higher regional block failure and complication rates during ambulatory regional anesthesia, the rates of successful blocks and overall satisfaction are high, enough that obese patients should not be excluded from ambulatory regional anesthesia procedures.[122]

INTRAOPERATIVE CONSIDERATIONS

Positioning

Obese patients may require specially designed tables or two regular operating tables for safe anesthesia and surgery. Regular operating tables have a maximum weight limit of approximately 205 kg, but wider and higher-capacity operating tables that can hold up to 450-kg patients and accommodate the extra girth are available. Electrically operated or motorized tables facilitate maneuvering into various surgically favorable positions. Use of belts, straps, and malleable bean bags helps keep obese patients from falling off the operating table. Pressure areas on the body should be protected with care to avoid neural injuries and possible pressure necrosis. Brachial plexus and lower-extremity nerve injuries are frequent. A documented association between ulnar neuropathy and increasing BMI quoted a >30% incidence of ulnar neuropathy in patients with BMI ≥38 kg/m^2 compared with only 1% in the control group.[123] Peripheral neuropathy occurs more frequently after bariatric surgery than after other abdominal surgery. Intraoperative neural compression or stretching from improper positioning is one of the most common etiologies. Malnutrition may be an important contributing factor; inflammation and altered immunity also play some role.[124] Other associated risk factors include greater absolute weight loss, a faster rate of weight loss, lower serum albumin and transferrin concentrations, prolonged postoperative gastrointestinal symptoms (nausea and vomiting, diarrhea, and dumping syndrome), and reduced vitamin and calcium supplementation.[124] Attention to patient positioning and duration of immobility during surgery helps to reduce the incidence of compression injuries and rhabdomyolysis during bariatric surgery. Micronutrient deficiencies (e.g., vitamins B_6, B_{12}, D, and E, folate) and mineral deficiencies (e.g., calcium, magnesium, phosphorus, selenium, and copper) contribute to nonmechanical peripheral neuropathies, especially in nutritionally noncompliant patients undergoing post–bariatric surgery procedures.[125] Nerve compression injury is more likely to occur in patients with micronutrient deficiencies.

Supine positioning of the obese patient causes aortic and IVC compression and leads to ventilatory impairment with further decrease in FRC and oxygenation. Trendelenburg positioning, further worsens FRC and should be avoided whenever possible. A simple change of the obese patient from the supine to sitting position causes a significant increase in cardiac output, oxygen consumption, and pulmonary artery pressure. The head-up (semirecumbent) or reverse Trendelenburg (semi-Fowler) position unloads the weight of the intraabdominal contents from the diaphragm, leading to increased pulmonary compliance and improved FRC and oxygenation. Both intraoperative positive end-expiratory pressure (PEEP) and reverse Trendelenburg position significantly decrease alveolar–arterial oxygen tension difference and increase total respiratory compliance to a similar degree in the obese, but reverse Trendelenburg position results in lower airway pressures. However, both maneuvers decrease cardiac output significantly, which partially counteracts their beneficial effects on oxygenation.[126] Prone positioning in the obese patient should be correctly performed with freedom of abdominal movement to prevent detrimental effects on lung compliance, ventilation, and arterial oxygenation. Prone positioning increases intraabdominal pressure, worsening IVC and aortic compression and further decreasing FRC. Lateral decubitus positioning allows for good diaphragmatic excursion during mechanical ventilation because the panniculus is displaced off the abdomen, reducing intraabdominal pressure.[127] Changing from sitting to lateral decubitus position after placing an epidural catheter may cause catheter dislodgment, resulting in inadequate analgesia because movement from sitting to lateral position increases the distance from the skin to the epidural space.[128]

Monitoring

Noninvasive blood pressure measurements can be falsely elevated if a cuff is too small for the limb. The blood pressure cuff bladder should encircle a minimum of 75% of the upper arm circumference or, preferably, the entire arm. Forearm blood pressure is a fairly good predictor of upper arm blood pressure in most patients; however, forearm measurements with a standard cuff may overestimate both systolic and diastolic blood pressures in obese patients.[129] Invasive arterial pressure monitoring is not always necessary but may be indicated for the morbidly obese with severe cardiopulmonary disease and for those with poor fit of the noninvasive blood pressure cuff. Central venous and pulmonary artery catheters may be indicated in patients undergoing extensive surgery in whom significant fluid shifts are anticipated and in those with significant cardiopulmonary impairment. Perioperative intravenous access can be problematic in this patient population and is another indication for central venous catheterization. Routine insertion of a central venous catheter is not necessary in obese patients because insertion of peripheral lines almost always is successful.[130]

Induction, Intubation, and Maintenance

Obese patients desaturate rapidly after loss of consciousness because of increased oxygen consumption and decreased FRC; therefore, adequate preoxygenation is vital prior to the induction of anesthesia. Application of positive-pressure ventilation during preoxygenation decreases atelectasis formation and improves oxygenation in morbidly obese patients.[131] Four vital capacity breaths with 100% oxygen within 30 seconds have been suggested as superior to the usually recommended 3 minutes of 100% preoxygenation in obese patients.[132] Preoxygenation in the head-up or sitting position is more effective and significantly extends the tolerance to apnea in obese patients when compared with

FIGURE 22–6. "Stacking" using towels and blankets. (From Ogunnaike and Whitten[97] with permission.)

the supine position.[133,134] This position provides the longest safe apnea period during induction of anesthesia.[135] The extra time gained helps preclude hypoxemia if intubation is delayed.

Obese patients may require larger doses of induction agents because blood volume, muscle mass, and cardiac output increase linearly with the degree of obesity. However, cardiovascular and respiratory depression may result from larger doses. Any of the intravenous induction agents is suitable after considering problems peculiar to individual patients. An increased dose of succinylcholine is necessary because of an increase in pseudocholinesterase activity. Myalgia following succinylcholine is not frequently seen in morbidly obese patients; therefore, succinylcholine is highly recommended for tracheal intubation.[136] If difficult intubation is anticipated, awake intubation under topical or regional anesthesia is a prudent approach. During awake intubation, sedative–hypnotic medications should be reduced to a minimum on order to prevent cardiorespiratory depression. An experienced colleague who is immediately available or, better still, is present in the room during induction and airway management can help with mask ventilation or further attempts at intubation. During endotracheal intubation under general anesthesia, hypoxia and aspiration of gastric contents should be prevented at all costs. Preparation should be made for the possibility of difficult intubation, and a surgeon capable of surgically accessing the airway should be readily available. Towels or folded blankets under the shoulders and head can compensate for the exaggerated flexed position of posterior cervical fat (Figure 22–6). The object of this maneuver, known as "stacking," is to position the patient so that the tip of the chin is at a higher level than the chest to facilitate laryngoscopy and intubation. The head-elevated laryngoscopy position (HELP), or "ramped" position,[137,138] is a step beyond "stacking." It significantly elevates the obese patient's head, neck, upper body, and shoulders above the chest to a point where an imaginary horizontal line can be drawn from the sternal notch to the external ear to better improve laryngoscopy and intubation. To facilitate proper HELP placement, the preformed Troop Head Elevation Pillow (C&R Enterprises, Frisco, TX, USA) in combination with a standard intubation pillow can be used in place of folded towels or blankets (Figure 22–7). The advantage of the preformed pillow is that it can be prepositioned, inserted, and removed much faster with less effort than that required to build and dismantle a ramp made from blankets and towels.[139]

Continuous infusion of a short-acting intravenous agent such as propofol, any of the inhalational agents, or a combination can be used to maintain anesthesia. Desflurane, sevoflurane, and isoflurane are minimally metabolized and therefore are useful choices in obese patients. Desflurane may provide better hemodynamic stability.[140] Sevoflurane provides rapid recovery, good hemodynamic control, prompt regaining of psychological and physical functioning, and infrequent incidence of nausea and

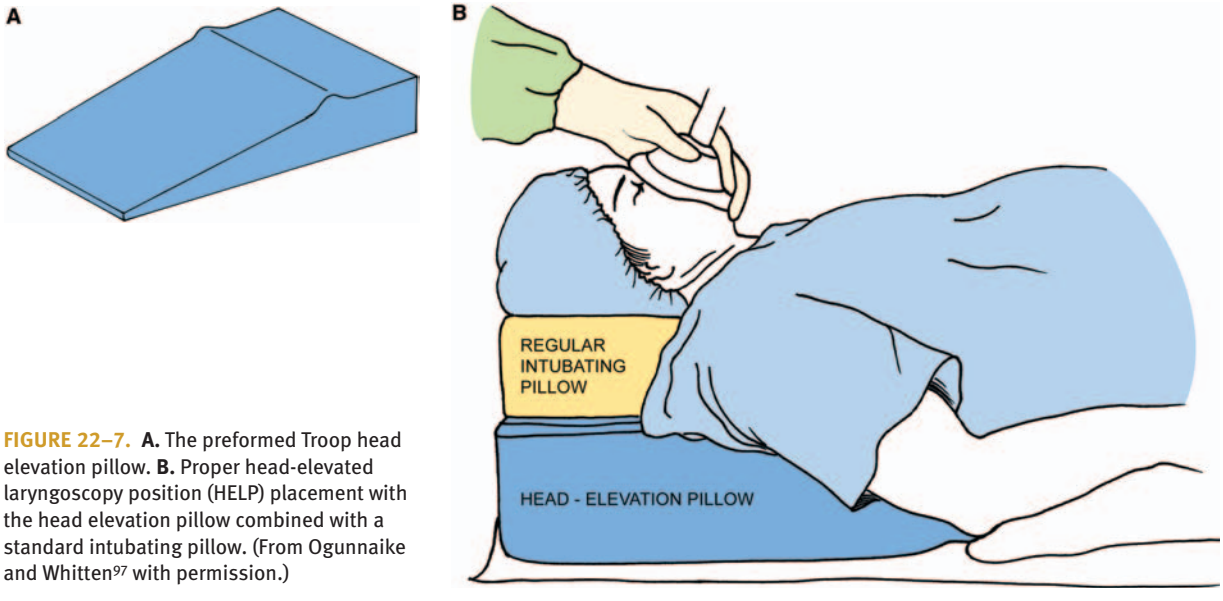

FIGURE 22–7. **A.** The preformed Troop head elevation pillow. **B.** Proper head-elevated laryngoscopy position (HELP) placement with the head elevation pillow combined with a standard intubating pillow. (From Ogunnaike and Whitten[97] with permission.)

vomiting when compared to isoflurane.[141] A bispectral index (BIS)-guided study demonstrated an insignificant difference between sevoflurane and desflurane with respect to emergence and cognitive psychomotor recovery characteristics when careful anesthetic titration was used.[142] Obese patients have been found to awake significantly faster after desflurane than after sevoflurane anesthesia; desflurane also resulted in higher oxygen saturation on arrival in the PACU.[143] Propofol–nitrous oxide anesthesia adjusted to a BIS level of approximately 60 combined with thoracic epidural analgesia provides intraoperative hemodynamic stability and prompt recovery during laparotomy for gastric bypass surgery.[144] Overall, the evidence on significant delayed recovery and awakening from all currently available volatile anesthetic agents in obese patients when compared to the nonobese is conflicting. Metabolism of volatile anesthetics is greater in obese than in normal-weight patients, which is reflected by a greater increase in serum inorganic fluoride level, including during anesthesia with sevoflurane, whose biotransformation has not been shown to result in significant differences in plasma fluoride levels or in differences in preoperative and postoperative liver function and renal function tests between obese and nonobese patients.[145] In obese patients, a potentially hepatotoxic reductive pathway metabolizes halothane, resulting in an increased incidence of "halothane hepatitis." Fortunately, halothane is rarely needed in modern practice. Rapid elimination and analgesic properties make nitrous oxide an attractive choice for anesthesia in obese patients, but high oxygen demand in this patient population limits its use. This high oxygen demand is the result of excess metabolically active fat tissue and an increased workload on muscles and other supportive tissue that significantly increases mean oxygen consumption. Short-acting opioids such as remifentanil at the lowest possible dose, combined with a low-solubility inhalation anesthetic, facilitates a more rapid emergence without increasing opioid-related side effects.[146] Cisatracurium possesses an organ-independent elimination profile and is a favorable nondepolarizing muscle relaxant for maintenance of anesthesia in the obese patient with high prevalence of renal and hepatic compromise. Vecuronium and rocuronium are other useful choices.[147] Dexmedetomidine, an α_2-agonist with sedative and analgesic properties, provides hemodynamic stability without myocardial depression. It has no clinically significant adverse effects on respiration, which makes it an attractive agent for use as an anesthetic adjunct in obese patients. Furthermore, it reduces the postoperative opioid analgesic requirements and their subsequent detrimental respiratory depressant effects.[89]

Ventilatory tidal volumes >13 mL/kg offer no added advantages during ventilation of morbidly obese patients during anesthesia. Increasing the tidal volumes further only increases airway pressures and lung compliance without significantly improving arterial oxygen tension but results in severe hypocarbia that increases shunt fraction at $Paco_2$ <30 mm Hg.[148] Arterial oxygenation during laparoscopy in morbidly obese patients is affected mainly by body weight and not by body position, pneumoperitoneum, or mode of ventilation. Oxygenation is not significantly improved by increasing either the respiratory rate or tidal volume.[149] PEEP is the only ventilatory parameter that has consistently been shown to improve respiratory function in obese subjects.[150] However, PEEP may decrease venous return, cardiac output, and subsequent oxygen delivery.

Excess adipose tissue may mask peripheral perfusion, making fluid balance difficult to assess. Blood loss usually is greater in the obese than in the nonobese for the same type of surgery because technical difficulties in accessing the surgical site necessitate larger incisions and more extensive dissection. Early infusion of colloids and blood products may be necessary because obese patients are less able to compensate for small volumes lost, but rapid infusion of excessive amounts should be avoided because of high prevalence of preexisting congestive cardiac failure.

Regional Anesthesia

A regional anesthetic technique is a useful alternative to general anesthesia in the morbidly obese because it may help avoid potential intubation difficulties. However, it can be technically difficult given the inability to identify usual bony landmarks because of masking by excess fat. A peripheral nerve stimulator with an insulated needle helps with regional nerve blocks. Neuraxial block is easier in the lumbar region because the midline in this area has a thinner layer of fat than do other areas of the spinal column. Longer needles and the sitting position are other useful tools that facilitate induction of neuraxial anesthesia. Ultrasound[151] and fluoroscopy[152,153] can be used to guide a needle or continuous infusion catheter into the spinal or epidural space. Low-current electrical stimulation through an epidural catheter to achieve trunk or limb movement also can be used for confirmation of epidural catheter placement.[154] Epidural vascular engorgement and fatty infiltration reduce the volume of the space, making dose requirements of local anesthetics for epidural anesthesia 20–25% less in obese patients. Subarachnoid blocks are not technically as difficult as epidural blocks, but the height of a subarachnoid block in obese patients can be unpredictable because it may spread considerably cephalad within a short time, causing cardiovascular and respiratory compromise. Continuous catheter subarachnoid block is an attractive technique that allows careful titration of the local anesthetic to desired effect and level, thus avoiding the unpredictability of the single-shot technique.[155] Combined epidural and balanced general anesthesia allows for better titration of anesthetic drugs, use of larger oxygen concentration, and optimal muscle relaxation. It also allows for postoperative analgesia through the same catheter used to provide surgical anesthesia, thereby facilitating early postoperative mobilization.

POSTOPERATIVE CONSIDERATIONS

Emergence

Prompt extubation prevents the morbidly obese patient, who may have underlying cardiopulmonary disease, from becoming ventilator dependent. Tracheal extubation should be considered only when there is complete reversal of neuromuscular blockade and full recovery from the effects of anesthetics. Preferably, the patient should be extubated in the semirecumbent position, which has less adverse effects on the respiratory system. Supplemental oxygen should be administered after extubation. Lifting devices such as the HoverMatt (Patient Handling Technologies, Allentown, PA,

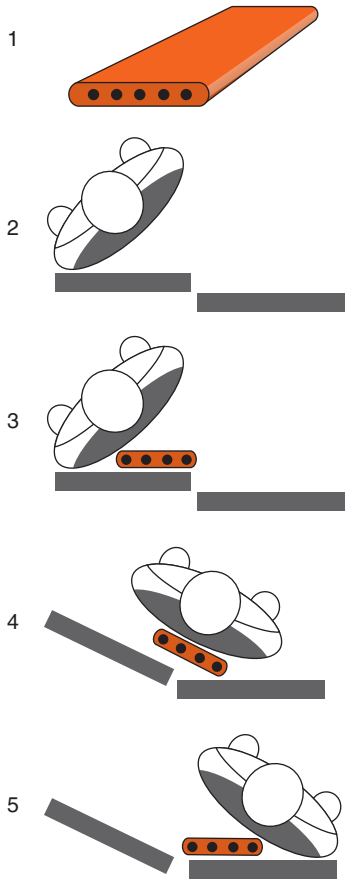

FIGURE 22–8. Illustration of the Walter Henderson maneuver. **1,** Patient Transfer Device (PTD, also known as patient roller); **2,** patient tilted to slip roller under; **3,** roller slipped under patient; **4,** table tilted to roll patient downhill onto bed; **5,** patient rolled onto bed. (From Ogunnaike and Whitten[156] with permission.)

USA) and the Patient Transfer Device (Alimed, Dedham, MA, USA), are useful for transporting morbidly obese patients onto or off the operating table. The Walter Henderson Maneuver (Figure 22–8) can be used to safely and gently transfer obese patients onto their postoperative beds.[156]

Risk of airway obstruction at extubation is increased in the obese OSA patient; up to 5% incidence of life-threatening postextubation obstruction is seen. Negative-pressure pulmonary edema can result from postextubation obstruction and is best treated by reintubation, which can be difficult in a patient with OSA. Extubation in the fully awake state is advocated. Any regional technique, if instituted for postoperative analgesia, should be operative at the time of extubation.

Patients on preoperative CPAP should continue on it postoperatively. CPAP pneumatically splints the pharynx and protects against airway obstruction during sleep. CPAP should not be immediately applied to obese OSA patients upon arrival in the PACU because it impairs access to suctioning and dealing with postoperative nausea and vomiting; it also impairs communication between patient and caregiver, and it interferes with monitoring of facial color. Intraoperative and postoperative events, such as facial edema, may change mask fit, and CPAP requirements may change significantly because CPAP is meant to be used for natural, not drug-induced, sleep.[15] Another indication for CPAP is to counter the increased incidence of postoperative atelectasis in morbidly obese patients after general anesthesia.[157] Postoperative CPAP does not increase the incidence of major anastomotic leakage after gastric bypass surgery despite the theoretical risk of anastomotic injury from pressurized air delivered by CPAP.[158] The obese patient may avoid taking deep breaths because of the pain after abdominal surgery. Adequate analgesia and a properly fitted elastic binder for abdominal support may encourage patients to cooperate with early ambulation and deep breathing exercises with the aid of incentive spirometry. Pulse oximetry and ABG analysis should be monitored appropriately.

Postoperative Analgesia

Perioperative use of regional anesthesia and analgesia reduces the incidence of postoperative respiratory complications. Epidural analgesia with local anesthetics, opioids, or both is an effective analgesic technique. Intrathecal opioid is another viable option. Potential advantages of epidural analgesia in obese patients include prevention of DVT, improved analgesia, and earlier recovery of intestinal motility. Lesser oxygen consumption and decreased left ventricular stroke work are other benefits. Morphine-based patient-controlled analgesia (PCA) has been deemed equivalent to low thoracic/high lumbar continuous infusions of bupivacaine/fentanyl epidural analgesia in morbidly obese patients undergoing gastric bypass surgery with regard to the quality of pain control at rest, frequency of nausea and pruritus, time to ambulation, time to return of gastrointestinal function, and length of hospital stay.[159] Incisional local anesthetic infiltration plus PCA was found to produce lower pain scores when compared to epidural anesthesia and analgesia and postoperative PCA for gastric bypass surgery. In addition, infiltration analgesia as part of a multimodal regimen offers a simple, safe, and inexpensive alternative to epidural analgesia alone.[160] A combination of intraoperative nonopioid analgesics and anesthetic adjuvants (ketorolac, clonidine, ketamine, lidocaine, magnesium sulfate, and methylprednisolone) that produce analgesia by mechanisms different from opioids decreases sedation during recovery from anesthesia and reduces postoperative morphine requirements when compared to intraoperative fentanyl anesthesia in morbidly obese patients.[161] Delayed respiratory depression is one of the known complications of neuraxial opioids. When this is coupled with a potentially difficult airway in the obese patient, closer monitoring in a step-down or intensive care unit is a wise choice until this complication is no longer a threat. Increased analgesic requirements during the first 3 postoperative days increase the danger of life-threatening apnea during drug-induced sleep. This stage is followed by the next 3 days of deep rapid eye movement (REM) sleep rebounds, which also increase the danger of natural sleep-induced apnea. Therefore, the first postoperative week is a period of increased risk of prolonged apnea during sleep for the postoperative obese patient, especially those with OSA.[15]

RESUSCITATION

The need for cardiopulmonary resuscitation during anesthesia for the morbidly obese is always a possibility. Of concern are the equipment and technical aspects of resuscitation. Chest compressions may not be effective when improperly performed. Mechanical compression devices may be required. The maximum 400 J of energy on regular defibrillators is sufficient for the morbidly obese, because their chest wall usually is not much thicker, but the higher transthoracic impedance from the fat may obligate several attempts.[162] Mask ventilation is more difficult because of poor mask fit, redundant oropharyngeal tissues, and reduced chest wall compliance. Limited neck mobility and mouth opening and a short thick neck may make intubation difficult. The gum-elastic bougie is a useful tool that aids suc-

cessful intubation in the obese patient during emergency situations. The intubating and ProSeal laryngeal mask airways (LMAs) and the esophageal tracheal Combitube are useful temporary supraglottic airway devices. An increased risk of aspiration may be associated with the classic LMA. Transtracheal jet ventilation and retrograde wire intubation may be difficult to establish because of the difficulty in palpating anatomic landmarks. Tracheostomy and percutaneous cricothyrotomy should be reserved as final options and should be performed by experienced practitioners.[163] Pulse oximetry may be unreliable because of increased finger thickness; the earlobe may be a better choice.

CHAPTER 23

Evaluation of the Patient with Alcohol or Drug Addiction

Paul S. Pagel, MD, PhD,
Judith A. May, MD, and
David C. Warltier, MD, PhD

The lifetime prevalence of alcohol and drug addiction is estimated to be approximately 14% and 7%, respectively, of the U.S. population.[1] These data confirm that addiction is a major public health problem in the United States. The literature describing the evaluation and treatment of patients with addiction is exhaustive. A large number of peer-reviewed medical journals are dedicated to the study of addiction, two divisions of the National Institutes of Health (Alcoholism and Alcohol Abuse, Drug Abuse) are responsible for providing major federal funding for basic science and clinical research on addiction, and several major textbooks have been authored by world-renowned experts in addiction medicine that thoroughly describe the salient features of substance abuse disorders and their treatment. The American Society of Addiction Medicine was founded in 1954 and currently has more than 2700 members dedicated to the treatment of patients with addiction. It is not our intention to comprehensively review addiction medicine and its complex relationship to the practice of anesthesiology. Nevertheless, it is important that anesthesiologists be very familiar with basic concepts, including the pathophysiology of the addiction, the medical consequences of substance abuse, and the process of recovery, so as to provide appropriate care for patients suffering from this very common disease. For the purposes of this chapter, the terms *alcohol* and *ethanol* are used interchangeably.

ADDICTION: DEFINITIONS AND NEUROBIOLOGY

Addiction is defined by loss of control over an abusable substance, including an inability to voluntarily self-regulate drug use, compulsive preoccupation with obtaining or using a drug, and continued use despite of adverse consequences.[2] Addiction is a multifaceted medical illness that develops as a result of interactions between the availability, cost, and pharmacology of a drug of abuse, environmental and psychosocial factors (e.g., occupation, peer group), genetic predisposition, comorbid psychiatric disorders, and drug exposure. Addiction has a highly variable clinical course. Initial drug use is voluntary behavior, and most users do not develop drug-dependence. However, repetitive drug exposure in a susceptible individual appears to cause fundamental changes in central nervous system function that produce the disease. Experimental evidence collected to date suggests that genetic predisposition to addiction may be related to alterations in neurocircuitry that enhance sensitivity to the reinforcing effects of drugs of abuse, thus overwhelming cognitive control of behavior.[3] A patient may enter recovery with abstinence and treatment, but once present, addictive disease is regarded as permanent. However, addiction may be managed successfully as a chronic disease, and many patients respond positively to treatment with long periods of abstinence.[4]

The neurobiology of addiction is summarized in a number of excellent reviews and textbook chapters, and is not discussed in detail here.[3,5] Three concepts may be inferred from this large body of literature that have immediate bearing on the anesthesiologist caring for the patient with addiction: uniform drug reward and reinforcement, cross-addiction, and disease permanence. The mesocorticolimbic dopamine system is central to the pathophysiology of addiction.[5] This neurocircuitry involves the ventral tegmental area of the midbrain where dopaminergic neurons originate and the basal forebrain, the nucleus accumbens, and the amygdala to which these neurons project. All drugs abused by humans have been shown in animals to interact with this system to produce reinforcement.[3] Different pharmaco-

KEY POINTS

1. Addiction is a very common medical illness. It is characterized by loss of control over an abusable substance, including an inability to voluntarily self-regulate drug use, compulsive preoccupation with obtaining or using a drug, and continued use despite adverse consequences.
2. Addiction may be managed successfully as a chronic disease, and many patients respond positively to treatment with long periods of abstinence.
3. Consultation with an addiction medicine specialist is encouraged when providing care for active or recovering alcohol or drug abusers during the perioperative period.
4. Preoperative assessment of all patients presenting for surgery should include a routine evaluation for alcohol or drug abuse.
5. Establishing a supportive, nonjudgmental but firm approach to the patient with active alcoholism or drug addiction is vital for successful care.
6. Preoperative history, physical examination, and laboratory testing should be guided by the known medical consequences of alcohol and drug addiction.
7. A blood alcohol concentration and a urine drug screen should be obtained in all active and most recovering alcohol or drug abusers.
8. Polysubstance abuse is common among alcohol or drug users.
9. Infectious diseases are epidemic in injection drug users.
10. Alcohol abuse has extensive medical consequences that impact every major organ system and is a major risk factor for perioperative morbidity and mortality.
11. Abuse of sedative–hypnotics, opioids, cocaine, amphetamines, hallucinogens, and inhalants is associated with a wide variety of drug-specific medical complications.
12. Withdrawal is commonly encountered during the perioperative period in alcohol or drug abusers, and prophylaxis against withdrawal should be instituted before surgery.
13. Recovery involves abstinence in combination with a series of personal changes to maintain sobriety.

logic classes of drugs of abuse, including many of those routinely used by anesthesiologists, may initially activate different locations within the reinforcement cascade by several mechanisms, but all lead to reward stimulation.[5] As a result, exposure to one drug may mimic the reinforcing effects of another, a process known as *cross-addiction*. Permanent alterations in reinforcement neurocircuitry also appear to persist despite long-term abstinence and support the clinical notion of addiction as a chronic, incurable disease.[4] These latter data are particularly important to the recovering patient as drugs commonly used during and after anesthesia (e.g., sedative–hypnotics, opioids) may reactivate addiction regardless of the relative length of abstinence.

APPROACH TO PREOPERATIVE EVALUATION

Medical and psychiatric diseases are very common in patients with addiction, and several factors that contribute to the higher risk of many diseases in this patient population have been identified. Drugs of abuse produce direct toxic effects on a variety of organ systems that have immediate consequences or may also contribute to or exacerbate preexisting medical conditions. Addiction may be responsible for personal behavior (e.g., sharing injection equipment, high-risk sexual activity) that markedly increase risk to infectious diseases such as endocarditis, hepatitis, and AIDS. Depressed socioeconomic conditions (e.g., unemployment, reliance on housing in shelters, homelessness) may also pose an enhanced risk of other infectious diseases such as community-acquired pneumonia and tuberculosis. Access to and delivery of routine and preventive healthcare to many patients with addiction are often incomplete or ineffective. In those patients who receive regular healthcare, active abuse of alcohol or drugs may reduce prescription medication compliance and substantially curtail attendance at followup appointments with physicians. Nevertheless, it has been convincingly demonstrated that many of these patients benefit from routine healthcare, particularly when it is linked to substance abuse treatment.[6] Such an integration of service delivery significantly improves patient outcome and also is an important goal during the perioperative period.

Preoperative assessment of all patients presenting for surgery should include a routine evaluation for alcohol or drug addiction. Previously undiagnosed alcoholism is present in many hospitalized patients,[7] and physicians often fail to detect it.[8] These data provided compelling evidence that the anesthesiologist may play a pivotal role in the primary diagnosis of addiction and the initiation of interventions to treat the disease. The CAGE and Michigan Alcohol Screening Test (MAST) questionnaires are brief but extensively validated screening instruments that may be used to detect the presence of a substance abuse disorder.[9] The simple four-question CAGE test is particularly useful as a screening tool for the anesthesiologist precisely because of its brevity and predictive value:

> *C*—Have you ever felt you ought to *C*ut down on your drinking (drug use)?
>
> *A*—Have people *A*nnoyed you by criticizing your drinking (drug use)?
>
> *G*—Have you ever felt bad or *G*uilty about your drinking (drug use)?
>
> *E*—Have you ever had a drink (or used a drug) first thing in the morning ("*E*ye-opener") to steady your nerves or get rid of a hangover?

Two or more positive responses to the CAGE questionnaire strongly imply the presence of addiction and a single affirmative answer indicates that further assessment should be conducted. Corroborating history, including evidence of alcohol- or drug-related amnesia ("blackouts"), chronic marital or family difficulties, habitual criminal activity, homelessness, multiple detoxifications or previous rehabilitation attempts, and recurrent unemployment, also suggest the diagnosis of a substance abuse disorder.[10] A blood alcohol concentration and a urine drug screen should be obtained in the patient with a known history of addiction, a positive preoperative screening evaluation, or, when indicated by other clinical conditions (e.g., trauma, altered mentation, obtundation). These data definitively identify the pharmacologic class of drugs currently abused by the patient, alert the anesthesiologist to the likelihood of withdrawal, and allow the anesthesiologist to anticipate potential interactions between the drugs of abuse and those used for anesthesia and pain management. A positive laboratory test also provides important corroborative evidence of the presence of a substance abuse disorder that may encourage the previously undiagnosed patient to seek treatment. More frequently, a positive test provides the anesthesiologist with the opportunity to challenge denial (a nearly universal response of the patient with addiction when first confronted about the disease), facilitates an initial discussion about treatment alternatives between the physician and the patient, and affords a strong rationale for immediate consultation with an addiction medicine specialist.

Establishing a supportive, nonjudgmental but firm approach to the patient with alcoholism or drug addiction is vital for successful care and cannot be overemphasized. This strategy is especially important for the anesthesiologist because previous evidence has revealed that patients with addiction often encounter physicians during the perioperative period whose attitudes about and treatment of these patients may be prejudicial.[11] For example, general surgeons were shown to possess the weakest educational background and the least desire to learn about resources for substance abuse management as compared to psychiatrists and internists.[12] Anesthesiologists also display more negative attitudes about patients with substance abuse disorders than primary care physicians who routinely care for this patient population.[13] Lack of educational background in addiction and continued identification of addiction within a "moral" model or as a secondary consequence of other underlying psychopathology are frequent causes of negative physician attitudes about the disease. Discrimination against the patient by the physician, cynicism about the potential for long-term recovery, anger about continuing alcohol or drug use, frustration over relapse, and lack of compassion represent common examples of negative attitudes that may directly interfere with a meaningful therapeutic relationship between the anesthesiologist and the patient with addiction. Such negative attitudes may be especially destructive in these patients because diminished self-esteem, shame, and anxiety are characteristic features of the disease.

Thus, it is imperative that the anesthesiologist establish trust and reassure the patient that addiction will be appropriately managed as part of the perioperative plan. The establishment of such a positive relationship between the anesthesiologist and the patient facilitates more comprehensive assessment about specific drugs of abuse, the duration and patterns of drug abuse, the number and severity of previous withdrawal episodes, periods of abstinence, previous treatment attempts, and other relevant past medical and psychiatric history related to substance abuse for which the patient may have received treatment. In addition, a positive rapport in the setting of an acute surgical intervention allows the anesthesiologist to strongly encourage the active alcoholic or drug user to seek treatment for addiction.

Providing reassurance about prompt and effective treatment of acute and chronic pain to the patient with addiction deserves emphasis during the preoperative evaluation. Chronic pain resulting from a variety of alcohol- or drug abuse-related medical illnesses was previously identified in as many as 60% of chemically dependent patients enrolled in methadone maintenance programs or residential treatment facilities.[14] Opioid addicts may also display hyperalgesia, in part as a result of drug tolerance.[15] However, even well-intentioned and informed physicians may be hesitant to provide adequate doses of opioid analgesics to the patient with addiction because of fears about contributing to the disease process. Other physicians may intentionally withhold or restrict opioid analgesics because they are anxious about adverse consequences imposed by federal or state regulatory agencies,[15] are concerned that patient requests for these drugs may represent manipulative, addictive behavior,[16] or have negative, moral attitudes about addiction. These factors contribute to inadequate treatment of pain in patients with addiction,[17] and result in these patients harboring suspicions that they will be deliberately abused by physicians or nursing staff. This situation may be further complicated by the recognition that patients with addiction are known to self-medicate or manipulate prescribed drugs to treat pain. Thus, an environment of "mutual mistrust" concerning the treatment of acute or chronic pain using opioid analgesics may exist between patients with substance abuse disorders and their physicians.[16] The potential for such a conflict should be acknowledged and honestly addressed by the anesthesiologist and surgeon during the preoperative evaluation. Guidelines for pain management in patients with addiction have been established that urge consultation with an addictionologist, meticulous observation of adherence with and clinical response to prescribed opioids, and continuous assessment of function.[18]

HISTORY, PHYSICAL EXAMINATION, AND DIAGNOSTIC TESTING

In addition to the chief complaint that led to the original surgical referral and other pertinent past medical history, the preoperative history and physical examination should be guided by the known medical consequences of alcohol and drug abuse, the common occurrence of polysubstance abuse, and the presence of other coexisting diseases. A thorough review of systems should be based on the identity of abused drugs obtained in honest dialogue with the patient, concomitant with laboratory determination of blood alcohol concentration and the results of a urine drug analysis. Importantly, the recognition that constitutional complaints or new presenting symptoms may or may not indicate drug use or withdrawal is a critical feature of the history and physical examination that deserves special emphasis. For example, alcohol or opioid withdrawal is typically characterized by fever, myalgia, tachycardia, hypertension, and gastrointestinal symptoms, but such generic complaints may also indicate the presence of an underlying infectious disease. Weight loss because of malnutrition is a very common finding in drug abusers, but infectious diseases, human immunodeficiency virus (HIV), and occult malignancy must also be considered in the differential diagnosis. Similarly, a seizure certainly suggests the presence of alcohol or opioid withdrawal in the patient with a recent history of heavy abuse, but other causes of seizure cannot be immediately excluded. Thus, a presumptive diagnosis of an alcohol- or drug-related complication may often be inferred based on the history, but the anesthesiologist must remain vigilant to the possibility that other disease states contribute to the presentation independent of alcohol or drug abuse.

The complete physical examination of the alcohol or drug abuser is primarily directed toward the medical ramifications of documented abused substances, but routine investigation of other coexisting diseases and the potential for complications arising from polysubstance abuse should not be overlooked. Examination of the skin may reveal evidence of acute or chronic infection (e.g., cellulitis, abscess), repetitive injection drug use ("track" marks), or peripheral venous thrombosis. The presence of such findings suggest that the ability of the anesthesiologist to successfully place intravenous or intraarterial catheters before surgery may be limited. Skin examination may also reveal the stigmata of advanced liver disease. Diffuse lymphadenopathy strongly suggests the presence of systemic infection, tuberculosis, or HIV. Poor dentition, oral-pharyngeal carcinoma, or nasal septum damage may be detected during examination of the airway. Such findings may have potentially important implications for airway management. Wheezing, rhonchi, rales, or evidence of pulmonary consolidation detected during the lung examination suggests the presence of reactive airway disease, acute or chronic bronchitis, heart failure, or pneumonia that may be directly or indirectly related to alcohol or drug abuse and merit further investigation. A cardiac murmur in the drug abuser strongly suggests that active or healed endocarditis may be present. An abdominal examination directed specifically toward the liver is indicated in this patient population because most drugs of abuse are associated with the development of hepatic disease. Lastly, the neurologic examination may reveal evidence of altered mental status, cerebrovascular accident, head trauma, central nervous system infection, or sensory-motor peripheral neuropathy.

Standard recommendations for obtaining preoperative laboratory and diagnostic tests in healthy individuals are often inadequate in patients with a history of alcohol or drug abuse. As in healthy patients, the preoperative laboratory and diagnostic evaluation of alcohol or drug abusers should be guided by the results of the history

and physical examination. Nevertheless, the anesthesiologist should maintain a high level of suspicion about the potential existence of other subclinical medical complications of alcohol or drug abuse that may have a substantial impact on perioperative management and obtain laboratory or diagnostic tests accordingly. For example, hepatic dysfunction resulting from drug toxicity or infection is very common in alcohol and injection-drug abusers, and obtaining liver function tests, a coagulation panel, and viral hepatitis testing is certainly warranted even if these patients are apparently asymptomatic. Similarly, a tuberculin skin test and a chest radiograph should be performed because subclinical tuberculosis may be present. Serum electrolyte, blood urea nitrogen, and serum creatinine concentrations and a urinalysis should also be obtained in this patient population because renal insufficiency resulting from viral hepatitis or HIV infection commonly occurs. After obtaining informed consent, routine screening for HIV should be performed, especially in alcohol or drug abusers who acknowledge high-risk behavior. A positive HIV screen facilitates further diagnostic testing to confirm the presence of active infection, allows the early initiation of medical treatment for the disease, and also alerts the surgical team to the potential for transmission of the virus during the perioperative period.

INFECTIOUS DISEASE IN INJECTION-DRUG USERS

Infectious diseases are epidemic in injection-drug users.[19] The majority of hospital admissions of injection-drug users are related to acute infection, and the presence of chronic infectious diseases (e.g., hepatitis C, HIV) frequently complicates the perioperative management of many of these patients. Drug users may develop infections because of direct injection of pathologic organisms, high-risk sexual behavior or injection activity, immunosuppression resulting from chronic disease or malnutrition, and compromise of protective reflexes during intoxication or withdrawal. As a result of these factors, the clinical presentation of many infectious diseases may be profoundly different in injection-drug users as compared to patients from the general population. Self-medication with illicit opioid analgesics or illegally obtained antibiotics and the presence of acute intoxication or drug withdrawal may also complicate the diagnosis and treatment of infection in injection users. This section focuses on the infectious diseases that are most relevant to the practice of anesthesiology (Table 23–1).

Skin and Soft Tissue

Skin and soft-tissue infections (e.g., cellulitis, abscess, ulcer) are frequently responsible for hospital admission of injection-drug users, and may also be initially diagnosed by the anesthesiologist during the preoperative evaluation. Skin and soft-tissue infections are observed in as many as one third of all active users,[20] and may be further complicated by the development of necrotizing fasciitis. *Staphylococcus aureus* and β-hemolytic streptococci are the most frequently identified pathogens responsible for skin and soft-tissue infections,[19] although geographical variations in organism identity are regularly reported. This latter observation was dramatically emphasized in small groups of heroin addicts from the United Kingdom and California who suffered major neurologic complications and mortality related to soft-tissue infection with *Clostridium* species (e.g., tetanus, botulism) as a result of drug contamination with bacteria.[21] Injection of drugs mixed with saliva or licking of needles immediately before administration also predisposes the injection-drug user to polymicrobial infections resulting from a variety of aerobic and anaerobic oral flora. The route of administration of injected drugs, the presence of concomitant HIV infection, the frequency of injection, and the combined use of heroin and cocaine (known as a "speedball") have been identified as risk factors for abscess development. For example, a higher prevalence of abscess formation has been observed in users who injected drugs subcutaneously or intramuscularly (termed "skin popping" or "muscling," respectively) as compared to those who use an intravenous route of administration. Ranked in descending order of occurrence, arms, legs, buttocks, deltoids, and neck are the most common locations for abscess formation and correlate with typically used injection sites.[22] Injection of vasoactive drugs such as cocaine may produce cutaneous or muscular ischemic necrosis at the injection site and contribute to the development of superinfection or ulcer formation. Infections of large skeletal muscles (pyomyositis), most often produced by *S. aureus*, are also associated with injection drug use in patients with HIV. Treatment of abscess, ulcer, or pyomyositis usually requires the combination of intrave-

TABLE 23–1.

Infectious Complications of Alcohol and Drug Abuse

- Skin and muscle
  - Cellulitis
  - Abscess
  - Ulcer
  - Cutaneous or muscular necrosis (cocaine or amphetamines)
  - Pyomyositis
  - Thrombophlebitis
  - Necrotizing fascitis
- Cardiovascular
  - Endocarditis (right › left)
  - Septic embolization
  - Hematoma
  - Ischemic vasculitis (cocaine or amphetamines)
  - Vascular thrombosis
  - Mycotic aneurysm
- Pulmonary
  - Septic pulmonary embolism (tricuspid valve endocarditis)
  - Community-acquired pneumonia
  - Tuberculosis
  - Pneumocystis pneumonia (HIV)
- Neurologic
  - Brain or spinal cord abscesses
  - Cerebral infarction
  - Cerebral mycotic aneurysm
  - Meningitis
  - Encephalopathy
  - Vertebral osteomyelitis
  - Botulism
  - Tetanus
- Hepatic/gastrointestinal
  - Viral hepatitis (all forms)
  - Hepatic abscess
  - Hepatic granulomatosis (talc)
  - Spontaneous bacterial peritonitis
- Renal
  - Nephrotic syndrome (hepatitis B, HIV)
  - Nephritic syndrome (hepatitis C)
  - Rhabdomyolysis
- Immunologic
  - HIV/AIDS

nous antibiotics and surgical incision and drainage. Necrotizing fasciitis is associated with substantial morbidity and mortality, and aggressive surgical intervention is required to effectively manage this devastating complication of injection drug use.

Cardiovascular System

A common complication of injection drug abuse is endocarditis.[23] The frequency of injection and the presence of simultaneous HIV infection are risk factors for the development of infective endocarditis. Interestingly, concomitant alcohol abuse may actually reduce the risk of the disease. Mortality in patients with infective endocarditis resulting from injection drug abuse may exceed 35%,[24] and is probably higher in immunocompromised patients. The overall incidence of infective endocarditis has been estimated at 1.5–20 cases per thousand person-years among active injection-drug users.[25] Endocarditis may affect any heart valve, but infection of right- as compared to left-heart valves is more frequent and also is associated with lower mortality.[26] In patients from the general population, infective endocarditis most often develops as a result of transient bacteremia seeding a preexisting left-heart valvular abnormality resulting from congenital, rheumatic, or myxomatous disease. In contrast, injection drug use more commonly produces infection of structurally normal right-heart valves. The tricuspid valve is most often affected in injection-drug users. The reasons for this clinical presentation appear to be multifactorial and include toxic effects of a drug or its contaminants on valvular endothelium, an enhanced susceptibility of right-heart valves to particular skin organisms, and preexisting thickening of the tricuspid valve leaflets.[25] *Streptococcus viridans* and enterococcus are typically identified as the bacteria responsible for endocarditis in patients without a history of substance abuse, but more virulent species, most notably *S. aureus* (with or without methicillin-resistance), are most often implicated in injection-drug users with endocarditis. A higher incidence of endocarditis resulting from gram-negative bacilli and fungi also occurs in patients who use injection drugs as compared to those who do not.

Endocarditis is characterized by the presence of persistent bacteremia, and the diagnosis of the disease follows standard criteria.[27] Transthoracic or transesophageal echocardiography is commonly used during evaluation of the patient with suspected endocarditis to provide direct visual evidence of a vegetation that consists of platelets, fibrin, and sequestered bacteria usually located on the valve surface. Notably, a normal echocardiogram alone does not definitively exclude the diagnosis. The clinical presentation of endocarditis is typified by persistent fever, a variety of cardiac abnormalities (e.g., new murmur, valvular insufficiency, congestive heart failure, intraventricular conduction defects), evidence of septic embolization from the affected valve, bacterial seeding of other organ systems (e.g., meningitis, brain abscess, osteomyelitis), and immune complex-related complications (e.g., glomerulonephritis, Roth spots, Osler nodes). In contrast to findings in the general population, injection-drug users with endocarditis often present with cough, pleuritic chest pain, and bilateral pulmonary infiltrates that occur as a consequence of septic embolization from the tricuspid valve. Necrotizing or cavitary pulmonary defects produced by these septic thromboemboli may also be complicated by bronchopleural fistulae, hemoptysis, pneumothorax, empyema, or invasion of a major bronchial structure. Primary treatment of endocarditis with organism-specific antibiotics or antifungal drugs also may require simultaneous surgical intervention to manage the cardiovascular or neurologic sequelae of the disease.

Vascular infections frequently occur in injection-drug users. Contaminated injection equipment, hematoma surrounding a direct vascular injury, local ischemic damage from vasoactive drug injection (e.g., cocaine, amphetamine), or thrombosis may contribute to the development of thrombophlebitis or the formation of arteriovenous fistulae. Intravenous drug administration using contaminated supplies may also produce thrombophlebitis and septic embolization. When such emboli lodge in the vasa vasorum of an arterial wall, a mycotic aneurysm may be produced. Right- or left-heart valve endocarditis-induced septic embolization is the most frequent cause of pulmonary or brain mycotic aneurysm formation, respectively. Regardless of the embolic source, the vast majority of these infected, mushroom-shaped, arterial defects resolve with intravenous antibiotic treatment directed against the primary underlying organism. Nevertheless, some patients with mycotic aneurysms may develop signs and symptoms despite appropriate antibiotic treatment. The clinical presentation of a mycotic aneurysm is typified by the presence of a painful, pulsatile mass accompanied by a bruit, thrill, surrounding cellulitis or abscess formation, or frank rupture. In many cases, surgical excision is required for definitive treatment of the infection or to prevent rupture.

Lung

Community-acquired pneumonia is very common in injection-drug users and is a major cause of hospital admission in this patient population. Several factors contribute to this enhanced susceptibility including increased aspiration risk resulting from drug-induced depression of airway protective mechanisms, poor nutritional status, diminished immunologic responses, and compromised mucociliary and phagocytic function associated with tobacco smoking.[28] Residence in homeless shelters or incarceration in the penal system may also predispose drug users to developing pneumonia because of more frequent exposure to other infected individuals. Injection drug users with HIV are particularly susceptible to community-acquired pneumonia and have a risk of developing the disease that is approximately five times greater that drugs users who do not have HIV.[29] *Streptococcus pneumoniae* and *Haemophilus influenzae* are the most frequently identified pathogens responsible for pneumonia in injection-drug users with or without HIV infection. Other bacteria, including *Legionella* species, *Chlamydia pneumoniae*, *Pseudomonas aeruginosa*, and *S. aureus*, are also more commonly encountered in injection-drug users with pneumonia as compared to the general population. HIV-positive patients with AIDS are especially susceptible to opportunistic pulmonary infection with *Pneumocystis carinii*, *Mycobacterium tuberculosis*, *Mycobacterium avium intracellulare*, and cytomegalovirus.

Tuberculosis is also common in injection-drug users, especially in those users who are coinfected with HIV.[30] Injection-drug users have a prevalence of latent tuberculosis infection that is

3–5-fold higher than that observed in the general population (approximately 5%). The mechanism responsible for reactivation of tuberculosis or whether active drug use plays a role in this reactivation remains unknown. It appears highly likely that many of the previously discussed factors that predispose injection-drug users to develop other infectious diseases may also contribute to the reactivation of latent tuberculosis. The immunosuppression that characterizes advanced HIV infection promotes reactivation of latent tuberculosis and contributes to the development of extrapulmonary manifestations of the disease including vertebral osteomyelitis, meningitis, and empyema that may occur in as many as 80% of these patients. Notably, reduced delayed hypersensitivity responses to tuberculin are also observed in immunocompromised patients that complicate interpretation but do not necessarily preclude use of these important diagnostic skin tests. Standardized treatment of tuberculosis has been established and usually involves drug therapy with isoniazid, rifampin, ethambutol, and pyrazinamide.[31] Rifampin stimulates methadone metabolism, and opioid addicts in methadone maintenance programs often require dosing adjustments to avoid withdrawal.[32] This drug interaction between rifampin and methadone also has potentially important ramifications for the anesthesiologist when using opioids during the perioperative period. Rifampin and pyrazinamide have also been reported to exacerbate preexisting hepatitis or contribute to the development of severe liver dysfunction in injection-drug users with tuberculosis.

Central and Peripheral Nervous System

Signs and symptoms of acute intoxication or withdrawal often complicate the diagnosis of neurologic infection in injection-drug users. Meningitis, brain abscess resulting from septic embolization, cerebral infarction, or rupture of a mycotic aneurysm may occur in as many as 40% of injection-drug users with endocarditis. These central nervous system consequences of endocarditis may be accompanied by bacteremia-induced vertebral osteomyelitis with extension into the epidural space. The resulting epidural abscess may compromise spinal cord integrity. Alternatively, central nervous system infections may be produced by bacterial invasion from ear, sinus, or mastoid infections, bacteremia resulting from another infectious source, or traumatic injury. Management of most of these bacterial complications requires appropriate antibiotic therapy and surgical intervention. Immunosuppressed injection-drug users infected with HIV are particularly susceptible to central nervous system infections produced by unusual pathogens such as tuberculosis, *Cryptococcus*, *Aspergillus*, and *Toxoplasma gondii*. Viral hepatitis may also produce encephalopathy independent of liver dysfunction.

Injection drug users are also susceptible to the development of two major neurotoxin-mediated infectious diseases. Botulinum toxin is released by subcutaneous or intramuscular injection sites infected with *Clostridium botulinum* and produces blurred vision, dysphagia, descending bilateral flaccid paralysis, and respiratory failure as a result of irreversible inhibition of acetylcholine release. Treatment with antitoxin may limit the progression of the disease until regeneration of axons occurs. Several cases of wound botulism were recently reported in drug abusers from California who had injected black tar heroin. Injection drug use is also a major risk factor for the development of tetanus. Tetanolysin produced by the anaerobic bacterium *Clostridium tetani* irreversibly blocks release of inhibitory transmitters in spinal motor neurons, and as a result, causes spastic paralysis characterized by trismus, dysphagia, hydrophobia, and profound, unrelenting muscle contraction in the upper and lower extremities. Neutralization of circulating tetanus toxin with hyperimmune globulin precedes surgical debridement so as to avoid the release of additional tetanolysin from the infected injection site. Like botulism, recovery of neural function from tetanus requires axonal regeneration.

Hepatitis

Drug abuse is strongly associated with the development of all known forms of viral hepatitis. Collectively, these diseases have potentially devastating consequences for drug users and also pose substantial risks of transmission to anesthesiologists and other health professionals who are responsible for their care. Hepatitis A virus (HAV) is the most common form of viral hepatitis in the United States, and drug abuse has been identified as a major risk factor for the transmission of the virus. Antibodies directed against the HAV are present as many as 60% of injection-drug users. Fecal–oral transmission of the RNA-based HAV may occur in drug users by inhalation, intranasal, or oral routes of administration, or by sharing of contaminated injection equipment. Under most circumstances, hepatitis A is a self-limited disease characterized by fever, fatigue, gastrointestinal complaints, jaundice, hepatosplenomegaly, and nonspecific abnormalities in liver function tests concomitant with the presence of IgE followed by IgG anti-HAV antibodies that confer immunity against subsequent infection. In contrast to the findings in many patients with hepatitis B virus (HBV) infection, a carrier state does not occur with HAV infection, extrahepatic manifestations of the disease are unusual, and most cases require only supportive care. However, acute HAV infection has been reported to cause fulminant hepatic failure and death in a subset of patients who are coinfected with hepatitis C virus (HCV) or those affected by other chronic hepatic pathology.[33]

Transmission of the DNA-based HBV among drug abusers most often occurs as a result of sharing contaminated injection supplies or high-risk sexual activity. Drug abuse is responsible for as many as 20% of new HBV cases that are reported annually in the United States, and HBV antibodies are present in between 50% and 80% of all injection-drug users. The duration of injection drug use is strongly correlated with the presence of HBV infection, but infection with the virus most often occurs relatively early in the history of injection drug use. Acute infection with HBV has a widely variable clinical course. Many patients infected with HBV remain completely asymptomatic, and less than half develop the classical signs of jaundice, hepatosplenomegaly, and elevated serum transaminases. Although the vast majority of these patients require only supportive care, a very small number ($< 0.1\%$) develop fulminant hepatic failure. The time-dependent progression of specific HBV antigens and their respective antibodies during the course of acute HBV infection is well known and is not reviewed in detail here. The pres-

ence of antibodies directed against the HBV surface and core antigens that occur with the resolution of acute infection confers protection against subsequent infection in most patients with the disease. Unlike HAV, chronic HBV infection also occurs in a small percentage of patients (5–10%), and is characterized by the continued presence of HBV surface or e antigen, variable degrees of hepatic inflammation and dysfunction, and persistent infectivity. Importantly, chronic HBV infection is associated with the subsequent development of cirrhosis and hepatocellular carcinoma. Treatment with interferon-α and lamivudine (3TC) may reduce the development of these morbid complications in patients who are chronically infected with the HBV. Membranous nephropathy and renal insufficiency may also occur during HBV infection as a result of HBV e antigen deposition in glomerular capillaries.

As many as 80% of injection-drug users who are chronically infected with HBV are coinfected with the incomplete RNA hepatitis D virus (HDV), which requires the presence of HBV for activity. The mechanisms of HDV transmission are similar to those previously described for HBV. The incidence of fulminant hepatic failure is substantially greater during coinfection with HDV and HBV as compared to HBV alone. HDV superinfection of patients who are chronic HBV carriers also portends to more rapid development of end-stage liver failure. Notably, injection-drug users who were coinfected with HDV and HBV demonstrated accelerated deterioration of hepatic histology and function as compared to those infected with these viruses who did not inject drugs. The presence of antibodies directed against HDV is required to established the diagnosis of HDV during acute or chronic HBV infection.

Injection-drug use is the major route of transmission of HCV in the United States today. The vast majority of injection-drug users demonstrate evidence of HCV exposure. As observed in epidemiologic studies of HAV and HBV transmission, frequency of drug injection, use of contaminated injection supplies, incarceration, and coincident participation in high-risk sexual behavior have been identified as major risk factors for the transmission of HCV. Most injection-drug users develop the HCV shortly after beginning injection activity. The initial presentation of HCV infection is usually subclinical. A small minority of patients with acute HCV infection will completely eliminate the virus, but as many as 85% proceed to develop a persistent infection. Recent estimates suggest that more than 4 million Americans are chronically infected with HCV.[34] Serum antibodies directed against the virus concomitant with the presence of HCV RNA establish the diagnosis of chronic infection. Ominously, as many as 20% of patients with chronic HCV develop cirrhosis, and hepatic failure resulting from this complication is currently the most common indication for liver transplantation in this country. Older patients who abuse alcohol or those coinfected with HIV appear to be particularly susceptible to more rapid progression of end-stage liver disease resulting from chronic HCV infection.[35] The combination of peginterferon (interferon with a polyethylene side chain) and ribavirin is currently the most efficacious drug regimen for the treatment of chronic HCV infection, may be continued for as long as 12 months depending on the viral load response, and appears to substantially reduce the incidence of cirrhosis and hepatic failure.[36] Chronic HCV infection is also associated with membranoproliferative glomerulonephritis with or without cryoglobulinemia in injection-drug users. This combined nephrotic–nephritic syndrome is characterized by proteinuria, hematuria, hypertension, and renal insufficiency. A membranous glomerulonephropathy produced by the deposition of virus core protein has also been described in injection-drug users with chronic HCV infection. Lastly, injection-drug users with hepatitis-induced cirrhosis are at risk of developing bacterial hepatic superinfections or spontaneous bacterial peritonitis. Gram-negative enteric bacilli are the most common cause of these frequently fatal complications.

Human Immunodeficiency Virus

Injection-drug use is a major risk factor for the transmission of HIV. The Centers for Disease Control and Prevention identified injection-drug use as the presumed route of transmission in 31% of adults with newly diagnosed HIV infection.[37] Injection-drug use was also implicated as the primary cause of 39% of reported cases of maternal-fetal transmission of the virus. The use of highly active antiretroviral therapy (HAART) has profoundly altered the natural history of HIV infection, substantially prolonged survival in patients infected with the virus, and reduced annual mortality resulting from AIDS. When combined with intensive public health emphasis on reducing transmission risk and treatment of HIV-positive patients by specialists knowledgeable about the disease, widespread use of HAART, rapid development of new drugs to treat HIV/AIDS, and evidence-based drug prophylaxis directed against opportunistic AIDS-related infections (e.g., *P. carinii* pneumonia, *T. gondii* encephalitis, disseminated *M. tuberculosis* and *M. avium intracellulare*) has transformed HIV infection from a "death sentence" diagnosis into a manageable chronic illness. The initial HIV infection is usually characterized by a variety of nonspecific signs and symptoms (e.g., fever, pharyngitis, lymphadenopathy) that typically occur within 4 weeks of exposure. The vast majority of patients display positive serology for the virus within 6 months of infection. Viral replication within the lymphatic system occurs rapidly during this latent phase of the disease, and prognosis is strongly correlated with viral load after the initial replication has stabilized. The clinical diagnosis of HIV is usually not established until several years after the initial transmission in many patients, often in conjunction with the appearance of manifestations of immunocompromise. The presence of HIV RNA and at least two specific HIV antigens are required for the diagnosis to be made. Progression of HIV infection from the latent phase to AIDS is characterized by continued viral replication and release from lymph node reservoirs accompanied by an insidious decrease in CD4 cell number. Without treatment, most patients with HIV die approximately 10 years after initial infection, although a small subset with persistently elevated CD4 cell counts and depressed viral load has also been identified in whom longer life expectancy occurs. HIV-induced nephropathy often complicates management of black patients infected with the virus and primarily occurs at later stages of HIV disease. HIV-nephropathy pre-

sents as a clinical nephrotic syndrome histologically characterized by focal and segmental glomerulosclerosis, and rapidly leads to dialysis-dependent renal failure in the absence of antiretroviral treatment. The pathophysiology of HIV-induced nephropathy remains unclear despite extensive study, but appears to involve direct viral infection of the kidney.

HIV treatment is very complex and is not reviewed in detail here. In general, medical management of HIV follows well-established guidelines[38] based on CD4 cell number, viral load, drug resistance, and the prevention or treatment of AIDS-related opportunistic infections. The combination of a protease inhibitor with nucleoside and nonnucleoside reverse transcriptase inhibitors forms the basis of antiretroviral therapy in HIV infection and is tailored to produce sustained reductions in viral load and enhanced immunologic function. The use of this HAART strategy has substantially prolonged life expectancy and improved quality of life for patients with the disease. Despite the optimism provided by promising developments in HIV treatment, injection-drug users continue to suffer a higher incidence of HIV-related complications and more rapid progression to AIDS as compared to those infected with the virus who do not use injection drugs. As a result, a disproportionate number of AIDS cases occur in injection-drug users in major United States cities.[39] Active drug abuse contributes to reduced adherence with HAART (which often requires taking multiple daily doses of several medications with significant side-effect profiles on differing schedules) as does the presence of coexisting psychiatric disease (most notably, depression), marginalized socioeconomic conditions, and important drug interactions between antiretroviral drugs and methadone. This latter caveat is particularly important to recognize because several protease inhibitors (e.g., ritonavir, nelfinavir, lopinavir) and nonnucleoside reverse transcriptase inhibitors (e.g., efavirenz, nevirapine) are known to increase methadone metabolism, and recovering opioid addicts enrolled in methadone maintenance programs may either discontinue HAART or resume illicit opioid abuse because of withdrawal symptoms.[40] Such drug interactions between antiretroviral therapy and opioids may also have important ramifications for the anesthesiologist caring for the patient with HIV during the perioperative period.

DRUG-SPECIFIC MEDICAL COMPLICATIONS OF ABUSE

Alcohol

Alcohol abuse has profound and extensive medical consequences that impact every organ system (Table 23–2). Heavy alcohol use (defined as at least 5 drinks per day on more than 5 days of the week) has been documented in 7% of the U.S. population and is even more prevalent in patients presenting for medical or surgical evaluation. Alcohol abuse is a major risk factor for perioperative morbidity and mortality,[41] and yet many clinicians often fail to recognize the disease. Achieving preoperative abstinence before elective surgery substantially reduces the incidence of postoperative complications.[42]

Blood ethanol concentrations as low as 0.05 mg/dL produce acute hemodynamic effects that may have potentially important consequences for patients with heart disease. Mildly intoxicating doses of ethanol decrease myocardial contractility in vitro and cause left ventricular systolic and diastolic dysfunction in vivo. Such actions may result in further reductions in global cardiac performance in patients with preexisting cardiomyopathy. The mechanisms responsible for ethanol-induced myocardial depression remain unclear despite extensive study. Ethanol may produce toxicity by attenuating the availability of calcium for activation of the contractile apparatus and inhibiting myofilament calcium sensitivity or by adversely affecting myocardial metabolism of free fatty acids and proteins. The direct myocardial depressant actions of small amounts of ethanol may not be readily apparent because the drug and its major metabolites (e.g., acetaldehyde, acetate) dilate cutaneous and splanchnic arteriolar resistance vessels. Thus, ingestion of alcohol increases cardiac output in healthy individuals concomitant with a reduction in systemic vascular resistance despite a modest decline in intrinsic contractile function. Conversely, ethanol and its metabolites also indirectly enhance sympathetic nervous system activity and thereby produce tachycardia and hypertension mediated by stimulation of cardiac β_1-adrenoceptors, arterial vasoconstriction, and attenuation of baroreceptor reflex control of the circulation.[43] These actions combine to produce increases in myocardial oxygen consumption and may contribute to the development of myocardial ischemia or infarction in heavy ethanol users with coronary artery disease. In fact, a higher incidence of acute myocardial ischemia has been previously reported after ingestion of large quantities of ethanol in these patients, often in the absence of classical anginal symptoms that are frequently obscured by the presence of the drug. Myocardial ischemia or infarction may also occur during ethanol withdrawal in patients with coronary artery disease as a result of exaggerated sympathetic nervous system activity or coronary vasospasm.

There is a strong cause-and-effect relationship between alcohol abuse and hypertension.[44] The combination of repetitive, heavy ethanol use and withdrawal enhance centrally mediated sympathetic nervous system activity and produce hypertension by overwhelming the direct but transient vasodilatory effects of the drug and its metabolites.[43] This alcohol-induced hypertension is mediated by activation of vascular smooth muscle α_1-adrenoceptors, is reversible with abstinence, and rapidly recurs with relapse. The "pressor" effect of ethanol is also characterized by prominent blood pressure responses to other forms of physiologic stress that have also been observed in alcoholics after prolonged abstinence. Alcohol-induced hypertension is dose related, occurs more frequently in white men and postmenopausal women, and is exaggerated by the presence of underlying essential hypertension.

Heavy alcohol use is linked to the development of coronary atherosclerosis and is associated with increased morbidity and mortality resulting from coronary artery disease.[45] These adverse effects of alcohol abuse may be attributed to the presence of long-standing hypertension and increases in blood homocysteine concentrations. Conversely, consumption of modest amounts of alcohol produces significant myocardial protection against ischemic injury.[46] Several large-scale epidemiologic studies provide compelling evidence that chronic consumption of small amounts of ethanol reduces cardiovascular mortality, decreases the in-

TABLE 23–2.

Medical Complications of Alcohol and Drug Abuse

Drug	Cardiovascular	Pulmonary	Neurologic	Hepatic/GI	Renal	Other
Alcohol	LV dysfunction Myocardial ischemia or infarction Coronary artery disease Hypertension Cardioprotection (modest doses) Cardiomyopathy Reduced systemic vascular resistance (hepatic cirrhosis) Atrial and ventricular arrhythmias ("holiday heart") Sudden cardiac death	Respiratory depression/failure Aspiration Exacerbation of asthma Reduced functional vital capacity (ascites) Hypoxemia Hepatopulmonary syndrome Pulmonary hypertension Community-acquired pneumonia	Seizures during use or withdrawal Ischemic or hemorrhagic stroke Cerebral protection against ischemia (modest doses) Impaired cognition Compression neuropathy Peripheral polyneuropathy	Alcoholic fatty liver Alcoholic hepatitis GERD Upper GI bleeding Pancreatitis (acute or chronic)	Renal tubular dysfunction Renal tubular acidosis Hepatorenal syndrome	Myelopathy Alcoholic ketoacidosis ↓Potassium ↓Magnesium ↓Phosphate ↓Vitamin K-dependent coagulation factors Pancytopenia Malnutrition Immunosuppression
Sedative–hypnotics		Respiratory depression Atelectasis Aspiration	Sedation, obtundation, and coma			
Opioids	Reduced LV preload Bradycardia Cardioprotection Endocarditis	Talc granulomatosis Septic pulmonary emboli Mycotic pulmonary aneurysm Pulmonary hypertension/RV failure Pneumo-, hemo-, chylothorax Empyema Mucosal damage Bronchospasm Barotrauma Emphysema Respiratory depression/failure Aspiration pneumonitis Noncardiogenic pulmonary edema Pneumonia Hypersensitivity pneumonitis	Seizures (meperidine, pentazocine) Ischemic or hemorrhagic stroke Myelopathy Guillain-Barré syndrome Encephalopathy	Ileus Intestinal pseudoobstruction Hepatic granulomatosis	Heroin nephropathy(?) Nephropathy related to infectious disease	Malnutrition Immunosuppression
Cocaine	Sympathetic nervous system activation Myocardial ischemia/infarction	Pulmonary vasoconstriction Reduced diffusion capacity	Ischemic stroke Hemorrhagic stroke	Bowel ischemia/infarction Bowel obstruction or drug toxicity (body "packing" or "stuffing")	Infectious disease-related nephropathies Renal ischemia/infarction	Malnutrition Immunosuppression

TABLE 23–2.

Medical Complications of Alcohol and Drug Abuse (Continued)

Drug	Cardiovascular	Pulmonary	Neurologic	Hepatic/GI	Renal	Other
	Coronary vasospasm Accelerated atherosclerosis Hypertension Ventricular arrhythmias Sudden cardiac death Dilated cardiomyopathy Pulmonary edema Aortic or coronary dissection Peripheral vascular insufficiency	Alveolar hemorrhage Noncardiogenic pulmonary edema Eosinophilic hypersensitivity pneumonitis ("crack lung") Mucosal injury Sinusitis Burns ("freebasing")	Cognitive dysfunction Seizures	Cocaine hepatitis	Renal insufficiency caused by hypertension Rhabdomyolysis Thrombotic microangiopathy	
Amphetamines	Similar to cocaine Necrotizing vasculitis	Similar to cocaine Pulmonary hypertension	Ischemic and hemorrhagic strokes Seizures associated with drug toxicity Paranoia/psychosis	Hepatic failure (MDMA) Hepatitis A (methamphetamine)	Accelerated hypertensive renal disease Necrotizing vasculitis Rhabdomyolysis	Iatrogenic hyponatremia Malnutrition Immunosuppression
Marijuana	Myocardial ischemia/infarction (patients with CAD) Ventricular ectopy	Chronic bronchitis Emphysema CO-hemoglobinemia Fungal pneumonia Hypersensitivity pneumonitis				
Hallucinogens	Similar to cocaine and amphetamines		Hallucinations, delusions, paranoia Seizures Myoclonus Ischemic or hemorrhagic stroke	Hepatic necrosis	Rhabdomyolysis	Profound hyperthermia
Inhalants		Respiratory depression Bronchospasm Hemoptysis Aspiration Barotrauma Asphyxiation Methemoglobinemia (amylnitrate)	Dementia (toluene) Lead encephalopathy (gasoline) Polyneuropathy (hexane)			Metabolic acidosis (toluene)

Abbreviations: CAD, coronary artery disease; CO, carbon monoxide; GERD, gastroesophageal reflux disease; GI, gastrointestinal; LV and RV, left and right ventricular, respectively; MDMA, 3, 4-methylenedioxymethamphetamine.

cidence of coronary artery disease, and improves survival during acute myocardial infarction. Favorable alterations in lipid metabolism, direct antioxidant effects, inhibition of platelet aggregation, antifibrinolytic actions, and arterial vasodilatation mediated by release of nitric oxide have been proposed as potential mechanisms for these beneficial effects. More recently, a growing body of experimental evidence suggests that chronic, moderate ethanol consump-

tion activates many of the endogenous signal transduction pathways that were previously implicated in cardioprotection produced by classical and delayed ischemic preconditioning.[46] These findings suggest a molecular basis for myocardial protection by chronic ingestion of modest amounts of alcohol. Small quantities of specific alcoholic beverages (e.g., red wine, beer) may further reduce the incidence of and complications related to coronary artery disease by exerting antioxidant effects or augmenting vitamin B_6 metabolism. Despite these convincing data suggesting that small amounts of alcohol may produce favorable cardiovascular effects, substantial individual variability in ethanol-induced myocardial protection may exist, and "rebound" phenomena that theoretically increase the risk of cardiovascular complications have also been described with abrupt cessation of alcohol intake. This latter caveat may be of particular importance as temporary abstinence from alcohol consumption is required during the perioperative period.

Alcohol abuse is associated with a dilated cardiomyopathy characterized by myocardial hypertrophy, biatrial and biventricular dilation, interstitial fibrosis concomitant with loss of actin and myosin proteins, profound disruption of myocyte organelle structure, and severe contractile dysfunction culminating in congestive heart failure and death.[47] The development of alcoholic cardiomyopathy requires prolonged alcohol abuse, and patients with this disorder are typically older, heavier alcohol abusers than alcoholics who maintain relatively normal cardiac geometry and performance. Alcoholic cardiomyopathy occurs independent of the malnutrition that frequently accompanies alcohol addiction, is most often observed in black men, and is most likely unrelated to preservatives or other substances that may be added to alcoholic beverages by manufacturers. The mechanisms responsible for alcoholic cardiomyopathy are unknown, but direct toxicity of the drug or its metabolites has been proposed as a major etiology of the disorder. Left ventricular systolic dysfunction in patients with alcoholic cardiomyopathy may be further accelerated by the sustained increases in afterload that result from the alcohol-induced hypertension. Notably, alcoholic cardiomyopathy may often be detected in clinically asymptomatic alcoholics using noninvasive techniques (e.g., echocardiography, cardiac magnetic resonance imaging) and may be reversible with abstinence at this early stage in the natural history of the disease.

Advanced hepatic cirrhosis resulting from alcohol abuse produces alterations in systemic hemodynamics that may obscure the presence of alcoholic cardiomyopathy. Decompensated cirrhosis is characterized by increases in cardiac output that occur in response to marked decreases in systemic vascular resistance.[48] A correlation between the degree of hepatic dysfunction and the magnitude of reduction in systemic vascular resistance was previously established.[48] The abnormal arterial–venous shunting that accompanies chronic hepatic dysfunction does not appear to be primarily responsible for the hyperdynamic circulatory responses. Instead, enhanced production of nitric oxide has been implicated as a likely cause of cirrhosis-induced declines in peripheral resistance,[49] as nitric oxide synthase inhibitors abolished increases in basal forearm blood flow in patients with alcoholic liver disease. Notably, the presence of ascites and consequent reductions in left ventricular preload may stimulate compensatory sympathetic nervous system-mediated vasoconstriction that attenuates cirrhosis-induced vasodilatation.

Atrial or ventricular arrhythmias are frequently observed in alcohol abusers, and develop most often after a binge-drinking episode. This "holiday heart" syndrome usually occurs in otherwise healthy individuals in the absence of demonstrable heart disease or abnormalities in serum electrolyte concentrations. However, the sudden appearance of a new arrhythmia may also suggest the presence of alcoholic cardiomyopathy in a small minority of patients. Atrial fibrillation is the most commonly encountered arrhythmia associated with alcohol, and the unanticipated presentation of atrial fibrillation suggests that the diagnosis of alcohol abuse should be entertained. The mechanisms by which alcohol precipitates atrial fibrillation remain unclear despite extensive study. An increased risk of sudden cardiac death has also been reported in alcohol abusers with or without coronary artery disease, presumably as a result of malignant ventricular arrhythmias.[50] Hypokalemia and hypomagnesemia are common in patients with alcohol addiction, and these electrolyte abnormalities may play an important contributing role to the development of ventricular arrhythmias. Other potential etiologies for alcohol-induced sudden cardiac death include acute myocardial ischemia, coronary vasospasm, or withdrawal-induced increases in sympathetic nervous system activity.

Alcohol abuse produces a wide variety of pulmonary complications that are related to the acute and chronic effects of the drug.[51] Ethanol is a potent depressant of centrally mediated respiratory activity, and acute intoxication may be associated with hypoxemia, hypercarbia, respiratory acidosis, atelectasis, and respiratory failure. Such complications may be more pronounced in patients with preexisting respiratory pathology (e.g., chronic obstructive or restrictive pulmonary disease, obstructive sleep apnea, upper airway neoplasm). Aspiration pneumonitis complicated by adult respiratory distress syndrome may occur during acute intoxication as a result of an altered level of consciousness and compromise of airway protective reflexes. Ingestion of ethanol is known to exacerbate bronchospastic lung disease, especially in patients with histamine-sensitive asthma. Acetaldehyde-induced mast cell degranulation with the subsequent release of histamine, leukotrienes, and other inflammatory mediators has been implicated as a potential mechanism of alcohol-induced bronchospasm. Conversely, other patients with asthma have described symptomatic improvement with alcohol ingestion, suggesting that the acute effects of ethanol on airway reactivity may be difficult to predict.

Several important pulmonary complications of chronic alcohol abuse occur in patients with cirrhosis. The presence of large quantities of ascitic fluid substantially reduces vital and functional residual capacities, resulting in atelectasis, tachypnea, dyspnea, and rapid arterial oxygen desaturation during induction of general anesthesia. This clinical picture may be further exacerbated by pleural effusion resulting from negative intrathoracic pressure-mediated movement of ascitic fluid across the diaphragm to the pleural space. Hypoxemia may also develop in patients with alcoholic cirrhosis

because of abnormal pulmonary arterial–venous shunts. This "hepatopulmonary syndrome" is characterized by markedly reduced pulmonary vascular resistance and is observed in as many as 15% of patients with cirrhosis.[52] Enhanced production of nitric oxide and altered hepatic metabolism of estrogen and progesterone have been proposed as potential etiologies for hepatopulmonary syndrome. Conversely, a small minority of patients with alcoholic cirrhosis develop pulmonary hypertension, most likely because the unopposed actions of circulating vasoactive substances that normally are metabolized by the liver. Notably, the diagnosis of this "portal" pulmonary hypertension may be overlooked because many of the signs and symptoms of right ventricular failure mimic those of chronic hepatic dysfunction. In fact, portal pulmonary hypertension that is unresponsive to pulmonary vasodilators is a relative contraindication to liver transplantation in patients with alcoholic cirrhosis. Lastly, chronic alcohol abuse is associated with enhanced susceptibility to pneumonia caused by a variety of pathologic organisms including *Klebsiella* and *Streptococcus pneumoniae* and *M. tuberculosis*. Depression of immunologic function, concomitant tobacco abuse, and malnutrition probably contribute to the increased incidence of community-acquired pneumonia in this patient population.

Seizures and cerebrovascular accidents are common neurologic complications observed in alcohol abusers. In the absence of other possible causes (e.g., past history of epilepsy, central nervous system infection or trauma, cerebrovascular accident), alcohol-induced seizures are most often associated with drug withdrawal and are either single, grand mal events or occur in brief clusters of global epileptiform activity. Status epilepticus or focal seizure activity are infrequently observed during alcohol withdrawal seizures. The exclusion of other potential seizure etiologies in conjunction with a history of abrupt cessation of heavy alcohol consumption within 48 hours of the event is required for the diagnosis to be established. Anticonvulsant medications are usually not required for the treatment of alcohol withdrawal seizures, as these events are typically self-limited. Seizures may also occur during active alcohol consumption independent of withdrawal. The mechanisms responsible for seizures under these conditions are unclear, but alcohol may stimulate central nervous system excitability *via* its actions on glutamate metabolism and *N*-methyl-D-aspartate (NMDA) receptor activity. Similar to previously reported reductions in cardiovascular risk associated with moderate alcohol consumption, many epidemiologic studies suggest that daily ingestion of small quantities of alcohol may reduce the risk of cerebrovascular accidents.[53] It appears highly likely that many of the factors implicated in alcohol-induced cardioprotection are responsible for these beneficial actions against stroke. In contrast, chronic alcohol abuse is strongly associated with an increased incidence of hemorrhagic and ischemic strokes. The presence of hypertension, concomitant cardiovascular disease, direct vasoconstriction of cerebral arterioles, and a prothrombotic state contribute to the enhanced risk of stroke in alcohol abusers.

Sustained impairment of cognitive function frequently occurs in chronic alcohol abusers and may be observed as a consequence of closed cranial trauma, infection, hepatic encephalopathy, or malnutrition. Dementia occurs in as many as 10% of patients with alcohol addiction. Severe alterations in cognitive function produced by alcohol abuse may jeopardize the ability of the anesthesiologist or surgeon to obtain informed consent and may also undermine compliance with treatment during the perioperative period. Thiamine deficiency precipitated by alcohol-induced malnutrition produces Wernicke encephalopathy, and if inadequately treated, causes Korsakoff syndrome. Characterized by confusion, memory and attention deficits, nystagmus, and ataxia, Wernicke encephalopathy is initially fully reversible with appropriate thiamine replacement. In contrast, Korsakoff syndrome is identified by irreversible memory deficits, amnesia, inability to recall new information, and confabulation. Nutritional deficiency of nicotinic acid also occurs in alcohol abusers and causes pellagra. A reversible encephalopathy, characterized by cognitive impairment, delusion, hallucination, and delirium, is the major neurologic complication of pellagra. A more ominous cause of alcohol-induced impaired cognition is Marchiafava-Bignami disease, a rapidly progressing neurologic disorder that is histologically characterized by segmental demyelination of the corpus callosum.

Myopathy and neuropathy are frequently observed in alcohol abusers. The clinical spectrum of alcoholic myelopathy ranges from an isolated increase in blood creatine kinase concentration in the absence of symptoms to severe muscle wasting that resembles polymyositis. Peripheral compression nerve palsies, rhabdomyolysis, and compartment syndromes commonly occur because alcohol abusers may lose consciousness and remain immobile for prolonged periods. A sensory-motor polyneuropathy has also been described in alcohol abusers characterized by progressive distal extremity sensory deficits, weakness, and pain with or without autonomic nervous system dysfunction. Like alcoholic cardiomyopathy, alcohol-induced myelopathy and polyneuropathy most likely occur as a direct result of drug toxicity, although malnutrition may also play an important contributing role.

Alcoholic liver disease is perhaps the most well-recognized complication of alcohol abuse. The importance of this disorder should not be overlooked, as hepatic failure resulting from alcohol abuse is responsible for more than 25,000 deaths annually in the United States.[54] Until it was surpassed by chronic HCV, alcohol-induced hepatic cirrhosis was the most common indication for liver transplantation in this country. The total amount of alcohol ingested per day and the duration of alcohol abuse are major risk factors for the development of alcoholic liver disease. Female gender, malnutrition, coexisting HBV or HCV infection, obesity, and genetic predisposition also have been identified as risk factors for the development of alcoholic liver disease. Abuse of alcohol produces three important hepatic manifestations that represent a continuum of progressive disease but may also simultaneously coexist. Fatty liver may be observed in chronic alcohol abusers but may also occur after several days of binge drinking in healthy individuals. Clinical signs and symptoms of alcohol-induced fatty liver include nausea, vomiting, anorexia, and right upper quadrant pain concomitant with preserved or mildly elevated liver function tests. The relative perioperative risk associat-

ed with alcoholic fatty liver has not been rigorously evaluated, but it is probably prudent to delay elective surgery until abstinence is achieved and clinical symptoms resolve.

The presentation of alcoholic hepatitis is similar to that of viral hepatitis, and is characterized by fever, jaundice, abnormal liver function tests, and right upper quadrant pain. Severe alcoholic hepatitis is associated with high mortality, is often accompanied by ascites, encephalopathy, and coagulopathy, and represents a contraindication to elective surgery.[55] Portal hypertension, ascites, esophageal varices, hepatic encephalopathy, spontaneous bacterial peritonitis, and coagulopathy resulting from decreased synthesis of coagulation factors and thrombocytopenia typify end-stage liver disease resulting from cirrhosis. In addition to clinical signs and symptoms, the diagnosis of alcoholic liver disease is established on the basis of a history of sustained alcohol abuse concomitant with characteristic abnormalities in liver function tests. Markedly increased blood gamma-glutamyl transpeptidase concentrations are accompanied by elevations in aspartate aminotransferase (AST) that usually exceed those of alanine aminotransferase (ALT), hyperbilirubinemia, hypoalbuminemia, and prolonged prothrombin time. Surgical risk in patients with alcoholic cirrhosis depends on the severity of the disease. For example, one study quoted mortality rates for alcohol abusers with the Child classifications A, B, and C hepatic disease undergoing abdominal surgery as 10%, 31%, and 76%, respectively.[56] The evaluation of patients with liver disease and its consequences for anesthetic management are discussed in further detail in Chapter 56.

A number of gastrointestinal complications have potential implications for anesthesiologists who are caring for patients with alcohol addiction. Gastroesophageal reflux frequently occurs in association with acute alcohol ingestion because of reductions in lower esophageal sphincter tone. Chronic alcohol use also reduces maximal lower esophageal sphincter pressure. These actions predispose the alcohol abuser to the risk of acid aspiration. The presence of upper gastrointestinal bleeding also increases aspiration risk during induction of general anesthesia. Upper gastrointestinal hemorrhage may occur as a result of direct alcohol-induced esophageal, gastric, or duodenal mucosal injury, esophageal varices, or tears of the gastroesophageal junction produced by vomiting (i.e., Mallory-Weiss syndrome). Clearly, severe upper gastrointestinal bleeding may cause profound hypovolemia requiring aggressive volume replacement with blood products and often compels immediate endoscopic or surgical intervention in order to successfully manage. Active upper gastrointestinal hemorrhage or the presence of esophageal varices also represent relative contraindications to the use of intraoperative transesophageal echocardiography. Alcohol abuse is a major risk factor for the development of acute and chronic pancreatitis. Acute pancreatitis resulting from alcohol abuse is characterized by inflammation of the organ that may also involve surrounding structures and presents with severe abdominal pain, nausea and vomiting, and hyperamylasemia concomitant with a history of prolonged alcohol consumption. Acute alcoholic pancreatitis may be complicated by respiratory insufficiency, renal failure, and sepsis. Enzymatic autodigestion of the pancreas and the release of cytotoxic reactive oxygen intermediates have been implicated in the pathogenesis of alcohol-induced acute pancreatitis. Pain and variable degrees of endocrine and exocrine dysfunction are typical features of chronic pancreatitis and are exacerbated by further alcohol abuse. Chronic administration of opioids or celiac plexus neurolytic blocks are often required for pain management in patients with alcohol-induced chronic pancreatitis.

Hepatorenal syndrome is the most devastating renal complication of chronic alcohol abuse and is almost always fatal without liver transplantation. Hepatorenal syndrome is characterized by profound hepatic dysfunction, splanchnic vasodilatation, and intense renal arterial vasoconstriction.[57] The diagnosis of hepatorenal syndrome requires the exclusion of other causes of nephrotoxicity and is distinguished by progressive oliguric renal failure and reduced glomerular filtration rate that are unresponsive to volume administration concomitant with a gradual increase in serum creatinine concentration and a markedly reduced urine sodium concentration. The diagnosis of hepatorenal syndrome may initially be difficult to establish because reduced muscle mass resulting from chronic malnutrition is commonly observed in alcohol abusers, and increases in serum creatinine and blood urea nitrogen concentrations may not become apparent until late in the natural history of the disease. Hepatorenal syndrome may occur in conjunction with a major complication of alcohol-induced end-stage liver disease (e.g., sepsis, upper gastrointestinal hemorrhage), but also may develop insidiously without an apparent underlying cause.

Alcohol abuse produces several important acid–base and electrolyte derangements as a result of the combination of gastrointestinal losses and malnutrition. Perhaps the frequent severe metabolic complication in this regard is alcoholic ketoacidosis. This anion gap acidosis may be profound, usually occurs in alcohol abusers after binge drinking, and results from enhanced lipolysis and attenuated gluconeogenesis associated with profound carbohydrate malnutrition. Chronic diarrhea or renal tubular damage may cause nonanion gap metabolic acidosis in alcohol abusers as well. Hypokalemia is very common in alcohol abusers, occurs as a consequence of losses from the gastrointestinal tract combined with secondary hyperaldosteronism, and unless corrected, may exacerbate preexisting hepatic encephalopathy or precipitate rhabdomyolysis. Other common electrolyte abnormalities in alcohol abusers are hypomagnesemia and hypophosphatemia. Gastrointestinal loss, malnutrition, and alcohol-induced renal tubular dysfunction combine to produce these deficiencies in alcohol abusers. Notably, hypomagnesemia worsens hypokalemia, and treatment of potassium deficits requires simultaneous administration of magnesium. Alcohol abuse-induced hypophosphatemia is also associated with an increased risk of rhabdomyolysis and encephalopathy.

Ethanol causes direct bone marrow toxicity and produces pancytopenia that may be further exacerbated by splenic sequestration concomitant with portal hypertension. Iron and folate deficiency with or without acute or chronic blood loss and hemolysis resulting from fragility of red blood cell membranes also contribute to anemia in alcohol abusers. Because alcohol-induced anemia is often multifactorial

in nature, evaluation of mean corpuscular volume may not accurately reflect the underlying etiology. Leukopenia is also a common finding in alcohol abusers and substantially elevates infection risk on the basis of both reduced number and activity of polymorphonuclear leukocytes. Alcohol-induced thrombocytopenia may be profound, and in combination with reduced synthesis of vitamin K-dependent coagulation factors, substantially increases the risk of bleeding associated with gastrointestinal causes, traumatic injury, or surgical intervention.

Sedative–Hypnotics

The clinical pharmacology of barbiturates and benzodiazepines are discussed in Chapter 39. Briefly, barbiturates, benzodiazepines (including the ultrashort-acting agent flunitrazepam, known as the "date rape" drug), and the γ-aminobutyric acid (GABA) derivative γ-hydroxybutyrate (GHB, termed "liquid Ecstasy") act through GABA receptors to exert anxiolytic, anticonvulsant, amnestic, and sedative effects.[58] The major complications associated with abuse of these drugs are respiratory depression and overdose, especially in the presence of alcohol or opioids. Barbiturate or benzodiazepine abuse produces sedation, obtundation, or coma with eventual loss of airway protective reflexes and contributes to progressive alveolar hypoventilation, hypoxemia, hypercarbia, respiratory acidosis, and death. In the past, death from barbiturate abuse-mediated respiratory depression was not uncommon, but the clinical use of these drugs in the treatment of anxiety disorders has been largely usurped by benzodiazepines or specific selective serotonin reuptake inhibitors (SSRIs) that display a substantially greater margin of safety. Nevertheless, death resulting from benzodiazepine overdose has been reported, although most often in conjunction with the abuse of other drugs.

Opioids

Heroin is the most commonly abused opioid in the United States. The Office of National Drug Control Policy estimates that more than 900,000 individuals in this country suffer from heroin addiction.[59] Heroin and other opioid abusers have markedly elevated risk for developing a wide variety of potentially devastating medical complications. The clinical pharmacology of opioids is very well known to anesthesiologists and is reviewed in detail in Chapter 41. This section instead focuses on pathology specifically associated with opioid abuse. Cardiovascular stability is a hallmark of administration of opioids, and even large quantities of opioids (such as those used during cardiac anesthesia) typically produce only minor alterations in systemic hemodynamics. Most naturally occurring and synthetic opioids dilate venous capacitance and splanchnic arteriolar vessels, causing small reductions in arterial pressure independent of the histamine release that may occur with some opioids (e.g., heroin, morphine). It is precisely these actions of opioids on ventricular loading conditions that make these drugs especially useful for the clinical treatment of heart failure complicated by acute pulmonary edema. Opioids also produce modest reductions in heart rate but do not substantially affect myocardial contractility or cardiac output under most clinical conditions. Opioids exert cardioprotective effects against infarction[60] and may also produce antiarrhythmic actions in ischemic myocardium. As a result, opioid abuse usually produces few, if any, direct cardiovascular consequences, in contrast to stimulants such as cocaine or amphetamines. As discussed earlier, endocarditis is the major cardiovascular complication associated with opioid abuse.

Opioid-induced pulmonary complications are diverse and are responsible for as much as 20% of all hospital admissions related to the abuse of these drugs. Intravenous abuse of opioids may produce acute or chronic pulmonary consequences associated with substances that contaminate the drug or those related to the route of administration. For example, magnesium silicate (talc) is frequently used in oral preparations manufactured by pharmaceutical companies or may be mixed with an illicit opioid to dilute the drug. Injection or inhalation of magnesium silicate or other contaminants may cause pulmonary granulomatosis, a form of diffuse micronodular interstitial fibrosis characterized by dyspnea on exertion, cough, and diminished diffusion capacity. The clinical presentation of "talc granulomatosis" is similar to sarcoidosis and may be complicated by frank occlusion of pulmonary arterial branches by granulomas, pulmonary hypertension, and right ventricular failure. Chronic hypoxemia and reactive pulmonary arterial vasoconstriction resulting from interstitial fibrosis may also contribute to the development of pulmonary hypertension or cor pulmonale under these conditions. Bullous emphysema has been reported as another chronic complication of talc granulomatosis in intravenous opioid abusers. As discussed earlier, septic pulmonary embolism is a frequent complication of injection drug abuse that may occur as a result of thrombophlebitis at the injection site or more commonly, tricuspid valve endocarditis. Mycotic aneurysms also occur as a consequence of seeding of the pulmonary vasculature with septic thromboemboli, and rupture of a pulmonary mycotic aneurysm may cause life-threatening hemoptysis. Broken needle fragments may embolize to the lung parenchyma, but do not typically require removal unless complicated by infection or hemorrhage. Pneumothorax, hemothorax, chylothorax, and empyema are also well-known complications associated with attempted opioid injection into the internal jugular or subclavian vein (termed "pocket shooting").

Smoking or nasal inhalation of opioids is also associated with several pulmonary complications. Particulate substances are distributed throughout the bronchial tree depending on size, and contribute to mucosal irritation, inflammation, fibrosis, and granulomatosis. Chemical compounds produced by ignition of drugs or solvents also produce mucosal damage. Thus patients who use inhaled opioids are susceptible to the development of bronchospasm, bronchitis, airway injury, or hemoptysis. Barotrauma (e.g., pneumothorax, pneumomediastinum) may occur during inhaled opioid abuse as a result of intense breath-holding performed to enhance the actions of the drug. Such a sustained Valsalva maneuver produces lung hyperinflation and pronounced negative intrathoracic pressure that may result in peribronchial dissection of air or rupture of alveolar blebs. Barotrauma may also occur if smoke is forcefully exhaled from one user into the lungs of another (known as "shotgunning"). Lastly, chronic abuse of inhaled opioids is associated with the development of emphysema.

Pulmonary complications may also result from the direct actions of opioids on central nervous system control of respiration, airway reactivity, pulmonary arterial vascular tone, and immunological response to infectious agents. Opioids bind to μ_2 receptors in the pons and medulla, thereby attenuating respiratory automaticity, inhibiting centrally mediated airway protective reflexes, and reducing the influence of carbon dioxide on respiratory drive in a dose- and route of administration-dependent manner. These actions produce respiratory depression culminating in apnea, a major cause of mortality associated with opioid overdose.[61] Loss of airway reflexes combined with a diminished level of consciousness also predisposes the opioid abuser to aspiration pneumonitis and its associated complications (e.g., hypoxemia, respiratory insufficiency requiring mechanical ventilation, superimposed bacterial pneumonia). Opioid-induced release of histamine from mast cells may precipitate bronchospasm in drug abusers with asthma. Histamine release by opioids may occur as a result of direct activation of μ opioid receptors or via an IgE-mediated mechanism.

Noncardiogenic pulmonary edema occurs in up to one-half of all patients presenting with opioid overdose and is associated with substantial mortality. Pulmonary edema has been described with either intravenous or inhalational opioid abuse and appears to be dose related. Pulmonary edema has also been reported in first-time opioid abusers independent of dose. The mechanisms responsible for opioid-induced pulmonary edema remain unclear. Opioids may directly increase pulmonary capillary permeability, thereby facilitating accumulation of protein and fluid in the alveoli by hydrostatic forces. A neurogenic component to pulmonary edema has also been proposed in which opioids precipitate a pronounced centrally mediated efferent response that causes pulmonary venoconstriction and increases pulmonary capillary permeability.[62] Histamine release by opioids may also produce constriction of pulmonary veins and enhance permeability of pulmonary capillary membranes. Aspiration pneumonitis and secondary bacterial pneumonia often complicate the management of patients with opioid-induced pulmonary edema. A hypersensitivity pneumonitis characterized by dyspnea, cough, and bilateral pulmonary infiltrates appearing several days after nasal inhalation has been described in heroin users. Opioid abuse attenuates phagocytosis by neutrophiles and macrophages, reduces T-cell and killer cell activity, decreases CD4 cell count, promotes leukocyte apoptosis (programmed cell death), depresses white blood cell chemotaxis, and curtails delayed hypersensitivity reactions.[63] These profound affects on the immune response to pulmonary pathogens markedly increase the risk of infection in the chronic opioid abuser.

Opioid abuse is associated with several important neurologic consequences. Seizures are a rare side effect of heroin or morphine abuse or withdrawal, and the occurrence of seizures in patients who have abused these opioids should prompt the clinician to investigate other potential etiologies (e.g., infection, trauma, cerebrovascular accident, toxicity or withdrawal related to other drugs of abuse). In contrast to the findings with heroin and morphine, meperidine abuse is associated with the development of seizures because of the epileptogenic properties of normeperidine, a major meperidine metabolite.[64] Seizures have also been reported after intravenous abuse of the mixed opioid agonist–antagonist pentazocine in combination with the antihistamine tripelennamine (known as "T's and Blues"). Heroin abuse is reported to cause ischemic cerebrovascular accidents independent of other causes of stroke. Ischemic strokes may occur as a result of embolization of pulverized oral medication after injection, severe hypotension after overdose, or cerebral vasculitis. In contrast, hemorrhagic strokes usually occur in opioid abusers concomitant with infectious disease-related complications or renal failure. A myelopathy characterized by sensory loss, paraparesis, and urinary retention has been described in heroin abusers that may be related to spinal cord infarction or vasculitis. Immunologically mediated Guillain-Barré syndrome and brachial or lumbar plexopathies have also been reported in heroin addicts. Lastly, a profoundly debilitating and often fatal leukoencephalopathy is described in heroin abusers who inhaled drug vapors produced by heating on metal foil (known as "chasing the dragon").

Heroin use is associated with the development of focal and segmental glomerulosclerosis concomitant with hypertension and progressive renal insufficiency. Initially, heroin nephropathy was attributed to drug impurities and the presence of contaminants. However, clinical description of heroin nephropathy has declined significantly because of its close resemblance to HIV and HCV nephropathies.[65] Thus it appears highly likely that heroin nephropathy is probably a manifestation of coincident HIV or HCV infection and is not mediated by the drug itself or other substances that contaminate it.

Cocaine

More than 3.6 million Americans are chronic cocaine users.[66] The vast majority of the cocaine-induced medical consequences are related to pharmacologic properties of the drug[67] or infectious diseases associated with its use. In addition to its well-known local anesthetic effects, cocaine produces intense vasoconstriction in nearly all vascular beds as a result of inhibition of presynaptic reuptake of norepinephrine, enhanced actions of circulating endogenous catecholamines, and augmented centrally mediated sympathetic nervous system activity. From a cardiovascular perspective, these actions produce tachycardia and hypertension, and as a result, pronounced increases in myocardial oxygen consumption. The acute hemodynamic effects of cocaine ingestion are associated with direct coronary vasoconstriction, vasospasm, and prothrombotic effects (e.g., increased platelet adhesion and aggregation) whose combined actions may produce myocardial ischemia and infarction.[68] This pathophysiology was dramatically emphasized by Mittelman et al., who reported that the risk of myocardial infarction was increased by greater than 20-fold during the first hour after cocaine use as compared to other times.[69] In fact, cocaine ingestion may be responsible for as much as 25% of acute myocardial infarctions in younger patients (ages 18–45 years),[70] independent of route or frequency of administration, drug quantity, or plasma concentration. With the exception of smoking, other classical risk factors for coronary artery disease are typically absent and angiographically documented coronary stenoses are present in only 50% of these patients.[68] Cocaine inhibits sarcolemmal Na^+, voltage-dependent Ca^{2+}, and K^+ channel conductance, attenuates Ca^{2+}-induced

Ca^{2+} release from the sarcoplasmic reticulum, and reduces myofilament Ca^{2+} sensitivity.[71] When combined with the sympathomimetic and vagolytic actions of the drug, these important alterations in cardiac electrophysiology may precipitate malignant ventricular arrhythmias and sudden cardiac death independent of myocardial ischemia or other preexisting heart disease.

Accelerated coronary atherosclerosis has been observed in chronic cocaine abusers that may contribute to the risk of myocardial ischemia or infarction.[72] The mechanisms responsible for this accelerated atherosclerosis are unclear, but release of inflammatory cytokines, repeated exposure to elevated circulating catecholamines, enhanced vascular endothelial permeability permitting intimal diffusion of atherogenic lipoproteins, and chronic vasospasm have been implicated as potential contributing factors. Repeated cocaine abuse is also associated with focal myocarditis and necrosis, pathologic findings that are very similar to those observed during chronically elevated levels of circulating catecholamines (e.g., pheochromocytoma). Cocaine-induced hypertension may contribute to the development of left ventricular hypertrophy, dilated cardiomyopathy with left ventricular systolic and diastolic dysfunction, and acute pulmonary edema, especially in patients with preexisting hypertension or concomitant alcohol abuse. Severe hypertension after cocaine ingestion may also contribute to the development of acute aortic or coronary artery dissection. In addition, the pronounced arterial vasoconstriction associated with cocaine ingestion may result in acute peripheral vascular insufficiency and limb ischemia. Notably, a greater risk of aortic or mitral valve endocarditis has also been suggested in cocaine as compared to heroin or amphetamine abusers.[68]

The pulmonary complications of cocaine abuse most often occur as a consequence of inhalation of the drug and are exacerbated by habitual tobacco or marijuana smoking. Like other inhaled drugs of abuse, inhalation of cocaine may be associated with bronchospasm, chronic bronchitis, barotrauma, hemoptysis, or pulmonary fibrosis.[73] As a result of its sympathomimetic properties, inhaled cocaine produces intense pulmonary vasoconstriction and increases vascular permeability. These actions contribute to an acute and marked reduction in diffusion capacity similar to that observed in chronic tobacco smokers. More ominously, the effects of inhaled cocaine on the pulmonary circulation may produce diffuse alveolar hemorrhage or noncardiogenic pulmonary edema resulting from elevated pulmonary capillary permeability.[73] Other noncardiogenic mechanisms for cocaine-induced pulmonary edema have also been described, including a high negative intrathoracic pressure etiology during inhalation and a neurogenic cause based on marked increases in sympathetic nervous system activity in the pulmonary circulation.[73] Despite the acute pulmonary vascular effects of cocaine use, frank infarction of lung parenchyma has only been infrequently reported. Nevertheless, irreversible pulmonary hypertension may occur in cocaine addicts resulting from pulmonary arterial medial hypertrophy and the frequent development of interstitial fibrosis mediated by the deposition of talc, silica, or other substances used to "cut" the drug.[73] Inhalation of cocaine may predispose the patient to the development of infection, as the drug not only suppresses B- and T-lymphocyte function, but also substantially impairs the activity of alveolar macrophages. A delayed eosinophilic hypersensitivity pneumonitis that bears many similarities to Loeffler disease has also been described after cocaine inhalation. This "crack lung" syndrome typically occurs hours after a period of intense abuse and is associated with pleuritic chest pain, hemoptysis, diffuse infiltrates, hypoxemia, fever, and eosinophilia.[74] Upper airway complications, including mucosal irritation and burns, are common among cocaine abusers. Vasoconstriction produced by a nasal route of administration of the drug may result in septal perforation, acute or chronic sinusitis, epiglottis, airway obstruction, or an upper airway vasculitis that is similar to Wegener granulomatosis.[73] Severe upper airway burns may also occur as a result of "freebasing," a potentially explosive chemical process in which a highly flammable solvent is used to transform cocaine from a salt to a base and increase the potency of the drug. A higher prevalence of tuberculosis has also been reported in drug users who smoke crack cocaine as compared to those who inhale other drugs of abuse.

Two major acute neurologic complications associated with cocaine abuse are cerebrovascular accidents and seizures. Cocaine-induced stroke may occur as a consequence of a cardiac event (e.g., myocardial infarction, ventricular arrhythmias) or an infection (e.g., meningitis, intracranial septic emboli), but these etiologies are not responsible for cerebrovascular accidents in many patients. Ischemic strokes, including transient ischemic attacks and cerebral infarction, constitute approximately half of all cocaine-induced cerebral vascular accidents and are attributed to the potent actions of cocaine as a cerebral vasoconstrictor concomitant with its prothrombotic effects. In fact, direct cerebral vasoconstriction was observed during administration of cocaine using magnetic resonance angiography in volunteers.[75] Hemorrhagic strokes resulting from cocaine abuse most often occur in conjunction with pronounced arterial hypertension, and are frequently associated with the presence of a previously unrecognized cerebral aneurysm or arteriovenous malformation. Cognitive dysfunction has also been reported in chronic cocaine abusers consistent with a form of multiinfarct dementia. Cocaine-induced seizures are usually single, grand mal events that most often resolve without the need for therapeutic intervention. Notably, seizures produced by cocaine abuse may occur without signs or symptoms of systemic drug toxicity. Seizures most often occur in direct association with inhalational or intravenous and less frequently intranasal cocaine abuse, but may also develop several hours after exposure, presumably because the major product of cocaine metabolism (benzoylecgonine) also has epileptogenic effects.

Specific gastrointestinal and hepatitic complications of cocaine use have been described. Large or small intestinal ischemia, infarction, or perforation and resulting peritonitis may occur as a consequence of the combination of cocaine-induced mesenteric vasoconstriction and direct toxic effects on intestinal mucosa. Bowel obstruction or acute drug toxicity has been reported with the intentional ingestion of wrapped packages of cocaine (known as "stuffing" or "packing") that is performed to either illegally smuggle the drug into the United

States or avoid imminent arrest when in its possession.[76] These complications often require immediate surgical management. Cocaine hepatitis is a relatively uncommon disorder caused by the combination of hepatic vasoconstriction and the presence of toxic oxidative metabolites generated through cytochrome P450 3A1, a secondary route of cocaine metabolism. Cocaine hepatitis develops shortly after drug use, is most often associated with other signs and symptoms of systemic toxicity, and may also occur in conjunction with simultaneous alcohol abuse that induces P450 enzymatic activity. Cocaine-induced hepatotoxicity may also occur in patients with reduced plasma pseudocholinesterase activity (the major route of cocaine metabolism) because the P450 3A1 pathway assumes a greater role for drug metabolism under these conditions. Centri- or panlobular hepatic necrosis and marked elevations in serum aminotransferase activity are characteristic findings in patients with cocaine hepatitis.

Acute and chronic renal diseases are quite common in patients who abuse cocaine. Many of the renal consequences of cocaine use are related to infectious diseases, especially in intravenous users. Nephrotic syndrome is associated with HIV or hepatitis nephropathy, glomerulonephritis may occur as a result of bacterial endocarditis or sepsis, and a mixed nephritic–nephrotic syndrome is most often observed with chronic HCV infection. Abuse of cocaine in particular may produce renal insufficiency as a result of infarction, accelerated hypertension, rhabdomyolysis, or thrombotic microangiopathy.[77] The pronounced sympathomimetic actions of cocaine and its prothrombotic effects cause direct renal arterial vasoconstriction and thrombosis, similar to the findings in myocardium. These actions produce acute renal ischemia and infarction. As previously discussed, cocaine abuse may produce severe hypertension, and such sustained elevations in arterial blood pressure may contribute to exacerbation of preexisting renal insufficiency. Acute tubular necrosis resulting from rhabdomyolysis has also been described in patients who abuse cocaine. Another cause of cocaine-induced acute renal insufficiency is thrombotic microangiopathy that may occur in conjunction with hemolytic uremic syndrome or renal infarction.[78]

Amphetamines

Drugs in the amphetamine class, including *d,l*-amphetamine, methylphenidate, methamphetamine, and 3,4-methylenedioxy methamphetamine (MDMA, known as "Ecstasy"), are commonly abused and cause a wide variety of acute and chronic medical consequences that may substantially influence perioperative management. In recent years, abuse of MDMA and methamphetamine has increased dramatically, attracting the attention of federal regulatory agencies and the national media. Similar to the actions of cocaine, amphetamines produce sympathetic nervous system activation, inhibit the presynaptic reuptake and potentiate the actions of biogenic amines, and exert direct agonist actions on peripheral α- and β-adrenoceptors to varying degrees, depending on minor structural variations in their β-phenylethylamine chemistry. As a result of these sympathomimetic effects, amphetamines cause dose-related hypertension that may be sustained for several hours because of the pharmacokinetics of these drugs. Tachycardia may be more commonly observed with methylphenidate and MDMA, presumably because these drugs produce relatively greater activation of β_1-adrenoceptors than other amphetamines. These hemodynamic effects increase myocardial oxygen consumption and are associated with acute myocardial ischemia and infarction, left ventricular dilation, malignant ventricular arrhythmias, and sudden cardiac death. Notably, the cardiovascular effects of amphetamines are known to be markedly potentiated by strenuous physical activity, and deaths attributed to MDMA at night clubs or dance parties (such as "raves") may be related to this apparent hemodynamic synergism.[79] As observed in cocaine abusers, pathologic examination of hearts from amphetamine abusers revealed focal myocarditis and necrosis consistent with chronic catecholamine exposure. Amphetamines produce arterial vasospasm and promote thrombosis as a result of their sympathomimetic effects, and these actions probably contribute to myocardial damage as well. Methamphetamine abuse has been linked to the development of necrotizing angiitis, a vascular disease of the intima and media that is very similar to polyarteritis nodosa.

Similar to the findings with inhaled opioids and cocaine, inhalation of amphetamine may be associated with barotrauma, mucosal irritation and hemoptysis, and the development of cardiogenic and noncardiogenic pulmonary edema.[73] Amphetamine overdose may cause central nervous system depression or seizures, and aspiration of stomach contents is quite common under these conditions. In contrast to cocaine, amphetamines are sequestered within pulmonary parenchyma. When combined with the potent pulmonary arterial vasoconstriction produced by these drugs, this action may contribute to the well-known relationship between amphetamines and pulmonary hypertension. Inhaled methamphetamine and intravenous methylphenidate were shown to cause pulmonary hypertension in patients who chronically abused these drugs. Epidemiology studies also suggested a strong link between the amphetamine derivative fenfluramine and the subsequent development of pulmonary hypertension in many patients who had been prescribed this drug as an appetite suppressant.[80] Amphetamines may also reduce immune function and increase the risk of bacterial, viral, or fungal pneumonia. For example, inhaled amphetamine caused the expression of immunosuppressive cytokines and reduced CD4 cell number, actions that may predispose the patient with HIV to pulmonary infection.

Cerebrovascular accidents in amphetamine abusers may be ischemic or hemorrhagic in origin. Similar to cocaine, amphetamine-induced ischemic strokes may occur as a direct consequence of cerebral vasoconstriction. Unlike the findings with cocaine, however, necrotizing or small-vessel hypersensitivity vasculitis was also implicated as an underlying etiology of ischemic stroke in patients who abuse amphetamines.[81] Hemorrhagic strokes resulting from amphetamines, including MDMA, are most frequently caused by a hypertensive crisis. In contrast to seizures produced by cocaine, those associated with amphetamine abuse most often occur concomitant with clinical signs and symptoms of drug toxicity. Amphetamine abuse is associated with symptoms of exaggerated

paranoia and withdrawal from these drugs often leads to prolonged clinical depression as a result of the absence of stimulant effects.

Fulminant hepatic failure resulting in the need for urgent liver transplantation has been reported in MDMA abusers.[82] Hepatotoxicity may occur independent of drug dose and is accompanied by jaundice, pruritus, severe hyperbilirubinemia, and elevated transaminases (AST > ALT). MDMA-induced hepatic injury may be associated with acute drug toxicity or may occur days or even weeks after ingestion, possibly because of delayed drug metabolism by cytochrome P450 2D6 in susceptible patients with reduced enzymatic activity or as a result of an immunologically mediated mechanism. The clinical presentation of hepatic failure is often associated with hypovolemia, hyperthermia, and rhabdomyolysis. Methamphetamine use is associated with the development of HAV.

Amphetamine abuse alters kidney perfusion by virtue of the actions of these drugs on arterial blood pressure and may produce acute and chronic renal failure. Accelerated hypertension and acute renal failure have been observed in methamphetamine and MDMA abusers. Necrotizing vasculitis with microaneurysm formation and thrombosis mimicking polyarteritis nodosa has also been reported in patients who abuse amphetamine that contributes to ischemia and chronic renal insufficiency. Rhabdomyolysis and acute tubular necrosis often accompany MDMA abuse, especially in the presence of hyperthermia and hypovolemia induced by intense physical activity. Interestingly, many MDMA abusers recognize the risk of developing acute hypernatremia under these conditions and attempt to prevent this complication by ingesting large quantities of water, thereby inadvertently causing neurologically significant hyponatremia.

Marijuana

Marijuana or hashish use is associated with increases in heart rate and cardiac output, reductions in systemic vascular resistance, and relative maintenance of arterial blood pressure. These hemodynamic effects occur in parallel to plasma concentrations of Δ^9-tetrahydrocannabinol (the psychoactive drug in marijuana and hashish), are more pronounced following inhalation as compared to other routes of administration, and may be accompanied by the occurrence of premature ventricular ectopy. The cardiovascular actions of marijuana are usually well-tolerated by healthy individuals, but may have important consequences for patients with heart disease. Marijuana-induced tachycardia enhances myocardial oxygen consumption, and elevated levels of carboxyhemoglobin resulting from smoking the drug also reduce myocardial oxygen supply. Thus, patients with coronary artery disease may be at risk of developing myocardial ischemia or infarction in association with marijuana abuse. In fact, the incidence of acute myocardial infarction was reported to be approximately 5-fold higher within the first hour after marijuana use as compared to other times.[83] Disruption of myocardial oxygen supply–demand relations may also compromise cardiac performance in marijuana users with heart failure resulting from ischemic cardiomyopathy.

Marijuana smoking is associated with several pulmonary complications that are similar to those produced by tobacco smoking. Chronic bronchitis and emphysema have been reported in marijuana smokers, and concomitant tobacco smoking further contributes to the development of these chronic pulmonary diseases. Marijuana smoking results in greater tar deposition and substantially higher concentrations of carboxyhemoglobin than tobacco smoking,[84] effects that are partially related to deep, sustained inhalation and intense breath-holding performed to maximize drug delivery. Similar to the findings in tobacco smokers, pulmonary defenses against pathologic organisms are compromised by marijuana smoking as indicated by alveolar macrophage dysfunction, reduced cytokine formation, and diminished ability to combat oxidative stress. Chronic, heavy marijuana smoking may also precipitate the development of lung or oropharyngeal cancer. Marijuana is often contaminated with fungi (e.g., *Aspergillus*) or actinomycetes, and inhalation of these substances during smoking may cause infections or hypersensitivity reactions. Immunosuppressed marijuana users (such as those with advanced HIV infection) appear to be particularly susceptible to aspergillosis pneumonia.

Hallucinogens

Phencyclidine and lysergic acid diethylamide (LSD) cause cardiovascular sympathomimetic effects, and complications similar to those produced by cocaine and amphetamines are associated with abuse of these drugs. Thus, phencyclidine or LSD ingestion may be associated with myocardial ischemia and infarction resulting from increased myocardial oxygen consumption, coronary vasoconstriction or vasospasm, and prothrombotic effects. Severe hypertension, left ventricular hypertrophy, and malignant ventricular arrhythmias have also been observed in phencyclidine and LSD abusers. Notably, the mechanisms by which phencyclidine and LSD stimulate the sympathetic nervous system are at least partially distinct from than those responsible for the sympathomimetic actions of cocaine or amphetamines, and as a result, cardiovascular cross-tolerance between phencyclidine or LSD and these other stimulants may not occur. In addition to cardiovascular consequences, phencyclidine and LSD abuse also produce several important neurologic complications. Like ketamine, phencyclidine causes an acute dissociative state that bears striking similarity to schizophrenia. Thus, the phencyclidine abuser may present in a highly agitated state characterized by delusions, hallucination, and paranoia, or, conversely, may demonstrate frank catatonia. LSD also produces hallucinations that may compromise patient compliance with treatment. LSD users often report "flashbacks" (i.e., recurrence of hallucinations that are temporally remote to the original abuse event). Abuse of large quantities of phencyclidine, LSD, or other hallucinogens (e.g., mescaline) may produce seizures, myoclonus, and coma. Phencyclidine or LSD abuse is also associated with ischemic or hemorrhagic stroke concomitant with cerebral vasoconstriction or hypertensive crisis, respectively. A syndrome of pronounced hyperthermia accompanied by acute submassive liver necrosis that resembles the clinical presentation of malignant hyperthermia has been described in conjunction with phencyclidine use.[85] Rhabdomyolysis and acute tubular necrosis has also been reported in phencyclidine abusers.

Inhalants

Inhalants are volatile hydrocarbons (e.g., hexane, xylene, toluene) contained in a wide variety of common products including paints, solvents, and adhesives. Because they are readily commercially available, inhalants

are frequently abused by teenagers. Inhalants may be directly sniffed or forcefully inhaled using an airtight container (termed "huffing"), producing rapid intoxication. Inhalant abuse is associated with several respiratory complications. In addition to respiratory depression resulting from sedation, inhalant abuse may contribute to the development of bronchospasm in the presence or absence of preexisting asthma, airway mucosal irritation, hemoptysis, hypersensitivity pneumonitis, aspiration, and barotrauma.[86] Methemoglobinemia and the cyanosis that it precipitates may occur in association with abuse of amyl nitrate or related compounds (termed "poppers"). Asphyxiation resulting from respiratory depression or suffocation on a plastic bag used as a container for the inhalant has also been reported. Toluene inhalation may result in a white matter dementia characterized by extrapyramidal signs and symptoms, cerebellar ataxia, and oculomotor effects. Inhaled toluene also causes a nonanion gap metabolic acidosis and hypokalemia that occurs as a consequence of generation of hippuric acid, a product of toluene metabolism. Lead encephalopathy has also been described in individuals who inhale gasoline. A progressive sensory-motor polyneuropathy ("glue sniffer's neuropathy") may occur in conjunction with inhalation of hexane-containing adhesives.

ALCOHOL AND DRUG WITHDRAWAL

Signs and symptoms of withdrawal are commonly encountered during the perioperative period in alcohol or drug abusers, and prophylaxis against withdrawal should be instituted before surgery in patients with a history of recent heavy use. Alcohol withdrawal is associated with substantial increases in postoperative morbidity and mortality.[87] Alcohol withdrawal typically begins within 24 hours after the last drink and produces a wide spectrum of clinical consequences. Interestingly, the severity of withdrawal does not appear to be correlated with the total quantity of alcohol ingested or duration of alcohol consumption. Early alcohol withdrawal is characterized by constitutional complaints including headache, anxiety, nausea, vomiting, diarrhea, and sleep disturbances (Table 23–3). These symptoms are frequently associated with physical signs, including fever, diaphoresis, tachycardia, hypertension, hyperreflexia, and tremor. Visual, auditory, or tactile hallucinations may also be present, but the patient may initially be able to recognize that these hallucinations do not reflect reality. In the vast majority of patients, alcohol withdrawal resolves spontaneously without advancing to seizures or delirium (also known as *delirium tremens* or DTs). As discussed previously, alcohol withdrawal seizures are usually single grand mal events, correlate closely with maximal increases in electroencephalographic activity, and occur in between 10% and 33% of alcohol abusers in the absence of prophylactic treatment with benzodiazepines.[88] Alcohol withdrawal-induced status epilepticus occurs in less than 3% of patients who develop seizures.[89] Notably, the incidence of alcohol withdrawal seizures increases in patients who have experienced multiple episodes of abuse and withdrawal. Delirium tremens usually occurs 3–4 days after the last drink and is characterized by exaggerated signs and symptoms of withdrawal concomitant with vivid hallucinations that cannot be discerned from reality, profound confusion, disorientation, and marked agitation. Alcohol withdrawal delirium usually resolves after 2–3 days, is more frequent in older patients, and continues to carry a mortality rate of approximately 1% because of delayed or inadequate treatment and the presence of coexisting diseases.

Comprehensive descriptions of the pathophysiology and treatment of alcohol withdrawal are beyond the scope of this chapter. Briefly, alcohol abuse is hypothesized to chronically stimulate inhibitory GABA-mediated neurotransmission and attenuate autonomic nervous system sensitivity. In response, an upregulation of GABAergic and central and peripheral adrenergic receptors occurs. Thus, anxiety, tremor, hyperreflexia, and a reduction in seizure threshold occur alcohol withdrawal because GABA receptors are no longer stimulated and central nervous system excitatory neurotransmission is relatively unopposed. In addition, sudden abstinence from alcohol consumption causes rebound activation of the sympathetic nervous system, producing the characteristic findings of fever, diaphoresis, tachycardia, and hypertension observed during withdrawal. Benzodiazepines (e.g., lorazepam, chlordiazepoxide, oxazepam) are the primary drugs used to treat alcohol withdrawal because these agents activate GABA receptors and thereby en-

TABLE 23–3.

Common Signs and Symptoms of Alcohol or Drug Withdrawal

- General
  - Fever
  - Chills
  - Headache
  - Diaphoresis
  - Myalgias
  - Fatigue
  - Piloerection (opioids)
- Cardiovascular
  - Tachycardia
  - Hypertension
- Gastrointestinal
  - Nausea
  - Anorexia
  - Vomiting
  - Diarrhea
- Ophthalmologic
  - Lacrimation (opioids)
  - Pupillary dilation (opioids)
- Otolaryngologic
  - Rhinorrhea (opioids)
- Neurologic
  - Anxiety, irritability, and agitation
  - Mood disorders
    - Depression (cocaine, amphetamines)
  - Drug Craving
  - Sleep disturbances
    - Insomnia (alcohol, sedative–hypnotics, marijuana)
    - Hypersomnolence (cocaine, amphetamines, hallucinogens)
  - Hyperreflexia
  - Tremor
  - Disorientation (alcohol, sedative–hypnotics)
  - Delusion (alcohol, sedative–hypnotics)
  - Hallucination (alcohol, sedative–hypnotics)
  - Seizure (alcohol, sedative–hypnotics)
  - Delirium (alcohol, sedative–hypnotics)
  - Coma and death (alcohol, sedative–hypnotics)

hance inhibitory neurotransmission. $Beta_1$- (e.g, metoprolol) or α_2-adrenoceptor (e.g., clonidine) agonists may also be used to control the clinical manifestations of increases in sympathetic nervous system tone. Frequent evaluation of the signs and symptoms of alcohol withdrawal using a previously validated instrument such as the revised Clinical Institute Withdrawal Assessment Scale for Alcohol should be used to guide pharmacologic management and supportive care.

The clinical ramifications of sedative–hypnotic withdrawal are very similar to those observed during alcohol withdrawal, largely because the primary site of action of these drugs is also the GABA receptor. Abrupt discontinuation of benzodiazepines or barbiturates is characterized by fever, tachycardia, hypertension, gastrointestinal complaints (e.g., nausea, vomiting, diarrhea), and evidence of neurologic excitability (e.g., anxiety, agitation, tremor, hyperreflexia). More severe withdrawal from these drugs is associated with hallucinations, seizures, delirium, and death. The onset of the withdrawal syndrome is dependent upon the elimination half-life of the abused drug. The type, dose, potency, and duration of sedative–hypnotic use are the major factors that determine the severity of withdrawal. In contrast to the findings during alcohol withdrawal, the duration of sedative–hypnotic withdrawal may be very prolonged, often extending from several weeks to months. Barbiturates and benzodiazepines are frequently abused by patients who are addicted to alcohol or other drugs, and signs and symptoms of sedative–hypnotic withdrawal are exaggerated by simultaneous withdrawal from other substances of abuse. Other factors that contribute to the severity of sedative–hypnotic withdrawal include coexisting psychiatric conditions (particularly anxiety disorders and depression), family history of alcohol abuse, age, and female gender. The addition of an acute surgical stress response may also increase the severity of benzodiazepine or barbiturate withdrawal. As a result, continued use of the abused sedative–hypnotic or initiation of an equivalent dose of a cross-tolerant alterative drug is recommended throughout the perioperative period so as to avoid withdrawal.

Prompt recognition and appropriate treatment of opioid withdrawal are important clinical objectives during the perioperative period in the opioid abuser. In contrast to alcohol or sedative–hypnotic withdrawal, mortality rarely occurs during opioid withdrawal unless significant comorbid medical conditions are present. Nevertheless, the signs and symptoms of withdrawal are so intensely uncomfortable that untreated opioid abusers will often leave the hospital against medical advice in order to seek and abuse illicit opioids. In fact, many opioid addicts report that continued drug use is at least partially motivated by a strong desire to avoid withdrawal symptoms, and not because of a specific euphoric effect per se. Acute opioid withdrawal is characterized by fever, anxiety, irritability, intense drug craving, altered thermoregulation, rhinorrhea, piloerection, pupillary dilation, and gastrointestinal complaints (e.g., nausea, vomiting, diarrhea). Hypertension and tachycardia also occur in response to activation of the sympathetic nervous system. The onset of acute opioid withdrawal is dependent on the elimination half-life of the abused drug. For example, signs and symptoms of opioid withdrawal usually occur within 6 hours after heroin abuse, but the onset of withdrawal may be delayed if the patient abuses methadone or a sustained-release opioid (e.g., oxycodone, morphine). Similarly, the pharmacokinetics of the abused opioid are also responsible for the total duration of the withdrawal syndrome. The duration of abuse, dose of drug, and route of administration (intravenous > inhaled) are the major determinants of the severity of opioid withdrawal.

The pharmacologic management of opioid detoxification and withdrawal is complex, and several approaches have been proposed that are not reviewed in detail here. During the perioperative period, the easiest and most effective strategy for managing opioid withdrawal is methadone substitution therapy[90] using a validated withdrawal evaluation tool to guide treatment. Briefly, an oral or intravenous loading dose of methadone is administered at the onset of withdrawal, and subsequent doses are titrated until symptoms are adequately controlled and a stable daily dose is established. This methadone dose may either be continued unchanged throughout the hospital course or gradually reduced as signs and symptoms of opioid withdrawal improve. Notably, methadone substitution therapy for acute opioid withdrawal should not be confused with pain management. Perioperative opioid withdrawal may also be treated independent of substitution therapy using the combination of a benzodiazepine and an α_2-adrenoceptor agonist administered on a scheduled basis to control anxiety and sympathetic nervous system activation, respectively. Regardless of the approach, consultation with an addictionologist is strongly recommended to guide perioperative therapy and establish plans for postoperative addiction treatment.

Cocaine or amphetamine withdrawal is characterized by drug craving, depression, anhedonia, and hypersomnolence.[91] These symptoms of abrupt discontinuation of stimulant abuse are usually self-limited but may initially be severe (known as a "crash"), usually may be treated with supportive care alone, and most often do not require pharmacologic intervention. Notably, the appearance of cocaine or amphetamine withdrawal symptoms (particularly hypersomnolence) during the perioperative period may be confused with a neurologic complication. Abrupt cessation of marijuana use is associated with anxiety, irritability, insomnia, and gastrointestinal complaints in a minority of patients. Treatment of these symptoms is primarily supportive, but antidepressant medications (e.g., trazodone) may benefit some patients. Specific phencyclidine or hallucinogen withdrawal syndromes also have not been described, but a minority of patients report constitutional complaints, including anxiety, fatigue, hypersomnolence, depression, and anhedonia. These acute symptoms and the delayed psychiatric sequelae ("flashbacks") of phencyclidine or hallucinogen abuse most often respond to supportive care, but some patients with severe manifestations may benefit from a trial of benzodiazepines or specific serotonin reuptake inhibitor antidepressants.

GENERAL PRINCIPLES OF PERIOPERATIVE MANAGEMENT

A detailed description of the perioperative management that is unique to each of the substances that might be abused by the active alcohol or drug

abuser is beyond the scope of this chapter. Rather, the broad pharmacologic diversity of drugs of abuse combined with the wide range of complications that accompany substance abuse requires that the anesthesiologist have a firm understanding of ramifications of substance abuse, and apply this understanding to the specifics of each perioperative experience. As in the case of any patient affected by a chronic disease, the anesthetic approach to the patient with addiction varies depending on the type, location, and duration of the anticipated surgical procedure and the presence, severity, and relative stability of alcohol- or drug-related comorbidities. However, several general principles should guide the perioperative care of the patient with active substance abuse (Table 23–4). Historical evidence of abstinence from alcohol and other drugs of abuse, confirmed by timely laboratory evidence to assure the validity of the historical information, is strongly recommended before a patient undergoes elective surgery because of the well-recognized increases in the rate and severity of perioperative complications and the potentially life-threatening consequences of unanticipated withdrawal perioperatively. Cessation of drug use before elective surgery also promotes stabilization of many abuse-related medical complications and may increase the probability that the patient will comply with postoperative instructions upon discharge (e.g., followup appointments, wound care, physical therapy). In some patients, abstinence before elective surgery may be facilitated by frank discussions with the anesthesiologist and surgeon regarding the consequences of continued abuse preoperatively. Other patients may require the assistance of an addiction medicine specialist in order to achieve abstinence before an elective procedure. Unfortunately, attaining preoperative abstinence may be an unrealistic goal for many alcohol or drug abusers, especially those who are undergoing urgent or emergent surgery. Under such circumstances, perioperative alcohol or drug withdrawal must be anticipated, and appropriate measures (e.g., drug prophylaxis guided by history and laboratory tests, anticipated admission to an intensive care unit) should be instituted well before the expected onset of withdrawal signs and symptoms. Vigilance about the potential for drug withdrawal is essential for all patients with a history of recent substance abuse, and the benefits of proactive intervention cannot be overemphasized.

TABLE 23–4.

General Recommendations for Perioperative Management

Preoperative
Supportive, nonjudgmental but firm approach
Obtain a urine drug screen and blood ethanol concentration
Achieve abstinence and stability of medical comorbidity before elective surgery
Anticipate and treat alcohol or drug withdrawal, especially in alcohol or drug abusers undergoing urgent or emergent surgery
Consult an addiction medicine specialist
Assure that anxiety and pain are appropriately treated
Intraoperative
Consider regional or local anesthesia or nerve blocks if possible
Anticipate hyperalgesia, especially in opioid abusers
Use general anesthesia or opioids as clinically indicated
Postoperative
Plan postoperative analgesia including alternative approaches before surgery
Use continuous local anesthesia, nonopioid analgesics, or alternative pain approaches if possible, but do not avoid opioids if clinically indicated
Use scheduled but not "as needed" administration of opioids
Frequently assess behavioral and functional responses to pain therapy
Integrate initiation for addiction into the discharge plan

A straightforward, nonjudgmental approach to the patient by physicians and nursing personnel will often encourage the alcohol or drug abuser to cooperate with the treatment plan. Patients should be assured repeatedly that withdrawal symptoms, anxiety, and pain will be addressed appropriately. A clear plan for postoperative pain management should be discussed before surgery. Use of continuous local anesthesia, nerve blocks, nonopioid analgesics, neuraxial techniques, or alternative analgesic modalities may be employed for postoperative pain management, but opioids administered on a scheduled basis should be used as clinically indicated. As discussed previously, it is critically important that pain be promptly and adequately treated so as to avoid the development of a "mutual mistrust" relationship between the alcohol or drug abuser and healthcare providers.[16] The anesthesiologist and other clinicians must recognize that hyperalgesia is common in patients with substance abuse disorders, and all must be prepared to manage pain accordingly. A continuous evaluation of the adequacy of pain management, based on the behavioral and functional responses of the patient, should be conducted throughout the perioperative period.

The active participation of an addiction medicine specialist throughout the entire hospital course is strongly advised because the addictionologist may contribute substantially to the evaluation and treatment of alcohol- or drug-related coexisting diseases, provide guidance about the management of perioperative alcohol or drug withdrawal, and serve as an additional resource for pain management strategies. Perhaps most importantly, the addictionologist also facilitates the transition to addiction treatment during postoperative discharge planning. The anesthesiologist and surgeon should recognize that the perioperative experience provides a unique opportunity to intervene in cases of substance abuse, and to facilitate the initiation of a plan for treatment of patient's addictive disease.

THE RECOVERING PATIENT

Recovery is a complex process requiring intense, continuous personal effort that not only involves abstinence but also requires a series of changes to maintain sobriety (Table 23–5). Successful recovery requires acquisition of knowledge about substance abuse disorders, renewal of self-esteem and personal responsibility, development of sober living abilities and social interactions, identification with sources of inspiration, and a unified approach to guide these changes.[92] The terms "cured," "former," "recovered," and "ex-"

TABLE 23–5.

Therapeutic Objectives in Addiction Management

- Affective
  - Manage anxiety, depression, shame, and guilt
  - Increase coping skills
  - Increase emotional awareness of negative consequences of use
- Behavioral
  - Eliminate drug use behaviors
  - Expand healthy behaviors
- Cognitive
  - Reduce denial
  - Enhance personal awareness of addictive disease in self and others
  - Increase recognition of negative consequences of use
- Physiological
  - Treat withdrawal symptoms and medical consequences of alcohol or drug abuse
  - Encourage healthy activities
  - Reestablish personal responsibility for health
- Social
  - Increase personal responsibility
  - Increase honesty, reliability, and trustworthiness
  - Establish sober social networks
  - Increase social coping skills
- Spiritual
  - Increase self-esteem and reduce self-loathing
  - Reestablish personal values
  - Increase appreciation of transcendence

alcoholic or addict are inappropriate to describe the *recovering* patient. The incidence of relapse appears to be inversely related to the duration of recovery, but return to use has been observed in patients with decades of recovery. Abstinence alone does not constitute recovery because effective skills for coping with stress independent of drug ideation (e.g., craving) or use may not have been developed. Whether an abstinent individual has more difficulty coping with the perioperative experience than a patient in a well-established recovery program is unknown, however. Mutual-help organizations including Alcoholics Anonymous (AA) and other twelve-step programs, individual psychotherapy, behavioral modification, and pharmacologic therapy may all be effective in the management of addictive disease. The standard of care in addiction treatment in the United States is based on the Minnesota model,[93] a multidisciplinary approach that includes involvement in a twelve-step program, individual and group psychotherapy, patient and family education, vocational rehabilitation, and spiritual renewal. Treatment within the Minnesota model relies primarily on the experience of other recovering patients. Alcoholics Anonymous and related groups are fellowships of recovering patients who help each other maintain sobriety. The twelve steps are the central tenet of the Alcoholics Anonymous program that serve as guidelines for recovery. Other components of recovery within Alcoholics Anonymous include regular meeting attendance and sponsorship that increase the probability of maintaining sobriety.

Several medications are presently used in sobriety maintenance therapy that may have important implications for the anesthesiologist (Table 23–6). Strategies include alteration of a drug's metabolic consequences (e.g., disulfiram in alcoholism), reduction of drug reward (e.g., acamprosate in alcoholism), receptor antagonism (e.g., naltrexone in opioid addiction), and drug substitution therapy (e.g., methadone in refractory opioid addiction). Several drugs have documented efficacy in the treatment of patients with alcohol or opioid addiction, but effective pharmacologic therapy for addiction to other drugs of abuse has yet to be demonstrated. A more frequent incidence of anxiety, psychotic, and affective disorders is also observed in recovering patients. Psychoactive drugs used to treat these concurrent disorders reduce the incidence of relapse by decreasing self-medication of psychiatric symptoms, and may also have anesthetic consequences that are reviewed elsewhere.

Disulfiram is an alcohol-sensitizing drug that is still occasionally used in the treatment of alcoholism. Disulfiram inhibits aldehyde dehydrogenase, leading to acetaldehyde accumulation and a severe aversive reaction when alcohol is ingested. Disulfiram also irreversibly inhibits other sulfhydryl-based enzyme systems responsible for drug metabolism. Inhibition of dopamine β-hydroxylase by disulfiram reduces presynaptic neuronal synthesis of norepinephrine and may produce an attenuated cardiovascular response to indirect-acting sympathomimetic amines. Disulfiram also reduces the clearance of diazepam, midazolam, and chlordiazepoxide, and interferes with the metabolism of barbiturates, tricyclic antidepressants, phenytoin, and warfarin by inhibiting hepatic microsomal enzymes. Calcium carbimide is another alcohol-sensitizing drug used clinically in Europe and Canada that reversibly inhibits alcohol dehydrogenase and may cause less-pronounced drug interactions. The μ opioid receptor antagonists, naltrexone and nalmefene, reduce alcohol ideation and decrease the incidence of relapse in recovering alcoholics.[94] Clinical experience with naltrexone and nalmefene has been less successful in opioid addiction, but may be used as "insurance" in abstinence-based recovery. Naltrexone and nalmefene increase the threshold dose of opioid required to produce euphoria. The recovering patient who continues to receive an opioid antagonist during the perioperative period will have an increased requirement for opioid analgesics. Conversely, the μ receptor is upregulated during chronic opioid antagonist treatment, and withdrawal of naltrexone or nalmefene is associated with increased sensitivity to opioid agonists.

Acamprosate is an amino acid derivative that substantially reduces ideation[95] and improves treatment retention in recovering alcoholics. Acamprosate decreases neuronal hyperexcitability caused by chronic alcohol abuse by altering GABA- and glutamate-mediated neurotransmission. These actions reduce drug craving, a major cause of relapse in recovering alcohol abusers. To date, the anesthetic implications of acamprosate have not been described. Antiepileptics (e.g., carbamazepine, valproate, gabapentin) also attenuate alcohol- or opioid-mediated drug craving.[96] Carbamazepine and other antiepileptics hasten recovery from intermediate- and long-acting nondepolarizing muscle relaxants by enhancing the clearance of these drugs, increasing plasma concentrations of α_1-acid glycoprotein, and producing proliferation of postsynaptic acetylcholine receptors. Selective serotonin reuptake inhibitors appear to reduce

TABLE 23–6.

Pharmacological Therapy in Relapse Prevention

Medication	Drug of Abuse	Pharmacology	Mechanism of Action	Anesthetic Implications
Disulfiram; calcium carbimide	Alcohol	Enzyme inhibition	Adverse side effects	Altered response to sympathomimetics; alerted drug metabolism; discontinue disulfiram 10 days before surgery
Naltrexone; nalmefene	Alcohol	Modulation of drug reward	Decrease drug ideation	Altered response to opioid agonists; discontinue 3 days before surgery
	Opioids	Direct receptor antagonist	Decrease euphoric threshold to opioids	
Acamprosate	Alcohol	Modulation of drug reward	Decrease drug ideation	Unknown
SSRIs	Alcohol? Benzodiazepines? Barbiturates?	Modulation of drug reward	Decrease drug ideation; decrease consumption in active users	Rare; may cause hypotension and bradycardia
Antiepileptics	Alcohol; opioids	Reduce neuronal excitability	Decrease drug ideation	Prolonged duration of neuromuscular blockers
Methadone; LAAM; buprenorphine	Opioids	Direct receptor agonist	Decrease drug ideation, positive reward, and withdrawal symptoms	Continue maintenance dose

Abbreviations: LAAM, levomethadyl acetate; SSRIs, selective serotonin reuptake inhibitors.

drinking in alcoholics with depression and may also prevent relapse in recovering patients with anxiety or affective disorders.[97] Profound bradycardia and severe hypotension during anesthesia have been rarely reported in patients treated with these drugs.

Methadone, the long-acting μ agonist levo-α-acetyl-methadol (LAAM), and the partial agonist buprenorphine have been used effectively in the treatment of patients with opioid addiction as substitution pharmacotherapy in combination with behavioral interventions. Methadone, LAAM, and buprenorphine decrease withdrawal symptoms, inhibit drug ideation, and attenuate the positive reward associated with subsequent opioid use. Clearly, patients chronically treated with methadone, LAAM, or buprenorphine remain physically dependent on opioids despite attenuation of addictive behavior. Thus, verification of the dose of methadone, LAAM, or buprenorphine with the patient's addiction specialist before surgery and unconditional administration of the drug throughout the perioperative period to prevent withdrawal are required. Patients receiving opioid substitution therapy may experience exaggerated pain responses to nociceptive stimuli because of drug tolerance.[15] These patients often require large quantities of additional opioids for the control of surgical pain, and may benefit from alterative pain control modalities. Substituting a new opioid for methadone, LAAM, or buprenorphine for maintenance therapy during the perioperative period is inappropriate. Increasing the dose or frequency of administration of these drugs to manage acute pain is also not recommended because the boundaries between treatment of addiction and pain may be obscured.

Anesthesia and surgery may expose the recovering patient to several potential obstacles that increase the possibility of relapse. Numerous anecdotal descriptions of profound drug craving or frank relapse have been reported after brief perioperative exposure to sedatives or opioids in recovering patients with years of sobriety, but the precise incidence of such phenomena has not been defined. Anxiety about the perioperative experience may be heightened in the recovering patient because of concerns about the possibility for relapse and the fear that pain will not be adequately treated because of the history of addiction. Anxiety and pain have been identified as important precipitants of relapse, and inadequate treatment of pain precipitates drug ideation.[98] Recovering patients may also display abnormal behavioral responses to stress that increase the risk of relapse.[99] Similar to the active alcohol or drug abuser, the recovering patient may encounter surgeons or anesthesiologists during the perioperative period who remain cynical about the sincerity or efficacy of the recovery process. Conversely, other apparently well-intentioned physicians may withhold or restrict pain medication from the recovering patient, fearing that a relapse will be inadvertently provoked. The recovering patient may be left inadequately treated, a situation that may be further complicated if justified requests for additional analgesics are misinterpreted as addictive behavior.

The preoperative evaluation allows the anesthesiologist to obtain a detailed history of addiction and recovery and provides an opportunity to reduce anxiety about the operative experience. Many patients will openly disclose their addictive disease and recovery, but others may be reticent to acknowledge this history because they are apprehensive about the stigma that is still associated with the disease. Under these circumstances, the history of addiction and recovery may be elicited by tactfully asking direct questions in response to negative answers to routine

inquiries about alcohol or drug use. The history of alcohol or drug abuse, type and quality of and compliance with a recovery program, and participation in mutual-help groups are important components of the past medical history. Involvement of an addictionologist, rehabilitation counselor, or sponsor in the patient's recovery should be noted, the duration and relative success of recovery explored, and the history of and apparent factors responsible for triggering relapse episodes identified. Encouraging the patient to intensify the practices of their recovery program has been recommended because the patient's support system is a powerful defense against relapse during periods of stress.[98]

Much of the end-organ damage that occurs as a result of chronic substance abuse is reversible with long-term abstinence, but some permanent pathology that requires further evaluation or stabilization before surgery might remain. A urine drug screen may be indicated to exclude drug use and identify the need for further referral. Most recovering patients are aware that many drugs used for premedication have abuse potential and may refuse premedicants on these grounds. Patients familiar with biofeedback, guided imagery, or meditation may want to use these relaxation techniques instead of drug therapy. Euphoria-associated premedication before surgery may theoretically stimulate drug ideation, but use of anxiolytics to control anxiety may be more important because apprehension and exaggerated stress responses are common in the recovering patient. Twelve-step meetings and increased sponsor contact may also be useful anxiolytics for the recovering patient.

Clear strategies for the conduct of anesthesia and the management of postoperative pain should be established with the recovering patient before surgery. Reassurance that the history of addiction will not be an obstacle to anesthetic technique and the adequate treatment of postoperative pain should be provided. The anesthesiologist's broad expertise in pain management also deserves strong emphasis during preoperative discussion with the recovering patient. The anesthesiologist should also discuss evaluation of the recovering patient's behavioral responses to pain management with the nursing staff before surgery. This discussion should emphasize that abnormal attitudes or conduct that signify drug ideation or loss of control over pain medications needs to be immediately identified and reported. However, unusual behavior specifically related to pain therapy may instead indicate the presence of pseudoaddiction, a phenomenon that refers to drug-seeking behavior related to inadequate analgesia. In contrast to true addiction, pseudoaddiction is characterized by extinction of aberrant behavior when adequate analgesia is achieved.

Analgesics without abuse potential may initially be proposed for the relief of postoperative pain. These drugs may be used with or without continuous regional local anesthesia or selective nerve blocks in some recovering patients to provide adequate pain control and may also serve to reduce opioid analgesic requirements. Alternative pain modalities might also be considered. Importantly, the potential benefits of these methods must be weighed against the risk of inadequate analgesia, a significant factor in precipitating relapse. Opioids remain the most efficacious clinically available analgesics for treatment of surgical pain. Use of opioids should be guided by specific clinical indications. The selection of the specific type of opioid and the route of administration may be less important than the scheduling of administration. Mixed opioid agonist–antagonists theoretically offer a reduced risk of abuse than pure μ agonists, but these drugs are not completely devoid of abuse potential and do not provide clear benefits over μ agonists for postoperative analgesia. Neuraxial administration of opioids has been advocated because of theoretical reductions in the incidence of euphoria and the potential for associated drug craving, but this hypothesis has not been rigorously investigated. Scheduled administration of opioids or patient-controlled analgesia (administered by intravenous or epidural routes) may provide benefits over intermittent dosing in the recovering patient by simplifying the pain management plan for nursing staff, reducing delays in drug administration that contribute to inadequate analgesia, and eliminating patient requests for opioids that may be misinterpreted as addictive behavior. However, the use of patient-controlled analgesia in recovering patients is controversial because of the dynamics of self-administration. Prescription of opioids solely on an "as-needed" basis is not recommended in order to reduce associations between pain symptoms and the administration of a reinforcing drug that may increase overall pain perception and inappropriately justify greater drug use.

PART 3

SAFETY AND RISK REDUCTION IN ANESTHESIA PRACTICE

CHAPTER 24

Anesthesia Risk

Fredrick K. Orkin, MD, MBA, MSc, and David E. Longnecker, MD, FRCA

"What is the risk of anesthesia?" patients often wonder. Their concern really is multipart. First, how likely is something to go wrong? then, what "bad things" could happen? and finally, what can be done to reduce the risk to me and to others following me in the future?

Anesthesia care providers try to allay patients' concerns by noting that most anesthesia side effects are common and may be annoying, but fortunately they are transient. Serious, life-threatening complications now are uncommon, if not rare. Whereas such comments may offer comfort, they do little to specify the magnitude and types of risks that a given individual faces, nor do they indicate that we know how to reduce the risks. Yet both have been active topics of ongoing research and efforts to improve anesthesia safety.

What lends poignancy to an otherwise arcane consideration of anesthesia risk is the recognition that an anesthetic usually confers no therapeutic benefit to the patient but rather facilitates other therapeutic or diagnostic interventions. This facilitation results from one of the most widely heralded humanitarian achievements of modern medicine, yet anesthesia care is accompanied by an ever-present possibility of harm. The potential for harm is expressed quantitatively by a variety of risk metrics, most commonly as the incidence rate for an adverse event. These metrics allow investigators to estimate the contributions of various aspects of anesthesia care (e.g., anesthesia methods and drugs, clinical care sites, temporal periods) to overall anesthetic risk. These findings allow clinicians to formulate approaches to care that are built on knowledge gained from past experience and to benchmark the impact of changes in care using quantitative metrics.

Anesthesia risk has been a critical concern since the first demonstrations of clinical anesthesia 160 years ago, when anesthesia was particularly hazardous. Over decades, interest in identifying, characterizing, and decreasing anesthesia-related harm has increased. These efforts have included inquests, case reports, case series, study commissions, registries, cohort studies (some with multi-institutional and geographically diverse data), clinical trials, clinical practice guidelines and standards, establishment of the multidisciplinary Anesthesia Patient Safety Foundation (emulated in Australia and elsewhere), and use of simulation for clinical training, among other initiatives (see Chaps. 3 and 25 for additional information).

The intensity of these myriad efforts illustrates the specialty's commitment to decreasing the occurrence of adverse events and thereby improving

KEY POINTS

1. Anesthesia risk estimates are wholly dependent on the circumstances in which they are generated; estimates developed in one clinical setting or selected population may not be relevant to other settings or specific patients.
2. The risk of death related primarily to anesthesia is estimated to be as low as approximately 1:200,000 anesthetics in large populations.
3. Such a very low anesthesia-attributable mortality rate reflects improvement of perhaps two orders of magnitude over more than 50 years.
4. Despite the very low anesthesia-attributable mortality rate, the very large and increasing number of anesthetics engenders a substantial burden of mortality and morbidity, much of which may be preventable.
5. Approximately 75% of risk actually relates directly to patient-specific characteristics, including age, gender, and comorbidity; 20% to surgical issues, such as experience and judgment; and the remaining 5% to anesthesia factors, including experience, board certification, pharmacologic issues, and overall management of care.
6. The overall anesthesia-attributable mortality rate is now so low that demonstrating further improvement is no longer logistically feasible. However, there are opportunities for meaningful advances in selected subpopulations of high-risk patients or high-risk procedures.
7. The very low anesthesia-attributable mortality should not be a cause for complacency but rather an impetus toward a wider emphasis on improving anesthesia-related morbidity in selected populations and even broader outcomes of care.
8. Although randomized clinical trials have rightly become the "gold standard" for establishing efficacy in clinical research, randomized clinical trials have a limited role in studying anesthesia risk, particularly because they cannot conveniently, efficiently, and at reasonable cost unravel the confounding clinically relevant variables.
9. Whereas much of what has been learned about both anesthesia risk and studying risk comes from large prospective cohort studies of mortality, such studies cannot fully capture the multidimensionality of anesthesia risk and risk-related nuances that require adoption of a broader definition of anesthesia care and often the study of large observational datasets.
10. The study of observational data requires rigorous attention to methodology, lest bias enter to impair the risk estimates, and multivariable statistical modeling to deal with confounding among clinically relevant variables.
11. The American Society of Anesthesiologists physical status classification correlates with risk for mortality and morbidity, but it is somewhat subjective and, without embellishment with other clinical information, is not as strong a predictor of poor outcomes than other, morbidity-specific measures.
12. Well-conducted studies of observational clinical data reveal that anesthesia risk is influenced much more by *how* the anesthesiologist provides care rather than specifically *what* methods are used.

anesthesia safety. An almost 100-fold decrease in estimates of anesthesia-attributable mortality among studies over the past 5 decades documents the specialty's high level of professionalism and leadership toward ever-greater patient safety, which has been cited by the Institute of Medicine as a model for the rest of healthcare.[1]

The risk of death related primarily to anesthesia has been estimated to be as low as approximately 1:200,000 anesthetics in large populations.[2] (This chapter emphasizes that such estimates vary greatly depending on circumstances of the given study, and that no rate can be considered representative of all clinical settings.) Yet the now very frequent administration of anesthesia—almost 48 million surgical procedures[3] in the United States plus an uncertain number of diagnostic procedures undertaken with anesthesia—engenders several hundred anesthesia-associated deaths each year. Many more—perhaps 10–15 times as many—perioperative deaths occur in circumstances where perioperative anesthesia management, surgical care factors, and/or patient-specific characteristics jointly contribute to poor outcomes. Moreover, an even greater prevalence of anesthesia-associated morbidity poses a substantial burden of individual suffering and societal costs. Thus, despite substantial improvement in anesthesia safety, potentially preventable anesthesia-associated mortality and morbidity remain "of sufficient magnitude to constitute a public health problem," as Beecher and Todd[4] noted more than 50 years ago.

The effort to decrease anesthesia risk has been a major focus of scholarly activity, resulting in more than 3000 English-language, MEDLINE bibliographic citations on "anesthesia risk" since 1966 and many more citations relating to the risk of specific morbidities. As might be expected, this literature can be unwieldy, confusing, sometimes contradictory, and often uneven in scientific quality, leaving the practitioner little guidance about what can be applied in practice or conveyed to patients with confidence.

Rather than exploring those studies in detail, this chapter surveys the factors that must be considered when evaluating the literature on anesthesia risk. We review the definition of risk, the special problems in studying anesthesia risk, the relevant study designs, and the salient findings from selected studies of mortality and morbidity that inform us about anesthesia risk analysis. We see how characteristics of the system of care, including the patient, the procedure, and the clinical setting, may influence outcomes, and where opportunities for further risk reduction may lie. The goal is to inform and educate the practitioner so that anesthesia practice can be guided by an understanding of the principles of anesthesia risk, without great reliance on equations and statistical formulas that are the basis of epidemiology and risk analysis.

We see how our understanding of anesthesia-associated risk has developed historically and intuitively, from a single-minded focus on the risk of death associated with anesthetic administration to the multifaceted potential role of anesthesia in a continuum of care management that includes myriad healthcare factors that act collectively to influence patient outcomes, all with the goal of improving care.

WHAT IS ANESTHESIA RISK?

A seemingly simple concept, risk often is misunderstood, perhaps in part because of inconsistent and imprecise usage of the terms *"risk"* and "risk factors."[5,6] The resultant confusion is not trivial, given the recent controversy regarding *when* the celebrated decrease in anesthesia risk may have occurred[7,8] and even *whether* it actually occurred.[9,10] Thus, it is appropriate first to define risk.

Risk is a probabilistic term that expresses the likelihood of an outcome. Risk is a ubiquitous, natural part of life, because everything we do, including doing nothing, poses an uncertain outcome. In common usage, *anesthesia risk* connotes an undesirable or negative occurrence, such as death or injury. However, colloquially, in addition to referring to the chance of an outcome (e.g., *risk* of death during anesthesia), we occasionally use the term to refer to the outcome itself (e.g., *death* as one risk of anesthesia). A detailed analysis of the many possible anesthesia-associated adverse outcomes is beyond the scope of this chapter. Thus, this chapter focuses on developing an understanding of the probabilistic concept of risk, which may be applied either broadly or in subspecialty areas. Risk is defined as *the probability of an outcome within a population.*[5,6]

This definition quantifies the occurrence of a *specific* outcome within a *specified* population that is exposed to a *specific* hazard (e.g., anesthesia, air travel, etc.) under *specific* conditions. For example, the population receiving general anesthesia might share "exposure" to a hazard (e.g., loss of protective airway reflexes) during the period of observation; however, only some among the population develop the adverse outcome (e.g., aspiration pneumonitis) that is associated with this hazard. (Note the distinction between hazard and risk: *hazard* is a characteristic of the system, whereas *risk* is a statistical probability; thus the terms cannot be used interchangeably.) Although the definition of risk is precise, differences in risk estimates among reports that purport to have studied the same outcome can vary widely to the casual observer. These differences usually result from differences in study design, not from differing definitions of risk. Careful reading of a report often reveals possible sources of the differences (Box 24–1).

Although the bulk of the anesthesia risk literature relates to estimates of risk (including identification of risk factors), an important subset of our risk literature relates to the other, less

BOX 24–1.

Common Sources of Differences in Anesthesia Risk Estimates Across Studies

- Characteristics of study population (e.g., age, gender, comorbidities, genomics)
- Magnitude or duration of the exposure
- Definition of the outcome
- Sensitivity and specificity of the diagnostic methods used to identify the outcome
- Surveillance interval following exposure
- Method of attributing outcome to anesthesia management
- Characteristics of the healthcare setting
- Sampling variation (especially with small sample size)
- Other factors that might affect the likelihood of the occurrence of the outcome

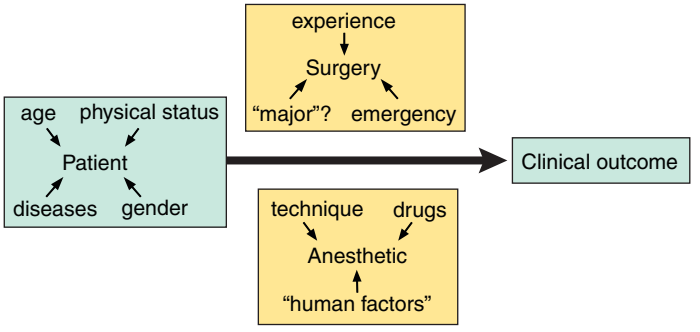

FIGURE 24–1. Traditional model of the determinants of the patient's clinical outcome after surgery and anesthesia care. (Modified from Orkin,[158] Fig. 1.)

common usage of *risk*: descriptions of specific adverse outcomes. Examples include case reports, case series (e.g., critical incident studies[11]), and registries such as the American Society of Anesthesiologists (ASA) Closed Claims Project.[12] Because such reports do not include information on the "at-risk" or "exposed" population, incidence rates cannot be estimated and risk factors for the occurrence of the outcomes cannot be identified. Yet such reports are widely used to alert us to possible, but still unquantified, risks, and they have been especially useful in developing initiatives to improve safety (see Chaps. 3 and 25).

How Does *Anesthesia Risk* Differ from *Anesthesia Safety*?

Risk and *safety* often are discussed colloquially as if they were closely related, yet they are not. Whereas *risk* is an objective, probabilistic term, *safety* connotes personal and/or social value judgment about the acceptability of a given level of risk.[13,14] We generally regard as safe that which poses an acceptable level of risk, given that nothing is risk-free.[14,15] The acceptability of a given risk level is a function of each individual's *risk tolerance,* which, in turn, is influenced by factors characterizing the adverse outcome, exposure, and perceptions of the individual evaluating the risk (Box 24–2).[13,16]

The perceptions of risk, and the tolerance for risk, vary considerably among individuals and over time. Some might consider the risks of space flight as unacceptable, whereas astronauts and recent space tourists do not. Similarly, many Americans reassessed their risk tolerance for commercial aviation immediately after the events of September 11, 2001, with many preferring to drive even though commercial air travel posed lower risk. Some even purchased firearms, although evidence indicates that the risks from firearm accidents are far greater than the chance of being killed by a terrorist.[16] Not surprisingly, parents are generally much more concerned about the safety of anesthesia for their children than for themselves, even though the risk of injury is generally similar.

HOW IS ANESTHESIA RISK MEASURED?

Models for Studying Anesthesia Risk

The perspective taken in studying anesthesia risk may be narrow or broad—the latter approach has evolved more recently. Most investigators who published before the late 1980s probably were guided by the more restrictive model depicted in Fig. 24–1. In this approach, a population of patients is "exposed" to the dual "hazards" of anesthesia and surgery, and the model counts clinical outcomes (deaths, adverse events) that result from this experience.

A revisionist model (Fig. 24–2), consistent with studies of anesthesia risk undertaken since the latter 1980s, recognizes that anesthesia care and surgery occur in a complex matrix of administrative, cultural, and clinical processes, all of which can add hazards to the system.

The revisionist model also includes a far broader array of outcomes, well beyond those purely clinical (Box 24–3). Although most of the anesthesia risk literature focuses on clinical outcomes, such as death or morbidity, it also is important to explore the influence of anesthesia care on other outcomes, such as cost, patient performance (e.g., quality of life), quality of service, and patient satisfaction. These assume greater importance now with the growing call throughout medicine for greater patient-centered care (see Chap. 3).

BOX 24–2.

Factors Associated with Decreased Tolerance for Risk

A. Features of the adverse outcome
   1. Greater versus lesser severity
   2. Permanence versus reversibility
   3. High versus low frequency
   4. "Dread disease," especially social and economic implications
   5. Immediate versus delayed onset
   6. Occurrence in all people versus only in sensitive people
   7. Relationship to intervention known with certainty versus not well established

B. Characteristics of exposure (intervention)
   1. Optional (e.g., cosmetic services, treatment for self-limited disease) versus essential (e.g., therapy for life-threatening disease)
   2. Related to exposure versus its absence
   3. Alternatives available versus only available intervention
   4. Imposed versus voluntarily assumed
   5. Misuse is likely versus unlikely

C. Perceptions of evaluator regarding circumstances of exposure
   1. New versus established
   2. Synthetic or imposed versus natural
   3. Greater uncertainty versus highly predictable result
   4. Less knowledge of situation
   5. Less personal control versus more control
   6. Less trust in the circumstances versus greater trust
   7. Relates to one's child versus oneself versus a stranger

Quantifying Anesthesia Risk

If exposure to a "hazard" increases the likelihood of an adverse outcome, then duration (or dose) of exposure should be a better predictor of development of the outcome than just occurrence of exposure. Indeed, this intuitive notion

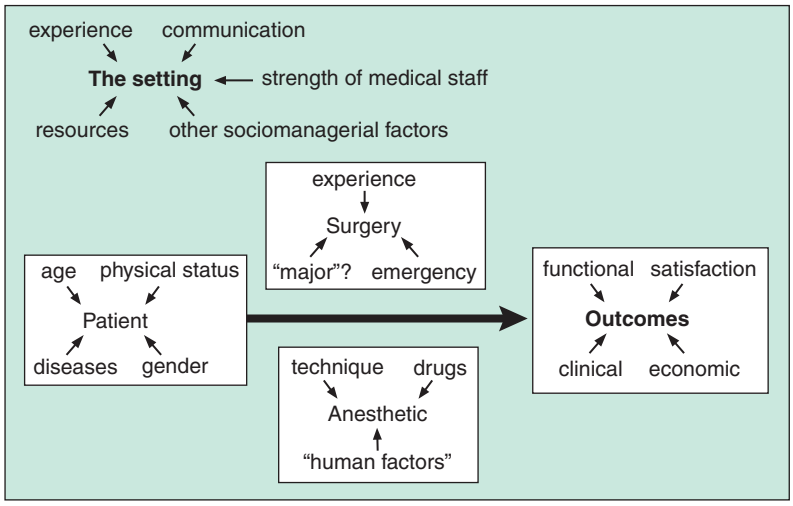

FIGURE 24–2. Revisionist model of the determinants of the patient's outcomes after surgery and anesthesia care. This model acknowledges that the outcomes are far broader than purely clinical and that the care setting also has diverse influences on the care and its results. (Modified from Orkin,[158] Fig. 2.)

is the basis for the investigative approach in toxicologic and epidemiologic studies of health hazards. Time-related exposure risks (e.g., 1-year odds) of real-world health hazards have been tabulated.[16] Runciman and Moller[17] applied this notion to quantify the mortality risk of anesthesia and complex surgery in relation to a variety of real-world hazards (Box 24–4). Although the mortality rates they present for various hazards are only approximations, the relative risks are informative for both providers and patients: having anesthesia is as risky as being hospitalized, 20 times more hazardous than commercial flight, but 10 times safer than parachute jumping!

Despite the intuitive appeal and potential empirical value, examples of anesthesia risk studies examining time-related hazards are few. This may reflect both lack of interest in time-related hazards, as several well-conducted studies suggested that outcome differences among general anesthetics are minimal, if any,[18,19] and historically the lack of equipment for detecting and recording time- and dose-related delivery of anesthetics (e.g., minimum alveolar concentration-hours of desflurane). Many studies note an association between greater duration of anesthesia (or surgery) and poorer outcome, but longer duration of anesthesia is not necessarily equivalent to a greater total anesthetic dose and probably reflects longer surgery, among other factors discussed when considering sources of risk.

However, Monk et al.[20] have reported that greater cumulative deep hypnotic time—estimated as the time when the bispectral index is < 45—was independently associated with greater 1-year postoperative mortality. Hopefully, this report will encourage other investigators, especially those in settings with computer-based record-keeping technology that captures duration and weighted-average dose of inhalation agents, to validate and further elucidate this and other possible effects related to the cumulative total dose of anesthesia.

In the absence of time-related risk data, anesthesia risk is commonly summarized as an incidence rate that is computed, in its simplest form, as the quotient of the number of cases and the overall population:

$$Risk = Incidence\ Rate = \frac{Persons\ with\ Outcome}{Population\ Exposed\ to\ Hazard}$$

Four important features of this simple relationship are apparent. First, a risk cannot be estimated without knowing the size of the population from which the cases (i.e., those with the outcome) arose. Thus, the absence of the denominator precludes estimating risk in studies using case series and registry data. Second, risk estimates can span a remarkably wide range. The calculated risk value is bounded by 0, in which circumstance no one experiences the outcome, and 1, in which everyone suffers the outcome. Depending on the outcome studied, anesthesia risk estimates span much of this range, from death primarily related to anesthesia care in large, unselected populations (e.g., as low as 0.000005) to postoperative nausea in especially susceptible individuals under specific circumstances (e.g., as high as 0.8). Because decimal values can be unwieldy (and thus error-prone) and awkward in conversation, we commonly refer to risks > 0.01 in their percentage form (e.g., the risk of perioperative death in relation to cardiac surgery is "3.0%" rather than "0.03"). For smaller

BOX 24–3.

Taxonomy of Outcomes

I. Clinical outcomes
  A. Clinical endpoints
    1. Symptoms (e.g., nausea, cough)
    2. Laboratory values (especially abnormal values)
  B. Complications and adverse events (e.g., dental injury, pulmonary aspiration, arrhythmia, cardiac arrest)
  C. Death
II. Functional health status (health-related quality of life)
  A. Physical
  B. Mental (including psychological and well-being)
  C. Social
  D. Role
III. Patient satisfaction
  A. Patient-based assessment of care
    1. Quality (e.g., satisfaction with pain control)
    2. Convenience
    3. Access to care
    4. Adequacy of information (e.g., education)
IV. Economic consequences
  A. Length of stay (hospital, intensive care unit)
  B. Utilization of specific healthcare resources (e.g., drugs, tests, procedures)
  C. Institutional performance
    1. Readmission of discharged patients
    2. Unplanned admissions from ambulatory surgery
    3. Other institutional implications of errors and complications ("rework")
  D. Costs
    1. Direct costs
    2. Indirect costs (e.g., lost wages, lost productivity, disability)

BOX 24–4.

Average Fatal Accident Incidence Rates (Deaths per 100 Million Hours of Exposure)

Being pregnant	1
Traveling by train	5
Working at home	8
Working in agriculture	10
Testing positive for human immunodeficiency virus after receiving one unit of blood	10
Being in traffic (overall, in any capacity)	50
Working in the construction industry	67
Flying in a commercial aircraft	100
Being a patient in an Australian hospital	2,000
Being anesthetized	2,000
Parachute jumping	20,000
Having elective abdominal aortic surgery	200,000
Having emergent abdominal aortic surgery	2,000,000

Modified from Runciman and Moller,[17] Table 1.17.

risk values, we often express the risk in either the scientific notation (e.g., 5×10^{-6} rather than 0.000005) or, more commonly, the ratio of 1 to the smallest number of individuals whose exposure to the hazard would result in one case (e.g., risk of death primarily related to anesthesia is "1 in 200,000" or "1: 200,000" rather than "0.000005").

Third, by definition, the calculated risk is the risk faced by the population under study, whereas we are often interested in the risk faced by a particular individual or perhaps a specific group of individuals who were not part of the study population and may have special characteristics that might place them at greater or lesser risk. Thus, risk estimates in the literature, especially some very low mortality rates widely touted in public media, may not relate well to the person(s) we are concerned about. Again, risk estimates are very much the products of the circumstances in which they are generated (Box 24–1).

Fourth, this simple and common risk calculation is but one approach to expressing the magnitude of risk. The magnitude of risk can be expressed in alternative ways, some of which are particularly useful in understanding clinical trial results and comparing treatment benefit or harm across studies (Table 24–1).[21] Such risk metrics are easily computed from summary results presented in the literature (Box 24–5).[22]

TABLE 24–1.

Risk Metrics and the Epidemiologist's 2 × 2 Table

		Outcome	
		Present	Absent
Exposure	Present	a	b
	Absent	c	d

Risk Metric	**Definition**	**Calculation**
Relative risk (RR)	Proportion of original risk present with new intervention	$\frac{a/(a+b)}{c/(c+d)}$
Relative risk reduction (RRR)	Proportion of outcome risk removed by intervention	$\frac{c/(c+d) - a/(a+b)}{c/(c+d)}$
Absolute risk reduction (ARR)	Proportion of persons spared outcome by intervention	$\frac{c}{c+d} - \frac{a}{a+b}$
Number needed to treat (NNT)	Number of persons treated with intervention to save one	$\frac{1}{ARR}$
Odds ratio (OR)	Ratio of proportion of persons with outcome to those without outcome	$\frac{a/b}{c/d}$

Modified from Jaeschke R, Guyatt G, Barratt A, et al. Therapy and understanding the results: measures of association, In: Guyatt G, Rennie D, eds. Users' Guides to the Medical Literature: A Manual for Evidence-Based Clinical Practice. Chicago: AMA Press, 2002:351.

Risk Values Are Estimates

If 5 of a 10-patient cohort receiving a new antiemetic regimen experience postoperative vomiting, we conclude that the emesis rate is 0.5. To increase our confidence in the results, we study another

BOX 24–5.

Calculating Risk Metrics

Often, we can extract greater risk-related information from studies, particularly clinical trials, by calculating a set of risk metrics (Table 24–1).[21] The first step is to express the study results in an epidemiologist's "2 × 2 table" and then compute a set of risk metrics. The computations are simple but error-prone. An interactive, Internet-based calculator is available.[22]

Example 1: How effective is intensive insulin therapy in intensive care?

Van den Berghe et al.[23] reported that an intensive insulin regimen was associated with a 48% decrease ($P = 0.005$) in mortality among those receiving more than 5 days' intensive care. Such a decrease certainly appears very meaningful, yet we recognize that a small *P* value is not a measure of *clinical* significance and is influenced by sample size. Creating a 2 × 2 table from their results (a = 22, b = 208, c = 49, d = 243), we can calculate the risk metrics, including a number needed to treat (NNT) of 13.6. Such a very low NNT value indicates that the intensive insulin regimen is a very potent intervention.

Example 2: Reconciling perioperative, prophylactic atenolol recommendations.

Mangano et al.[24] recommended prophylactic, perioperative atenolol for all patients at risk for coronary artery disease, but more recently Lindenauer et al.[25] have suggested that β-blocker use be reserved for patients at high risk because lower-risk patients are harmed. Can we reconcile the two recommendations? One hypothesis is that Mangano et al. studied higher-risk patients. From a 2 × 2 table constructed from Mangano's principal results (a = 9, b = 90, c = 12, d = 89), we calculate risk metrics, including an NNT of 36 and odds ratio of 0.74. These risk metrics approximate those for the highest-risk patients studied by Lindenauer et al., thus supporting our hypothesis.

cohort of 10 patients. Naïvely, we expect the same rate as the circumstances are unchanged. The second cohort's rate is 0.6. Still seeking confirmation, we study a third and fourth cohort, whose rates are 0.2 and 0.5. Now we are confused!

Our experience teaches us four important additional lessons about studying risk in small clinical studies. First, the clinical experience of each 10-patient cohort is but a sample of the experiences of a universe of patients whom we rarely can study. The observed adverse-event rate in any sample is only an estimate of the true adverse-event rate in the much larger population. If the true emesis rate in the population receiving this anesthetic regimen is 0.5, we are likely to observe this rate in many cohorts, but we may not because of sampling variation.

The second lesson is that the rates calculated from small samples can vary greatly. Thus, for our sample of 10 patients, there is a finite set of possible rates (i.e., 0, 0.1, 0.2, ... 0.9, 1.0). Related is our third lesson: with larger samples, the set of possible rates grows, with the values closer to each other (e.g., for a sample of 20 patients, the possible rates are 0, 0.05, 0.10, 0.15, etc.).

The fourth and most informative lesson is that rates calculated for successive cohorts hover around the population's rate and that one may compute a likely range (confidence interval [CI]) for the rates calculated for successive cohorts. As the cohort's sample size increases, the CI for the rate narrows, enhancing the precision of the rate estimate (Fig. 24–3 and Box 24–6).[26] Thus, other things being equal, we intuitively regard rates calculated from larger cohorts as more reliable than those from smaller studies, and the statistics support our intuition.

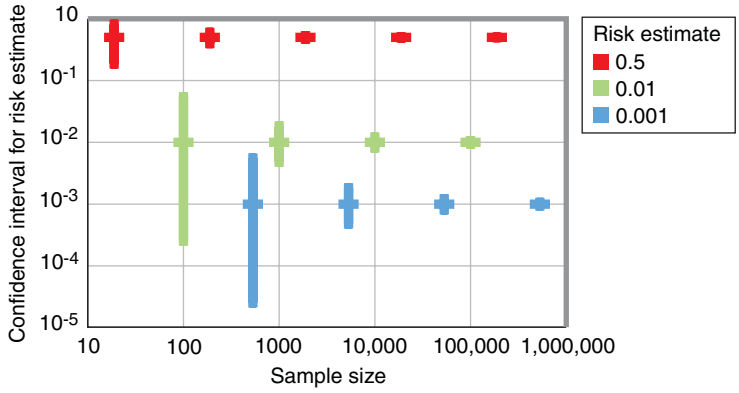

FIGURE 24–3. Span of 95% confidence interval (*vertical bar*) as a function of risk estimate (*horizontal line in vertical bar*) and sample size. Smaller risk estimates require sharply increasing sample size for precision.

WHAT ARE THE CHALLENGES IN ESTIMATING ANESTHESIA RISK?

Generic Challenges in Studying Anesthesia Risk

Identifying the Outcomes of Interest

Diagnostic Problems Diagnosing or identifying an adverse event is critical to the assessment of risk and is not a trivial problem. Identifying the occurrence of death might seem inordinately simple, but postanesthesia death may not be recognized if the defined surveillance interval is brief, such as the first 48 hours postoperatively or during hospitalization only. This "ascertainment bias" results in underestimation of the true mortality rate.

Even greater challenges are posed by specific adverse events, such as pulmonary aspiration, pulmonary edema, myocardial ischemia, or myocardial infarction (MI), which often present in a graded fashion, from barely detectable to life-threatening. This raises the possibility that differences in the observed

BOX 24–6.

Calculating Confidence Intervals

When perusing medical literature, physicians hone in on *P* values, looking specifically for values "less than 0.05" that are commonly accepted to denote "statistical significance." The latter is not the same as *clinical* significance, and a smaller *P* value does not indicate a stronger basis for clinical decision making. Indeed, the *P* value tells whether the study result could have happened by chance (not necessarily of great relevance to the clinician), and the size of the *P* value is itself sensitive to the study's sample size (i.e., smaller *P* value for same "effect size" with larger sample size).

Instead, recognizing that study results vary, the clinician is most interested in knowing the range in which the study result is likely to lie, were the study to be repeated. The 95% confidence interval (CI) is the range in which the result would lie in 95 of the next 100 repeat studies.[26]

A special situation arises when an outcome of interest (e.g., a complication) does not occur, in which case the rate obviously is 0. But we can have little confidence that the true rate is 0%. Clearly, the lower limit of the confidence interval is 0%, but what is the upper limit? Although we can resort to statistical software or tables, there is a handy "Rule of 3" for computing an estimate of the upper limit of the 95% CI: the quotient of 3 divided by the sample size in which no event was observed.[27] (Similarly, there is a "Rule of 5" for estimating the upper limit of the 99% CI.)

Example 1: Among 9152 gastroenterologic endoscopies in an ambulatory surgery center where nurses administered propofol sedation, using an anesthesiologist-furnished protocol, there were 7 (0.08%) cases of "respiratory compromise" (3 prolonged apnea, 3 laryngospasm, 1 aspiration requiring hospitalization).[28] What is the likely variation about this rate? Using statistical software, we compute the 95% CI to be 0.03–0.16%, suggesting that these important complications are likely to continue to be rare.

Example 2: A clinical trial of gastroenterologist-administered sedation for advanced upper endoscopy compared propofol in 38 patients to meperidine/midazolam in 37 patients.[29] Apart from brief, transient respiratory depression monitored by capnography, no major complications occurred. How confident can we be about the risk of major complications? Using the Rule of 3, we compute the upper limit of the 95% CI as approximately 8% (statistical software: 9.5% and 9.3%, respectively). Thus, with the risk of a severe complication as high as 1:11, this small trial does not instill a sense of safety.

risk (incidence rate) of these and other outcomes might be influenced greatly by the prevalent diagnostic methods or definitions. For example, the observed rate of myocardial ischemia is greater if the diagnosis is made by continuous Holter monitoring than by clinical symptoms such as angina. Such imprecision constitutes an important source of systematic error (ascertainment bias, information bias) that can lead to failure to recognize outcome occurrences (misclassification bias) and inaccurate risk estimates.

Diagnostic challenges often are compounded by problems with the definitions and classifications that are inherent in clinical information systems and administrative databases. Institutional clinical information systems may use nonstandard definitions for data elements, such as adverse events, diagnoses, surgical procedures, and thresholds for abnormalities among laboratory values. Administrative databases, which classify the diagnoses, complications, and surgical procedures relating to care in a standard procedure coding system, typically have few anesthesia-specific categories [e.g., "E" codes in the *International Classification of Diseases, Ninth Revision, Clinical Modification (ICD-9-CM)* system], and some can be quite arcane (e.g., ICD-9-CM code 968.3: poisoning by intravenous anesthetics).

Surrogate End Points Even if the outcome of interest (e.g., death, specific adverse event) can be identified accurately, it may occur so infrequently that the proposed study may not be feasible. (We consider the statistical basis later.) Not unexpectedly, investigators have opted for alternative end points that are surrogates or intermediate variables—symptoms, signs, clinical events, laboratory values, and even process variables—which occur more often than the outcome and are believed to be linked to that outcome. Thus, blood pressure is used as an end point in clinical trials because high blood pressure is a known risk factor for stroke and MI; similarly, myocardial ischemia is commonly used as a surrogate for MI.

Such approaches are appropriate only if the surrogate end point truly predicts the occurrence of the outcome. However, this requirement is often not met, possibly because the outcome may occur via some pathway(s) not mediated by the surrogate.[30] Among recent examples is ventricular ectopy as the surrogate end point in the evaluation of drugs to prevent sudden death. Food and Drug Administration approval of a new class of antiarrhythmic drugs followed clinical trials demonstrating their efficacy in treating ventricular ectopy, but a subsequent trial revealed a *greater* risk for sudden death among those receiving the new drugs, and the drugs were withdrawn.[31] Problematic surrogate end points in anesthesia have included the interval to eye opening after general anesthesia, which does not correlate well with earlier discharge after ambulatory surgery, lower rate of unplanned hospital admission after ambulatory surgery, greater patient satisfaction, and overall lower cost of care.[32]

Broadened Array of Outcomes The end points of interest have expanded from "clinical outcome," such as mortality or specific adverse events or complications,[18,33–35] to a broader and more comprehensive set of "outcomes" that reflect many facets of the care process, including the results of the care particularly from the patient's perspective, or administrative end points such as the cost of services (Box 24–3). Studies of anesthesia risk already include some nonclinical outcomes, such as unplanned hospital admission after ambulatory surgery[36,37] and poorer quality of immediate postoperative recovery.[38]

Undoubtedly, more studies will include measures of what has been termed "health-related quality of life,"[39,40] increasingly termed "patient-reported outcome measures."[41] As the terminology suggests, the patient is the direct source of the information. These measures take the form of a large number of generic health scales (e.g., Medical Outcome Study's SF-36 Health Survey[42]) and disease- and condition-specific specific scales (e.g., Visual Analog Scale for Pain,[43] McGill Pain Questionnaire[44]). Such instruments have been validated in large populations, typically with chronic disease, for use in longitudinal and cross-sectional studies,[45] and are beginning to be used in settings such as chronic pain clinics. Apart from their possible use as outcome measures, patient-reported measures may also be used as patient descriptors (e.g., quantitating severity of a symptom or disability).

Patient-Specific Descriptive Data

Risks are not distributed randomly. Some individuals are more likely to experience health problems as a result of diverse factors, including genetics, coexisting disease, personal health behaviors (e.g., smoking, diet, exercise), socioeconomic status, and environmental setting. Thus, estimating anesthesia risk requires accurate information to characterize each patient, including nonclinical information. Such information enables categorizing patients by likelihood of poor outcome (risk stratification) and "risk adjusting" their data for outcome comparisons.[46]

The ASA physical status classification originally was advanced to standardize terminology and group patients in six categories for review of clinical outcome.[47] Subsequently, it was reformatted to five categories by Dripps et al.[48] and adopted by the ASA.[49] Only later was it found to correlate with clinical outcomes.[18,33–36] In addition, the Charlson Comorbidity Score,[50] a disease-specific classification system, is increasingly used in anesthesia risk studies. (We consider these metrics in detail when exploring the patient's role in risk.)

With growing interest in healthcare disparities, noting the patient's race and ethnicity accurately will be important. Although multiple formats are available for recording such information, the prevailing guidance is that the patient's self-designated race and ethnicity be noted, using categories from the US Census Bureau (White; Black or African American; Hispanic or Latino; Asian or Pacific Islander; or American Indian or Alaskan Native).[51]

Duration of the Surveillance Interval

Intuitively, we know that the longer we watch for problems, the more likely we are to capture all such occurrences. Too short a surveillance interval risks missing some occurrences and, thus, can lead to systematically underestimating risk (ascertainment bias). Yet, as the time between the "exposure" (e.g., administration of anesthesia) and event increases, the greater the chance that the occurrence may be associated with circumstances partially or totally independent of the exposure. These other circumstances might include even chance patient-specific factors (e.g., MI that might have occurred 2 weeks preoperatively

while walking the dog). This dualism of comprehensiveness versus precision plagues most cohort studies in the anesthesia risk literature.

Variation in length of the surveillance interval is especially apparent in the early studies of anesthetic-associated mortality. Bodlander,[52] Harrison,[53] Tiret et al.,[54] and Dornette and Orth[55] considered a death eligible for further evaluation as possibly "anesthesia-related" only if it occurred during or within 24 hours of administration of the anesthetic or after failure of the patient to regain consciousness after anesthesia. Turnbull, et al.[56] Hovi-Viander,[57] Lunn and Mushin,[58] Marx et al.,[59] Cohen et al.,[19] Dripps et al.,[48] Monk et al.,[20] and Mangano et al.[24] extended the surveillance interval progressively to 48 hours, 3 days, 6 days, 7 days, 30 days, 1 year, and 2 years, respectively. Beecher and Todd[4] adopted an empirical approach, using the duration of the surgical hospitalization.

Extending the surveillance interval captures the delayed deaths from complications that may have their origin with anesthetic care, such as MI, which historically has occurred most commonly several days postoperatively, or pulmonary aspiration with subsequent pneumonia and terminal respiratory failure days or weeks after our care, and thus would escape our recognition if the surveillance interval were short. Even the approach of Beecher and Todd[4] using the duration of the surgical hospitalization can be problematic if the patient dies shortly after an early discharge. Of note, Warner et al.[60] found that 39% of major morbidity occurred more than 2 days but within 30 days after ambulatory surgery among 45,090 adults, including 2 of 5 cases of respiratory failure, 5 of 14 cases of MI, and 3 of 5 cases of pulmonary embolism. Their study population was not sufficiently large to differentiate observed adverse-event rates from those estimated in the catchment population; however, it is clear that substantial numbers of events would have been missed had the surveillance interval been limited to the immediate postoperative period.

Although there are no formal guidelines on duration of the surveillance interval, a 6-week period had been used in the National Halothane Study,[61] 30 days has been adopted by the Veterans Affairs (VA) National Surgical Quality Improvement Project (NSQIP) database,[62] and 30 days is commonly used with Medicare data. At least for most procedures, this interval represents a reasonable compromise between too short an interval (which overlooks adverse events that may be temporally related to surgical and anesthesia care), and too long an interval (which introduces significant logistic problems for followup and perhaps captures adverse events unrelated to the hazards of surgery and anesthesia).

Although one might naïvely expect that the derived mortality rates would increase uniformly with the surveillance interval, such a facile relationship often does not exist, presumably because multiple technical differences among studies (Box 24–1).

Assessing the Relationship with Anesthesia Care

Problem of Attribution The late Emanuel Papper, an esteemed, mid-20th century leader of American anesthesiology, fondly recounted that, as chair of a preeminent department, he was often asked to personally administer anesthesia to notables. One such morning, as he was about to induce anesthesia, he was interrupted by a colleague summoning him to an urgent phone call in his office. Apologizing to the patient and others eager to get underway, Dr. Papper excused himself, and, when he returned 15 minutes later, cardiopulmonary resuscitation was underway!

Attributing causation is inherently problematic. Most cohort studies of anesthesia-associated mortality have included a panel of blinded case reviewers who were asked to attribute the death to one of several possible causes. Was anesthesia care the *primary cause* of death? Or was anesthesia management a *contributory cause* (along with patient- and surgery-related factors) to the death? Or was the poor outcome unrelated to anesthesia care? Panels were often composed mostly or wholly of anesthesiologists. However, recognizing the complexity of the care process and the multifactorial etiology of many adverse events, some study panels have been more balanced. The review committee used by Holland[63] had six anesthesiologists, three surgeons, an obstetrician, a general practitioner, and a medical administrator. Holland assigned cases to one of four categories: wholly related to anesthesia or anesthetic management; probably related to anesthesia or anesthetic management; related to both anesthesia and surgery; or entirely due to surgery. Lunn and Devlin[2] sent a questionnaire to the patient's anesthesiologist and surgeon; the forms were reviewed by blinded assessors who adjudicated differences of opinion and obtained further information if needed to make assignments of attribution.

Unmasking Biases Even without close proximity to care, the mere occurrence of a poor outcome that *may* be related to anesthesia management can bias our judgments regarding quality and appropriateness of care.[64] As Keats[65] noted more than 25 years ago, an underlying assumption in much of the anesthesia risk literature has been the belief that a poor outcome is presumptive evidence of error on the part of anesthesia providers. He emphasized that high interrater reliability in peer review does not assure that judgments are accurate. Review panel determinations are necessarily products of their collective current knowledge of practice at the particular time, as well as numerous other biases that result from inadequate study designs, limited statistical capabilities, and the complexity of phenomena being studied. Despite these limitations and the resulting widely ranging risk estimates, many important insights about risk, and the study of risk, evolved from this literature.

Characterizing the Population

Our discussion thus far has focused largely on patients experiencing an outcome of interest (becoming "cases") after exposure to a "hazard." However, if we do not give due consideration to the larger "at-risk" population from which these cases emerge, we have only a set of cases and cannot quantify the risk. Fortunately, the intellectual basis for estimating anesthesia risk developed in tandem with the early development of anesthesiology. Pioneers in establishing what would become the field of epidemiology recognized the importance of relating the cases to the larger population to estimate risk and compare estimates across different populations (Box 24–7).[66]

Ecology of Care Later investigators extended the interest in characterizing the at-risk population by noting that a large population is not homogeneous with regard to health status or the

BOX 24–7.

Epidemiologic Pioneers in Developing Mortality Rates

Victorian England had become infatuated with the potential use of statistics to help solve diverse societal problems by the 1830s. Three individuals emerged—in close proximity to each other and to the embryonic field of anesthesiology—to provide what would become foundations of epidemiology.[66] Shortly before the demonstration of clinical anesthesia, William Farr began collecting what we now term *vital statistics* (e.g., births, deaths) and undertook Britain's first census. He classified people according to age and occupation groups, and diseases according to crude etiologies.

Farr's early example of health data collection and classification undoubtedly aided pioneer anesthesiologist John Snow (who administered chloroform obstetrical anesthesia to Queen Victoria) in his parallel interest in fighting the British cholera epidemics of 1849 and 1853. He classified cholera cases by London district, juxtaposed the populations of those districts, and calculated cholera death rates as the quotient of the cases and "exposed" populations. The resultant district-specific death rates enabled identification of "high-risk" districts. He then focused on water supply to those districts, particularly in relation to locations of cholera cases. When he noted the association of the highest mortality on Broad Street with service by the water company with especially high rates, he famously curtailed the epidemic by removing the handle of the Broad Street water pump, as well as proved his hypothesis that a water-borne agent was responsible for cholera transmission.

At the same time, Florence Nightingale, another Farr collaborator, was nursing the wounded during the Crimean War. She used similar data collection to develop mortality rate estimates, coupled with innovative analyses and graphics, to lobby successfully for British Army healthcare reform by showing that mortality rates relating to infectious disease, poor nutrition, and unsanitary conditions were greater for English solders than for civilians.

need for healthcare services. In describing "the ecology of healthcare," they noted a hierarchy in which the need for health services and, by implication, poorer health status or greater patient acuity, increases sequentially in the spectrum from the unselected general population to outpatient care settings to community hospital settings, and finally to the academic medical center (Fig. 24–4A).[67] Surgical care is delivered in a similar spatial distribution (Fig. 24–4B). Thus, risk estimates derived in one setting may differ from those in another environment (Berkson fallacy).[68] Recognizing these relationships can help reconcile seemingly disparate risk estimates from studies undertaken in widely differing clinical settings.

Statistical Problems in Studying Anesthesia Risk

Dealing with Low-Incidence Phenomena

Although some anesthesia-related events may occur frequently (e.g., postoperative nausea), most severe adverse events do not. The incidence rates may be so low that estimating rates of occurrence with acceptable precision (i.e., narrow CI) or demonstrating meaningful differences in occurrence (e.g., comparisons of drug regimens or sites of care) can be problematic (Fig. 24–5 and Box 24–8).

The most obvious remedy is merely using a larger sample size. Yet, even when feasible, a larger sample usually connotes a longer patient accrual period, during which other countervailing circumstances may arise (e.g., deterioration in quality of data collection because of study team turnover or loss of enthusiasm, emergence of better technology that obviates study, information that alters or invalidates earlier results, changes in concurrent care processes that affect the event being studied). Other options include using a more sensitive end point, repeated measurements, matched cases and controls, multiple controls, lower statistical certainty ('power'), a higher-risk population, or concurrent multicenter trials.

Multiinstitutional studies, such as the 10-hospital Beecher-Todd study,[4] 34-hospital National Halothane Study,[61] or the 460-hospital study by Tiret et al.[54] in France, offer the added benefit of enhancing the external validity (applicability to other settings, termed "generalizability" in epidemiology) of the results, particularly if the cooperating institutions have different patient populations, surgical mixes, and/or administrative characteristics. Yet multiinstitutional designs may introduce additional logistical and managerial challenges, to assure that the study is conducted the same way in each setting, and a sufficiently large sample size may be too costly.

Alternatively, investigators may opt to study the occurrence of a surrogate end point (e.g., myocardial ischemia) that is associated with the outcome of interest (e.g., MI) but occurs more frequently. As noted earlier, the linkage between the surrogate and outcome may not be sufficiently tight for reliable, meaningful, or even valid results.[30,32]

One especially productive approach involves consortia that jointly collect large amounts of data prospectively for purposes other than a single study. Mangano's Multicenter Study of Perioperative Ischemia Group comprises more than five dozen hospitals throughout the developed world, each contributing the same data elements to a growing database on patients having cardiac and noncardiac surgery. For more than 15 years, this group has studied important perioperative risk topics, including the long-term risk of cardiovascular events,[70] atrial fibrillation after cardiac surgery,[71] mortality reduction with prophylactic use of β-adrenergic blocking agents,[24] aspirin-related mortality from cardiac surgery,[72] and risks related to use of aprotinin in cardiac surgery.[73]

Similarly, in the early 1990s, the dozen US Department of Veterans Affairs hospitals that performed cardiac surgery joined to create a common database,[74] which became the model for an expanded project covering all major surgery in more than 120 VA hospitals, the VA NSQIP.[75] This database has contributed greatly to risk assessment and acquisition of clinical data for measuring outcomes and quality of care[62,75,76] and has been adopted by the American College of Surgeons for national use. Anesthesia-specific data elements are few and limited (e.g., principal anesthesia method); however, the VA NSQIP database includes prospectively defined comorbidities and postoperative complications for thousands of patients having each surgical procedure and is begin-

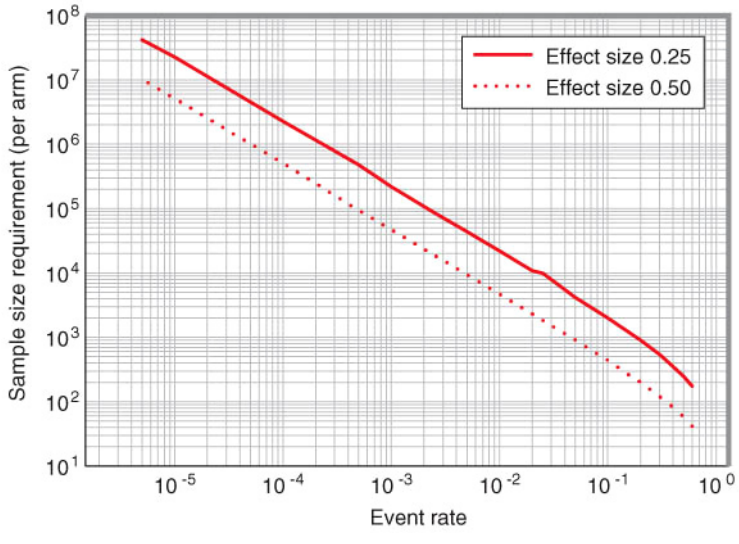

FIGURE 24–5. Sample size requirement for clinical studies comparing risk estimates as a function of adverse-event rate and magnitude of outcome difference ("effect size") sought, with a probability of finding such a difference ("power") of 0.80 and of falsely concluding that no difference exists ("type I error") of 0.05.

ning to enhance our understanding of preoperative risk assessment and choice of anesthesia method.[77–80]

Ultimately, as clinical information systems become ubiquitous, data from customary clinical care will routinely become part of vast institutional databases that will create innumerable opportunities for observational studies not even imagined by the early pioneers who first used computers to develop crude estimates of anesthesia risk.[59] Challenges awaiting those exploiting such clinical treasure troves include assuring that the information systems use standard terminology for diagnoses, surgical procedures, complications, and other clinical information; adequate software to merge data from different databases in real time; availability of sufficiently robust risk-adjustment methods for meaningful and valid comparisons; and user-friendly software to facilitate use of such databases without reliance on computer technicians.

Ever larger administrative databases have developed as a byproduct of the payment system for healthcare; the Medicare Provider Analysis and Review (MEDPAR) inpatient ("Part A") file is frequently used. Besides dealing with a dataset that often includes millions of patient encounters and the challenges of merging this hospital file with other files (e.g., physician or "Part B" file), numerous coding issues, including very limited clinical detail as well as inconsistency and imprecision (e.g., is a given coded disorder a comorbidity or complication?), plague efforts to risk adjust outcomes data.[46] Nonetheless, Medicare data have been used to explore risk in relation to a variety of topics, including the influence of medical direction of anesthesia care,[81] board certification of the anesthesiologist,[82] and location of surgical care.[37,83] Such data have also enabled identification of patient and hospital characteristics that influence anesthesia time for common major operations.[84]

Dealing with Covariates and Confounding

Clearly, anesthesia care occurs in a multivariable setting. The outcome of each episode of anesthesia care—whether administration of anesthesia in the operating room, critical care in an intensive care unit, pain management, or other care—ultimately reflects the interaction of various patient characteristics ("covariates"), includ-

BOX 24–8.

Estimating Sample Size Requirements for Risk Studies

Among important steps in planning a study comparing interventions is estimating the minimum sample size needed to demonstrate a true difference, if it exists. Studying too many subjects takes more time, wastes other resources, and potentially puts individuals at unnecessary risk. Studying too few may result in not finding a statistically significant difference—and not knowing whether that reflects an inadequate sample size or the intervention's true lack of benefit.[69] Thus, institutional review boards now require an explicit sample-size determination in study protocols; in the current environment, proceeding in its absence may be construed to be unethical.

Generically, the estimate is obtained by considering the smallest difference that the investigator believes is *clinically* important or beneficial ("effect size"), the desired level of certainty about the result ("statistical power" or "power"), the risk of accepting a false result ($\alpha = 0.05$), and numerical value(s) with which the intervention is compared (mean and standard deviation as a measure of variation, for continuous variables; proportion, for binary data). By consulting a statistical table, working through a cumbersome formula, or using statistical computing software, one can determine the minimal sample size to detect a given effect size (e.g., "small" = "0.25" for 25% change, "moderate" = "0.50" for 50% change) at a specified statistical certainty or "power" (e.g., minimum = 0.80, with more conservative power being 0.85 or 0.90). The smaller the effect size and/or the smaller the event rate, the greater the sample size needed to demonstrate a meaningful difference with a given power. The sample-size requirement rises in an accelerating fashion as the event rate decreases (Fig. 24–5), placing a severe burden on investigators studying low-incidence events.

Example 1: A new antiemetic drug is being tested to reduce the nausea associated with laparoscopic cholecystectomy. Half of patients have emetic symptoms (rate = 0.5); the investigator believes that a clinically beneficial drug would halve that rate (effect size = 0.5). The comparison involves a "two-sided test" of statistical significance, to identify the possibility that the intervention raises rather than lowers the rate. Assuming minimal power (0.80), the sample-size requirement is 58 patients in each arm of the clinical trial.

Example 2: Another investigator studying the same drug, under the same clinical circumstances, believes that nausea is so distressing that a meaningful clinical effect would be a 25% decrease in symptoms (effect size = 0.25). Assuming minimal power (0.80), the sample size needed is 247 patients in each arm.

Example 3: Recent studies suggest that the anesthesia-attributable death rate associated with anesthesia care may be as low as approximately 1:200,000 (rate = 0.000005). An investigator wishes to study a new configuration of patient monitoring devices and believes that a meaningful clinical benefit would be a 50% decrease in this rate (effect size = 0.50). Assuming minimal power (0.80), the sample size needed is 10,202,941 patients in each arm of the trial!

ing age, gender, ASA physical status, and presence of specific comorbidities, as well as factors relating to the particular situation (e.g., surgery, obstetric delivery).

When complications occur among elderly men, are the poor outcomes related to the age or gender of the patients as well as the care? Might advanced age merely be common in the study sample? Or perhaps advanced age is a proxy for some underlying severe comorbidity (e.g., coronary artery disease) that happens to be more common in older men? Only by disentangling these myriad relationships can we truly understand anesthesia risk and begin to target remedial efforts to the appropriate factor(s) (see Chap. 25).

Underlying this complexity is the reality that covariates may be *confounding variables* that share two properties: they may be associated with the exposure (the care) because an older or sicker person is more likely to have the care, *and* they also may be independent risk factors for poor outcome (i.e., morbidity begets a poor outcome by itself unrelated to the care). Thus, covariates may "confound" the relationship between the exposure and outcome, resulting in an anesthesia risk estimate that mixes the risk due to anesthesia care with that due to the confounding variable.

Such *confounding* can be controlled in the study design by randomization and inclusion criteria in a clinical trial or by matching (e.g., assuring that a specified covariate is present in the study sample in the same proportion as the population).

Stratification If confounding has not been controlled in the study design, as would be the case in an observational design, *stratification* can be used. An anesthesia risk estimate can be calculated for men and women separately, then compared to the rate for the combined study sample, thereby revealing the influence, if any, of gender. Almost all cohort studies of anesthesia-associated death attempted stratification, even if they did not use the term. Indeed, the earliest such study by Beecher and Todd[4] contains dozens of tables presenting bivariate relationships, in which mortality is tabulated by anesthesia method, by anesthesia drugs, by year, etc. The reader gains an appreciation of how unevenly mortality is distributed across study groups, but there are far too many confounding variables for this rudimentary stratification to control.

Multivariable Modeling When more than a few confounding variables are present, multivariable modeling is used to both control confounding and determine the independent contributions of different factors. (Strictly defined, *multivariate modeling* refers to simultaneously predicting multiple outcomes, whereas *multivariable modeling* involves predicting a single outcome at a time.)

In developing the "model," the outcome is viewed as a numerical result of a mathematical function that is composed of risk factors identified by prior research on the selected outcome, candidate variables of special interest to the investigators, and any variables that may potentially confound the relationships between risk factors and outcome. The particular mathematical form of the model is set by the type of outcome. Most commonly, dichotomous outcomes (e.g., death vs. survival) typically are modeled using logistic regression analysis, yielding a set of odds ratios (ORs). As in bivariate circumstances (Table 24–1), the OR is the

ratio of the probability (odds) of the outcome in the "exposed" group to that in the nonexposed group; however, the multivariable modeling yields a set of "adjusted" ORs that reflect the ORs for each variable (covariate) with the influence of other variables held constant. If time to event is believed important in genesis of the outcome, the relationship is modeled with a proportional hazards model, yielding equivalent hazards ratios; the study by Monk et al.[20] identifying cumulative deep hypnotic time as a predictor of 1-year mortality is an example.

Although intuitive as one's "chance" of experiencing the outcome, ORs often are less useful in estimating the risk faced by a given individual, even one from the study sample, because several predictors (e.g., male gender *and* advanced age) may be relevant for some individuals. For example, should OR values for each relevant predictor be added or multiplied? Alternatively, Sinclair et al.,[85] among others, demonstrated the usefulness of the logistic regression equation, a part of the analytic output not typically presented in study reports, in estimating patient-specific risk of postoperative nausea by substituting into the equation the patient's particular numerical values for the independent predictors.

Propensity–Score Matching Generally, modeling controls confounding adequately; however, confounding and related bias is ever present and often undetected.[86] One particular type of confounding that is an especially problematic source of bias is *confounding by indication*, where clinical features prompt use of a given intervention that is also related to the patient's outcome. An example is the predilection of anesthesia providers for decades to administer spinal anesthesia preferentially to "poor-risk" patients, believing that this method poses a lesser physiologic trespass. Not surprisingly, many early outcome comparisons noted that spinal anesthesia, sick patients, and often higher mortality were associated! Because conscientious physicians will naturally opt to "do what's right" for their patients, confounding by indication is a frequent problem with observational data.

A special approach for dealing with the selection bias underlying confounding by indication is propensity–score matching. This method uses logistic regression first to identify from the observational data matched patient pairs that, based on their covariates, are equally likely to receive the intervention.[87,88] Then, using the matched-pairs subgroup, logistic regression analysis identifies independent predictors for the outcome. This approach has been applied to diverse risk-related topics, including pulmonary artery catheter use in critical care,[89] anesthesia choice for hip fracture repair,[90] medical direction of anesthesia care,[81] and anesthesiologist's board certification.[82] This approach is now commonly applied where observational data are used because a clinical trial is either logistically difficult or not feasible. As with modeling generally, the propensity–score approach cannot control for confounding by covariates that are unknown or overlooked in the analysis; such oversight itself is unlikely to be detected.[91]

Recursive Partitioning An alternate approach for studying risk amid confounding avoids fitting data to a mathematical regression equation and instead uses the covariates to repetitively partition the study population into "high-risk" and "low-risk" subgroups with regard to the outcome. "Recursive partitioning" (also termed "data mining") exploits lack of homogeneity among the study population to yield a tree-like graphic that depicts how each subject fared with regard to the outcome. This classification approach has been used to identify MI risk among emergency room patients presenting with chest pain,[92] poor credit risks for financial services, and, most recently, genotypes in genomic analysis, but it is only beginning to find use in studying anesthesia risk.[93]

HOW DO WE INTERPRET ANESTHESIA RISK STUDIES?

Study Designs for Anesthesia Risk

Taxonomy of Study Designs

Interpreting anesthesia risk literature requires an appreciation of the strengths and limitations of study designs. Box 24–9 presents a taxonomy of study designs used in anesthesia risk studies. An initial distinction is whether the study reflects an experimental (e.g., clinical trial) or a nonexperimental design; in the latter, the investigator observes what is often a natural or unplanned experiment, hence the alternative name, "observational design."

BOX 24–9.

Taxonomy of Study Designs for Studying Anesthesia Risk

I. Experimental designs
  A. Randomized clinical trial (RCT)
  B. Nonrandomized clinical trial
II. Nonexperimental (observational) designs
  A. Person-level observation
    1. Longitudinal measurements
      a. Cohort study
      b. Case-control study
    2. Cross-sectional measurements
    3. Case aggregations (case series, registry)
  B. Aggregate-level observation (ecology)

An often misunderstood distinction is whether the design is *prospective* or *retrospective.* When the exposure (intervention) *and* outcome(s) occur before data collection has started, the study is termed *retrospective*; otherwise it is *prospective*. This distinction is important because prospective data more likely rely on uniform definitions of all design components e.g., patients, intervention, outcome(s) that suit the research objectives (e.g., specified diagnostic criteria for identifying adverse cardiovascular events), resulting in more reliable data. In contrast, retrospective studies typically involve generic definitions that may have been created for other purposes (e.g., billing) and, in practice, may provide vague and less reliable data for the proposed research.[94,95] However, a retrospective design is not per se less reliable and may be the only approach when a prospective design is too costly or infeasible because of technical or ethical issues, such as when the intervention of interest has become standard care and cannot be randomly allocated to subjects.

Experimental designs are, by their nature, prospective, whereas nonexperimental (observational) designs may be prospective, retrospective, and even use both types of data. Most anesthesia risk reports have been retrospective, although prospective designs have been more prevalent in recent studies.

Among nonexperimental designs, an important distinction is whether the

TABLE 24–2.

Comparison of Study Designs for Studying Anesthesia Risk

	Study Design		
Design Attribute	**Randomized Clinical Trial**	**Cohort Study**	**Case–Control Study**
Purpose	Establish efficacy of an intervention or study effects of an exposure	Study ≥1 outcomes after an exposure	Study ≥1 exposure resulting in an outcome
Basic design	Experimental	Observational	Observational
Study perspective	Prospective	Prospective	Retrospective
Clinical setting	Ideal clinical practice	Customary clinical practice	Customary clinical practice
Role of subjects	Allocated to exposure groups usually via randomized process	Classified in groups based on exposure status	Sampled from source population based on outcome status
Measurement perspective	Prospective	Prospective or retrospective	Retrospective (for measurements); retrospective or prospective (for disease)
Risk metrics	Incidence, and absolute and relative risks	Incidence, and absolute and relative risks	Odds ration (which can yield relative risk)
Benefit	Minimizes bias	External validity (generalizability)	External validity (generalizability)
Disadvantage	Possibly limited external validity (generalizability)	Possibly unknown biases	Possibly unknown biases

data collection describes individuals (person-level) or groups of individuals (aggregate-level), because the strength of associations is stronger with the former and may not even be valid with the latter. Most anesthesia risk studies have used person-level data, yet many commentators have invoked group or ecologic characteristics when attempting to explain the decrease in anesthesia-attributable deaths, by citing greater prevalence of patient monitoring devices, adoption of patient monitoring standards, greater attention to risk management, better training and trainees entering the specialty, and a growing and more adequate supply of anesthesiologists, among other trends affecting anesthesia practice generally (see Chaps. 3 and 25). These aggregate associations often seem logical and intuitive, but direct cause-and-effect relationships often are lacking for a variety of reasons (e.g., it would be unethical to have a control group who did not receive mandated standard monitoring, to validate causal relationships between monitoring and outcomes).

Finally, there is a distinction within person-level designs between studies using longitudinal measurements that are made over time and others using cross-sectional measurements that resemble snapshots capturing one time period. Here, too, anesthesia risk studies fall almost wholly in the longitudinal category. Although they cannot provide probabilistic risk estimates because they present information on only affected individuals, case aggregation designs (e.g., registry, case series[12]) are shown in the design taxonomy. The adverse-event cases presented in such aggregations usually are not representative of the universe of such cases because they tend to reflect the worse outcomes, unusual outcomes, or those that are particularly timely (i.e., current "hot issues") rather than systematic observations (selection bias). Thus, such data may lead to skewed or erroneous conclusions about the universe of patients suffering adverse events.[96] Yet those reports can provide highly detailed descriptions of individual adverse events and associated circumstances, which may lead to hypotheses regarding etiology and, in turn, more definitive research using population-based, quantitative approaches.

Ranked in order of reliability of results, the clinical trial is first, followed by well-conducted prospective cohort studies, other cohort studies, case-control studies, and case aggregations.[97] When similar results are obtained from studies using different designs, we gain confidence in those results. The salient features of the three principal designs used in anesthesia risk studies are compared in Table 24–2 as an aid to surveying examples that inform us about anesthesia risk.

Randomized Clinical Trial The randomized clinical trial (RCT) is the "gold standard" experimental design for assessing efficacy in clinical research because it minimizes *bias*, or systematic error that leads to incorrect conclusions. This protection results from randomly allocating patients to the intervention or control group; blinding the investigators to the intervention allocation; prospectively defining explicit patient inclusion and exclusion criteria; and using formal treatment protocols and end points. However, reducing bias is achieved at a cost: omission often of certain patient populations (e.g., women of childbearing age, children), limited comorbidities that may occur in wider unselected patient populations, and limited practice settings (typically academic medical centers) that may not be representative of the larger universe of patients and practitioners.

RCTs may pose practical considerations (e.g., high cost, logistics) and, for many potential applications, ethical concerns. Randomization has been especially problematic in studies of technology that achieved widespread application in clinical practice (e.g., pulmonary artery catheter, fetal heart rate monitoring) before efficacy and effectiveness were established, as well as for common care that patients and healthcare providers customarily expect. Even when an RCT has been completed, its results are necessarily average effects for the population studied, and applying global evidence to individual patients or groups who might differ from the population average may be inappropriate.[98]

The RCT is generally not applicable to studies of anesthesia-associated mortality, because very large populations

are required to achieve sufficient statistical certainty ("power") when studying low-incidence events (Fig. 24–5 and Box 24–8). However, the RCT can be used to compare different anesthetic drugs and methods with regard to morbidity, which occurs much more frequently than death and thus can be studied with feasible patient populations.

In 1992, Forrest et al.[18] reported no material differences in severe postoperative morbidity rates "up to 7 days" following then-common general anesthetic regimens (enflurane, halothane, isoflurane, fentanyl) in a multicenter RCT of 17,201 patients, to which multivariable modeling was applied. This report confirmed the findings of Cohen et al.,[19] who had used similar modeling to study 7-day postoperative mortality among a prospective cohort of 100,007 patients treated in one university hospital over a 9-year period. Principal anesthetic method had no independent predictive power once patient- and surgery-specific factors had been entered into the statistical model. These "negative" results for specific anesthesia techniques are important, given early studies[4,48,59] of anesthesia-associated mortality in which specific anesthetic methods and drugs had been implicated, based on study designs and statistical methods that were incapable of controlling confounding.

In addition to comparing anesthetic methods, RCTs can help determine whether a putative risk factor has a true causal relationship with an outcome, or whether there is only an association with that outcome. Both postoperative tachycardia[99] and hypothermia with shivering[100] were known from cohort studies to be associated with perioperative cardiac morbidity and mortality, but whether these were associations or causal relationships was unknown. In RCTs, prophylactic use of a β-adrenergic blocking drug (atenolol)[24] and maintenance of perioperative normothermia[101] each was shown to reduce the risk (incidence) of perioperative severe cardiac events, implying a causal relationships in each case.

RCTs, which typically test the efficacy of one intervention, often leave clinicians without guidance for the management of less controlled, multifactorial situations that are common in customary clinical practice. (If studies show that drug A alone is beneficial and drug B alone is beneficial, there is no assurance that the combination of drugs A plus B will be beneficial or even will be without harm.) However, a large multisite RCT that uses a factorial design can test several interventions (singly and in combination) efficiently, providing a systematic approach that can give rise to development of clinical practice guidelines, as demonstrated for the prophylaxis of postoperative nausea.[102,103]

Prospective Cohort Study The next best study design for the study of anesthesia risk is the cohort study, a nonexperimental observational design in which the investigator follows one or more designated groups (i.e., surgical population) through an "exposure" (i.e., anesthesia and surgery) and over time for occurrence of disease, broadly defined to include adverse events and complications. Because this type of study is done in a customary clinical setting, the results are expected to have external validity and thus be generalizable to other clinical settings.

This description clearly mirrors the model presented in Fig. 24–1 but is difficult to conduct well. The challenges include prospectively defining all components of the model with the same rigor as in an RCT; indeed, this design is analogous to a nonrandomized clinical trial. Among the definitional challenges shared with the RCT is the need to capture all relevant information (i.e., patient characteristics, surgery factors, outcomes) with precision and accuracy. Thus, there must be explicit criteria for data being collected, and all investigators at all study sites must adhere to those definitions, lest important clinical outcomes be systematically overrepresented or underrepresented in the data (information bias; misclassification bias).[104]

Omission of important variables is an ever-present possibility. If they are not included in the data collection, their relationships to outcomes cannot be evaluated. Other challenges include tracking patients closely so that none are lost to followup, thereby introducing further error (ascertainment bias), and making the cohort as inclusive as possible so that the results have external validity.

Among exemplary examples of prospective cohort studies are those of Cohen et al.[105] Their initial study, conducted in one teaching hospital, relied on an anesthetic record designed for the study, which included check boxes for explicit, specific information from the preanesthetic assessment, anesthesia management, operation, and postoperative adverse events. Consistent definitions of data elements were developed through discussions with physicians and nurses in the setting; then informational sessions on the study and its data form were held for anesthesia providers and nursing personnel. Data collection on the same form continued in the postanesthesia care unit as well as on the ward for up to 7 days. A specially trained anesthesia nurse reviewed all records, following 112,000 patients during the study's 9-year duration; indeed, the study ended when that nurse retired!

Patient- and surgery-related risk factors identified in that and a subsequent study[19] were used by Cohen et al.[106] to risk-adjust rates of anesthesia-associated adverse events to characterize quality of care in four hospitals in which 27,184 anesthetics were administered over a 15-month period. Despite the modeling, there were large variations (2- to 5-fold) in rates of minor adverse events but smaller variations in major morbidity and mortality rates across the hospitals. Although one hospital had a lesser mortality rate, it had greater rates for all major events. Physician reviewers were unable to attribute any of the deaths, partially or wholly, to anesthesia care. The investigators concluded that measuring quality of anesthesia care using the incidence of major adverse events is unsatisfactory because of the uncertain contribution of anesthesia care to the events, as well as the fact that the incidence variations may reflect institutional differences over which anesthesia personnel have no control. They suggested greater attention to reducing the large variation among rates of minor adverse events, particularly those of concern to patients (e.g., nausea).

Case-Control Study This is a targeted, highly efficient, nonexperimental, observational design that is ideal for studying risk for low-incidence events in busy clinical settings. Its advantages accrue from avoiding the large samples and often long followup of subjects needed in cohort designs. In contrast to the cohort design, where large populations are studied but only a small fraction develop the outcome of interest, the case-control design emphasizes the outcome. Properly used, this de-

sign provides information similar to that from the cohort design, but more quickly and at lower cost. Remarkably, this design remains underused.

The investigator defines the outcome of interest and identifies from a log or an institutional database patients ("cases") who meet the definition. Patients not experiencing the outcome ("controls"), who had care at about the same time, are identified in the same institutional source; typically one or a few controls are randomly selected and matched with a case. For both cases and controls, a dataset is created that includes all patient-, procedure-, and perhaps institution-specific information believed relevant to the outcome occurrence. Alternatively, a case-control study can be developed within a completed cohort study (nested case-control study); the "controls" are sampled randomly from the cohort. Logistic regression analysis is used to identify independent predictors of the outcome. Although this study design does not yield the most common risk metrics (e.g., incidence rate), the ORs (really the ratio of incidence rates) provide valuable insights relating to the outcomes and can yield relative risk.

Despite its many advantages, the case-control design poses many potential challenges that may increase bias. Among the most critical requirements is that all data elements must be defined explicitly, because ad hoc decisions made during data collection may introduce bias. Also, control patients should be selected without regard to their covariate values (e.g., age, gender, ASA physical status); usually this is not a problem if cases are matched only on temporal period of care and if the controls are selected randomly.

A most informative application is the study by Gold et al.,[36] seeking predictors of unplanned hospital admission after ambulatory surgery. They identified 100 patients ("cases") admitted from a university hospital's ambulatory surgery unit during a 3-year period in the mid-1980s and, for each case, four patients not admitted ("controls") during the same 6-month period. The dataset created from review of the medical record included patient-specific information, surgical information, anesthesia information, and postoperative symptoms. Using conditional logistical regression analysis that compares each case to its matched controls, the investigators identified independent predictors associated with hospital admission: anesthetic method (general anesthesia), surgical site (abdominal), postoperative emesis, and duration of surgery. The identification of several modifiable factors provided guidance in managing patient selection, case scheduling, and anesthetic management to reduce unplanned admissions.

Retrospective Cohort Study A particularly instructive example is a late 1970s study of predictors of respiratory failure after thymectomy, a complication then occurring in up to half of patients with myasthenia gravis who had this potentially curative operation via a then-common transsternal incision. Leventhal et al.[107] sought to create a clinical prediction rule,[108] similar to that for cardiac risk,[33] that would assist clinicians in making postoperative ventilatory decisions.

Leventhal et al.[107] identified in a university referral site's medical record log 24 patients who had a thymectomy, of whom eight had not responded to a standardized postoperative extubation strategy. They extracted data elements believed important in the literature on respiratory failure in myasthenia. Using discriminant analysis—a multivariable predictive method that predates logistic regression analysis—they computed integer "points" that captured the relative importance of critical variables in independently predicting risk of postoperative respiratory failure. Using this tool, a busy clinician could tally "points" for those clinical attributes present; if a patient had more than a specified threshold number of points, then respiratory failure was predicted.

Scaled conservatively so that no patient was predicted incorrectly to tolerate extubation, the prediction rule had a sensitivity of 1.0 and a specificity of 0.88, with an overall correct classification of 91%. Seeking validation, they applied the model to another 18 patients whose charts had been unavailable. They noted a lesser but adequate performance (78% correct),[109] which is common when prediction rules are validated in a different sample.[110]

Subsequent validations emphasized the importance of clinical nuances in influencing results in anesthesia risk studies. Leventhal et al.[107] envisioned this when they noted that their prediction rule was not intended to be absolute but rather to be used as a guide to help the clinician focus on important patient characteristics and as an example of a general approach to rationalizing clinical decision making. They ended the study when the management of myasthenia changed to include preoperative plasmapheresis and immunotherapy as well as less invasive surgical approaches. Thus, it was of little surprise that Grant and Jenkins[111] found that the prediction rule had "some value" for patients undergoing thymectomy (74% correct), although their population included some patients who had the less invasive transcervical incision and their overall management was not standardized; however, the rule had "no value" when applied to hysterectomy. Similarly, Eisenkraft et al.[112] noted the prediction rule performed poorly when applied to transcervical thymectomy.

Mortality As a Risk of Anesthesia

Early "Anesthesia Deaths"

In 1848, only 15 months after William Morton's successful demonstration of clinical anesthesia in Boston, an Edinburgh medical journal reported the inquest held after the death of Hannah Greener, a 15-year-old British girl who had a toenail removed under chloroform anesthesia, some 4 months after she had a similar procedure performed with diethyl ether anesthesia.[113] This first report of a death associated with anesthesia not only initiated a decades-long debate over the relative safety of ether versus chloroform but also indicated that the seemingly reversible state of anesthesia, "administered in order to allay sensibility while undergoing a painful surgical operation," could be fatal. Similar case reports followed.

Were these "anesthesia deaths" common, rare, or perhaps occasional? Although case reports and subsequent case series provided descriptions of the fatal events and even clues to possible etiologies, they could not quantitate the frequency of these catastrophes and allow an estimate of the risk in undergoing anesthesia. Anesthesia risk measurement benefited from the early epidemiologic work of anesthesiologist John Snow (Box 24–7).

Cohort Studies of Anesthesia-Associated Mortality

Table 24–3 presents the principal results of international studies in which

"Multiple" indicates that the study involved many hospitals, but the actual number is unspecified.
Parenthetical values reflect circumstances in which the number of anesthetics was estimated.
[a]ASA physical status 1 and 2 patients only.
[b]Suburban community hospital.
[c]Urban teaching hospital.

the mortality risk of surgical anesthesia was studied. These studies were major, often pioneering efforts, with most performed before the advent of modern information technology that facilitates aggregating and analyzing vast data and before epidemiology and biostatistics had reached their current level of sophistication. Despite these limitations, their reports provide estimates for surgery-related, anesthesia-attributable mortality and, in many, morbidity.

Crude Anesthesia-Attributable Mortality Estimates

In surveying the unadjusted or crude mortality estimates listed in Table 24–3, we are immediately impressed by a wide variation in rates. Undoubtedly much of the variation is due to different study designs and other factors listed in Box 24–1. Yet there is a suggestion of improved outcome over time, especially in well-developed countries.

Holland[63,122] documented a 5-fold decrease in anesthesia-attributable mortality in one Australian region over 25 years, much of which he attributed to enhanced risk management education of practitioners. Similarly, Lienhart et

al.[132] noted an 11-fold decrease in anesthesia mortality over 15 years in France when repeating (albeit with different methodology) the study by Tiret et al.,[54] which noted poor outcomes in relation to lack of postanesthesia care units.

Moreover, although we might regard the study results listed in Table 24–3 akin to a collection of mixed fruit, a plot of the primary-cause mortality estimates in those studies span almost two orders of magnitude (or a near 100-fold decrease) over 5 decades, and the putative improvement trend predates the vigorous US patient safety initiatives of the mid-1980s (Fig. 24–6). A bubble plot that visually emphasizes the widely varying study population sizes is even more suggestive that a meaningful decrease has occurred (Fig. 24–7), even if we might be uncomfortable concluding that any specific amount of "improvement" has occurred.

However, even if an apparent trend is wholly an artifact of differing methodologies, as some argue,[10] the clinical terrain has changed dramatically over the past half-century. Concerned in 1959 that mortality statistics were unchanged from those decades earlier, the National Academy of Sciences' Committee on Anesthesia invited Chauncey Starr from the National Academy of Engineering to comment. "Well, that is exactly the way it is in farming," he related as he began to discuss the Tractor Principle[133]: the rate of farming accidents remained high despite many safety improvements in tractors (e.g., wider wheel base, roll bars, seat belts). Seeking an understanding, Starr made site visits during which he learned that improved tractor design enabled farmers to plow on steeper inclines! The same is true in medicine, where we now routinely perform major, "high-risk" operations on patients who as recently as 30 years ago were "too sick" to be regarded as surgical candidates. Thus, even stable mortality rates in the face of increasing severity of illness could reflect improved clinical outcome.

Sources of Mortality and Morbidity Risk

Our literature abounds with attempts to allocate perioperative mortality and morbidity risk to specific characteristics of the patient, anesthetic, operation, or clinical setting. An important reference point is the perioperative mortality rate that was estimated to be 1.43% (or 1:70) for US hospital-based surgery in 2004[134] and has been relatively stable over several decades. Comparable mortality estimates based on individual cohort studies have ranged from 1:256 to 1:53,[4,19,35,48,59,135] without any apparent temporal trend.

The earliest attempt to identify specific sources of mortality risk appeared in Beecher and Todd's mid-20th century study,[4] which noted a perioperative mortality rate of 1:75 and ascribed 78% of deaths (1:95) to the patient's disease, 18% (1:420) to surgical management, and 3% (1:2680) solely to anesthesia management. They attributed approximately 5% (1:1560) to anesthesia when considering it as both a contributing and a primary cause. Subsequent studies attributed somewhat greater proportions of mortality to surgical and anesthesia causes, as understanding of the pathophysiology of disease and the physiologic effects of anesthesia and surgical intervention increased.[2,19,35,48]

However, substantial confounding underlies such seemingly simple categorizations. Being male, being elderly, and being in poorer condition (i.e., ASA physical status ≥ 3) each individually augments the risk of a given surgical procedure. An early (and still valid) effort to model perioperative mortality is that of Cohen et al.,[19] who identified the relative importance of patient characteristics (advanced age and ASA physical status, male gender), surgery-related factors (invasiveness, whether emergent), and anesthesia management (method and drug choice; Table 24–4).

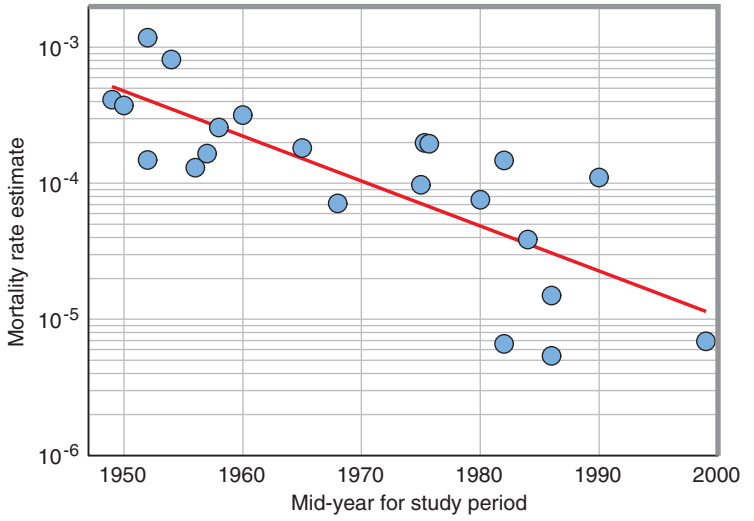

FIGURE 24–6. Rate of perioperative mortality primarily attributable to anesthesia care by the midpoint year of various international studies, from 1948–1999, as listed in Table 24–3.

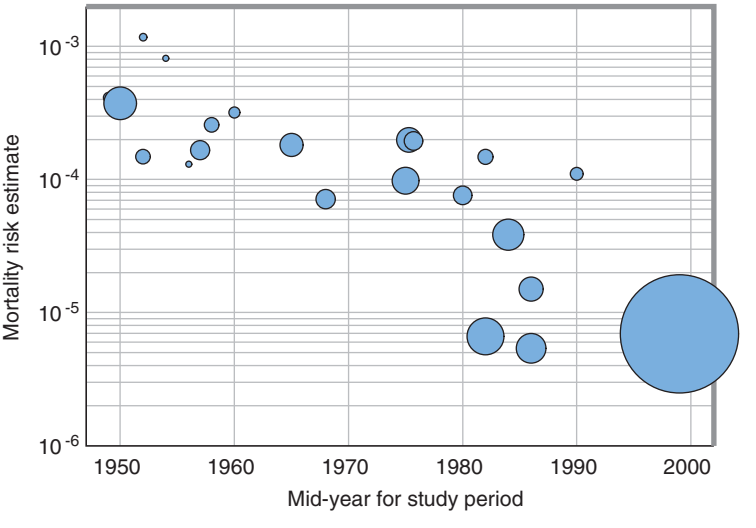

FIGURE 24–7. Bubble plot of Fig. 24–6, in which the size of the bubble is proportional to the number of patients in each study.

TABLE 24–4.

Factors Associated with Mortality Within 7 Days of Surgery

Factor[a]		Odds Ratio[b]	95% Confidence Interval
Patient related			
	Age, 60–79 vs. <60 y	2.32	1.70–3.17
	Age, ≥80 vs. <60 y	3.29	2.18–4.96
	Gender, female vs. male	0.77	0.59–1.00
	ASA physical status score, 3–4 vs. 1–2	10.65	7.59–14.85
Surgery related			
	Major vs. minor procedure	3.82	2.50–5.93
	Intermediate vs. minor procedure	1.76	1.24–2.50
	Length of anesthesia, ≥2 vs. <2 h	1.08	0.77–1.50
	Emergent vs. elective procedure	4.44	3.38–5.83
Other factors			
	Years of operation, 1975–1979 vs. 1980–1984	1.75	1.32–2.31
	Complication in operating room vs. none	1.42	1.06–1.89
Anesthesia related			
	Experience of anesthesia-provider, >600 cases for ≥8 y vs. <600 procedures for <8 y	1.06	0.82–1.37
	Inhalation agent with narcotic vs. inhalation alone	0.76	0.51–1.55
	Narcotic anesthesia alone vs. inhalation alone	1.41	1.01–2.00
	Narcotic with inhalation vs. inhalation alone	0.79	0.47–1.32
	Spinal anesthesia vs. inhalation alone	0.53	0.29–0.98
	Number of anesthetic drugs, 1–2 vs. ≥3	2.94	2.20–3.84

[a]Factors were evaluated in logistic regression analysis of data from 100,007 patients performed the five most frequently used anesthesia methods (inhalation alone, inhalation with narcotic, narcotic anesthesia alone, narcotic anesthesia with inhalation, spinal anesthesia).
[b]All odds ratios whose 95% confidence intervals do not include the value 1.0 are statistically significant.

Although definitive allocation of the components of perioperative risk, and specifically of anesthesia risk, is lacking, what follows is an attempt to dissect some of these relationships, with the goal of offering guidance to practitioners as well as identifying improvement opportunities.

The Patient

Importance of Comorbidity Intuition tells us that sick patients tend to do poorly. Among the many studies[4,10,18,19,33–36,48,50,54,58,59,62,70,71,74–77,83] documenting this truism is Pedersen's prospective cohort study[35] of 6307 patients, in whom the extent of comorbidity was associated with greater complication and mortality rates (Table 24–5).

Modeling Outcome with Patient Characteristics Although the general principle is now well established, capturing the precise quantitative relationship between comorbidity and clinical outcome remains elusive. The venerable ASA physical status classification, never designed as a risk metric, has long been known to correlate with perioperative outcome,[10,19,34,59,135] with mortality rising sharply with advanced physical status (Tables 24–4 and 24–6). ASA physical status interacts with age, becoming a much more potent predictor of major complications beyond middle age (Fig. 24–8).

Yet there is substantial subjectivity and variability in use of middle ASA physical status categories, even in settings where payment for services is unrelated to this classification.[136–139] Prediction improves when this metric is used in combinations in multivariable modeling with other covariates, such as age and/or the presence of specific morbidities.[18–20,24,33–36,62,70,76–79,83,106,140,141] Concerns about subjectivity of the ASA physical status metric may also be addressed in risk modeling studies by including the Charlson Comorbidity Score,[50] a morbidity-specific metric that has been at least as good an outcome predictor in several studies[20,90,142–144]; the Acute Physiology Score (APS) of the Acute Physiology and Chronic Health Evaluation (APACHE) II score, a metric commonly used in critical care[145]; or perhaps the Sickness at Admission Scale Score.[146]

Alternatively, there have been embryonic efforts to reduce the subjectivity in ASA physical status scoring by enhancing its specificity, thereby enhancing its precision and predictive power: Barbeito et al.[139] suggested adding a "G" to the scoring of parturients (e.g., "2-G" to indicate the gravid status), and Holt and Silverman[147] proposed a superscripted notion to indicate specific morbidity (e.g., "3^{RESP}" to indicate the affected organ system). Emphasizing the confounding of physical status by surgical complexity, Pasternak[148] suggested a preoperative assessment scale that includes both. These await further development and validation. The Charlson Comorbidity Score was developed to predict 1-year mortality among hospitalized *medical* patients,[50] and it is surprising that a similar morbidity-specific scoring system for predicting surgical mortality has not been developed.

Several simple scoring systems for organ- or operation-specific complications are available. The Cardiac Risk Index of Goldman et al.[33] provided an early model that was improved by Detsky et al.,[149] by adding angina to the risk factors. Lee et al.[150] developed and validated a Revised Cardiac Index that specified six independent predictors: history of ischemic heart disease,

TABLE 24–5.

Factors Associated with Perioperative Complications and Death

Probability of a severe perioperative respiratory or cardiovascular complication as a function of both American Society of Anesthesiologists physical status class and patient age, computed from the logistic regression equation developed in the clinical trial of inhalation anesthesia drugs conducted among 17,201 patients by Forrest et al.[18] (From Muravchick S. Anesthesia for the elderly. In: Healy TEJ, Knight PR, eds. Wylie and Churchill-Davidson's A Practice of Anesthesia. 7th ed. London: Arnold, 2003:990. Reproduced with permission of Edward Arnold, Ltd.)

history of congestive heart failure, history of cerebrovascular disease, preoperative treatment with insulin, preoperative serum creatinine >2.0 mg/dL, and high-risk surgical procedure. Similar clinical prediction rules have been developed for early outcome after coronary artery bypass surgery.[151]

Even in the absence of simple, comprehensive risk scoring systems, multivariable modeling of several large cohorts has identified a common set of independent risk factors for severe complications and death (Tables 24–4 and 24–5, and Box 24–10). Differences in the risk associated with specific morbidities among studies probably are explained, in part, by differences in how disorder-specific acuity of illness is measured.[152] Racial and socioeconomic characteristics, possibly proxies for unadjusted underlying comorbidity and/or problems with access to care, also influence outcome.[83,153,154]

BOX 24–10.

Independent Risk Factors for Severe Complications and Death

- Male gender[19,35,83]
- Advanced age[18,19,33,35,83,149]
- Advanced American Society of Anesthesiologists physical status class[18,19,33,62,76]
- Moderate and severe specific comorbidity[18,24,33,35,62,76,149,150]

Failure to Rescue Building on the relationship between patient health status and clinical outcome, Silber et al.[155,156] developed a novel outcome metric, failure to rescue. Using multivariable modeling, they showed that patient characteristics (e.g., age, gender, comorbidities) predict complications better than they predict death; whether a complication turns into a death reflects the capability of the facility to rescue the patient. The rescue capability itself is dependent on hospital characteristics that include proportion of board-certified anesthesiologists and ratios of nurses to patients.[82,155,157] Subsequently validated in many studies, this metric is included among quality indicators used by the Agency for Healthcare Quality and Research, National Quality Forum, University HealthSystem Consortium, and independent healthcare researchers.

The Healthcare Setting

Unexplained Variation in Outcomes Long before investigators had tools to identify the source of risk differences, they began to document variations in patient outcomes for ostensibly similar surgery.[158] Buried in the 1948 to 1952 Beecher-Todd study[4] is an unexplained, 3-fold difference in mortality across the 10 participating university hospitals. A decade later, the mortality variation was so great in the 34-hospital National Halothane Study (0.27–6.40%) that its statisticians concluded, "Such variation in so important an outcome of surgery compels attention."[159] Even after adjusting their data for age, ASA physical status, and surgical procedure, an unexplained, 3-fold variation remained.

Emergence of an Ill-Defined "Provider" Intrigued, one investigator joined with sociologists and statisticians to explore nonclinical factors, including structural characteristics of hospitals, as potential explanatory variables for the postoperative mortality variation among 1224 hospitals using a chart abstracting service in the early 1970s.[160,161] Despite similar case-mix adjustments, 3- to 4-fold variations remained for the 15 major surgical procedures studied in this Institutional Differences Study. Probing deeper in a 17-hospital subset with detailed institutional data, they explored the influence of the individual surgeon, anesthesia-provider type, and various measures of hospital structure and medical staff organization.[162,163] Although such factors were weak predictors of outcome, the mere presence of such relationships heralded the beginning of our understanding of the multifaceted role of an ill-defined "provider" in surgical outcomes. (Here, *provider* is a comprehensive term indicating not only the clinicians but also the facility, its associated staff, organizational structure, and policies.)

Role of Sociomanagerial Factors The Institutional Differences Study[161,163] identified diverse sociomanagerial factors that are associated with better surgical outcomes, including teaching-hospital status, greater number of residency programs, higher hospital expense per day, stringent medical-staff admission requirements, power over senior surgeons, higher proportion of surgeons' practices at the study hospital, and board certification of physicians. Subsequent studies have validated the influence of teaching-hospital status and board certification,[155,164–166] although research has not explored the full array of care.[167,168] Silber et al.[155] specifically identified a low proportion of board-certified anesthesiologists on the anesthesia staff as an important hospital characteristic associated with "failure to rescue" the surgical patient who experienced a complication. Generally, overall hospital characteristics are stronger predictors of clinical outcome than are surgeons' characteristics.[162,163]

As a natural extension, investigators explored whether mortality after high-risk surgery was influenced by provider experience. Studying procedures of varying complexity in the mid-1970s in 1498 hospitals using a chart abstracting service, Luft et al.[169] found an inverse relationship between mortality and procedure volume for high-risk procedures; a volume–outcome relationship existed for lesser-risk surgery but was weaker at low volumes. What underlies this phenomenon: a team effect in the hospital, expertise of individual surgeons, or regional referral patterns? Research has been more equivocal, in part, because of technical issues, such as low statistical power in comparisons of lower total-case volume and a statistical association (collinearity) affecting hospital and surgeon-specific volumes.[170,171] Yet accruing literature documents better outcomes for high-risk surgery performed at high-volume sites and suggests that a more experienced team may underlie the phenomenon.[172–174] As a result, performing high-risk surgery at high-volume sites has become a principle that guides contracting for services of some organizations (e.g., the Leapfrog Group) and third-party payers.

Certain aspects of critical care medicine are also associated with better surgical outcomes. Pronovost et al.[175,176] showed that the presence of a dedicated intensive care physician making daily rounds, a nurse-to-patient ratio of at least 1.2, a monthly case conference, and tracheal extubation in the critical care unit rather than the operating room are associated with better outcomes after abdominal aortic surgery. The implications of not having a dedicated critical care physician are so grave (OR for in-hospital mortality, 3.0; 95% CI, 1.9–4.9) that this has also become a Leapfrog Group standard. The contribution of nurse staffing ratios for good outcomes echoes the studies of general hospital nursing by Aiken et al.[157]

Delivering good outcomes in complex settings also requires effective team functioning, an essential part of an effective patient-safety climate.[1] Higher scores on the Safety Attitudes Questionnaire are associated with fewer medication errors, lower ventilator-associated pneumonia rates, and decreased risk-adjusted mortality.[177] Makary et al.[178] have developed a "teamwork culture" metric that is sensitive to operating room caregivers' perceptions and awaits validation for use in improvement work. Awad et al.[179] have shown that a preprocedural operating room briefing improves teamwork climate, including coordination among caregivers (see Chap. 3 for a more thorough discussion of team performance).

Mortality risk appears to be influenced by the facility in which the procedure is performed (i.e., a "provider" effect). Fleisher et al.[83] studied outcomes of Medicare patients having surgery in a hospital outpatient unit, freestanding surgery center, or surgeon's office. Although death rates on the day of operation were not different, there were differences among the rates for 7-day mortality (1:2000, 1:4000, and 1:2856, respectively) and 7-day hospital admission (1:48, 1:119, and 1:110, respectively). The readmission rates resembled those in other studies, but the authors could not exclude the likelihood that the differences across sites in both readmission and mortality rates reflected patient referral patterns (selection bias), with sicker patients treated in the more intensive settings (Fig. 24–4B).

The Surgeon and the Operation

The Surgeon's Characteristics The surgeon's board certification,[155,163,165] experience,[163,165] and case volume[163,165,170,172,173] each is associated with clinical outcome when comparing different hospitals, although these relationships may be weak when comparing individual surgeons at the same site. However, outcome variation has been demonstrated among individual surgeons for complex procures.[180] Lunn and Devlin[2] have called attention to the association of poor outcomes from surgery and anesthesia care provided by unsupervised and undersupervised trainees at night.

Outcomes associated with individual surgeons are confounded by diverse hospital characteristics, such as teaching-hospital status,[163,167,168] total hospital expenditures,[163] total case volume,[163,170,173] team culture,[177,178] critical care organizational characteristics,[175,176] and general nurse-to-patient ratio.[157]

The Operation The surgeon's influence on outcome is confounded by important characteristics of the operation. In most cohort studies, invasiveness of the surgical procedure (i.e., "major" vs. "minor" surgery) and whether the operation is undertaken emergently are potent independent determinants of both mortality and morbidity (Tables 24–4 and 24–5).[19,33,35,36,149] Underlying these relationships undoubtedly are the implications of the extent of physiologic derangement and the limited preparatory care before emergent surgery. Procedure invasiveness interacts with age, becoming a much more potent predictor of major complications beyond middle age, particularly for the more invasive procedures (Fig. 24–9).[18] Invasiveness (or complexity) of operation is so potent a predictor of outcome that it has been

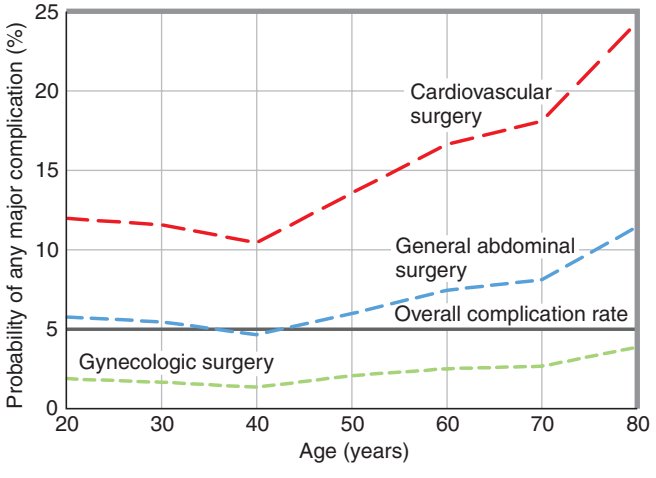

FIGURE 24–9. Probability of a severe perioperative respiratory or cardiovascular complication as a function of both type of surgical procedure and patient age, computed from the logistic regression equation developed in the clinical trial of inhalation anesthesia drugs conducted among 17,201 patients by Forrest et al.[18] (From Muravchick S. Anesthesia for the elderly. In: Healy TEJ, Knight PR, eds. Wylie and Churchill-Davidson's A Practice of Anesthesia. 7th ed. London: Arnold, 2003:990. Reproduced with permission of Edward Arnold, Ltd.)

included in several proposals for modifications of the ASA physical status classification or new approaches to preoperative patient assessment.[78,148]

An especially problematic procedure-related factor is duration of operation (or anesthesia). Consistent with the notion that increasing exposure to a potentially hazardous intervention risks a poorer outcome, duration of operation (or anesthesia) is associated with increased mortality and morbidity[19,35,37] (Tables 24–4 and 24–5) and hospital admission after ambulatory surgery.[36,37] Greater procedure duration may be a proxy for more extensive (perhaps unrecognized) surgical disease, lesser surgical skill, or the occurrence of intraoperative anesthesia and surgical complications, any of which may independently determine the postoperative outcome. Cohen et al.[19] specifically included occurrence of intraoperative complications among candidate predictor variables and found that such complications, rather than procedure duration, was an independent predictor of outcome (Table 24–4). Thus, unless the study has included occurrence of intraoperative complications in the outcome modeling, procedure duration alone should be regarded as a possibly "tainted" variable.

The Anesthesia Provider and the Anesthesia Care

The Anesthesiologist's Characteristics Board certification seems an even more important predictor of outcome with the anesthesiologist than with the surgeon.[82,155] Using sophisticated modeling, Silber et al.[155,156] showed that a lesser proportion of board-certified anesthesiologists on the anesthesia staff is associated with a greater likelihood of "failure to rescue." In a direct comparison of mortality among Medicare patients treated by mid-career anesthesiologists with and without board certification, Silber et al.[82] showed that absence of board certification is associated with greater likelihood of "failure to rescue" (OR 1.13, 95% CI 1.01–1.27) and higher mortality (OR 1.13; 95% CI 1.00–1.26). So confounded are the outcome predictors, however, that they noted that the poorer outcomes of noncertified practitioners may reflect hospital characteristics as well.

Apart from board certification, the effect of the anesthesiologist's experience on outcome is less clear. In a comparison of anesthesia providers at the Massachusetts General Hospital in the mid-1970s, Gilbert[181] detected slightly better outcomes only when anesthesia was administered directly by a senior anesthesiologist. Cohen et al.[19] were unable to detect an outcome difference among anesthesiologists with greater time in the specialty and greater case volumes (Table 24–4). Lunn and Devlin[2] noted the association between poor outcomes of surgery and anesthesia care and unsupervised and undersupervised trainees at night. Exploring the linkage between myocardial ischemia and MI in anesthesia for coronary bypass, Slogoff and Keats[182] famously identified Anesthesiologist 7, whose cases had a greater proportion of intraoperative ischemia and much greater postoperative infarction than did others in the group practice. They implied this was due to individual skill factors, but analysis was superficial and without risk adjustment of the clinical data.

Anesthesia Provider Type More extensive efforts to explore outcome differences by type of anesthesia provider also have been indeterminant, perhaps because of design flaws. Gilbert[181] found no outcome differences when comparing anesthesiologists providing direct care, anesthesiology residents medically directed by faculty anesthesiologists, and nurse anesthetists similarly medically directed. However, a fully trained anesthesiologist was involved in every case, the data were only partially risk adjusted (*note:* the physicians likely received the more difficult cases), and patients were not randomly allocated to providers. Similar flaws are present in an analysis based on the Institutional Differences Study. In one portion of the study, they compared "(nine) hospitals in which anesthesiologists primarily were the providers...and (seven) hospitals in which nurse anesthetists were primarily the providers."[183] Outcomes were the same in both groups, yet anesthesiologists were involved in all care.

Multiple design flaws also plague an analysis of postoperative deaths in North Carolina during the period 1969–1976, in which half of the anesthetics were administered by nurse anesthetists medically directed by the surgeon and the other half by anesthesiologists working alone or a team of a nurse anesthetist and an anesthesiologist.[184] Anesthesia-related death rates were similar across the three provider types; yet, unlike the studies by Gilbert[181] and Forrest,[183] there was no attempt to adjust the data for case-mix differences (e.g., age, ASA physical status) and type of operation (e.g., emergent vs. elective, major vs. minor). Because nurse anesthetists working without anesthesiologists (then and now) are located typically in smaller, often rural hospitals, the two other provider types (with anesthesiologists) likely were treating sicker patients having more complex procedures. Also, as with the other studies, there had been no random allocation of patients to provider type, resulting in likely selection bias.

The most recent provider-type comparison, although much more sophisticated, also suffers from serious design flaws. Pine et al.[185] compared mortality of Medicare patients having one of eight common surgical procedures, whose anesthesia was provided by nurse anesthetists working without anesthesiologists, anesthesiologists providing direct care, or an anesthesia care team of a nurse anesthetist medically directed by an anesthesiologist. After stratification by procedure and adjustment for patient characteristics, the mortality rates were similar across the three provider types. However, 80% of the cases in which nurse anesthetists worked without anesthesiologists were performed in rural hospitals; thus, those nurse anesthetists were most assuredly caring for a lower-risk population (severe selection bias). Direct comparison of outcomes in this circumstance is likely to be misleading, because patients in the three groups would be expected to differ markedly in measured *and unmeasured* risk factors and thus their likelihood of poor outcome.

Silber et al.[81] demonstrated in a matched-pair, propensity score analysis (addressing selection bias) that lack of medical direction by an anesthesiologist is associated with a higher failure-to-rescue rate (OR 1.10, 95% CI 1.01–1.18) and higher 30-day postoperative mortality (OR 1.08, 95% CI 1.00–1.15). They estimated that the higher mortality rate engenders 2.5 excess deaths per 1000 patients, which represents a number needed to treat (NNT) of 400 (Table 24–1). Although an NNT of 400 reflects a modest effect, anesthesiologist's medical direction gains enormous power because of the tens of millions of anesthetics administered each year.

The Anesthesia Care Outcome comparisons of specific anesthesia drugs and methods have not identified a single ideal approach to anesthesia but rather have emphasized characteristics, typically pharmacologic, that can be regarded as tradeoffs among different options. Keats[65] suggested that anesthesia agents are "inherently toxic" and that, as our knowledge grows, anesthesia risk diminishes. Past controversies about specific drugs were resolved by either learning how to use them safely or discarding those that were problematic, usually on a pharmacologic basis (e.g., methoxyflurane with dose-related nephrotoxicity). Thus, Beecher and Todd[4] attributed "intrinsic toxicity" to curare (a generic term applied to muscle relaxants) before it was appreciated that postanesthesia residual paralysis could be both hazardous and avoided with pharmacologic antagonism. That drug class now is a mainstay of anesthesia practice (see Chap. 33).

Perhaps expectedly, well-conducted studies have failed to identify important risk differences among anesthesia options. Cohen et al.[19] noted that anesthesia-related factors (e.g., principal anesthesia method) added negligibly to the contributions of patient- and surgery-related factors in accounting for mortality risk (Table 24–4). However, they did find markedly greater mortality if a single-agent anesthetic rather than "balanced anesthesia" with multiple drugs was used (OR 4.85, 95% CI 1.97–11.96). Although their inability to identify benefits of specific anesthesia methods arguably could result from selection bias (confounding by indication), Forrest et al.[18] were unable to detect meaningful morbidity differences among inhalation agents in a clinical trial that would minimize biased selection.

However, in support of a long-held belief that it is more important *how* rather than specifically *what* one does, Arbous et al.[186] showed that there are multiple opportunities to decrease anesthesia risk by adopting a set of good practices in the management of anesthesia care (Table 24–7). Although the efficacy of most of the practices identified by Arbous et al. are well documented in the literature (e.g., epidural opiates for postoperative pain management rather than intramuscular or intravenous narcotic administration; antagonism of nonmetabolized muscle relaxants at conclusion of anesthesia), these practices continue to require support and encouragement toward full adoption. Their results emphasize the inadequacy of viewing anesthesia care as merely the administration of drugs and use of certain methods and devices. We may infer that anesthesia risk studies that consider patient characteristics and their clinical outcomes—but omit intraoperative detail relating to the anesthesiologist's clinical practices—provide an incomplete and possibly misleading perspective. We also might speculate that the beneficial practices identified are likely to be among those that underlie the anesthesiologist's beneficial influence detected by the failure-to-rescue metric.

TABLE 24–7.

Anesthesia Management Factors Associated with 24–Hour Mortality and Coma

Factor[a]	Odds Ratio[b]	95% Confidence Interval
Preoperative Period		
Equipment check with protocol and checklist (vs. none or incomplete)	0.640	0.432–0.948
Documentation of equipment check (vs. none)	0.607	0.399–0.923
Intraoperative period		
Availability of and access to attending anesthesiologist (direct vs. indirect)	0.455	0.313–0.662
No intraoperative change of anesthesiologist (vs. change)	0.444	0.199–0.990
Presence of full-time anesthesia nurse (vs. part-time)	0.408	0.236–0.704
Presence of attending anesthesiologist at emergence and termination of anesthesia (2 practitioners vs. 1)	0.687	0.474–0.996
Reversal of opiates (vs. none)	0.636	0.100–4.027
Reversal of muscle relaxants (vs. none)	0.101	0.032–0.314
Reversal of opiates and muscle relaxants (vs. none)	0.290	0.175–0.482
Postoperative period		
Postoperative pain medication: opiate (vs. none)	0.165	0.108–0.254
Postoperative pain medication: local anesthetics (vs. none)	0.061	0.009–0.400
Postoperative pain medication: combination (vs. none)	0.324	0.140–0.752
Postoperative opiate route:epidural (vs. IV)	0.226	0.057–0.887
Postoperative opiate route: intramuscular (vs. IV)	0.130	0.074–0.335

[a]All factors adjusted for characteristics of patient (age, gender, ASA physical status classification); surgical procedure (time, duration, whether emergent, type, complexity); principal anesthetic method (inhalation, total intravenous, combined technique; regional [type]; or combination); and hospital (type, size).
[b]All odds ratios whose 95% confidence intervals do not include the value 1.0 are statistically significant.
IV, intravenous route of administration.

HOW DO WE INTERPRET ANESTHESIA RISK TO PATIENTS?

As if the evolving story of anesthesia risk were not sufficiently complex, communicating effectively with patients about anesthesia risk is even more challenging. Basic concepts of risk are confusing, if not foreign, to patients, and they are likely to be wary of risk-related statements, given the many prominent public reversals about the benefits and safety of common drugs (e.g., hormone replacement therapy, cyclooxygenase-2 analgesics).

Creating an Effective Message

Because the hallmark of effective communication is understanding the audi-

ence, we should tailor risk-related discussions to the specific patient's needs and knowledge, recognizing that a brief, targeted disclosure is likely to be mutually satisfying. We can allay their general concerns by noting that anesthesia care has never been safer, that it may be among the least hazardous parts of overall patient care, that common postanesthesia problems tend to be transient, that serious complications have become very uncommon, and that our expanding perspective on anesthesia care (e.g., postoperative pain management) means that they are also likely to be more comfortable and satisfied with their care. We can convey to patients that as a result of myriad improvements, anesthesia methods are more similar than different with regard to risk, and often their anesthesia preferences can be honored.

Problems with Risk Numeracy

We should avoid placing undue emphasis on specific risk estimates, in part because they are based on the experiences of large populations and may not predict well an given individual's clinical outcome (Box 24–1). Although patient-specific risks can be estimated from regression equations and patients often want to know their "chances" (even if they do not ask), the more problematic issue is that quantitative information about risk is meaningful only to the small minority having facility with probabilities and numerical concepts.[187–189] Rather than regarding an outcome occurring 1:100 as "common" and 1:1000 as "uncommon," patients tend to focus on the numerator almost to the exclusion of the denominator (i.e., odds are less important than the possibility that an event can occur). Framing is also a barrier to communicating risk, with 90% survival perceived as better than 10% mortality. Evolving guidance for enhancing effective risk communication includes understanding the patient's experience and expectations, presenting *relative* risks of competing options rather than risk estimates in isolation, using graphics ("decision aids") to help the presentation, encouraging a balanced discussion of options and uncertainties, developing recommendations informed by clinical judgment and patient preferences, and continually checking for understanding and agreement.[190,191] For some patients, comparing the risks of anesthesia to other well-known events, such as parachute jumping or flying in commercial aircraft, may be helpful (Box 24–4), but both the clinician and the patient must recognize that these broad generalities may not apply to any given patient.

HOW DO WE ACHIEVE FURTHER REDUCTION IN ANESTHESIA RISK?

The foregoing dissection of sources of risk emphasizes the need to move beyond the former narrow definition of anesthesia care as the use of drugs, methods, and devices, to embrace a far broader perspective of the overall anesthesia care process, from preoperative assessment to postoperative care, and its role in the overall system of care (see Chap. 3 for a discussion of the system of anesthesia care, within a larger system of overall care). A real benefit to adopting a more comprehensive view of anesthesia care has already been demonstrated by the mortality and morbidity risk reduction achieved by modulating the sympathetic nervous system by administering β-adrenergic blockers[24] and preventing hypothermia[100,101]; decreasing surgical wound infections by administering perioperative supplemental oxygen[192]; and decreasing perioperative mortality by adopting clinical practice patterns[186] and by having an anesthesiologist directing the anesthesia care.[81] The identification of an association between higher cancer recurrence- and metastasis-free survival rates and use of anesthesia approaches known to reduce stress[193] suggests that perhaps only our formerly narrow notions of "anesthesia" risk are preventing further decreases in anesthesia risk.

CHAPTER 25

Approaches to Quality Improvement in Anesthesia Care

David S. Smith, MD, PhD, and Lee A. Fleisher, MD

There has been a dramatic increase in the public's concern about the quality of patient care and the determination of the extent with which errors occur during the provision of that care since the 1999 publication of the Institute of Medicine monograph *To Err is Human*.[1] This concept of quality includes ensuring that the care is both beneficial and cost-effective and has placed unprecedented demands on all healthcare providers to prove the safety and value of the care they deliver.

Until recently, the autonomy of the individual practitioner to provide care in a manner in which they deemed best was paramount. In the hospital setting, the quality of care was ensured by preemployment credentialing with casual periodic renewal and episodic case conferences with the primary reliance on the individual professionalism of each practitioner. This no longer suffices. Groups, regardless of specialty, are being asked to identify potential sources of error both within their practices and within the entire healthcare system. It is now assumed by hospital chief executives and medical officers that groups will establish procedures and protocols to minimize risk and to collaborate with other professional groups within a health system. For example, it is expected that anesthesiologists will collaborate with surgeons and nurses to cross-check and confirm correctness at certain critical points in a patient's care (e.g., time-out before incision or checking transplantation organ compatibility). As part of the continued support of a group, they are expected to document the approaches being used to evaluate and improve the quality and safety of the care provided.

These concerns about patient safety are being driven at many levels (Table 25–1). In addition to traditional accrediting agencies, hospital boards of directors and credentialing committees, state boards of medicine, legislatures, the federal government, including Congress, and even the courts are increasingly involved. Patient safety and quality improvement is an area that is rapidly changing, the terminology often cryptic, and the sources of information outside those that are usually consulted by anesthesiologists. This chapter demystifies the processes related to quality improvement and discusses several available toolsets that provide quality assurance, including the approach in use at the University of Pennsylvania Health System. Questions addressed include: How does one determine the quality of care provided by a group of anesthesiologists? How does one identify errors in care? What is meant by a critical incident? How does one establish a process to improve the quality and safety of care provided? How should this process be documented?

KEY POINTS

1. There is significant public dissatisfaction with the level of safety associated with medical care in the United States. This issue has been taken up by many legislative and governmental regulatory bodies at both federal and state level.
2. The demand for greater patient safety (i.e., error reduction) has created multiple new levels of regulation and demands for accountability that go well beyond the traditional.
3. The traditional approach of practitioner accountability is giving way to approaches that additionally emphasize systems redesign and group managed processes.
4. The demands for accountability requires that individual practitioners, groups of practitioners, hospitals, and entire health systems implement methods that allow documentation of outcome and process.
5. Relying on review systems such as the case conference and focusing on the individual patient is inadequate for the level of error remediation demanded. New approaches that allow examination of aggregate performance across a hospital or health system need to be developed and implemented. This is particularly challenging for perioperative anesthesia care considering the already low level of adverse outcomes.
6. For many practitioners, reimbursement in the future will be linked to both outcome and demonstrated compliance with process variables such as perioperative antibiotic administration. Systems that allow documentation at the individual patient level need to be developed or reimbursement and accreditation may be compromised.
7. The level of sophistication with respect to outcome and process evaluation in the intensive care unit has increased significantly more than that in the operating room. A significant body of work exists to guide the improvement of care and to decrease the error rate in this subspecialty of anesthesia practice.
8. Safety and evaluation of outcome for acute pain therapy lags. Part of this may be related to the fact that decisions about acute pain therapy are often split between multiple groups. In addition, there is little definition of what are adequate levels of acute pain relief, how to accurately measure adequacy of pain relief, and how to monitor to prevent the complications of opioid-based pain therapy.

TERMINOLOGY

A variety of terms are used to define aspects of patient safety, risk reduction, and quality of care. Some of these terms are duplicative. For a number of terms the meaning has changed over time. The following are terms and their definitions as used by the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) in its recent standards and reporting documentation.

Medical Error

This is defined as an unintended act, whether by omission or commission, or an act that does not achieve its intended outcome. This is clearly a very broad definition. With regard to

TABLE 25–1.

Organizations with an Interest in the Quality of Medical Care and Patient Safety

- Agency for Healthcare Research and Quality (AQHR, part of the United States Department of Health and Human Services)
- American Medical Association (AMA)
- Anesthesia Patient Safety Foundation (APSF)
- American Society of Anesthesiologists (ASA)
- Centers for Medicare and Medicaid Services (CMS, part of the United States Department of Health and Human Services)
- Food and Drug Administration (FDA, part of the United States Department of Health and Human Services)
- Institute of Medicine of the National Academies (IOM)
- Joint Commission International Center for Patient Safety
- Joint Commission on Accreditation of Healthcare Organizations
- National Quality Forum (NQF)
- World Health Organization (WHO)
- Consumers of healthcare
- Legislative bodies both state and federal
- Local law enforcement organizations
- Purchasers of healthcare
- State boards of medicine

unintended acts, it is important to recognize that activities that were once considered appropriate care may now be considered a medical error and vice versa.

Sentinel Events

As defined by the JCAHO, a sentinel event is "an unexpected occurrence involving death or serious physical or psychological injury, or the risk thereof. Serious injury specifically includes loss of limb or function. The phrase 'risk thereof' includes any process variation for which a recurrence would carry a significant change of a serious event outcome." The JCAHO notes that the term *sentinel* reflects an event that requires immediate investigation and response. At a leadership level, the JCAHO requires an integrated patient safety program that includes in part (a) a definition of the types of occurrences to be addressed; (b) a mechanism to ensure that all relevant areas of the healthcare organization participate and that their activities are integrated; (c) a procedure of immediate response including care of the affected patient, containment of the risk to others, preservation of information for future review; (d) a clear system for internal and external reporting; (e) a defined mechanism for responding to various types of occurrences; and (f) reporting at least yearly on occurrence of errors and efforts to improve patient safety both proactively and in response to actual occurrences. Thus reporting, categorizing, and review of serious events is required and mechanisms need to be established to accomplish this goal (Table 25–2).

TABLE 25–2.

Joint Commission on Accreditation of Healthcare Organizations' Sentinel Events That Might Be Related to Anesthesia Care[a]

- Abduction
- Delivery of radiotherapy to the wrong body region or >25% above the planned radiotherapy dose.
- Discharge of an infant to the wrong family
- Events that result in an unanticipated death or major permanent loss of function and are unrelated to the natural course of the patient's illness or underlying condition
- Hemolytic transfusion reactions because of major blood group incompatibilities
- Prolonged fluoroscopy with a cumulative dose of >1500 rads to a single field
- Rape
- Severe neonatal hyperbilirubinemia
- Suicide during treatment or within 72 hours of discharge
- Surgery on the wrong patient or body part regardless of magnitude of procedure
- Unanticipated death of a full-term infant
- Unintended retention of a foreign body after surgery or other procedure

[a]Though some of these events may seem remote from the experiences of anesthesiologists whose practices are confined to the operating room, those doing interventional pain therapy, block placement with fluoroscopic guidance or intensive care need to be concerned with the broader range of these events.
Adapted from the Joint Commission on Accreditation of Healthcare Organizations. Sentinel event policy and procedures; updated June 2005. www.jointcommission.org

In addition to the JCAHO, other organizations have begun to require the documentation and reporting the equivalent of the JCAHO sentinel event. Currently in the United States (2007), about 25 states require reporting (Table 25–3). Although the specific events and terminology may vary, there are common concepts that tend to follow the JCAHO descriptions. For example, New Jersey requires reporting "every serious preventable adverse event, defined as an adverse event that is preventable and results in a patient death, loss of body part, disability, or loss of bodily function lasting for more than seven days or still present at the time of discharge (Interim Mandatory Patient Safety Reporting Requirements for General Hospitals, New Jersey Department of Health and Human Services, 2004). Preventable event means an event that could have been anticipated and prepared against, but occurs because of an error or other system failure." In the case of New Jersey, reporting is due within 2 days, but no later than 5 days after the event. Specifically delineated events that might be associated with perioperative anesthetic care include hemolytic reactions from administration of ABO-incompatible blood or blood products, electric shock, burns, injuries from the use of restraints, malfunction of ventilators or infusion pumps, surgery on the wrong body part, wrong patient,

and wrong surgical procedure. They also include intraoperative or postoperative (within 12 hours) coma, death, or other serious preventable adverse event for any American Society of Anesthesiologists (ASA) physical status (PS) 1 inpatient or any same-day-surgery patient regardless of ASA physical status. Other states, such as Pennsylvania, are less prescriptive. The Pennsylvania statute, Medical Care Availability and Reduction of Error (MCARE) Act (Act 13 of 2002), does not use the "sentinel event" terminology but rather defines a *serious event* as an event, occurrence or situation involving the clinical care of a patient in a medical facility that results in death or compromises patient safety and results in an unanticipated injury that required the delivery of additional healthcare services to the patient. The act further defines the term *incident* as an event that could have produced unexpected injury to a patient in a way similar to that defined under serious event. Several investigators have begun using state databases of reported events to determine the safety of different practices such as office-based anesthesia care.

Near Miss

This is defined as a "process variation" that did not affect the outcome, but for which recurrence carries a significant chance of a serious adverse outcome. These events are not subject to review by the JCAHO but need to be appropriately reviewed and changes made to decrease the risk of the event happening again.

Hazardous Conditions

These are defined as circumstances (not including the disease or condition for which the patient is being treated) that significantly increase the likelihood of a serous adverse outcome. A wet floor, for example, presents a hazardous condition that might increase the risk of a patient fall. The JCAHO has now made prevention of patient falls a national patient safety goal, thus identification of both those at risk and hazardous conditions for those who are at risk are a national priority.

Sentinel Event Alerts

The JCAHO introduced this mechanism to bring attention to situations that might lead to sentinel events. Among the many events are a number that potentially involve the practice of anesthesia or intensive care, including high concentrations of potassium chloride; wrong-side surgery; restraint deaths; high-alert medications; operative and postoperative complications; infusion pump malfunction; look-alike sound-alike drugs; medical gas mix-ups; needles and sharps injuries; dangerous abbreviations; ventilator-related events; delays in treatment; nosocomial infections; surgical fires; anesthesia awareness; and patient-controlled analgesia. Once an alert occurs, it is important that it is disseminated throughout the organization.

The specialty of anesthesiology has recently addressed one of these sentinel alerts in a more formal manner. On October 6, 2004, the JCAHO issued an alert on *Preventing and Managing the Impact of Anesthesia Awareness.* The alert stated that

> To overcome the limitations of current methods to detect anesthesia awareness, new methods are being developed that are less affected by the drugs typically used during general anesthesia. These devices measure brain activity rather than physiological responses. These electroencephalography (EEG) devices (also called level-of-consciousness, sedation-level and anesthesia-depth monitors) include the Bispectral Index (BIS), spectral edge frequency (SEF), and median frequency (MF) monitors. These devices may have a role in preventing and detecting anesthesia awareness in patients with the highest risk, thereby ameliorating the impact of anesthesia awareness. A body of evidence has not yet accumulated to definitely define the role of these devices in detecting and preventing anesthesia awareness; the Joint Commission expects additional studies on these subjects to emerge. In its review of the Bispectral Index (BIS) monitor, the Food and Drug Administration determined that "Use of BIS monitoring to help guide anesthetic administration may be associated with the reduction of the incidence of awareness with recall in adults during general anesthesia and sedation."

The JCAHO recommended that healthcare organizations which perform procedures under general anesthesia develop and implement an anesthesia awareness policy. Because many practitioners were concerned that a particular monitoring device was being endorsed, they developed a sample departmental policy on intraoperative awareness that is available to members. It is important to recognize that there are resources available to help address some of these alerts.

QUALITY OF CARE INDICATORS

A broad definition for reportable events such as those found for sentinel events or serious events presented earlier may be difficult for practitioners to use on a day to day basis to decide what should or should not be reported. Without detracting from the need to report at a broad level, defining specific reporting indicators provides operational definitions that speeds this decision making. The quality of care indicators in Table 25–4 are those in use by the Department of Anesthesiology and Critical Care at the University of Pennsylvania. They are based on material developed initially by an Anesthesia Care Task Force convened by the JCAHO in 1987, although they have been updated and adapted to meet the needs of the Department.[2] These are outcome indicators and do not include newly developed process indicators such as on-time antibiotic administration or time-out documentation.

Reporting of adverse events needs to be encouraged. The aviation industry has used self-reporting for a number of years to detect situations at risk for serious events (for an overview, see ref. 3). This reporting is nonpunitive, whereas failure to report may compromise one's employment position. An environment in which reporting is encouraged can only be created if the act of reporting does not create negative repercussions. Anonymous reporting may be helpful, but compromises the ability to followup and determine events at the level of detail that might be required. There has been debate about whether or not voluntary reporting is adequate and a number of institutions have reported their experiences with scanning of anesthesia records for vital sign excursions beyond predefined boundaries. Others have used chart review by sampling a portion of the anesthetics performed. Given the relative rarity of many of the most serious anesthesia-related incidents and events, sampled chart reviews may miss critical cases. Chart scanning for acceptable vital sign boundaries might

TABLE 25–4.

Quality Improvement Indicators Related to Anesthesia

Awareness under anesthesia
Blood or blood product transfusion reactions
Can't ventilate, Can't intubate
Cancellation of surgery after induction of anesthesia
Central nervous system complication[a] (stroke, failure to regain consciousness, etc.)
Code call related (includes failure to respond, inappropriate interaction, failure to establish an airway, etc.)
Death[a]
Dental injury
Myocardial infarction[a] (regardless of mildness, any postoperative troponin increase triggers review)
Perioperative cardiac arrest
Peripheral nervous system complications[a] (parasthesia, neuropathies, etc.)
Physical injury except for dental injury
Reintubation in postanesthesia care unit or operating room (unplanned, excludes predefined trials of extubation)
Severe anesthesia-related drug reactions (includes anaphylactic or phylactoid reactions; errors in drug administration with respect to drug given, dose given, or route given; idiosyncratic reactions; etc.)
Significant patient dissatisfaction with anesthesia care
Vascular injury (typically related to placement of central catheters; for example, carotid puncture with large-bore sheath)
Other (anything not covered above)

[a]Review cut off is 48 hours post operatively. These are the indicators currently used in the Department of Anesthesiology and Critical Care at the University of Pennsylvania, Philadelphia, PA.

generate more false positives than can be reasonably reviewed, depending on the patient population of a particular institution. "Buy in" for voluntary reporting provides the ability to identify the uncommon but serious events. Voluntary reporting need not be limited to members of an anesthesia department. We have found that observations by others, such as nurses and surgical house staff, can be valuable additions to the quality improvement process.

ASSESSMENT OF PATIENT QUALITY OF CARE INFORMATION

Peer Review

Peer review has been a part of anesthesia practice for more than 70 years. One of the earliest documented uses of peer review for anesthesia-related mortality was by Ruth, in 1935, when he helped establish the first anesthesia study commission to analyze perioperative deaths.[4] The commission relied on voluntary submission of cases and determined the cause of death by majority vote. The peer review process actually approaches the analysis of care in a much more systematic way today, but clearly there is a long tradition in the field of trying to identify those cases in which the actions of the anesthesiologist contributes to mortality. It is also common today for perioperative deaths (and major complications) to be reviewed by multiple individuals who were not directly responsible for the care of the patient. For example, the reviewers may include a quality assurance officer in the anesthesia department, but may also include individuals in surgery, nursing, and pharmacy.

Mortality and Morbidity Conferences

Mortality and morbidity conferences (Table 25–5) are a common occurrence in surgical departments, although less commonly used in anesthesia departments. In brief, all cases of mortality and morbidity that occur during a defined period are briefly presented to the rest of the department and the etiology of the complication and potential means of improving care in the future are discussed. Despite their long use and honored place in medical training and performance evaluation, these types of conferences have not produced the levels of safety currently expected. In many departments they tend to focus on technical aspects of the care provided and often digress into discussions of how, not whether, a particular intervention should have been done. In addition, they have had little impact on important issues of patient identification and wrong-side surgery. Because they tend to focus on the individual case they tend to fail in recognizing infrequent events. The single-case approach slights trends and risks that can only be detected by grouping events and performing various types of data analyses. Although this type of conference still has a place, as a tool to improve patient safety it has been less than optimal and other approaches need to be implemented as well.

One approach to using the morbidity and mortality conference effectively at the University of Pennsylvania is through the joint conferences with other departments. Specifically, we periodically present cases to a joint group of surgeons and anesthesiologists. There is a focus on cases in

TABLE 25–5.

Comparing Traditional Mortality and Morbidity Conferences to Systems-Oriented Conferences

Traditional	Systems-Oriented
Absolute individual practitioner responsibility	Examines the role of the "system" in contributing to error without diminishing the need for individual responsibility
Focuses on individual care	Allows for examination across larger patient groups, often beyond individual practitioner
Does not adequately recognize the role of groups and group interaction	Emphasizes group contributions toward common goal of patient safety and error reduction
Exhortation to "do better" key route for problem solution	Explores possible changes in the "system" to reduce probability of error
Continued high rate of medical error despite long history of this approach to improving patient care	Too new to know if there will be a significant reduction in error
"Shame" and "blame" may make discussions less than forthcoming	Emphasis on totality of risk may allow better discussion

which more effective teamwork or communication could have led to better outcomes. This joint multispecialty conference has proven to be a very effective method for obtaining more widespread buy-in to quality assurance processes. Senior faculty members and the respective departmental leaders have been very willing to participate. The concept has expanded from joint conferences with general surgery and anesthesia to conferences with other surgical specialties and even with our colleagues in perioperative nursing.

Root Cause Analysis

Root cause analysis is a more structured process than traditional peer review for identifying the causal or contributing factors leading to major morbidity or mortality (see www.patientsafety.gov/rca.html). A root cause analysis must include the following:

1. Determination of human and other factors
2. Determination of related processes and systems
3. Analysis of underlying cause-and-effect systems through a series of "why?" questions
4. Identification of risks and their potential contributions
5. Determination of potential improvement in processes or systems

The approach demands that bad outcomes not be attributed to the first error discovered, but rather that it is important to review all of the potential sources of error or systems problems that led to the adverse event. A systems approach allows one to discover all of the potential areas that can lead to an adverse event. Reason[5] popularized the concept of latent error; that is, risks associated with, but not manifest with, a process. Usually multiple latent errors are required before an adverse event occurs. For example, an anesthesiologist may give the wrong medication but contributing factors may be containers with similar size and lettering, low light levels in an operating room, a distressingly high level of music, and a malfunctioning inspiratory valve, the correction of which has created a distraction. Typically, these factors do not all occur at once and the patient receives the correct medication. Focusing only on the last error (the giving of the wrong medication) will not correct the underlying cause of the error nor will it decrease the probability of avoiding a similar error in the future.

Failure Modes and Effects Analysis

Failure modes and effects analysis (FMEA) is a systematic method of evaluating a process to identify where and how it may fail. Whereas root cause analysis assesses cause after an event has occurred, the goal of FMEA is to anticipate risks, alter processes and thus avoid adverse events. According to the Institute for Healthcare Improvement, FMEA includes review of the following:

- Steps in the process
- Failure modes (What could go wrong?)
- Failure causes (Why would the failure happen?)
- Failure effects (What would be the consequences of each failure?)

Tools have been developed to perform a FMEA. Each failure mode gets a numeric score that quantifies (a) likelihood that the failure will occur, (b) likelihood that the failure will be detected, and (c) the amount of harm or damage the failure mode may cause to a person or to equipment. The product of these three scores is the risk priority number (RPN) for that failure mode. The sum of the RPNs for the failure modes is the overall RPN for the process.

For example, FMEA can be used to look at blood bank processes even if no adverse event occurred. It can also be used by groups of clinicians to test or simulate a process before it is incorporated into routine clinical care. This may lead to improvements in the process. Paradoxically, a proposed "improvement in care" may be found to increase the RPN rather than decrease it and therefore should not be implemented. The RPN can also be used to determine if implemented process changes actually resulted in lower potential risk.

AN APPROACH TO QUALITY OF CARE IMPROVEMENT

Data Acquisition

Observer Reporting

Acquiring information about patient outcomes, adverse events, and incidents that might have led to adverse events is the first step for any quality review process. Event reporting by the caregivers or observers has been contrasted to chart review. Manual chart review can be labor intensive and the yield may be low for the infrequent events of most interest to anesthesiologists. Chart review may be complementary to incident reporting and in fact may identify different populations of patients.[6] Reporting by those involved needs to be encouraged. Ease of reporting,[7] comfort providing reports, and the feeling that reporting may lead to useful evaluation and change may contribute to higher reporting rates. A process that leads to retribution for error will decrease reporting.

Whether or not caregiver incident reporting produces adequate response rates is a topic for debate. Sanborn et al. suggested that in their institution there was a low level of compliance with voluntary reporting of defined intraoperative incidents.[8] In contrast, Lagasse described a program claiming a near 100% response rate with a nonthreatening quality assurance system.[9,10] Katz and Lagasse reported on incidents captured after 37,924 anesthetics by self-reporting, chart reviews, and an incident report process.[11] They found that self-reporting for events resulting in disabling patient injury was very high. They found no significant benefit to chart review compared to self-reporting.

Automated Data Acquisition

Over the past decade there has been a marked acceleration of the implementation of hospital information systems and continuing refinement of intraoperative data record keepers or anesthesia information management systems (AIMS). The AIMS have the ability to capture and identify multiple outcomes of interest and intraoperative events (e.g., blood pressure changes, drugs). Data from individual patients can be aggregated and linked to predefined clinical and/or resource use outcomes. Although there is concern about the accuracy of the information obtained from the AIMS related to the potential "smoothing" of intraoperative data, studies in this area have reported a higher degree of accuracy than data obtained from a traditional "hand written" record or self-reporting.[12,13] Of greatest concern in the potential use of these large databases

is the potential for "data mining." It is important to recognize that the associations that might be found from these types of analyses are just associations, and when a large number of variables are examples, there is a good statistical probability that these associations will be found. Thus it is important to recognize that these are hypothesis generating, rather than hypothesis confirming or disproving. Nonetheless, the increasing implementation of AIMS should lead to an improved ability to identify morbidity and mortality and to reconstruct the potential factors that led to the complications.

Computer-Assisted Data Acquisition

Computers can assist in the acquisition of incident and event information. In the fourth quarter of 2002 our institution went online with a computerized report-entry system. Embedded within the system are the quality improvement indicators that we had been following for anesthesia-related events. The system is accessible from any computer within the medical center's domain, which includes every operating room, strategic locations outside the operating room, postanesthesia care units, intensive care units, and all faculty offices. Prior to this system going online, we would typically receive about 50–100 reports per year regarding patient-related events. Most of these came from anesthesia faculty and residents. The year after the computer system went online, 250 events were logged in, with at least half coming from nonanesthesia observers. Currently we receive about 300 reports per year of events or incidents that might be related to the activities of anesthesiologists. The system has greatly improved our capture of potential issues. In addition, there is faster access to these reports than was possible when a paper-based system was in use.

Data Verification

The medical record is the ultimate source of data verification. With respect to serious events, discussions with those involved before memory fades and review of the anesthesia record and other associated records are critical. We have found that single reports may be inaccurate or the reporter unaware of the entire clinical situation. Thus reports are a start, and depending on the nature of the event, more investigation may be required. In some situations, we undertake these reviews internally. When there appears to be significant multidisciplinary issues, we ask our medical center risk management group to conduct a formal root cause analysis.

Database Entry

The data obtained often contains patient identifiers and information of a sensitive nature. Clearly, basic precautions to avoid theft of this data or its publication need to be taken. Password protection of computer files using strong passwords and possibly encryption appear necessary. Paper records should be kept in locked offices or filing cabinets. We do not store any of our patient safety data on portable computers. We store the data on medical center servers that are routinely backed up and maintained behind a firewall. Patient records are not removed from the medical center, as records of this nature have been, for example, stolen from automobiles and briefcases have been mislaid in restaurants. We attempt to maintain all of our patient safety/quality improvement data within the peer review system to decrease the risk of discoverability during any medicolegal process.

Consideration must also be given to the personnel entrusted with database entry. Diversion of records from their intended purposes by clerks and others has occurred. We also make sure that the records are not left out on desks when those doing data entry leave the area.

Review of Data

Moving Beyond the Assessment of a Single Case

The single case, unless intensively studied, may provide little information. Aggregating the data provides information about trends and special risks, depending on the frequency of event occurrence and the time over which the data is accumulated. Particularly for rare events, such as anesthesia-related deaths, occurrence and cause may not at all be evident without some sort of data accumulation. However, the key first step is to review the incident to determine its relevance to the anesthetic care provided.

Database Management and Incident Analysis Programs

Systematic data review can be done reasonably well using a computerized spreadsheet. Data entry and simple analysis, such as frequency, changes over time, and events based on practitioner, type of surgery, or other variables of interest, are relatively easily obtained. However, there is at least one product available that might simplify this task. Mention of this program is not an endorsement as we have not used it. The ASA has made available a program from Quality Assurance Research called QA/PDX. The program is available to ASA members; for information, see the ASA website at: www.asahq.org/qmdaform.htm. According to the information provided by the developers, the program is a relational database that can be used on virtually any computer that uses a Microsoft operating system including DOS legacy machines. The program has a defined data entry format as well as preconfigured reports.

Computer-Assisted Reporting Programs

Even though many large centers have developed their own reporting systems, a number of reporting systems are available for purchase. The advantages of using a computer-based (as opposed to a paper-based) system for the entire institution (in contrast to a single department) were mentioned earlier (see Computer-Assisted Data Acquisition). Although we have not had personal experience with any of these programs, each has been installed and recommended in a general way by a current user. These programs include Risk MonitorPro; WEBagent by Peminic; Quantros Occurrence report management system; and International Developers Healthcare Management System, which includes modules for incident and complaint management, and quality and peer-review management, as well as other process management programs.

Feedback

Obtaining and analyzing data actually may be easier than developing mechanisms to feed back this information to the involved practitioners and to other stakeholders. Our impression is that this part of the patient safety and quality improvement processes is the most difficult. In teaching departments, the normal turnover of residents, and in many cases, junior faculty, means that the "institutional" memory is short. The intervals required to review or reteach this information may be difficult to determine, as is maintaining an up-to-date

list of "what needs to be relearned." Because many of the issues relating to patient safety appear very basic, administrative, or bureaucratic, many department members are uninterested in learning about or implementing changes in their practice. For example, universal precautions during central line insertion appear to many anesthesiologists as an impediment rather than a process to be embraced and transmitted. We have found that a variety of approaches are needed to reach a majority of those who need to receive specific patient safety messages. We use conferences, e-mail—both in the form of a periodic "newsletter" and individual e-mail—individual conversation, and policy development to transmit the needed information to those who need it. We have found that developing policies that can alter processes at the level of the operating nurse or those who prepare the operating room between cases can often effect that change faster than working through physicians. Generally, residents are more receptive than faculty to change and getting resident "buy-in" can produce change reasonably quickly. The need for both repetition and followup suggests that in larger departments resources should be devoted to the education component of the patient safety and quality improvement processes. Several examples may be helpful. Intraoperative cardiac arrest related to potassium was not finally eliminated until concentrated potassium solutions were removed from the operating room. Virtually 100% compliance with operating room central line placement guidelines was achieved when a sterile gown, drape, and towel pack specifically for central line placement was developed and provided each time a central line kit was requested. In addition, the circulating nurse and scrub nurse have become actively involved, virtually forcing compliance.

AGGREGATED PATIENT OUTCOME AND SAFETY DATA IMPROVES ANESTHESIA CARE

One of the first reports in which anesthesia-related patient care data was aggregated was by Beecher and Todd, who studied anesthetic death in 10 institutions and published their work in 1954.[14] Their study included 599,548 instances of anesthesia. The cause of mortality was determined at the local institution by consensus of a surgeon and the chief anesthetist of the institution. Each death was characterized as having one primary cause, and may also have had multiple secondary causes. This approach allowed a more thorough analysis of the causes of mortality beyond a primary one.

Dripps and colleagues at the University of Pennsylvania surveyed their experience during the 10-year period from 1947–1957.[15] They noted 1285 operative deaths (death within 30 days) in approximately 120,000 instances of anesthesia, for a gross mortality rate of 1.1%. This definition includes late deaths, as opposed to the many studies that focus on the intraoperative period or the first 48 postoperative hours. After review of the hospital records, they determined whether anesthesia was definitely or possibly contributory to death. This approach allowed the authors to identify systematic issues that could be addressed.

Clifton and Hotton reported on 162 deaths associated with anesthesia in 205,640 operations performed in the Royal Prince Alfred Hospital in Sydney, Australia between 1952 and 1962.[16] One cause of postoperative mortality was respiratory insufficiency. These authors argued that many of these complications would have been prevented by the use of a recovery unit. The potential safety advantage of a postanesthesia care unit (PACU) was a general theme in these reports from the 1960s and this quality assurance process led to the routine availability of a PACU.

Numerous other groups have examined the incidence and etiology of perioperative morbidity and mortality over the years. For example, Tiret and colleagues carried out a prospective survey of complications associated with anesthesia in France from 1978 to 1982 in a representative sample of 198,103 instances of anesthesia chosen at random from hospitals throughout the country in a study done under the direction of the French Ministry of Health.[17] The investigators evaluated both deaths or coma within 24 hours of surgery. The French survey confirmed previous findings that major complications occurred more frequently in older patients, in patients who were undergoing emergent operations, and in patients with more extensive comorbidity, as measured by the ASA physical status classification.

One of the most important findings of the survey was that postanesthesia respiratory depression was the largest cause of death and coma that was wholly attributable to anesthesia. Almost all of the patients with respiratory depression leading to a major complication had received narcotics and muscle relaxants that had not been reversed. They also reported a high incidence of "anaphylactoid shock." The authors contended that this was primarily a result of Althesin and succinylcholine. Importantly, there was no category of drug overdose, which may have been a more appropriate label for some of these cases.

The need to look into perioperative morbidity and mortality on a national level was recognized in England. The pioneering work of Lunn and others led to the development of the Confidential Enquiry into Perioperative Deaths (CEPOD) study, which assessed nearly a million cases of anesthesia during a 1-year period in 1987 in three large regions of the United Kingdom.[18,19] Unique to this study was the establishment of "crown privilege" by the government to allow total confidentiality: "The Secretary of State is satisfied that the disclosure of documents about individual cases prepared for the Enquiry into Perioperative Deaths would be against the public interest and would undermine the whole basis of a confidential study. Therefore, the data/information sent to the Confidential Enquiry into perioperative deaths is protected from subpoena...."

Deaths within 30 days of surgery were included in the study. Anesthesia was considered the sole cause of death in only 3 individuals, for a rate of 1/185,000 cases, and anesthesia was contributory in 410 deaths, for a rate of 7/10,000. An important aspect of the CEPOD study was that it established both anesthesia- and surgical-related factors that contributed to mortality. Of the 410 perioperative deaths, there were 9 cases of aspiration or vomit and 18 cases of cardiac arrest.

These types of publications add greatly to understanding the cause of rare outcomes and provide individual clinicians with areas to focus their attention.

ASA CLOSED CLAIMS STUDY

Studies similar to the CEPOD study have not been performed in United States, most likely because of the legal

system. Consequently, potential causes (and treatments) of perioperative mortality had to be obtained from other sources. This led the Professional Liability Committee of the American Society of Anesthesiologists to conduct a nationwide survey of closed insurance claims for major anesthetic mishaps, which has resulted in a series of publications over the past several decades. The closed claims study allowed analysis of very rare events and potential treatments.

One example involved unexpected cardiac arrest during spinal anesthesia, which was observed in 14 healthy patients from the initial 900 claims.[20] The cases were analyzed in detail in order to identify patterns of management that may have led to the event. Two patterns were identified; oversedation leading to respiratory insufficiency and inappropriate resuscitation of high spinal sympathetic blockade. In another example, Caplan et al. reviewed the closed claims study for respiratory events.[21] They identified inadequate ventilation, esophageal intubation, and difficult tracheal intubation as the primary causes of respiratory events. Most of the outcomes were thought by the investigators to be preventable with better monitoring. Much of this work formed part of the basis for the American Society of Anesthesiologists Difficult Airway Guidelines and algorithm.[22]

VETERANS ADMINISTRATION (VA) HEALTH SYSTEM'S APPROACH TO QUALITY

Based on concern about quality of care within our Veterans Administration, Congress mandated the development of the National Veterans Administration Surgical Risk Study (NVASRS) in 1986. Between October 1, 1991 and December 31, 1993, the NVASRS was conducted in 44 VA Medical Centers and developed a risk-adjustment model for predicting 30-day outcome. Based upon the NVASRS, the National Veterans Administration Surgical Quality Improvement Program (NSQIP) was established in January 1994.[23,24] NSQIP collects data on 40 preoperative clinical risk factors (e.g., diabetes and heart disease), 20 categories of 30-day postoperative morbidity (e.g., venous thrombosis, wound infections, and pneumonia), and 30-day postoperative mortality on patients having major operations under general, spinal, or epidural anesthesia. During the past decade, the NSQIP group has published numerous articles demonstrating the factors associated with poor outcome and medical errors.[25] As of 2002, the 30-day postoperative mortality after major surgery in the VA has decreased by 27%, and the 30-day morbidity by 45%.

INVOLVEMENT OF THE PATIENT AND FAMILY

As part of some of the national patient safety initiatives, a critical component has been the involvement of the patient and family. For example, the JCAHO and the Institute for Healthcare Improvement (IHI) have both advocated advising patients to ask their physicians and other healthcare providers to wash their hands. This may seem like a simple request, but multiple observations suggest that handwashing is not a routine activity between patient encounters. Similarly, the Surgical Care Improvement Project (SCIP) has developed patient "tip sheets" to advise patients about appropriate questions and best practices which should be adopted at the individual hospital. For example, patients who are taking β-blockers are advised to ask about the use of protocols to maintain perioperative β-blockade and of other protocols to prevent deep vein thromboses. It is the authors' belief that this will become a more common practice in the future and the clinicians should be prepared for an educated public who questions their practices.

NATIONAL PATIENT SAFETY GOALS AS THEY RELATE TO ANESTHESIA PRACTICE

Over the past several years, a series of national patient safety goals have been advocated which are based on sentinel events and other sources of medical errors that have occurred in the past. Table 25–6 represents a list of those goals that have been adopted, and Table 25–7 is a list of those goals under consideration for 2007. The operating room is a high-risk area and adoption of systems to reduce this risk is critical.

EVIDENCE-BASED PRACTICES

On a national level, the ability to disseminate best practices has taken the form of standards and guidelines produced by national associations and the federal government. Practice policies or guidelines are the summation by clinicians of the available evidence about the benefits and risks of a treatment plan. Guidelines are a method of codifying recommendations regarding the use of a given technology or practice. There are several types of recommendations that fall into the general category of a practice parameter. A standard implies that a therapy or practice should be performed on patients with a particular condition. Standards are only approved if an assessment of the probabilities and utilities of the group indicate that the decision to choose the treatment or a strategy would be virtually unanimous. If a particular therapy or strategy is considered a standard, it should also be cost-effective. Standards are intended to be applied rigidly. The American Society of Anesthesiologists first adopted Standards for Intraoperative Monitoring in 1986, which were developed from safety guidelines adopted at the Harvard hospital system. Guidelines are intended to be more flexible than standards, but they should be followed in most cases. Depending on the patient, setting, and other factors, guidelines can and should be tailored to fit individual needs. Like standards, guidelines should be cost-effective. The American Society of Anesthesiologists has developed a series of guidelines, which it terms Practice Parameters or Practice Guidelines on a number of issues such as pulmonary artery catheter use and blood transfusions.[26–28] Similarly, the American Heart Association/American College of Cardiology has established *Guidelines for Perioperative Cardiovascular Evaluation for Noncardiac Surgery*.[29] Local practices can then be benchmarked against these national norms and local performance improvement initiatives can be developed. One example is the development of β-blocker protocols for patients who present to the hospital currently taking β-blockers. As more high-quality studies of best practices become available, practice guidelines will be used to disseminate these practices.

TABLE 25–6.

Joint Commission on Accreditation of Healthcare Organizations' Patient Safety Goals as They Apply to the Perioperative Period (2003–2006)

Standards and goals vary depending on the healthcare setting. The ones in this list apply to hospital and critical access hospital programs.

Goal 1: Improve accuracy of patient identification: 1A—Use at least two patient identifiers prior to giving medication or blood products, providing treatment or procedures.

Goal 2: Improve effectiveness of communication among caregivers: 2A—"Read-back" verbal orders or verbal test results; 2B—Standardize a list of abbreviations that are not to be used; 2E—Implement a standardized approach to "hands off" communications including an opportunity to ask and respond to questions.

Goal 3: Improve the safety of using medications: 3A—Remove concentrated electrolytes from patient care units (includes potassium chloride and sodium chloride greater than 0.9%); 3B—Standardize and limit the number of drug concentrations available within the organization; 3C—Identify a list of look-alike/sound-alike drugs used in the organization, and take action to prevent errors involving the interchange of these drugs; 3D—Label all medications, medication containers, or other solutions on and off the sterile field in perioperative and other procedural settings.

Goal 4: Eliminate wrong-site, wrong-patient, wrong-procedure surgery: Protocol-driven pre-operative verification process; mark the operative site; conduct a "time-out" before starting the procedure.

Goal 5: Improve safety of using infusion pumps.

Goal 6: Improve effectiveness of clinical alarm system: Assure that alarms are activated with appropriate settings; assure adequate level of audibility.

Goal 7: Reduce risk of healthcare-associated infections: 7A—Comply with Centers for Disease Control and Prevention hygiene guidelines; 7B—Manage as sentinel events all identified cases of unanticipated death or major permanent loss of function associated with a healthcare-associated infection.

Goal 8: Medication reconciliation: 8A—Develop a process for obtaining a complete list of patient's current medications; 8B—Develop a process for communicating the complete medication list to the next provider outside or within the organization.

Adapted from the Joint Commission website (www.jointcommission.org).

TABLE 25–7.

Draft Candidate 2007 Joint Commission on Accreditation of Healthcare Organizations National Patient Safety Goals as They Apply to the Perioperative Period

These are proposed standards and may be modified prior to adoption. Some may not be adopted. This list is based on material released November 2005.

Goal 3E: Reduce likelihood of patient harm associated with the use of anticoagulant therapy: strategies include the use of premixed heparin solutions, use of programmable pumps and independent double-checks for IV anticoagulants, dosing protocols based on patient weight, elimination of heparin flush in peripheral intravenous lines.

Requirement 15B: Prevent healthcare-associated pressure ulcers. Assess and periodically reassess each patient's risk for developing a pressure ulcer and take action to address any identified risks: strategies include maintaining and improving tissue tolerance to pressure, protecting against the adverse effects of external mechanical forces by reducing skin injury from friction and shear forces, repositioning, or mechanical loading and support surfaces.

Goal 16: Discourage disruptive behavior: Implementation strategies include developing a code of behavior, identifying unacceptable behaviors, staff reporting using a nonretributive process, education, programs to manage unacceptable behavior, and developing programs to manage stresses associated with the healthcare work environment.

Goal 18: Improve recognition and response to changes in patient's condition: Key strategy involves development of an early response team whose composition varies depending on the needs of the organization, The goal is to provide a route for healthcare staff members to obtain direct assistance when a patient's condition appears to be worsening.

In the absence of strong evidence to support a given practice, expert opinion can help define best practice. For example, there is little high-quality randomized data to support the decision to perform a routine laboratory test prior to surgery. After reviewing the data, the American Society of Anesthesiologists Task Force on Preoperative Evaluation chose to develop a practice advisory.[30] A practice advisory uses expert opinions and survey-of-practice results to help inform clinicians.

PROCESS MEASUREMENT AS PART OF THE QUALITY IMPROVEMENT PROCESS

Most of the discussion has dealt with outcome measurements, such as death or myocardial infarction. For anesthesia-related complications, however, outcome requires a fairly large sample size and may be hard to separate from other factors such as underlying disease or the surgical intervention. Easier to implement and measure are process-based indicators such as antibiotic administration, β-blocker administration or other processes that have been demonstrated to lead to improved outcome.[31,32] The key issue here is the relationship between the process being measured and outcome. In addition, meeting process mandates alone may not guarantee an acceptable outcome, thus the previously discussed patient safety and quality improvement processes cannot be abandoned. Of concern is the use of process variables to institute "pay-for-performance" compensation paradigms and whether or not the processes mandated will in fact correlate with improved patient care.

PATIENT SAFETY AND QUALITY IMPROVEMENT IN INTENSIVE CARE UNITS

As summarized by Wu et al., in the United States, ICUs account for approximately 10% of inpatient acute care beds.[33] ICU mortality has been estimated to be between 8% and 10%, which accounts for about 400,000–500,000 deaths each year.[34] Errors and adverse events appear to be common in ICUs and may be on the order of 1.7 errors per patient per day.[35] Consequently, many researchers have thought that

ICUs present an ideal area to study the effects of patient safety initiatives on outcome.[33]

Communication errors may contribute to as much as 67% of adverse events in the intensive care setting.[36] Pronovost et al. described several tools, including "the morning briefing" and the concept of "daily goals," that have improved certain measured outcomes.[36,37] The morning briefing approach highlights those patients with the most critical issues; it helps determine the order of rounding and provides focus for the day's activity. The morning briefing form asks three questions: "What happened overnight that I need to be aware of? Where should I begin rounds? What are your concerns regarding potential problems for today?" The authors note that this approach provides an immediate overview of the totality of care requirements in the ICU and allows a more rational allocation of resources. They also note, anecdotally, that the approach results in enhanced teamwork, better identification of defects, and an improved admissions/discharge process.

The "daily goals" is a second approach. It is "low tech" but has decreased ICU length of stay in the studied ICU from a mean of 2.2 to 1.1 days and allowed an additional 670 patients to be cared for during the year.[37] According to the authors, this approach allows explicit delineation of the goals for each patient and improved communication with nurses, house staff, and families.

The frequency of ICU-based incidents and their deleterious effect on patient outcome has led to considerable effort to define relevant variables that alter outcome. Berenholtz et al. described outcome variables such as ICU mortality rate, average days on mechanical ventilation, and suboptimal management of pain; process variables such as appropriate use of blood transfusion and appropriate peptic ulcer disease prophylaxis; access variables such as delayed admissions and rate of delayed discharges; and complication variables such as rate of unplanned ICU readmission and the rate of resistant infections as a starting point to determine which factors seemed the most relevant to improving patient outcomes in the ICU.[38]

Others have described various processes for data collection of adverse events, including collaborative, multi-institutional Internet-based reporting systems.[33,39] Approaches to encourage reporting within institutions include the trigger tool described by Resar et al., which is a mix of process and outcome variables that lead to further review.[40] Triggers in this series include chest tube insertion, positive blood cultures, death, and renal failure, among others. The selection was empirical. The authors determined a prevalence of 11.3 adverse events per 100 ICU days. Schuerer et al. describe an error-reporting system involving the use of pre-prepared cards listing various reporting indicators.[41] They noted that reporting increased with this system compared to the previous online system. This was attributed mostly to ease of reporting, although the attention paid to reporting, including in-service sessions, may have been a factor.

Other types of data acquisition besides reporting have been attempted. Beckman et al. compared incident reporting to a medical card review.[42] Even though the incident reporting and medical chart review often found similar events, they found that medical chart review seemed to detect infections, pain management problems, and myocardial infarction that were missed by the incident-reporting system. The authors believe that the two systems are complementary, but that the medical chart review requires a greater investment of resources.

Adverse events also occur while patients are being moved from other areas of the hospital to the ICU. Gillman et al., for example, determined that during a 6-month period 66 of 290 (23%) patients transferred from the emergency department to the ICU experienced some type of adverse event during the transfer process; these range from incorrect identification bands to hypertension, hypotension, hypothermia, and transport equipment problems.[43] Thus any program developed for ICU-related patient care quality needs to also account for patients coming into and leaving the unit.

Despite great efforts by a number of institutions, monitoring for patient safety and improving outcomes in the ICU setting is still in the developmental stage. Curtis et al. provides the most up-to-date summary.[44] However, they note that performance measures still need to be tested. For efficacy, Pronovost and Holzmueller note that quality improvement and patient safety within the ICU setting is multidisciplinary.[45] They emphasize the need to develop a culture that emphasizes these aspects of patient care. They note that developing work processes that reduce complexity, standardize, and automate may be most helpful in reducing error.

ACUTE PAIN MANAGEMENT

Quality and safety standards with respect to acute pain appear to be the least developed. Part of this relates to the fragmentation of acute pain care between surgeons, nurses, and anesthesiologists that occurs in many institutions. It is also related to philosophical differences among the participants toward the treatment of acute pain and the lack of a quantitative measure outside of patient observation. Practice guidelines from the American Society of Anesthesiologists emphasize that a single approach to pain management may not be appropriate for all types of patients and that multimodality approaches tailored to the patient's clinical conditions and therapeutic requirements have the greatest probability of producing adequate pain relief with the least risk of undesirable side effects.[46] The JCAHO has published specific pain-management standards that may help to increase the resources devoted to this often-ignored aspect of patient care.[47] The basic underpinning for determining the efficacy and safety of pain control efforts is the requirement that patient pain needs to have appropriate assessment and management. There are two problems, however, as regards this underpinning. First, many institutions have not yet implemented appropriate pain assessment and control programs. The American Pain Society guidelines were formulated in 1995 and provide a very precise approach to instituting an effective approach to acute pain care.[48] Second, and the focus of this section, is once an acute pain care plan is in place, how does one organize for monitoring it for safety and efficacy?

Garnerin et al. discuss a single event related to a pump error and the process of root cause analysis related to that error.[49] Karlsten et al. found that over a 3-year period the assessment of

pain according to the set protocols improved with repeated staff training, meetings and audits.[50] Bardiau et al. reported improved pain relief as indicated by Visual Analogue Scale (VAS) scores with the implementation of a multimodal pain therapy approach, routine VAS measurement, and nurse training.[51] Sartain and Barry reported improved pain control with the institution of an acute pain service.[52] Miaskowski et al. described the results of a prospective, multisite study involving 5837 patients of whom 49% were cared for by an anesthesia-based pain service.[53] Patients cared for by the acute pain service had significantly lower pain scores, they also had a lower level of complications. Meissner et al. described an ongoing benchmarking protocol for quality assessment.[54] This approach used a specialized pain nurse who interviewed patients on the surgical wards for quality of pain relief. Benchmarks included pain at rest, pain with ambulation, and maximal pain intensity since surgery. Specific side effects such as nausea, vomiting, and sedation were also determined. Other potential quality indicators might include the documentation of VAS, the frequency of VAS documentation, the appropriateness of pain medication for the expected level of pain, efficiency of transition from one pain modality to another and complications.[55] The large number of patients being treated for pain allows the construction of control charts based on type of surgery, pain therapy modality, and physical condition of the patient. This might allow determination of the success of pain control efforts and better determination of which approaches are the most effective in a particular patient population.

IMPEDIMENTS TO REVIEW OF QUALITY OF CARE ISSUES

Many physicians are concerned about the confidentiality and discoverability of discussions of patient outcome. Most states provide protection for discussions held within the purview of peer review committees. The degree of protection varies, but tends to protect the members of the committee, those who testify before the committee, and the written work product of the committee. Original patient records are, of course, discoverable even if taken into the "protected" environment of the peer review committee. Discussions outside the committee environment may be discoverable in legal proceedings. In general, case conferences and mortality and morbidity conferences avoid many of these issues by avoiding the use of specific patient identifiers.

THE FUTURE

Changing Patient Expectations

Patient expectations are changing. Many want greater involvement in their care process. Some demand input into the exact drugs used and evidence significant dissatisfaction with the care provided when their desires are not met. Many also want a near-risk-free experience and have little tolerance for what many of us view as relatively minor events, such as small degrees of hematoma or bruising, intravenous infiltration, and delays in start of surgery. "Service recovery," measures taken to satisfy the patient or the patient's family when care expectations are not met, has long been used to compensate patients for dental injury. It is now being expanded at our institution to reimburse the copay or uninsured portions of postoperative consultations related to certain aspects of anesthesia care, such as ophthalmology consults in the case of eye irritation, plastic surgery consultation for intravenous infiltration, or otorhinolaryngologic consultation for voice changes or persistent sore throat.

Changing Payer Expectations

Payers for medical care expect better outcomes and are willing to pay for these better outcomes through the use of incentives, for example, pay-for-performance. There are two different philosophic approaches to pay-for-performance: (a) focusing on the outcomes themselves and (b) focusing on care processes that are associated with the improved outcomes. An example of an outcome-oriented program is the National Surgical Quality Improvement Program. The American College of Surgeons has recently adapted NSQIP (ACS-NSQIP) to the private sector and allowed private hospitals to send a standard set of data to a national center and obtain observed versus expected mortality.

The process-variable approach is best exemplified by the SCIP. SCIP represents a partnership that was formed in 2003 and included representatives from of the American Hospital Association, the American College of Surgeons, the American Society of Anesthesiologists, the Association of Perioperative Registered Nurses, the JCAHO, the IHI, the Department of Veterans Affairs (VA), the Agency for Healthcare Research and Quality (AHRQ), the Centers for Medicare and Medicaid Services (CMMS), and the Centers for Disease Control and Prevention (CDC) (see www.medqic.org/scip). In 2005, the group set as a goal the reduction in number of surgical complications by 25% by the year 2010. Four major areas of surgical complications were identified: prevention of surgical site infections, perioperative myocardial infarction, postoperative pneumonia, and venous thromboembolism (pulmonary embolism and deep vein thrombosis).

The partnership has used expert panels composed of members from the steering committee and from more than 20 additional organizations to identify best practices supported by the literature or that are identified as class I recommendations in guidelines developed by the appropriate organizations. For example, the recommendations for perioperative β-blockade were restricted to class I recommendations of the American College of Cardiology/American Heart Association *Guidelines for Perioperative Cardiovascular Evaluation*. In fact, the *Focused Update on Perioperative Beta Blockade* was published in part to ensure that the SCIP measures would be consistent with the most current evidence. The measures for venous thromboembolism are based on recommendations from the American College of Chest Physicians. The best-described measures are those related to the prevention of surgical site infections. Both timing and appropriateness of perioperative antibiotics were incorporated from the previously commissioned Surgical Infection Project (SIP). Additional measures, such as perioperative normothermia in colon surgery and perioperative glucose control in cardiac surgery, were also part of this "module." At the time of the writing of this manuscript, the SCIP measures are voluntary. Hospitals can report on any one of the four major areas, but they

must report on all of the measures in that area. The IHI has also included the SCIP project in its national agenda. However, the antibiotic measures of SCIP, which were incorporated in SIP, are part of the new pay-for-reporting (P4R), initiative incorporated into the Medicare reimbursement policy. Many private insurers and states are also incorporating this measure; eventually, the overall performance on this measure may effect payment (pay-for-performance) rather than just reporting.

Although the U.S. Congress has clearly identified pay-for-performance as an important approach to controlling healthcare costs and improve quality, several investigators are concerned that better performance on process variables (e.g., antibiotic timing) may not lead to improvement in outcome. Werner and Bradlow found that hospital performance measures only predict small differences in hospital risk-adjusted mortality rates.[56] Despite these concerns, it seems likely that these trends of pay-for-performance and pay-for-results will be widely adopted. In fact, separate measures are being developed for physicians, through the American Medical Association Physician Consortium for Performance Improvement. The Consortium is comprised of more than 100 national medical specialties and state medical societies; the Council of Medical Specialty Societies; American Board of Medical Specialties and its member boards; experts in methodology and data collection; the Agency for Healthcare Research and Quality; and the Centers for Medicare and Medicaid Services. It is committed to the development, testing, and maintenance of evidence-based clinical performance measures and measurement resources for physicians. The measures are then proposed to the National Quality Forum (NQF) and will become those measured included in the pay-for-performance measures for CMMS.

Changing Hospital Expectations

Medical centers increasingly are expecting members of their clinical staff to actively participate in programs to improve patient outcomes and safety. Two of the areas for active participation of anesthesiologists are in the patient safety time-out process and in the proper identification of organ transplantation blood types. Requests to participate in multidisciplinary process-planning groups are increasing. There is an increasing concern with patient satisfaction and clinician groups are being increasingly asked to review processes that produce less-than-optimal outcomes, significant patient dissatisfaction, or have higher costs. This will only increase and a good understanding of the sources of patient dissatisfaction and poorer outcomes within the context of a specific practice will become increasingly necessary.

SUMMARY AND CONCLUSIONS

A robust quality assurance system is essential to ensure that we provide our patients with the highest quality of care. The history of the specialty of anesthesiology has been marked by a focus on patient safety and assessment of outcomes. Anesthesiology has been lauded as the specialty which has focused on achieving a 6-sigma approach to quality. Numerous national projects have attempted to identify factors that contribute to perioperative morbidity and mortality and have proposed systems to reduce complications through the publications of guidelines. These guidelines are now being converted into pay-for-performance initiatives to ensure that all practitioners practice according to the best evidence. Despite these national efforts, each individual provider and group of providers should develop its own system to both identify the causes of complications and to disseminate practices to reduce these same complications.

CHAPTER 26

Positioning of Patients for Operation

Vijaya Gottumukkala, MB, BS, MD (Anes)

POSITIONING OF PATIENTS

The term *surgical posture* or "*positioning*" in the perioperative context denotes the body position in which a patient is placed for the surgical procedure. The main purpose of "positioning" is to maximize anatomic exposure for the surgical procedure. The world's oldest known medical text on surgery (known as the Edwin Smith Papyrus), written approximately 1600 B.C., described different battlefield injuries. However, no mention was made about positioning. The first allusion to surgical positioning is believed to come from the Hippocratic Oath: "I will not cut for stone (i.e., lithotomy), even for patients in whom the disease is manifest...." In Epidemics, Book I, Second Constitution, Hippocrates advised primum non nocere, "to first do no harm." Thus, intraoperative positioning should be optimized for surgical exposure, ensuring patient safety at all times. Although anesthesia-related morbidity secondary to inadequate ventilation and oxygenation have improved as a result of better physiologic monitoring and the American Society of Anesthesiologists (ASA) standards on minimum monitoring, complications secondary to positioning are on the rise. Many problems arising from positioning, such as peripheral nerve injuries, fall under the legal doctrine of "Res ipsa loquitur." This Latin phrase literally means "the thing speaks for itself" and implies that the injury sustained is so evident that it would not have occurred without negligence from someone else. Thus, the plaintiff needs only to prove the injury. In cases of res ipsa loquitur, the burden of proof falls on the healthcare providers to prove their innocence, that is, that the care provided was not negligent. Therefore, safe intraoperative patient positioning is crucial, and a clear protocol must be in place and followed by all members of the perioperative team.

This chapter discusses the positions that are commonly used during surgical procedures (supine, lithotomy, sitting, head-down, prone, and lateral decubitus). The rationale and technique for safe establishment of each of these positions are described, followed by the associated pathophysiologic changes and the potential complications particular to each position. With advances in technology and the advent of new surgical therapeutic options, various modifications of the standard positions are continuously being added. It still is possible to minimize positioning-related injury to the patient even in these challenging situations by adhering to the basic principles.

Supine (Horizontal Dorsal Decubitus Position)

Because the majority of surgical procedures involve patients in the supine position, a clear understanding of the pathophysiologic effects of this position is necessary for the perioperative team. A significant portion of our life is spent in the supine position, and this position is not usually considered to pose significant physiologic stress on the body. However, patients with morbid obesity, mediastinal masses, or poor cardiac function and term parturients prone to aortocaval compression do not easily tolerate this position.

In the traditional supine position, the patient is placed on his/her back with some degree of neck flexion. The arms are either padded and restrained in a neutral position alongside the body or abducted on padded armboards. A pillow usually is placed under the knees to reduce the degree of lumbar lordosis and prevent excessive strain on the lumbar spine. This is an important consideration in the elderly and in those with mechanical low back pain.

Pathophysiology of the Supine Position

Cardiovascular Moving from erect posture to the supine position increases central blood volume considerably. As a result of this increased blood volume, compensatory stretch and baroreceptors in the central circula-

KEY POINTS

1. Proper positioning of the patient during the operative period is important for optimal surgical exposure and outcome.
2. Understanding the pathophysiologic changes and special considerations associated with each position helps in reducing positioning-related morbidity.
3. Improper positioning during surgery could lead to postoperative peripheral neuropathies, muscular sprain injuries, ischemic injury to skin and muscles, and visual loss.
4. Perioperative peripheral nerve injuries are the second most common cause of professional liability among anesthesiologists.
5. Male gender, extremes of body habitus, and prolonged hospitalization are considered risk factors for postoperative peripheral neuropathies.
6. Thorough assessment of risk factors for complications related to positioning should be an integral part of the preoperative evaluation.
7. As part of the informed consent, risks and benefits associated with positioning should be discussed with the patients.
8. Description of intraoperative positioning techniques and measures taken to prevent injury should be documented in the anesthetic record.
9. Familiarity and understanding of the American Society of Anesthesiologists (ASA) Task Force on Prevention of Perioperative Peripheral Neuropathies may help minimize the problems associated with positioning during the perioperative period.
10. Special attention needs to be paid to minimizing the potential for visual injuries in high-risk patients during the perioperative period.
11. A report by the ASA Task Force on Perioperative Blindness is an excellent source of current information and consensus expert opinion on this devastating problem.

tion initiate reflex responses that usually maintain blood pressure within narrow limits in healthy adults. Ward et al.[1] studied the overall hemodynamic changes during supine positioning and noted that MAP, heart rate (HR), and peripheral vascular resistance decrease whereas cardiac output and stroke volume increase in healthy adults. Although these changes are well tolerated by healthy subjects, an increase in myocardial oxygen consumption is noted in patients with coronary artery disease and poor myocardial function.

Pulmonary In the erect position, breathing normally is a function of muscles of the rib cage. In the supine position, however, muscles of the abdominal wall and diaphragm assume the predominant role. Significant changes in the anatomy of the upper airway and abdominothoracic areas occur in the supine position. These changes affect the cross-sectional area of the upper airway, ventilatory mechanics, and blood flow to the lungs, contributing to significant alterations in lung volumes and ventilation–perfusion matching.[2]

Cephalad displacement of the posterior diaphragm in the awake supine position allows for improved ventilation in basal portions of the lungs. Because regional blood flow in the lungs is determined by the vertical distance of the capillaries from the pulmonary hilum, there is increased perfusion in the basal segments in the supine position. Froese et al.[3] studied regional ventilation in awake spontaneously breathing patients as well as in those who are anesthetized (spontaneously breathing or paralyzed) and concluded that a more uniform ventilation per unit lung volume and an overall improvement of ventilation–perfusion matching occur in the supine position in healthy patients.

Functional residual capacity (FRC) decreases under anesthesia, with most of the reduction occurring immediately after induction of general anesthesia.[4] The relationship between closing volume (CV) and FRC reflects the degree of atelectasis, and therefore hypoxemia, during tidal ventilation. Closing volume (CV) is defined as the fraction of the total lung capacity below which airway closure occurs when external pressures overcome natural elastic recoil.[5] The relationship between CV and FRC in erect and supine patients can be divided into four groups (Fig. 26–1).[6] Craig et al.[6] showed that a conscious patient between the ages of 30 and 40 years can have basilar atelectasis upon assuming the supine position because CV exceeds FRC. Induction of anesthesia exaggerates these changes, which are further pronounced in obese patients and during procedures involving head-down positioning.

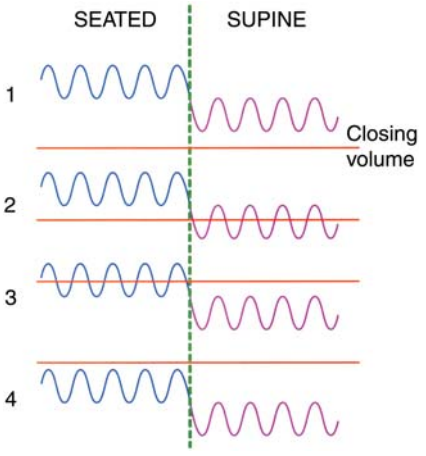

FIGURE 26–1. Classification of subjects into groups (1–4) according to the relationship of closing volume (CV) to functional residual capacity (FRC) in the seated and supine positions. Group 1: FRC › CV in both positions; Group 2: FRC › CV in seated position only; Group 3: CV in the breathing range in seated position and exceeded in supine position; Group 4: CV above breathing range in both positions. (From Craig et al.[6] with permission.)

Complications

Excluding peripheral neuropathies, the main complications in the supine position are backache and ischemic pressure injuries. Pressure point changes and alopecia result from ischemia to the tissues overlying bony prominences and the hair follicles, respectively. These complications can be minimized by maintaining tissue perfusion pressure and adequate padding of pressure points in the dependent regions of the body.

Backache in patients under supine position for long periods results from loss of normal lordotic curvature of the lumbar spine because of reduced tone of paraspinal muscles and ligaments. This problem may be exacerbated in the elderly and in patients with preexisting lower back pain problems or lumbar spinal stenosis. Using the lawn chair position or placing a pillow under the knees in the standard supine position may reduce the incidence of back ache.

Lawn Chair Position This is a modification of the standard supine position in which the lower and upper halves of the body are slightly elevated in relationship to the hips. This position results in improved tissue perfusion and hemodynamic status because of the better balance between the venous return from the lower half of the body and the perfusion pressure gradient to major organs. An additional advantage of this position is the greater degree of abdominal musculature relaxation, which is facilitated by the shortened distance from the xiphoid process to symphysis pubis.[7]

Lithotomy Position

This position is most often used for genitourinary, gynecologic, and colorectal procedures. The standard lithotomy position is achieved when the patient's legs are abducted from the midline, and the hips and knees are flexed so that the lower legs are parallel to the floor. It is prudent that both lower extremities be raised and lowered simultaneously while using this position to avoid rotational stress on the lumbar spine. To minimize the risk of injury to the patient, it is important to understand the advantages and limitations of the various supporting devices (candy cane, knee crutch, calf support, cushioned dorsal boot, adjustable knee and foot support) for the lower extremities. Improper use of these devices can lead to postoperative neuropathies, musculoskeletal strain to the lower spine, and ischemic injuries to the skin and muscles. Because many variations of the lithotomy position are currently used, Martin and Warner have proposed a standardized classification (low, standard, high, hemi, exaggerated, and tilted) to prevent miscommunication among members of the operating team (Figs. 26–2 through 26–7).[7]

Pathophysiology of the Lithotomy Position

The physiology of a patient in the lithotomy position is no different from that of a supine patient except for the physiologic consequences of leg elevation on the central blood volume, the effects of antigravity on tissue perfusion in elevated legs, and the deleterious ventilatory effects of excessive flexion at the hip joints.

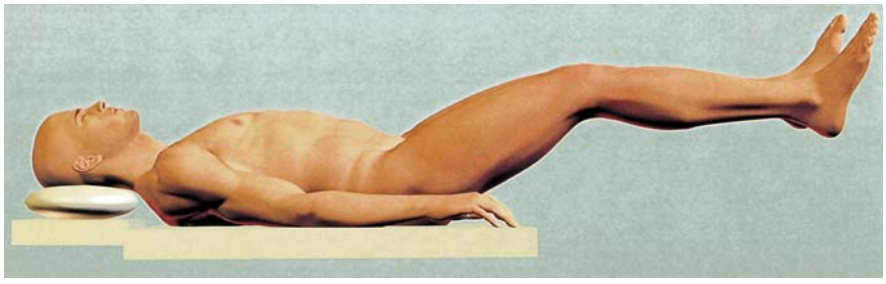

FIGURE 26–2. Low lithotomy position. (Redrawn from Martin and Warner[7] with permission.)

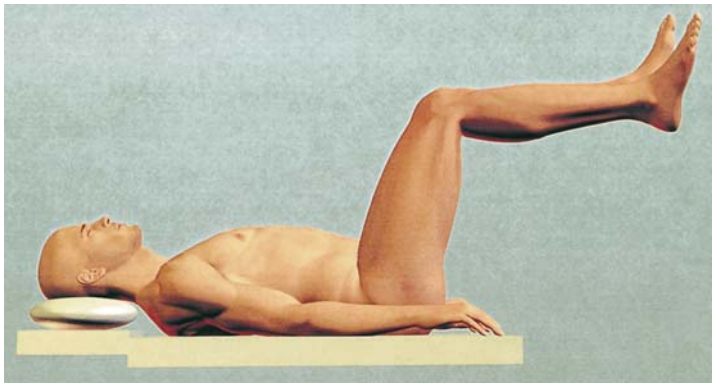

FIGURE 26–3. Standard lithotomy position. (Redrawn from Martin and Warner[7] with permission.)

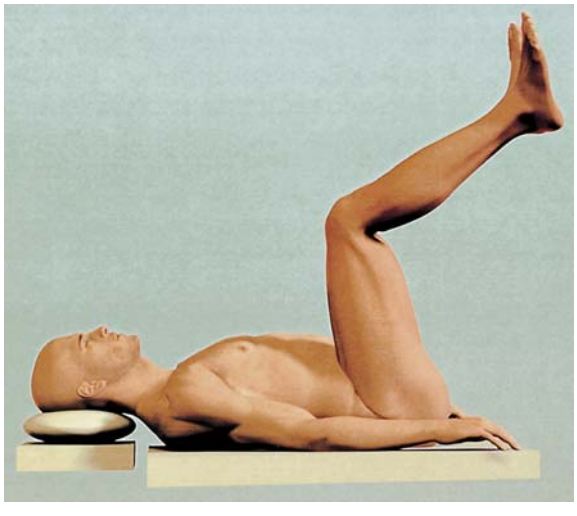

FIGURE 26–4. High lithotomy position. (Redrawn from Martin and Warner[7] with permission.)

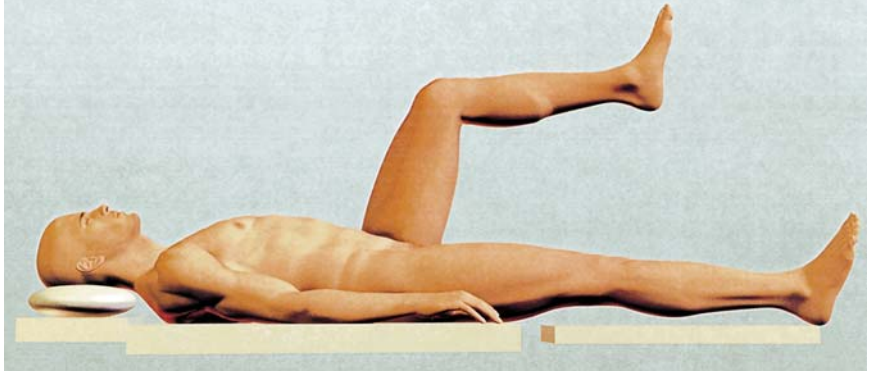

FIGURE 26–5. Hemilithotomy position. (Redrawn from Martin and Warner[7] with permission.)

As the legs are elevated, a significant amount of intravascular volume is added to the central circulation. Normal vascular compensatory reflexes tend to compensate for these transient increases in atrial filling pressures, increased intracranial blood volume, and internal carotid blood flow. In disease states, however, these changes may cause significant alterations to the cerebral and cardiac function. Kopman and Sandza[8] showed that patients with coronary artery disease poorly tolerate head-down tilts >10° and lithotomy position. Because lithotomy position is frequently combined with head-down tilt for improved surgical access, the cardiopulmonary status of the patient must be taken into consideration to minimize cardiac decompensation.

The mean arterial pressure (MAP) at a measurement site varies by 2 mm Hg with each vertical inch above or below the atrium. Enderby[9] clearly demonstrated the variations in MAP with positional changes (Fig. 26–8). This is particularly important in older patients (with peripheral vascular disease, diabetes, and hypertension) when compressive stockings are used and the patient is situated in lithotomy position for a prolonged period. Inadequate perfusion pressure to the lower extremities in such a situation can lead to ischemic complications of the skin and muscles, resulting in skin necrosis and myoglobinuria.

Under general anesthesia, with the assumption of the lithotomy position the tidal volume decreases by 3%. With a 10° head-down tilt, tidal volume decreases another 14%.[10] Although conscious patients usually can compensate and tolerate this change in tidal volume because of improved resting position of the diaphragm, anesthetized patients breathing spontaneously may develop basilar atelectasis and hypoxia. Patients with obesity, hiatal hernia, and gastroesophageal reflux disease may have decreased lower esophageal sphincter tone and barrier pressure, increasing the risk for regurgitation and aspiration of gastric contents in the lithotomy position.

Compartment syndromes have been associated with use of the lithotomy position lasting >5 hours.[11] Anatomic compartments are relatively rigid osseofascial partitions in the extremities comprised of muscles, nerves, blood vessels, and connective and ad-

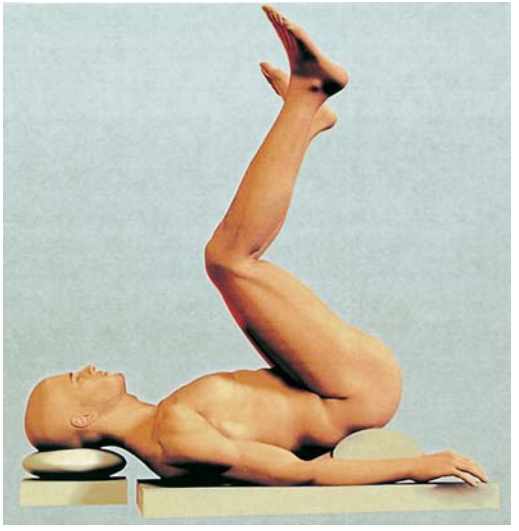

FIGURE 26–6. Exaggerated lithotomy position. (Redrawn from Martin and Warner[7] with permission.)

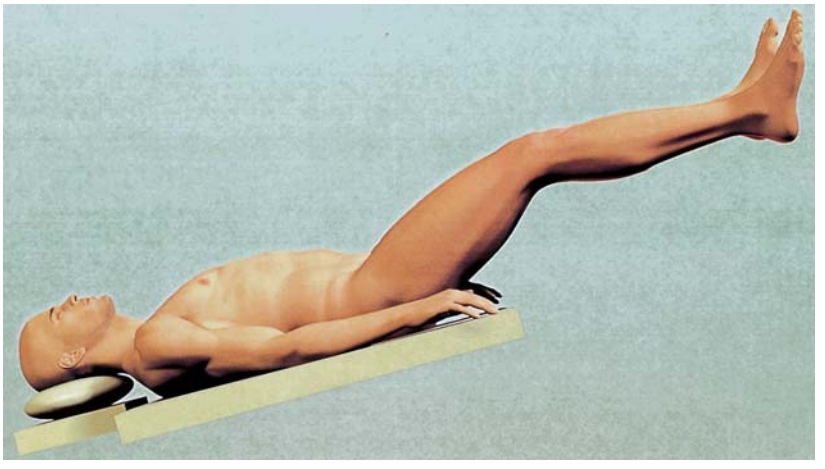

FIGURE 26–7. Tilted lithotomy position. (Redrawn from Martin and Warner[7] with permission.)

ipose tissues. A certain amount of perfusion pressure, 9–15 mm Hg in the lower extremity,[12] is required for normal perfusion of tissues in these compartments. If the pressure in the compartment rises as a result of external forces (dependent pressure, casts, stockings, tight dressings) or internally by edema/bleeding, the vascular driving pressure (MAP) must increase concurrently to prevent ischemic complications. Inadequate tissue perfusion and ischemia of the contents of these compartments lead to varying degrees of injury (endothelial injury, tissue necrosis, and myoglobinuria) that potentially could result in death. Because pain is the most specific symptom for diagnosis of compartment syndromes, a high index of suspicion should be maintained for patients at risk while receiving regional analgesia.

The respiratory complications of the lithotomy position are similar to those of the supine position. The lithotomy position can be an additional factor when diaphragmatic excursion is restricted as a result of excessively flexed thighs or a steep head-down tilt. The duration of the use of the lithotomy position and the body mass index of the patient are reliable predictors for complications pertaining to nerve injuries, respiratory problems, and the compartment syndromes.[11]

Sitting Position

An operative surgical site is intentionally elevated above the level of the heart

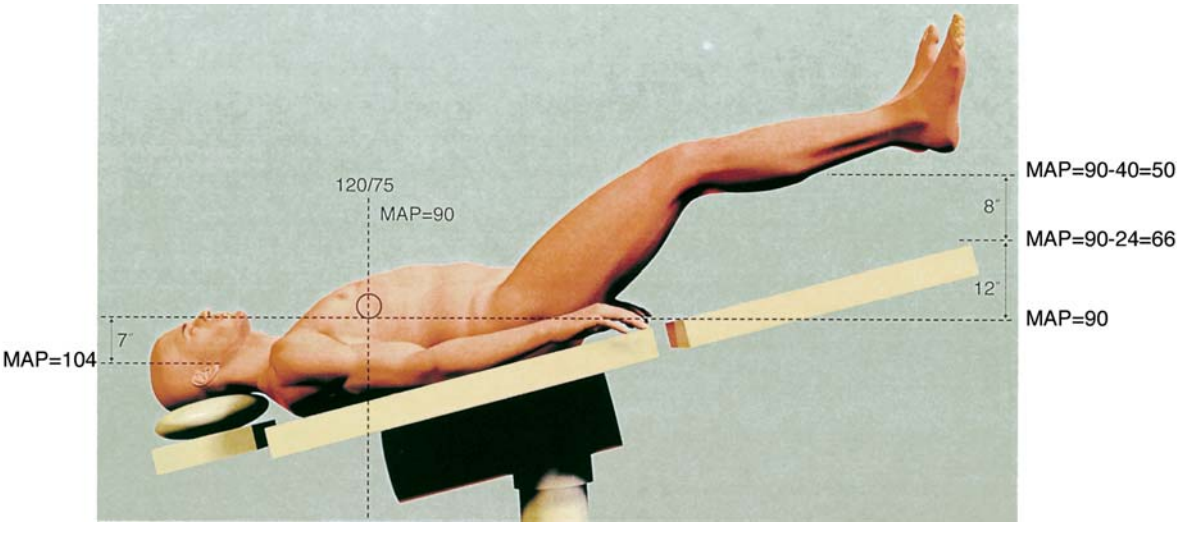

FIGURE 26–8. Effects of gravity on perfusion pressure in the lower extremities in the lithotomy position. MAP, mean arterial pressure. (Redrawn from Martin[11] with permission.)

to decrease bleeding in the operative field and to provide better surgical conditions. Although popular in the 1980s and early 1990s for posterior fossa neurosurgical procedures, sitting position now is commonly used for surgical procedures on the shoulder. Advantages of the sitting position to the anesthesiologist include easier ventilation because of unimpeded diaphragmatic excursion, easier access to the endotracheal tube and airway, unimpeded access to the chest wall for resuscitative measures, and unobstructed view of the face for monitoring cranial nerve function. Disadvantages include the need for a coordinated effort from the operating team (nursing, surgical, and anesthesia) to establish this position safely, hypotension and venous air embolism (VAE), consequences of excessive neck flexion (kinking of endotracheal tube and swelling of face and tongue), nerve injuries, pneumocephalus, and blindness.

Pathophysiology of the Sitting Position

Gravity and anesthetic agents have significant effects on cardiovascular function in the sitting position. In a healthy adult patient, stroke volume and cardiac output are decreased by approximately 12–20%, and cerebral perfusion pressure reduces by 15% without much change in HR.[13]

There is an overall increase in ventilation with increased VC and FRC. However, with positive-pressure ventilation and relative hypovolemia there is reduced perfusion in the nondependent lung fields leading to an increase in physiologic dead space.

During neurosurgical procedures, loss of cerebrospinal fluid (CSF) occurs upon opening of the arachnoid membrane. The loss of CSF allows air to enter the intracranial CSF pathway, leading to pneumocephalus and downward displacement of the brain. Although this gravitation of the brain may be tolerated in most patients, those with thin cerebral mantles may suffer from subdural hematoma.[6]

While positioning the patient, care should be exercised with the following basic principles: maintaining normal body alignment, protecting and padding all pressure points, avoiding placement of rigid oropharyngeal airways and excessive flexion of the neck, exercising care with extremities so that their limits of passive range of motion are not exceeded, establishing final position slowly to allow time for hemodynamic compensation, and exercising extreme caution with the horseshoe frame if used for support of the head (Fig. 26–9).

Complications The frequent and most common complications are related to the hemodynamic and ventilatory effects as described in the section on Lithotomy. Neurologic complications pertaining to neuropathies and blindness are detailed at the end of this chapter.

Venous air embolism The incidence of VAE in posterior fossa surgery in the sitting position is reported to be 41–45% with routine monitoring.[14] However, with the use of Doppler ultrasound the reported incidence is as high as 42–85%.[15] VAE often is clinically undetected and frequently not of serious concern in a healthy patient if the volume and rate of air entrainment are minimal. The amount of entrained air that is reported to be lethal in humans is approximately 300 mL.[16] Children generally have greater clinically significant hemodynamic derangement from VAE than do adults.

Significant morbidity and mortality from VAE is now $<1\%$,[17] predominantly as a result of better monitoring techniques, early detection, and prompt intervention. VAE has significant effects on the cardiopulmonary system, resulting in elevated pulmonary artery pressures, decreased cardiac output, systemic hypotension, and increased dead space ventilation. These physiologic changes result from mechanical effects of obstructed pulmonary blood flow from the air pocket in cardiac chambers and chemical mediator release from air–blood interface. The appearance of dysrhythmias can signal the presence of intracardiac air; therefore, a high index of suspicion is warranted.

Paradoxical air embolus occurs whenever there is a communication between the right and the left sides of the heart. Although left-sided pressures are generally higher than the right, right-sided pressures can exceed the left in pathologic conditions (pulmonary hypertension, pulmonic stenosis) and in healthy subjects during certain phases of the cardiac cycle. Thus, increased right-sided cardiac pressures could result in the appearance of the entrained air in the arterial circulation with its associated complications. Therefore, sitting position is contraindicated in patients with documented intracardiac defects or arteriovenous malformations. Patent foramen ovale is the most common congenital defect associated with a paradoxical air embolus.

Head-Down Tilt Position

The head-down position as introduced by Trendelenburg in the mid-19th century is still routinely used in genitourinary and colorectal procedures. Anesthesiologists also use this position for cannulation of central veins in the upper half of the body. Head-down tilt usually is combined with lithotomy to achieve optimal surgical conditions for genitourinary and colorectal procedures, but this combination has special physiologic consequences of which anesthesia providers must be aware. Steep head-down tilt is frequently used for laparoscopic gynecologic and urologic procedures.

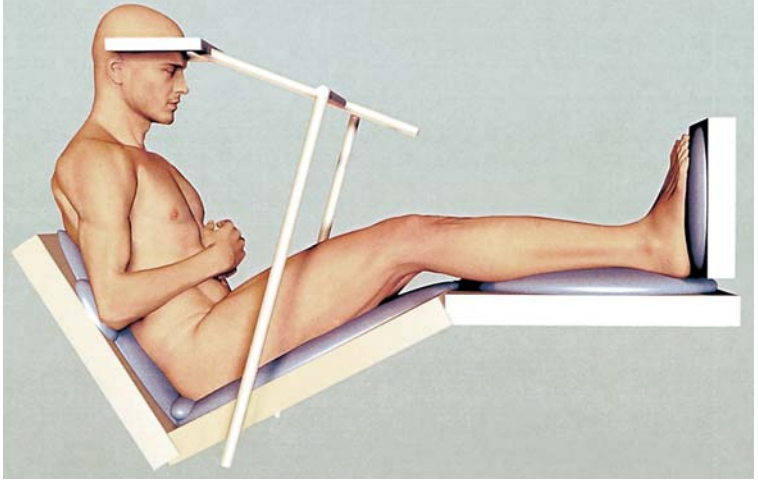

FIGURE 26–9. Sitting position. (Redrawn from Martin and Warner[7] with permission.)

Steep head-down position has significant deleterious effects on the cardiovascular, respiratory, and nervous systems. Although young healthy patients may tolerate this position for short periods without major sequelae, those with obesity, cardiovascular dysfunction, obstructive airway disease, and intracranial pathology may decompensate when placed in this position. Abdominal insufflation exaggerates and adds to the deleterious physiologic effects of this position. Therefore, special attention is needed for laparoscopic procedures in steep head-down tilt position. The earlier custom of head-down position to treat "shock" or hypotension has been disputed by Weil et al.[18] and Sibbald et al.[19]

Pathophysiology of Head-Down Tilt

Upon instituting head-down position, the central blood volume increases by approximately 1000 mL in an adult patient, increasing cardiac output and systolic blood pressure. However, an immediate systemic vasodilatation secondary to reflex barostimulation leads to decreased stroke volume, reduced cardiac output, and diminished perfusion of vital organs. The brain is particularly vulnerable to decreased perfusion (reduced cerebral perfusion pressure) because of increased venous and CSF pressure. Shenkin et al.[20] studied the effects of head-down tilt on cerebral hemodynamics in healthy adults and showed consistent decrease in cerebral blood flow in spite of increased mean carotid pressure. Increased cerebral venous pressure from the head-down position can result in increased intraocular tension, leading to ocular venous thrombosis and retinal detachment. These effects are particularly significant in patients with glaucoma. The occurrence of these complications can be minimized by using a less steep tilt and by decreasing the mean airway pressure.

Sing et al.[21] studied the effects of head-down tilt on hemodynamic indices in hypovolemic postoperative patients in an intensive care unit. All hemodynamic variables and indices were measured supine and at 10 minutes after the head-down tilt position. MAP, pulmonary capillary wedge pressure, and systemic vascular resistance increased, whereas cardiac index, oxygen delivery, and consumption remain unchanged. They concluded that the immediate increase in blood pressure was not accompanied by a similar improvement in tissue oxygenation.

Johannsen et al.[22] studied the cardiorespiratory effects of head-down position and intraperitoneal insufflation in healthy women undergoing elective diagnostic laparoscopies. They reported an approximately 42% reduction in stroke index and cardiac index, a 50% increase in systemic vascular resistance, and no significant changes in HR or MAP. These changes in cardiovascular variables remained abnormal until the patient was returned to the supine position and the abdomen was deflated. Therefore, the anesthesiologist must be particularly diligent in maintaining normal intravascular volume status when this position is used during surgery.

Current literature does not support the use of head-down tilt for treatment of hypovolemic shock. In such a situation, lawn chair position is ideal because it gently elevates the head as well as the legs on torso. The advantage of this position is that cerebral congestion is minimized and peripheral venous return is augmented, thereby augmenting cardiac output and cerebral oxygenation.

Atelectasis occurs when an anesthetized patient is placed in this position. The main reason for atelectasis and hypoxemia is decreased FRC (with induction of anesthesia, increased central blood volume, cephalad displacement of the diaphragm, and the weight of the abdominal contents impeding diaphragmatic excursion). As a result of these changes, increased impedance to the chest wall and lung inflation lead to decreased total compliance and increased work of breathing (if the patient is breathing spontaneously). The cardiopulmonary effects of these changes can be minimized by maintaining intravascular volume, minimizing the time spent in this position, ventilating the patient with larger tidal volumes, and adding positive end-expiratory pressure (PEEP). However, the effects of these ventilatory adjustments on cardiovascular indices and cerebral circulation must be taken into consideration so that oxygen delivery to the brain and vital organs is optimized. Position of the endotracheal tube must be checked frequently when the patient is placed in the head-down tilt position. Cephalad movement of the diaphragm and compression of the lung bases can shift the carina relative to the fixed endotracheal tube, resulting in endobronchial intubation. These changes are exaggerated with abdominal insufflation.

Prone Position

Prone, ventral decubitus, or ventral recumbent position is a posture in which the patient is resting "face down" upon the operating table. The prone position may be comfortable and even common for some individuals during normal sleep. However, when anesthetized in this position, potential complications can result from loss of active reflexes that normally protect from atelectasis, compressive ischemia, and skeletal stress (Figs. 26–10 and 26–11).

In the classic or horizontal prone position, the patient lies face down, resting on the ventral aspects of the

FIGURE 26–10. Prone position. (Redrawn from Martin and Warner[7] with permission.)

FIGURE 26–11. Prone position. (Redrawn from Martin and Warner[7] with permission.)

torso with legs extended and arms raised beside the head or tucked alongside the body. Care should be exercised during positioning of the arms to avoid stretch injury to the neurovascular structures. In the former position (arms raised beside the head), the shoulders and forearms should be ventral to the horizontal axis of the torso. In the latter situation (arms tucked beside the torso), excessive elevation or drooping of the shoulders should be avoided. In all variations of this position, pressure points (e.g., nipples and genitalia) should be carefully padded and care exercised to avoid any compressive ischemic injury. The patient's torso usually is bolstered or supported to avoid abdominal compression (to minimize undesirable effects on ventilation, venous return, and engorgement of epidural venous plexus) and to allow unimpeded chest wall expansion with ventilation. It is vital that the patient's face (eyes, tip of the nose), mouth, and endotracheal tube be visualized and accessible at all times.

The operating room table is generally angled or varied (crouching or kneeling) from the classic prone position when used to straighten the spine or decrease the lumbar lordosis for procedures on the dorsal lumbar spine. Numerous devices, such as the Tarlov seat, Andrews frame, and Hastings frame, are also used to help position the patient for surgical procedures on the dorsal spine. Each of these devices has the potential to cause further injury if care is not exercised during positioning and securing of the patient. Coordinated team effort during positioning and constant vigilance throughout the procedure is vital to minimize the risk of injury. It is extremely important to be diligent in supporting the head and to avoid any injury to the face during the prolonged spine procedures. Various devices for head support are commercially available. Some have a mirror attached to the base that allows visualization of the face at all times. Irrespective of the device used, it is the constant vigilance and monitoring of dependent areas and pressure points that may prevent any potential ischemic injury. It is widely believed that the most stable holder for the prone head is the three-pin C-shaped skull fixation frame. Patients with an unstable cervical spine must be managed in such a manner so that spinal cord function during and after the positioning process can be monitored.

The prone jackknife position is often used for anorectal surgery. The patient is first placed prone, and all pressure points are padded. The patient is situated on the table such that when the table is anteflexed the apex of the inverted "V" is at the patient's inguinal region. The final position must be achieved in graded steps to avoid sudden hypotension from venous pooling in dependent lower extremities and venous compression in the groin. A supportive pad usually is placed beneath the pelvis to prevent direct compression to the neurovascular bundle in the inguinal region. Care should be exercised in securing the patient after the desired position is achieved.

The anesthesia team should have a plan to manage the ventilation, invasive monitoring catheters and cables, intravenous lines, ostomy bags, and urinary catheter during the positioning process.

Pathophysiology of the Prone Position

It is unusual for a healthy adult patient to have significant hemodynamic disturbances during the positioning process if major venous compression is avoided. However, if pressure is exerted on the major vessels (aortocaval and iliac compression), decreased venous return leads to decreased cardiac output. In the presence of abdominal compression (compression of inferior vena cava), blood from the lower half of the body is diverted through other (perivertebral, intercostal, and lumbar veins) low-pressure venous systems to the right atrium, leading to congestion of vertebral venous plexuses. Engorgement of venous plexuses can lead to increased blood loss during surgical procedures on the spine if positioning is not optimized. Hemodynamic effects of the commonly used supporting devices in the prone position have been studied by various authors. The single most important factor that is consistently shown to have deleterious effect on hemodynamic function is the effect of the device on abdominal and thoracic compression.

Douglas et al.[23] showed an increase in FRC and arterial oxygen partial pressures with no change in respiratory mechanics after patients were placed prone and properly positioned. The relationship between transpulmonary and airway opening pressures is an important factor in determining the degree of atelectasis. In the supine position, transpulmonary pressures are less than airway opening pressures, leading to atelectasis in the dorsal lung units. Lamm et al.[24] showed that, in the prone position, the transpulmonary pressure generated in the dorsal lung units exceeded the airway closing pressures in dogs subjected to oleic acid–induced acute lung injury. This may explain the transient improvement in oxygenation in the prone position by increased homogeneity in the gravity-dependent ventilation–perfusion ratios in the dorsal lung regions without adversely affecting ventral lung regions.

No significant changes in cerebral hemodynamics occur if the head of the healthy prone patient is at the level of the heart and is not laterally flexed or rotated. If the head is positioned below the level of the heart in a healthy patient, cerebral blood pressure and vascular resistance in the carotid arterial system increase proportionally to maintain constant perfusion pressure and blood flow. In the presence of intracranial pathology, cerebral autoregulation is impaired; therefore, the patient's head should not be positioned below the level of the heart to prevent a pressure-dependent (gravity-induced) increase in cerebral blood flow. Severe rotation ($>60^\circ$) of the head and neck can have significant deleterious effects on the flow patterns in cerebral circulation. Complete obstruction of the contralateral vertebral blood flow with rotation of the head $>80^\circ$ in humans has been reported.[25] Care must be exercised during rotation of the head because patients can have significant asymptomatic occlusive cerebral vascular disease and/or congenital variations in cerebral vascular anatomy (circle of Willis). Exaggerated rotational movements in such situations can compromise blood flow in the region of the vertebrobasilar systems, leading to neurologic dysfunction.

Other complications related to prone postioning include injury to the eyes, ocular edema and blindness, compressive ischemic injuries to facial structures, compartment syndrome, VAE, breast and genital injuries, thoracic outlet syndrome, neuropathies, ostomy injuries, and hypothermia.

Lateral Decubitus Position

Lateral decubitus positions are described as right or left, depending on

the side of the body on which the patient lies. For example, patients are said to be positioned in right lateral decubitus position when they lie with their right side down.

In the classic lateral decubitus position, the patient is positioned on the side with his/her back perpendicular to the surface of the table. The head is supported such that the cervical spine is properly aligned with the rest of the body, and a supportive device (axillary roll or chest pad) is placed under the dependent thorax just caudad to the axilla to prevent compression and injury to the axillary neurovascular bundle. The dependent lower extremity is flexed at the hip and knee joints, and the nondependent leg is straightened in such a manner that the pelvis is stabilized and ventral tilt (forward roll) of the torso is avoided. Adequate padding is ensured to protect all the pressure points (pillow between the legs, foam for the dependent greater trochanter, fibular head and lateral malleolus) of the lower extremities. The dependent arm is flexed and supported on a padded arm board while the nondependent arm is slightly abducted and flexed at the shoulder and elbow joints such that the scapula is drawn away from the thorax (Fig. 26–12). Once the patient is positioned optimally, care should be exercised to avoid injuries related to restraint devices (bean bag, hook and loop straps).

The "kidney position" is a variation of the lateral decubitus position that is commonly used for renal procedures. In this version of the lateral decubitus position, the patient's dependent ilium is placed over the flexion point between the torso and thigh sections of the table. The table is then flexed, and the transverse elevating bar of the table (kidney bar) is raised until the lateral flexion has caused the muscles of the upper flank to become tight. During and immediately after the final position, all measures must be taken to avoid inferior vena caval and dependent rib cage compression.

Pathophysiology of the Lateral Decubitus Position

For the most part, the lateral decubitus position has minimal effects on major organ function when the patient is carefully positioned.

Sudden postural changes are poorly tolerated by deeply anesthetized and hypovolemic patients because of dose-dependent depression of carotid and baroreceptor function under general anesthesia. Gentle changes in position with frequent monitoring of blood pressure is indicated in elderly, hypovolemic, and hypertensive patients. Mediastinal shift to the dependent hemithorax and rotation of the heart on its longitudinal axis in the lateral position could impair venous return and decrease cardiac output. Impediment of venous return usually is not a problem except in lateral jackknife (venous pooling in lower extremities) or kidney positions (caval compression). The right lateral decubitus position appears to have greater propensity for caval compression and reduced venous return with kidney rest because of the closer proximity of the vena cava to the right flank.

Vital capacity in normal awake subjects decreases by a comparable 10% in the lateral and supine positions compared to the erect posture. The kidney position can decrease the vital capacity by another 5–10%. Most of this decrease is thought to result from reduced movement of the ribs and diaphragm. Although vital capacity and FRC are reduced, better ventilation–perfusion matching results from increased perfusion in the dependent lung and corresponding increase in ventilation from the stretched dependent hemidiaphragm. However, general anesthesia with or without spontaneous ventilation in the lateral decubitus position causes an increased mismatch in ventilation–perfusion ratios compared to that in awake subjects. This is further complicated by the institution of paralysis and mechanical ventilation, addition of PEEP, opening of the pleura in thoracic procedures, pathologic processes in the dependent and nondependent lung, and use of medications (vasodilators) that affect hypoxic pulmonary vasoconstriction.

Complications from the lateral decubitus position include pressure injuries (ischemic), muscular and ligamentous strain, whiplash-like injury to the cervical spine, neurologic injuries, and ocular complications (corneal abrasions, pressure effects, dependent edema, and blindness).

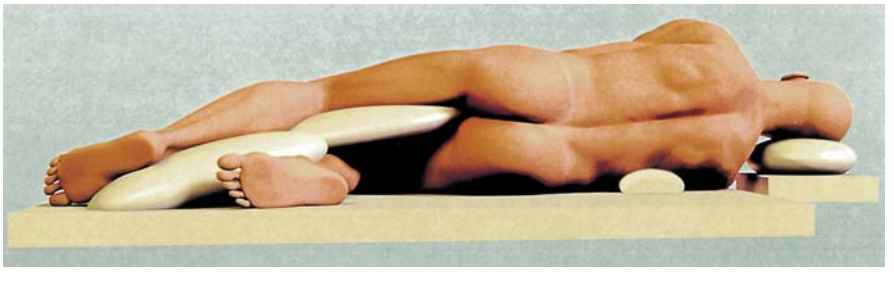

FIGURE 26–12. Lateral decubitus position. (Redrawn from Martin and Warner[7] with permission.)

Nerve Injuries Associated with Positioning

Perioperative peripheral nerve injuries are a significant source of morbidity for the patient and unfortunately will be encountered by even the most conscientious anesthesia provider. It is the second most common cause (after death) of professional liability among anesthesiologists, accounting for 16% of claims in the ASA closed claims database.[26] The claims secondary to nerve injuries have steadily increased in the last decade, and unfortunately the relationship between current conventional perioperative care with positioning and development of postoperative nerve injury is poorly understood.

Injuries to the ulnar nerve, brachial plexus, and lumbosacral roots account for most of the claims, with ulnar being the most commonly reported nerve injury during the perioperative period. Cited mechanisms for nerve injury during the perioperative period include compression, stretch, ischemia, direct trauma, and laceration. Although injuries to the brachial plexus and lumbosacral roots may be secondary to stretch or compression with malpositioning of the patient, those to ulnar nerve usually are unexplained and often puzzling. Ulnar nerve injury may occur despite protective padding and careful positioning. In fact, 27% of cases of ulnar nerve injury in the ASA closed claims database occurred despite documentation of adequate padding at the elbow.[26]

A retrospective review from the Mayo Clinic reported a 0.04% incidence of persistent ulnar neuropathy in noncardiac surgery, with 9% of

reported injuries in this study being bilateral.[27] Initial symptoms in most cases were noted only after a 24-hour period, and the distribution of sensory-only and mixed sensory and motor loss injuries was equal. More recent prospective data from the same authors report a higher incidence (approximately 0.5%) of perioperative ulnar neuropathies.[28] The incidence may be even higher in patients undergoing cardiac surgery. The most consistent risk factors appear to be male gender, prolonged hospitalization, and extremes of body habitus.[27] Morell et al. reported significant changes in ulnar nerve sensory thresholds with elbow flexion in human volunteers. In the flexed position, nearly all volunteers reported ulnar nerve paresthesias. All the volunteers reporting paresthesias had a significant increase in C fiber sensory threshold without any change in either Aα or Aβ fiber function. It could be that most hospitalized patients spend a considerably greater time with their elbows flexed, accounting for the finding that prolonged hospitalization is an independent risk factor for nerve injuries. Prielipp et al.[29] studied the effects of arm positioning on the pressure exerted at the elbow. They showed that the pressure exerted over the ulnar nerve was greatest when the forearm was pronated. It was also noted that up to 50% of male volunteers who experienced pressure on the ulnar nerve sufficient to impair electrophysiologic function did not perceive concurrent paresthesia in that nerve distribution. Thus, a significant number of male patients could be at increased risk for failure to respond to potentially damaging compression injury over the ulnar nerve during the perioperative period. An additional risk factor may be the sedated state of patients in the immediate postoperative period as a result of residual effects of anesthetics and narcotic medications.

Injury to the brachial plexus is the second most common perioperative nerve injury, with an estimated incidence of 0.2–0.6%.[30] The anatomy of the brachial plexus—long and mobile course of its components through the limited space between the first rib and the clavicle—makes it susceptible to stretch and compressive injury. Careful attention to arm positioning during supine position (abduction $<90^{\circ}$), steep head-down tilt (avoiding shoulder braces for support), prone positioning (avoiding improper placement of chest roll and positioning of arms), and lateral decubitus position (properly placed axillary roll) can help minimize the risk of injury.

Perioperative lower-extremity neuropathies have a clearer relationship with positioning when compared to upper-extremity nerve injuries. Warner et al.[31] reported an overall 1.5% incidence in all patients undergoing surgery in the lithotomy position. The risk increases with the duration (>2 hours) in the lithotomy position, and almost all of the reported injuries were sensory in nature. Paresthesia in the affected nerve distribution was the most common complaint. Symptoms in all of their patients were noted within 4 hours. The obturator was the most commonly affected nerve, with lateral femoral cutaneous, sciatic, and peroneal nerve injuries following in order. Sciatic nerve injury is most common after lithotomy positioning or some variant of it. Hyperflexion of the hip with extension at the knee along with external rotation of the thigh during positioning of the legs can produce excessive stretch of the sciatic nerve and result in injury. The common peroneal nerve is particularly vulnerable to compression injury because it wraps around the head of the fibula. Femoral neuropathy is more commonly associated with surgical factors, although ischemic injury could result from extreme abduction and external rotation of the thighs during lithotomy positioning.

Anesthesiologists should be familiar with and follow the recommendations of the ASA practice advisory for prevention of perioperative neuropathies (Box 26–1). For particularly long procedures, consideration should be given to minimizing the time spent in a position that amplifies physiologic perturbations or injury to the patient. It may be advisable to look for and document symptoms of nerve dysfunction preoperatively in high-risk patients (those with risk factors for perioperative neuropathies or those coming for high-risk surgery, i.e., long procedures or surgical positions at risk for injury). A description of the intraoperative positioning and measures taken to prevent injury should be documented in the anesthetic record at the beginning of the procedure and thereafter on a regular basis.

Visual Injury

Postoperative visual complications constitute a broad group ranging from temporary loss of visual acuity to devastating permanent loss of visual function. Corneal abrasions, periorbital and conjunctival edema, ocular hemorrhage, vitreous loss, retinal detachment, central retinal artery occlusion, and ischemic optic neuropathy are the range of complications that are encountered in the perioperative period.

The reported incidence of perioperative visual injury varies widely (< 0.06–25.6%). The American Association of Nurse Anesthetists (AANA) Foundation closed malpractice claims study[32] reports an incidence of 3.3%, and the ASA closed claims analysis[33] reports a similar 3.47% for all types of eye injury. In both closed claims projects, corneal abrasions are the most common complications encountered. Patient movement, chemical irritation from prep solutions, direct trauma from face mask, pressure from the laryngoscopic blade, pressure effects on the globe from lateral and prone positioning, prolonged procedures on the spine in prone position, intraoperative hypotension, and anemia all have been implicated as the reasons.

Lateral, prone, and Trendelenburg positions increase the risk for visual complications during the perioperative period. In all these positions, venous pressure in the eye can increase from direct pressure, edema, and/or stasis, leading to decreased choroidal perfusion and increased risk for ischemic optic neuropathy. Other associated factors for visual complications during the perioperative period include prolonged operations on the spine, large-volume blood loss, significant decreases in hemoglobin levels, and intraoperative hypotension. Contributing patient comorbid conditions include hypertension, diabetes, obesity, smoking history, hypercholesterolemia, alcohol abuse, atherosclerosis, anemia, Graves disease, and renal transplantation.[34] Shaw et al.[35] reported that 40 of their 312 patients scheduled for coronary artery bypass grafting procedures had preexisting ophthalmologic abnormalities on examination. Currently, preoperative screening ophthalmologic examination of surgical patients to predict postoperative visual complications is not common practice.

BOX 26–1.

Summary of ASA Task Force Consensus on Prevention of Perioperative Peripheral Neuropathies

Preoperative assessment
- When judged appropriate, it is helpful to ascertain that patients can comfortably tolerate the anticipated operative position.

Upper-extremity positioning
- Arm abduction should be limited to 90° in supine patients; patients who are positioned prone may comfortably tolerate arm abduction >90°.
- Arms should be positioned to decrease pressure on the postcondylar groove of the humerus (ulnar groove). When arms are tucked at the side, a neutral forearm position is recommended. When arms are abducted on armboards, either supination or a neutral forearm position is acceptable.
- Prolonged pressure on the radial nerve in the spiral groove of the humerus should be avoided.
- Extension of the elbow beyond a comfortable range may stretch the median nerve.

Lower-extremity positioning
- Lithotomy positions that stretch the hamstring muscle group beyond a comfortable range may stretch the sciatic nerve.
- Prolonged pressure on the peroneal nerve at the fibular head should be avoided.
- Neither extension nor flexion of the hip increases the risk of femoral neuropathy.

Protective padding
- Padded armboards may decrease the risk of upper-extremity neuropathy.
- Use of chest rolls in laterally positioned patients may decrease the risk of upper-extremity neuropathies.
- Padding at the elbow and at the fibular head may decrease the risk of upper- and lower-extremity neuropathies, respectively.

Equipment
- Properly functioning automated blood pressure cuffs on the upper arms do not affect the risk of upper-extremity neuropathies.
- Shoulder braces in steep head-down positions may increase the risk of brachial plexus neuropathies.

Postoperative assessment
- Simple postoperative assessment of extremity nerve function may lead to early recognition of peripheral neuropathies.

Documentation
- Charting specific positioning actions during the care of patients may result in improvements of care by (a) helping practitioners focus attention on relevant aspects of patient positioning; and (b) providing information that continuous improvement processes use can lead to refinements in patient care.

From Practice advisory for the prevention of perioperative peripheral neuropathies: a report by the American Society of Anesthesiologists Task Force on Prevention of Perioperative Peripheral Neuropathies. Anesthesiology 2000;92:1168–1182. Reprinted with permission of publisher.

Therefore, it is imperative for anesthesia providers to be highly cognizant of the potential for visual complications in high-risk patients. Anesthesia providers should pay special attention to avoid pressure effects on the globe and to maintain adequate oxygen delivery to the optic disk and retinal structures. A report by the ASA Task Force on Perioperative Blindness is an excellent source of current information and consensus expert opinion on this devastating problem (approved by the ASA house of delegates October 2005).[36]

CHAPTER 27

Electricity, Electrical Safety, and Instrumentation in the Operating Room

Robert H. Stiefel, MS and
Julian M. Goldman, MD

The role of technology in medicine has steadily increased during the past few decades, and there is every indication that this will continue. Most of this technology has been in the form of new electronic equipment. Safety has sometimes been overlooked; at other times, specific aspects of safety (notably, electrical safety) are overemphasized. This chapter describes the principles and practices of the safe use of medical equipment.

The safe use of modern medical technology depends first on an understanding of the operating principles of the technology. An understanding of electrical hazards also is necessary to operate electrical equipment safely. Such knowledge is based on an understanding of electricity and electronics. The first section of this chapter reviews the basic concepts of electricity and electronics. The second section of this chapter describes and explains the hazards of medical equipment use.

Standards and regulations for the use of medical equipment have been promulgated to avoid hazards to patients and personnel. The third section of this chapter describes the organizations that set standards, tells how and why they develop standards and gives an overview of some more important standards. From this information it becomes clear that proper use of standards is to provide safe, and safe use of, medical technology.

These three sections of this chapter provide the basis for development of an equipment safety program. The need to understand and apply electrical engineering principles to analyze and avoid equipment hazards, and to apply equipment safety standards, has spawned a new profession in heathcare known as *clinical engineering.* This field, practiced by biomedical and clinical engineers and technicians in hospitals, is described in the fourth section. This section concludes with a discussion of *technology management*—the term used to describe the involvement of clinicians, engineers, and administrators in planning and implementing the use of medical technology in the most effective manner.

An understanding and respect for the safe use of medical equipment is particularly important for anesthesiologists. Of the major disciplines of modern medicine, none depends more on technology for direct patient care and safety than does anesthesiology. Many of the devices used at the bedside for diagnosis and treatment of patients were developed first in the operating room by anesthesiologists. Anesthesiologists use the widest variety of medical equipment and routinely use it in the most precarious situations of any of the medical disciplines.

ELECTRICITY

Current is the flow of electric charge, with electrons being the most common charge carrier. The unit of measure of current is the *ampere* or amp, abbreviated A. One ampere is the flow of 1 coulomb per second, and 1 coulomb is 6.2420×10^{18} units of electric charge. An electron has one unit of negative electric charge. The symbol for current is I; the symbol for charge (in coulombs) is Q.

Voltage, also called *potential difference* or *electromotive force* (EMF), is the amount of potential energy available to move electrons (i.e., available for work). It also is the difference in potential energy between two points caused by differences in electrical charge or the energy released when electrons move from higher to lower potential. The unit of measure of voltage is the volt, and the symbol for voltage is V (or sometimes E). One volt represents the amount of power or work per unit of time to move 1 coulomb. The zero potential reference point is called *ground* or *earth.* Besides being a reference point, ground plays a major role in electrical safety. Hazard currents can be safely drained by connection to ground, as will be discussed later.

A *conductor* is a material through which electrons move easily (e.g., copper), and an *insulator* is a material through which electrons move poorly (e.g., glass). A *semiconductor* is a material that normally is an insulator but acts like a conductor when certain conditions are met (e.g., silicon crystals with a particular impurity added).

Direct Current

Direct current (DC) is unidirectional current and is constant in magnitude. Batteries provide a constant DC. By convention, the direction of current is from the more positive to the more negative voltage (Fig. 27–1). This was based on a guess by Benjamin Franklin when he needed to assign algebraic signs in equations describing electrical

KEY POINTS

1. Hazards to patients from medical equipment include fibrillation and burns, equipment failure, and misuse. Electrical safety concerns originating in the 1960s have led to the development of safety and performance standards, improved equipment designs, and in-house clinical engineering programs.
2. Medical equipment standards are promulgated by a variety of national and international organizations. Understanding and complying with these standards requires clinical engineering expertise.
3. Clinical engineering departments in hospitals help to ensure the safety and performance of medical equipment by providing evaluations, testing, maintenance, and training programs.
4. Safe and effective use of medical equipment involves the cooperation of clinicians, administrators, support staff, and manufacturers. A clinical engineer usually is best able to orchestrate these efforts.
5. A hospital-wide technology management program combines individual equipment programs and improves efficiency and quality.

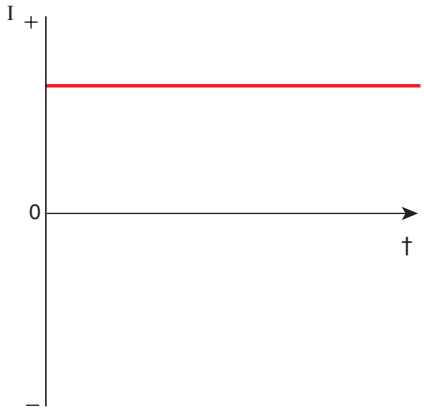

FIGURE 27–1. Direct current.

charges and forces. Unfortunately, his guess was incorrect. Electrons actually flow from negative to positive, opposite to the convention for current that was accepted before the discovery of electrons.

Resistance is the opposition to the flow of current. The unit of measure of resistance is the ohm, abbreviated Ω, and the symbol for resistance is R. A *resistor* is an electrical component designed to provide a specific value of resistance. Voltage, current, and resistance are related by Ohm's law, which states that voltage is directly proportional to current and to resistance (Fig. 27–2).

Power is work per unit time or the rate at which electrical energy is used. Its unit of measure, the watt (abbreviated W), is equivalent to 1 joule per second. The symbol for power is P, and it is calculated P equals IV equals I^2R.

Alternating Current

Alternating current (AC) differs from DC in that its polarity reverses periodically. As a result, its magnitude is constantly changing. A cycle is one complete wave pattern (from 0–A in Fig. 27–3). A *period* is the time of one cycle. The average value of AC for one period is zero. *Frequency* (f) is the number of cycles per second (cps) and is the inverse of the period. The unit of measure is the hertz, abbreviated Hz. By definition, 1 Hz is equal to 1 cps. There are 360° in one cycle, and the *phase* is the number of degrees between two AC waveforms at the same time.

Ohm's law (for direct current):

$V = I \times R$

where V = voltage (volts)
I = current (amps)
R = resistance (ohms)

FIGURE 27–2. Ohm's law (for direct current).

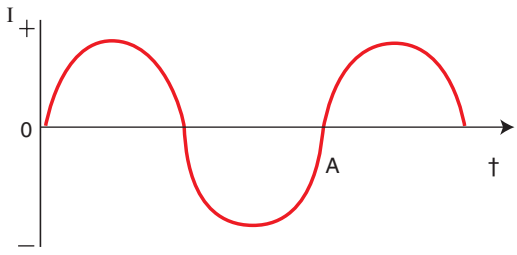

FIGURE 27–3. Alternating current.

Common household voltage (that available at electrical receptacles in the home) and the voltage at most hospital receptacles is nominally 120 volts AC (VAC) and has a 60-Hz sinusoidal waveform (period of 16.7 ms). (In most of Europe, Asia, and Africa, 50 Hz and 220 V are used.) The voltage given is the root mean square (RMS) value, which is 0.707 ($1/\sqrt{2}$) of the peak value or 0.354 of the peak-to-peak value of the voltage waveform (Fig. 27–4). The RMS value of AC voltage provides the same wattage as the same value of DC voltage. DC and AC are additive. Combinations of DC and AC can make virtually any desired waveform. Conversely, any electrical waveform can be described as a series of sine waves, each at a single frequency; this technique is called *Fourier analysis.*

AC adds a number of refinements (or complications) to the management of electricity. In contrast to DC, resistance is no longer the only opposition to AC. *Reactance* is the opposition to current that varies with frequency (resistance is constant). Together, resistance and reactance are called *impedance.* Impedance is measured in ohms, but its symbol is Z. *Reactance* also is composed of two parts: capacitive reactance and inductive reactance. Reactance has the symbol X; capacitive reactance is X_C, and inductive reactance is X_L. Impedance is calculated as follows:

$$Z = R^2 + (X_L - X_C)^2,$$

and Ohm's law becomes:

$$V = I \times Z.$$

A *capacitor* is an electrical component designed to provide a specific value of capacitance, which is the property of storing separated charges when a voltage is present between conductors. In construction, a capacitor is two conductive plates separated by an insulating material called a *dielectric.* The symbol for capacitance is C. Capacitance is measured in farads, abbreviated F. More often, values are given in microfarads (microfarads = μF, although mF also is used). Capacitance is related to current and voltage by the following formula:

$$I = C\,[dV/dt].$$

An *inductor* is an electrical component designed to provide a specific value of inductance, which is the property of a varying electric current to induce a voltage in a circuit. An inductor is a coil of wire, often around a metallic core. The symbol for inductance is L, and the unit of measure is the henry, abbreviated H. Inductance is related to current and voltage by the following formula:

$$V = L\,[di/dt].$$

An important application of inductance is in transformers. A transformer is constructed by placing two coils close to each other. An AC source is applied to one coil, and a current is induced in the other. Voltage can be

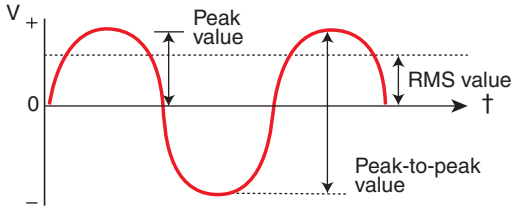

FIGURE 27–4. Root mean square (RMS) voltage.

adjusted up or down by selecting the ratio of turns of wire in the two coils:

$$V_1/V_2 = N_1/N_2,$$

where N is the number of turns of wire (Fig. 27–5). AC is used for transmission from electrical generators because transformers can convert AC voltages but not DC voltages. Increasing and decreasing high voltages is practical only with transformers. High voltage is more efficiently transmitted over long distances. If current is cut in half, the voltage must be doubled to transmit the same power (recall that P = IV). This reduces the power loss in the transmission lines to one quarter (I^2R, where R is the resistance of the transmission line).

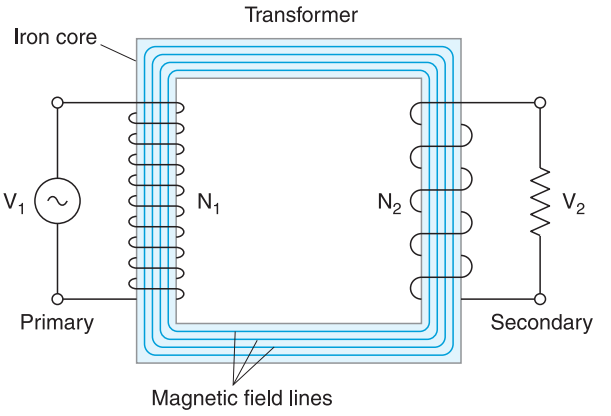

FIGURE 27–5. Example of a transformer.

AC versus DC

Sixty hertz was chosen for AC frequency for engineering reasons. Transformers work efficiently at 60 Hz. At higher frequencies, transmission losses increase. At lower frequencies, lights would flicker perceptibly. Unfortunately, 60 Hz also is in the middle of the range of frequencies to which muscles and nerves are most susceptible (see Hazards of Electricity below).

An interesting historical note on the selection of AC rather than DC involves William Kemmler, the first man legally electrocuted.[1]

In 1879, Thomas Edison invented the electric light. He then developed a DC distribution system, most of which was installed in the 1880s. George Westinghouse developed an AC distribution system late in the 1880s. Edison and Westinghouse waged an economic battle over whether AC or DC would become the standard for electrical distribution systems. The advantage of AC was that it could be transmitted at a high voltage for long distances without the unacceptably high losses that AC and DC suffer at low voltage, and then it could be dropped to a lower, safer voltage with a transformer for local distribution. Edison and others could show that AC was more dangerous. In animal experiments, AC voltages of 200 V were lethal, but DC was relatively safe at that level.

On June 4, 1888, Governor David Hill of New York signed a law making electrocution the method of execution for capital crimes committed after January 1, 1889. Electrocution had been selected by a commission assigned the task of finding an effective, humane means of execution to replace hanging. In March 1889, an electrical engineer, Harold Brown, was contracted to provide execution systems for the Auburn, Sing Sing, and Clinton prisons. Brown previously had published reports on the dangers of AC and the comparative safety of DC. He naturally chose Westinghouse AC generators, although he had to purchase them used because Westinghouse tried to prevent him from obtaining them (Westinghouse did not want his name associated with electrocution). The first system was installed in Auburn state prison in central New York State in June 1889.

Meanwhile, on March 29, 1889, in Buffalo, New York, William Kemmler killed his girlfriend after a drunken argument. On May 10, a jury found him guilty, and on May 14, he was sentenced to death by electrocution. Kemmler's attorney appealed on the grounds of cruel and unusual punishment. Hearings were conducted in New York City and Buffalo during July 1889. The defense attempted to prove that death by electric current was uncertain because people recovered after being struck by lightning. Brown testified on behalf of the State, describing his electrocution experiments on animals. Edison also was called by the State to testify. He opined that death by electrocution should be instantaneous. Kemmler's appeals ultimately were denied, and he was electrocuted on August 6, 1890.

Circuits

A *circuit* is any connection of electrical components. A *complete circuit* is one that starts and ends at the same point and is required for current to flow (Fig. 27–6). A *series circuit* has two-terminal components connected end to end, and the total current in the circuit passes through each component (i.e., the current is constant through a series circuit). If one light bulb in a series of bulbs burns out, they all go dark. A *parallel circuit* has two-terminal components connected side by side. The current divides between the components, but the voltage drop across each component is the same (i.e., the voltage is constant across a parallel circuit; Fig. 27–7). If one light bulb in a parallel circuit burns out, the others will be unaffected.

Semiconductors

Electricity becomes more interesting and useful—and more complicated—with semiconductors. Resistors, capacitors, and inductors are two-terminal,

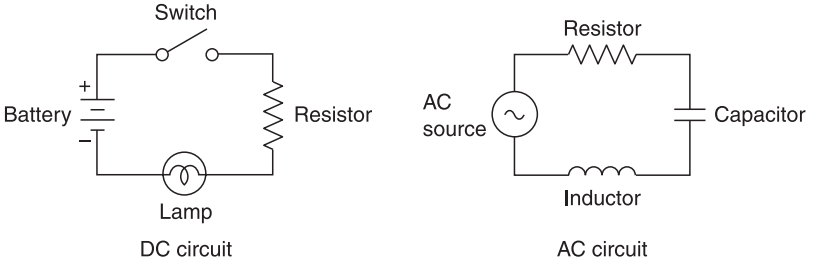

FIGURE 27–6. Direct current (DC) circuit and an alternating current (AC) circuit.

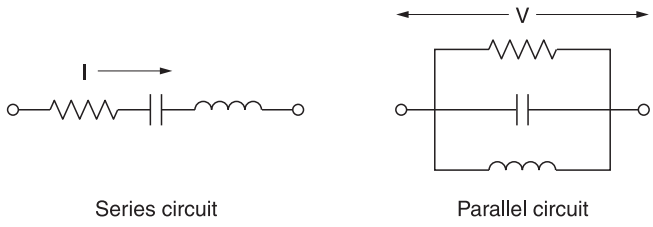

FIGURE 27–7. Series and parallel circuits.

linear, passive devices. In a linear device, a change in the input signal produces a proportional change in the output signal. A passive device is one with no built-in power source. A junction diode is the simplest semiconductor. It is a two-terminal, passive component, but it is nonlinear. It allows current in one direction and blocks current in the other Fig. 27–8). This characteristic is used to convert AC to DC—*rectification.* A *zener diode* is a diode that can conduct in the reverse direction when a sufficiently large reverse voltage is applied (Fig. 27–9). This voltage is called a *zener point,* and a zener diode is used as a voltage regulator, which establishes a fixed voltage.

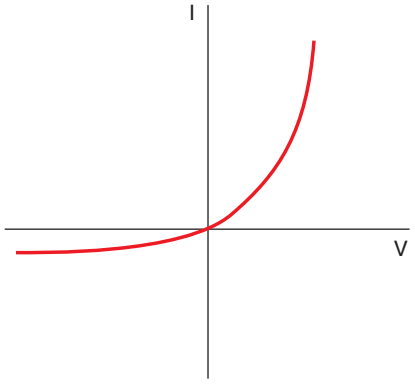

FIGURE 27–8. Current versus voltage in a junction diode.

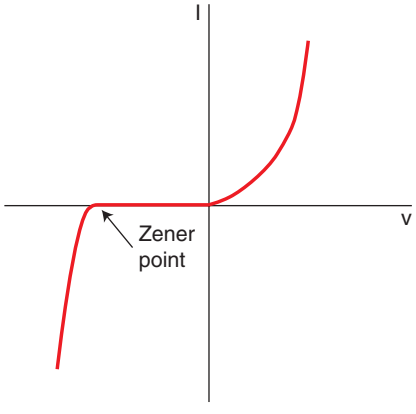

FIGURE 27–9. Current versus voltage in a zener diode.

A *transistor* is a three-terminal, nonlinear, active device. Active means that the output can have more power than the input. This characteristic permits amplification of signals. The extra power comes from an external power supply. Characteristics that are controlled by transistor circuits are input and output impedances, current and voltage gains, and phase and frequency responses. Types of transistors include bipolar-junction transistors and field-effect transistors. The symbols for resistors, capacitors, inductors, diodes, and transistors (as they appear in schematic drawings) are shown in Fig. 27–10.

Integrated circuits (ICs) are single semiconductor "chips" into which numerous transistors and passive components have been etched. A single IC can be a complete amplifier, a chip capable of storing thousands of bytes of digital memory, a computer's microprocessor, or any of hundreds of different analog or digital circuits. ICs account for the miniaturization of instruments and computers and for their phenomenal speed and versatility. For example, the IC that serves as the central processing unit of a modern personal computer contains over 1,000,000,000 transistors. Their reduced power requirements are another important advantage.

Analog and Digital Circuits

Circuits that manipulate continuous waveform voltages are called *analog circuits.* Signals can have a range of magnitudes. Natural phenomena typically are analog. Bipolar digital circuits have only two discrete voltage values, called *high* and *low* (or 1 and 0). Analog data can be converted to digital, and vice versa, by analog-to-digital (A/D) and digital-to-analog (D/A) converters. Data need to be in digital form to be used by digital computers. Digital data also have greater immunity to electrical noise. Spurious voltages added to an analog signal will alter the signal's value. Digital low and high signals need only be within 1.5 V of their nominal values of 0–5 V to be dependably interpreted.

Leakage Current

An unavoidable and undesirable side effect of electrical circuitry is leakage current. It is virtually impossible to contain all electrical energy within the wiring and components of electrical equipment. The primary source of leakage current is stray capacitance. Two conductors separated by insulation and air act like a capacitor, and AC current is conducted between them. The electrical power cord usually has the greatest amount of stray capacitance because of the length and proximity of the wires. Interestingly, leakage current will flow in the ground wire of a power cord even when a device is not turned on because AC voltage is present in the power cord as long as it is plugged in.

There also is resistive leakage because insulation is less than perfect. Although resistive leakage current is a

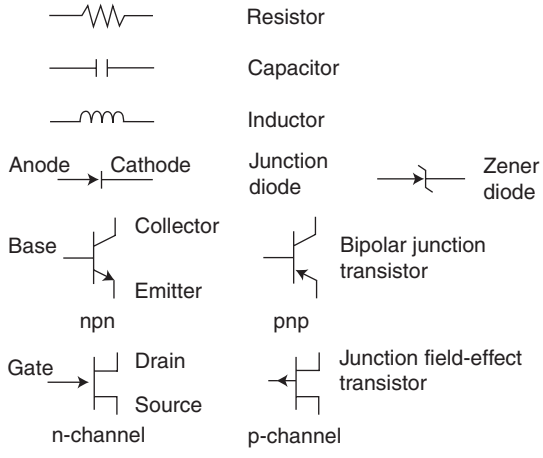

FIGURE 27–10. Electronic symbols.

minor source, it tends to increase as equipment ages. In addition to the degradation of insulation, there can be a buildup of dirt, dust, and moisture inside the equipment.

The ground wire in a three-wire power cord conducts leakage current from the chassis of equipment to ground. It also shunts fault currents (caused by damaged insulation, wiring, or components) to ground. If a fault current is large enough, it will cause a fuse or circuit breaker to open, preventing shocks to patients or operators and further damage to equipment. If a ground wire is missing or broken, leakage current or fault current energizes the chassis until it finds an alternative path to ground. This alternative path can be a patient or an operator. This is one of the more important considerations in electrical hazards, which is the topic of the section on Hazards of Electricity.

Isolated Power

In a conventional power distribution system, three wires feed into a circuit breaker box. These three wires are called *hot, neutral,* and *ground.* (This discussion is limited to 120 VAC systems.) The hot wire supplies current at 120 VAC, and the neutral wire provides the return path. The ground wire is for safety (i.e., for shock and fire protection from electrical faults). The circuit breaker box distributes power to branch circuits through individual circuit breakers. Each branch circuit feeds electrical receptacles, overhead lighting, or installed equipment (e.g., radiograph view box; Fig. 27–11).

An isolated-power system (or floating system) is a more specialized type of power distribution system. In an isolated-power system, the hot and neutral wires are *not* ground referenced. An isolation transformer and a line-isolation monitor (LIM) are installed directly in front of the circuit breaker box (Fig. 27–12A). Neither of the output leads from the isolation transformer is connected to ground. The output leads are referred to as *line 1* and *line 2.* Isolated-power sometimes is called *ungrounded,* but it is important to realize that a ground wire still is used. In this context, ungrounded simply means that neither of the power lines is connected to ground. The LIM monitors the degree of isolation of the isolated-power system by measuring the amount of current that would flow

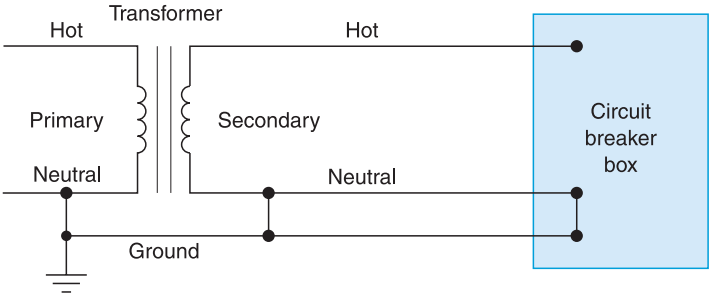

FIGURE 27–11. Conventional power distribution system. Note the connections of neutral wires to ground terminals on both sides of the transformer and in the circuit breaker box.

to ground if either power line were connected directly to ground (total hazard current). If this current exceeds a preset limit, the monitor lights and sounds an alarm (Fig. 27–12B). If adding a device to the circuit triggers an alarm, the hazard current display can be used to assist troubleshooting by measuring the contribution of a device to the total hazard current as the device is added and removed from the circuit.

In a conventional power distribution system, a ground fault (a short circuit from the hot conductor to ground) allows a large current to flow until the circuit breaker opens (circuit breakers typically are rated at 15 or 20 A). An ideal isolation transformer would not allow any current to flow from either power line to ground. A direct fault from either power line to ground would merely convert the isolated-power system to a conventional power distribution system. A second fault, from the other power line to ground, would be required for a large current to flow to ground.

No isolation transformer is ideal. Capacitance between the transformer wiring creates a high-impedance path to ground. Additional high-impedance paths to ground exist within the LIM and the power distribution wiring. Altogether, these allow up to 1.5 mA of leakage current. Each device connected to the system contributes its own inherent leakage current (generally <100 μA each). Because of this, the alarm point of the LIM usually is set at 1.7–2.0 mA. This limits the shock and fire hazards resulting from ground faults. In 1978, the total hazard current limit was increased from 2 to 5 mA to reduce nuisance alarms. Isolated-power systems originally were used in hospitals to eliminate sparks that could cause an explosion in the presence of flammable anesthetics. In the 1960s and early 1970s when electrical safety first became a major concern, isolated-power systems were touted as panaceas for shock hazards. The virtual elimination of flammable anesthetics and realistic, cost-effective electrical safety measures have minimized the use of isolated-power systems for shock and fire protection.

The remaining safety factor provided by isolated-power systems is branch circuit protection. In the event of a ground fault in a device connected to an isolated-power system, the LIM will activate audible and visible alarm signals. These alert the operator to the fault and do no worse than convert the isolated-power system to conventional power (i.e., one power line is grounded). This allows the branch circuit to remain energized and the equipment to continue operating. The circuit breaker does not open because the only additional current that flows is limited to the previous value that the LIM was measuring. This benefit also is minimized by more realistic electrical safety measures applied to the design, construction, and maintenance of modern medical equipment.

Isolated-power systems formerly were required in anesthetizing locations and were strongly recommended in heavily instrumented areas (e.g. critical care units). They are expensive, more than $2,000 for the hardware, plus extra costs for installation. Since 1984, isolated-power systems no longer have been required in nonflammable anesthetizing locations, but they still are allowed and continue to be included in the design of most operating rooms.

Ground Fault Circuit Interrupters

Ground fault circuit interrupter (GFCI) protection systems are used in wet locations in the home, where contact

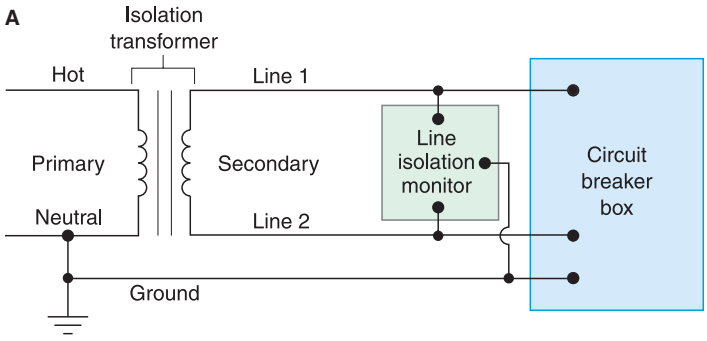

FIGURE 27–12. **A.** Isolated-power system. Note that neither side of the secondary of the transformer is connected to ground terminals, either at the transformer or at the circuit breaker box. **B.** Old and new (digital) line-isolation monitor status indicators. Digital panel indicates a total hazard current of 1.8 mA.

with a grounded surface is likely. A GFCI monitors the current flowing in both the hot and neutral lines. If an imbalance of current flow of >6 mA is detected, indicating that current from the hot conductor is returning to ground via any other pathway—including a potential victim of electrocution—the GFCI immediately interrupts the circuit. The GFCI reaction time varies inversely with the leakage current. For example, Underwriters Laboratories (UL) standard 943 specifies that at a leakage current of 250 mA, the GFCI must activate in <20 msec. (The threshold is 5 mA in the United States but may vary throughout the world.)

The GFCI effectively protects both grounded and ungrounded circuits from delivering a shock, but this protection comes with a price. Once activated, the GFCI interrupts all current flow from the circuit protected by the GFCI. Therefore, GFCI protection is reasonable only when interruption of electrical power is acceptable. GFCI activation may occur unpredictably, as very small, relatively harmless, leakage currents, which may be generated by capacitive coupling in electrical wiring systems, may activate the GFCI.

One must assess the utility of a GFCI in the context of the hazard introduced by loss of electrical power. ECRI Institute (formerly Emergency Care Research Institute) recommends never using a GFCI with "life-support or critical equipment,"[2] and the National Electrical Code (NEC) recommends against the use of GFCIs if "interruptions cannot be tolerated."[3] Despite the apparent clarity around the choice of protection, there is a significant practical problem. Currently, the choice of using a LIM or GFCI for protection is left to the institution. According to NFPA 99, GFCIs must be used in wet locations.[4] However, hospitals determine what they consider to be wet locations (with the exception of hydrotherapy tanks and pools, which are always considered wet locations).[2] Although operating rooms are not necessarily wet locations, one may encounter GFCI protected circuitry in modern operating rooms.[2]

Isolation Amplifiers

Amplifiers increase the magnitude of an electrical signal or modify the signal to filter unwanted noise or other effects. It is desirable to isolate electrical connections between instruments and patients from ground (discussed later in Electrical Hazards to Patients). To accomplish this, isolation amplifiers are used. They have the advantage of isolating the input connections from any AC-powered circuit. There are three basic design techniques used by isolation amplifiers.

- Optical isolation amplifiers work by using light to transmit the signal. A light-emitting diode (LED) puts out light with intensity proportional to the strength of the signal. A photodiode then picks up the light signal and converts it back to an electrical signal.
- The transformer isolation amplifier uses a transformer to couple the

input signal with the rest of the circuitry. Because transformers cannot amplify DC signals, to make the instrument usable down to DC levels, the input signal modulates a high-frequency carrier signal. After the transformer-coupling stage, the signal has to be demodulated before further processing.

- Capacitively coupled isolation amplifiers also need a high-frequency carrier signal to transmit the signal to be isolated across isolating capacitors. Again, the desired signal subsequently is removed via a demodulator circuit.

Interference

Electrical *interference* is any disturbance of the desired electrical signal. There are many possible sources of electrical interference, which sometimes may be hard to find or eliminate. The types of equipment most susceptible to electrical interference are physiologic monitors—equipment designed to detect generally low-level signals from a patient. Sources of interference include the following:

- Muscle artifact: muscle contractions produce electrical signals
- Broken input wires: open or intermittent circuits produce noisy signals
- Poor connections to the patient (e.g., dry electrodes)
- Electrical power distribution system: electric and magnetic fields produced by power lines can produce interference
- Ground loops: current created when two devices are electrically grounded to points that are not at the same electrical potential and then are connected to each other (e.g., through a patient); this current subsequently can interfere with the physiologic signal to be monitored
- Electromagnetic interference: transmitted signals picked up by circuitry (especially patient lead wires) and by the patient, which act like antennas; common sources include high-power, high-frequency equipment, such as electrosurgical units and x-ray machines, and portable communication equipment, such as two-way radios and cellular telephones.
- Triboelectric interference: generated by friction (including flexion) of insulation-covered wires

HAZARDS OF ELECTRICITY

The hazards of electricity for the human body can be divided into four categories:

- Ventricular fibrillation
- Respiratory arrest
- Thermal burns
- Electrolytic burns

All of these result from unwanted electric current flowing through the body. In addition, there can be hazards caused by the electrical distribution system and connected equipment:

- Fire and explosion
- Electrical distribution system failure
- Electrical equipment failure

Finally, a broad category can be added to the list of hazards—misuse.

Electrical Hazards to Patients

The human body is predominantly composed of conductive electrolyte solutions enclosed in a skin of high resistance. The skin's resistance varies depending on its condition. Dry, intact skin has a resistance of approximately one megohm (1 MΩ). Moisture (e.g., perspiration) reduces resistance to approximately 15 kilohms (15 kΩ). Electrode paste reduces skin resistance to approximately 1,000 ohms (1 kΩ) by a combination of electrolytic action and mechanical abrasion. If the skin's resistance is breached by needles or catheters, resistance drops to a few hundred ohms.

Macroshock is the term used for current applied at the body's surface. *Microshock* describes current applied directly to the heart, and an electrically susceptible patient is one with a direct, conductive path to the heart (e.g., pacing catheter, fluid-delivery catheter). The effect of electricity on the human body varies depending on a number of factors, including the magnitude, density, and frequency of the current; its path through the body; the weight of the subject; the duration of exposure; and the variability of response between subjects.

Fig. 27–13 shows the physiologic effects of a 60-Hz, 1- to 3-second duration current of varying magnitudes applied to the hands of a 70-kg man.[5,9–12,36] The threshold of perception is the minimum current that a subject can feel.[13] As the current increases, the effect increases from a tingling sensation to pain. Additional increases cause muscular contractions that prevent the subject from releasing his or her grasp—the *let-go current.* Just above the range of currents that prevents releasing the grip is the range that causes sustained contraction of the respiratory muscles. If the current is removed promptly, normal respiration resumes; if not, asphyxia can result. Ventricular fibrillation occurs when a critical number of myocardial cells are excited by a current of sufficient magnitude. This condition is not reversed when the current is removed. If a current that causes sustained myocardial contraction is removed, normal cardiac activity resumes. This is an effect similar to defibrillation (the return of rhythmicity after an abrupt excitation and subsequent depolarization of a large portion of the myocardium). Skin burns occur at high currents resulting from heating of the high resistance of the skin (analogous to the heating of a high-resistance filament in a light bulb). High currents can cause muscle contractions so strong that tendons tear away

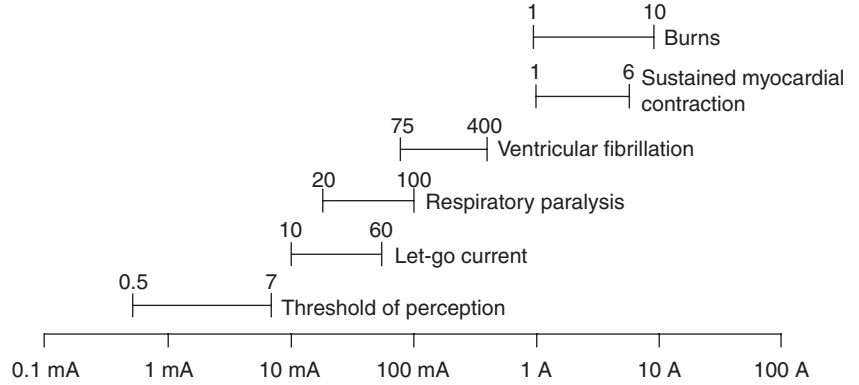

FIGURE 27–13. Threshold ranges of different effects for 1- to 3-second application of 60-Hz current.

from bones. Nervous tissue, including the brain, ceases all activity when subjected to high currents. Of these effects, ventricular fibrillation is the most dangerous to patients. For this reason, electrical safety in hospitals concentrates almost exclusively on preventing hazards that can cause ventricular fibrillation.

The path that the current takes through the body is important because it is only the percentage of the total current that passes through the heart that has the potential for causing fibrillation.[5,11] For example, if the two points of contact of the current source are on the same hand, there is little chance of fibrillation. A greater percentage of the current passes through the heart if it is applied between an arm and a leg rather than between both arms.

The longer the duration of the applied current, the less the magnitude of the current required to cause ventricular fibrillation.[10,11,14] There is a marked increase in the current required when the duration is reduced to <1 second. It can take 10 times as much current to cause fibrillation at 100 msec as it does at 1 second, but the current required at 5 seconds may be only about half that required at 1 second.

The frequency of the applied current has an interesting effect on the susceptibility of the body.[10,15] The body is most susceptible to frequencies between 10 Hz and 1 kHz. The frequency at which the minimum current is required to induce fibrillation is 50–60 Hz, the frequencies used for AC around the world. Below 10 Hz and above 1 kHz, the currents required to cause the same effects increase sharply. Studies of fibrillation thresholds have been conducted on dogs, pigs, sheep, and ponies. These studies have shown a direct relation between body weight and current, but the variability between subjects of the same weight is even greater.

There are two primary mechanisms for keeping equipment electrically safe: minimizing leakage current and grounding exposed conductive surfaces. Both are tested routinely as part of an electrical safety program, but there is no guarantee that either or both could not fail between equipment inspections.[16]

Leakage current can increase because of degradation of a single-layer insulation or because of a buildup of dust or other residue inside the instrument. Fault currents occur when something goes wrong—typically, a short circuit to the device's chassis. If there is only a partial short, one in which the current that can flow to ground is limited, the device continues to operate. This is likely when the fault is a result of a failed component or a frayed wire, wherein only a few strands of wire may be touching the chassis. A direct short of the hot wire of the power cord to ground or neutral would cause the instrument's fuse or circuit breaker or the circuit breaker in the distribution system's branch circuit to open. The former is more likely because the amperage rating of the instrument's fuse or breaker is much lower than that of the branch circuit.

Grounding the chassis of an instrument shunts leakage current or fault current safely to earth ground and away from patients and personnel. Grounding can fail inside the instrument, the power cord, the electrical plug, or the electrical receptacle. As in the case of excessive leakage current or a partial short, if an instrument loses its ground connection, it will continue to operate.

It is a fundamental principle in modern electrical equipment design that the equipment must remain *"single-fault" safe,* which means that failure of a single safety mechanism will not create a safety hazard. For example, a device may be protected both by having a chassis ground connected to a grounded power cord and by being designed with a low leakage current. If the power cord ground wire breaks, the low leakage current on the chassis surface will not present a new shock hazard. Similarly, an internal insulation failure that makes the chassis hot would not present a shock hazard because the current would be conducted to the power line ground, which would cause the panel circuit breaker to open. Because of this principle, equipment is designed with either basic insulation and grounding (as in the example above) or double (also called reinforced) insulation.

Fig. 27–14 illustrates the protection normally provided by grounding. In the event of a fault to the chassis (1), the fault current is safely shunted to ground (arrowheads). If the ground continuity is broken at any point between the device and the circuit breaker box, the chassis of the device becomes electrically energized. If a patient contacts or is connected to the device (2) and a grounded surface (3), such as an electric hospital bed, he or she becomes part of the circuit for the fault current (dashed line).

This discussion of electrical hazards to patients has concentrated on macroshock—current applied to the surface of the body. Electrically susceptible patients—those with a conductive path to the heart—are at risk for an additional hazard termed microshock. When all of the hazard current passes through the heart, much lower levels can cause ventricular fibrillation[17] There is no unanimous agreement on the minimum level of microshock current that can cause ventricular fibrillation in humans, but 100–200 μA is most commonly cited.[18–22] As little as 20 mA has caused fibrillation in a dog, using 60-Hz current, applied for 15 seconds through a 0.224-mm^2 contact area.[19]

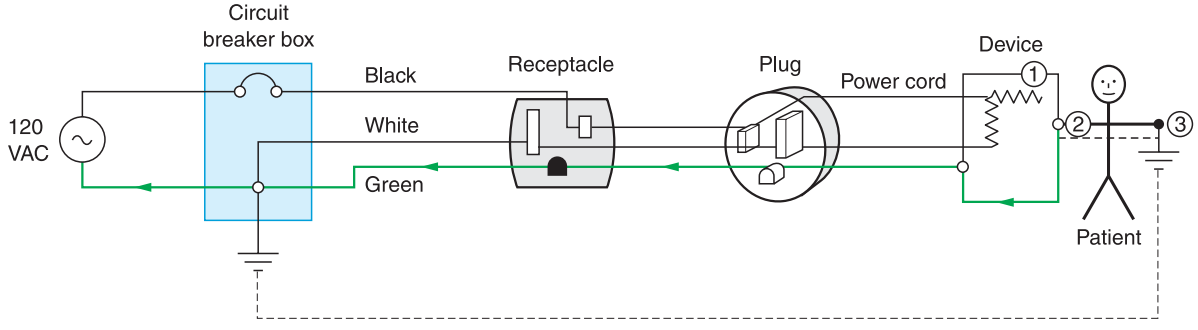

FIGURE 27–14. Arrows indicate safe path for leakage or fault current. If ground continuity were broken, leakage or fault current would follow an alternate path, which includes the patient, indicated by the dashed line.

Because the magnitude of the current that poses a microshock hazard is so small—roughly three orders of magnitude less than a macroshock hazard that can cause ventricular fibrillation—the problem of preventing it originally was more difficult. Temporary external pacemakers were AC powered, and the catheters and connectors were not protected from casual contact. Electrocardiographic (ECG) monitors had the right leg (RL) lead connected to chassis ground. Blood pressure transducers had metal cases that also were connected to ground. A variety of older equipment still was in use that had excessive leakage current or two-wire power cords. There was a lack of appreciation for the importance of relatively small differences in electrical potential between grounds in the patient's environment. The importance of electrical safety programs was not acknowledged at all hospitals.

Although virtually all of these initial problems have been eliminated in modern hospitals and very few accidental shocks or electrocutions in hospitals have ever been documented, a brief review of the hazards is worthwhile. It serves to reinforce the need for electrical safety programs, care in the design and selection of equipment, and avoidance of practices that may be hazardous to electrically susceptible patients. Fig. 27–15 illustrates just one of many scenarios that would allow the leakage current of one device to flow through a patient's heart. If the ground wire of the bed were broken, the leakage current of the bed would flow through the bed rail, the patient's arm and heart, the pacing catheter, the nurse or doctor handling the catheter, and the grounded medical device. If the ground of the device were broken, the device's leakage current would follow the same path in the opposite direction.

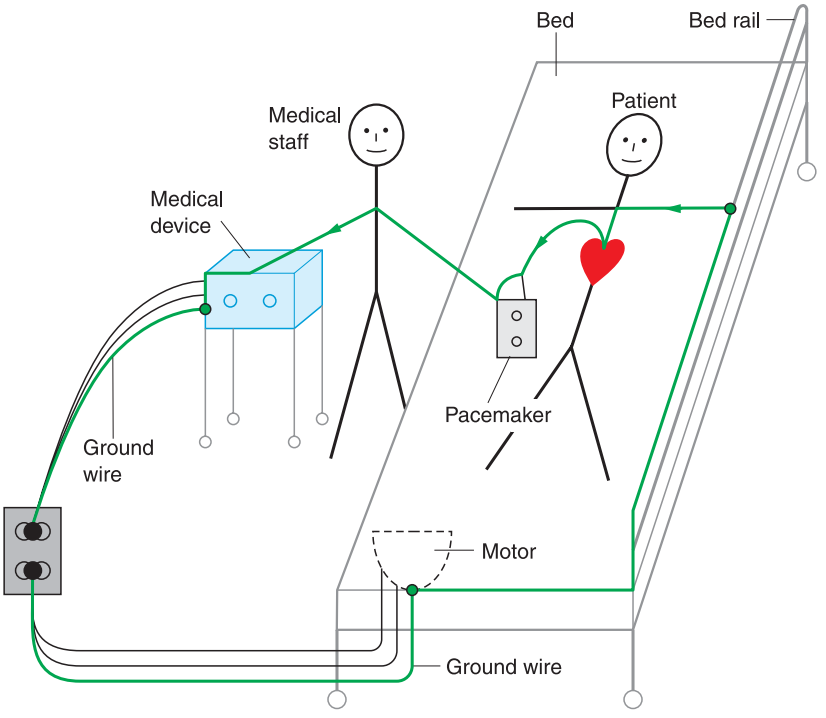

FIGURE 27–15. Electrically susceptible patient is at risk for microshock if either the ground wire of the bed or the ground wire of the device is broken. Arrows indicate current path through operator and patient.

Another different scenario is shown in Fig. 27–16. In this figure, only the ground wiring of the power distribution system is drawn. There are two receptacles on separate branch circuits. A device with a ground fault, allowing a 5-A fault current, is connected to the receptacle (1). Another device (3) grounds the patient via an RL connection (this may be an electrosurgical unit with a grounded return electrode). The patient also has a cardiac catheter with a relatively high resistance of 10 kΩ to ground. The resistance between the ground pins of each receptacle and the ground connection of the circuit breaker box is 0.2 Ω. The 5-A fault current through the 0.2-Ω ground resistance puts the ground of

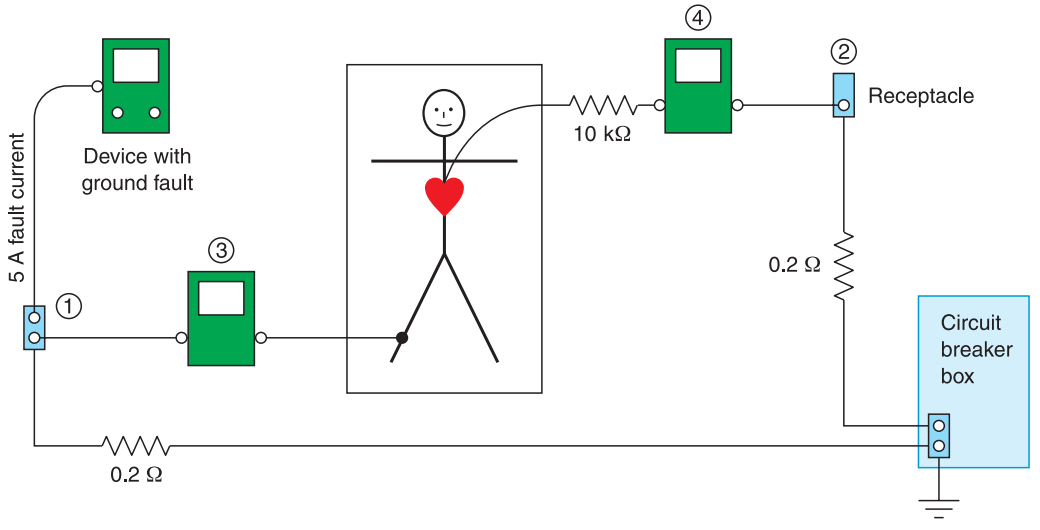

FIGURE 27–16. A 5-A fault current increases the ground at receptacle (**1**) to 1 V above the ground at receptacle (**2**). The patient is grounded via device (**3**) and has a fluid-filled cardiac catheter connected to device (**4**). Up to 100 μA can flow through the patient's heart (see text for analysis).

receptacle (1) at 1 V above the ground of receptacle (2). This potential, across the 10 kΩ of the cardiac catheter (other resistances in the path, including the patient, are not important), allows 100 μA to flow through the patient's heart.

These types of events are unlikely to occur because reasonable effective steps have been taken to prevent them. In particular, pacing catheters are protected from casual contact by the design of their connections and by precautions taken in their handling. Other catheters typically are effectively isolated from ground. It is possible that there can be broken ground wires or fault currents in equipment, although they are less likely to occur because of generally higher-quality components and construction. Perhaps the most important reasons that electrical shock incidents are so unlikely to occur are that electrical safety standards and tests (as part of an equipment inspection program) are so well established. Electrical safety standards and tests are measurements of the same parameters—grounding resistance and leakage current. Grounding resistance is measured as the electrical resistance from the ground pin of a device's power plug to exposed conductive surfaces of the device. Leakage current (sometimes called *risk current* by standards organizations) is measured as the current that flows under specified conditions and between specified test points through a circuit (test load) that simulates a body's electrical resistance.

Leakage current is measured at a variety of sites: from the surface of the device to ground (enclosure leakage current); in the ground conductor of the power cord (earth leakage current); from patient connections to ground, to the surface of the device, and to other patient connections (patient applied leakage current); and into patient connections with line voltage (120 VAC) applied to the patient connections (patient-isolated leakage current). Leakage current is measured under normal operating conditions and under a set of single-fault conditions. Normal operating conditions include every combination of power on and off, normal and reversed power polarity, and patient grounded and not grounded. Single-fault conditions include open power ground connection, a short circuit of either level of double insulation, and the failure of any component that can affect leakage current. The allowable leakage current varies, depending on the use (in the vicinity of patient or not), design (isolated patient connections or not), and condition (normal or single-fault) of the equipment.

Thermal burns result from resistive heating of tissue. This type of heating is called *joule heating*. The amount of heat produced, in joules, is proportional to current, resistance, and time: $H = I^2RT$. The threshold current for causing burns depends on a number of factors. The smaller the contact area, the greater the current density and the greater the heating for a given current. From the equation for joule heating, it is clear that the longer the current is applied, the greater the heating. This is further affected by the ability of the tissue to dissipate heat. Well-vascularized tissue is able to carry away heat more effectively than can poorly vascularized tissue. The higher the resistance of the tissue, the greater the heat production of a given current. Tissue resistance increases in the following order: nerves, blood vessels, muscles, skin, tendons, fat, and bone. Although the joule heating of tissue is independent of frequency, the path taken by the current is not. This is because the impedance of different tissues varies at different frequencies. At DC and low AC frequencies, current distributes itself throughout the body. Skin tissue exhibits a combination of high resistance and low capacitance. Therefore, at frequencies >10 kHz, more current flows along the surface of the body (i.e., through the skin). This makes skin more susceptible to burns at radiofrequency (RF) currents from electrosurgical units, which operate from 500 kHz to 3 MHz.

DC causes burns at low potentials and currents by electrolytic action. Saline in the body is converted to chlorine gas at the anode (positive) connection and sodium hydroxide and hydrogen at the cathode (negative) connection. Burns can occur at both connections but will be more severe at the cathode because of the caustic action of the sodium hydroxide.

Two points about electric shock hazards warrant emphasis. The first is that leakage current is an important hazard parameter, not voltage. One reason for this is that current density has the physiologic effect. The other reason is that the source impedance (the impedance "seen" when looking back into the leakage source) usually is much higher than the load (i.e., the patient). Thus, there will be a relatively low current through the load compared with the open circuit voltage (typically, 120 VAC).

The second point is that there historically has been an overreaction to potential or theoretic electric shock hazards, which has, without a doubt, resulted in wasted resources.[23] Time has been wasted looking for escaping microamperes, and money has been wasted on multiple layers of redundant electrical safety hardware. There simply has not been enough of a real danger to justify these expenditures. Equipment and user performance problems (as discussed later in Hazards of Misuse) are more frequent and at least as serious. The overemphasis on electrical safety has detracted from attention to more important concerns to the extent that some in-house equipment inspection programs test only safety and ignore performance measures.

Hazards of Electrical Distribution Systems and Equipment

Hazards with electrical distribution systems and equipment generally are more straightforward than the effects of electricity on patients. Despite (or perhaps because of) this, such hazards are more likely to occur. This section describes hazards associated with the use of electricity other than those that occur with the direct application of current to the body.

Historically, flammable anesthetics were the major explosion hazard. Now, nonflammable anesthetics are used exclusively, at least in the United States. Therefore, the risk of explosion in operating rooms has been dramatically reduced. Other flammable liquids or aerosols may be used, including some germicides and alcohol-based skin preparations. Use of such chemicals should be minimized. Alcohol-based prep must be permitted to air-dry prior to covering with surgical drapes, and pooling of prep solution must be avoided. Finding a suitable substitute probably is easier than eliminating sources of ignition (e.g., electrical equipment, static electricity) or being sure to eliminate remnants of the liquid or its vapors.

Fire hazards are more difficult to avoid entirely than are explosion hazards. Fires can start under a variety of

circumstances. Electrical fires can start from the overheating of worn insulation, deteriorated components, excessive friction of moving parts, dirt or dust buildup on hot assemblies, and a variety of other possibilities. In the operating room, the situation is exacerbated by the likelihood of increased oxygen or nitrous oxide concentrations, especially during head and neck surgery. Oxygen not only increases the intensity of fire, but it also reduces the temperature necessary for ignition. New technologies also can introduce new fire hazards. For example, lasers used for tracheal and oropharyngeal procedures have ignited endotracheal tubes in patients' airways. The oxygen-enriched atmosphere produces a fearsome fire that obviously is life threatening. Sloppy or thoughtless techniques also are a fire hazard (as well as being a surgical risk). Fires started by careless use of electrosurgical units continue to occur too frequently.

Likewise, there are many ways that the electric distribution system can fail. If there is a failure outside the hospital, the hospital should have an emergency alternative source of power. According to the National Fire Protection Association's standard, *Standard for Health Care Facilities* (NFPA 99),[4] hospitals should have an on-site generator(s) capable of powering what are defined as "essential electrical systems." This standard also has sections that provide detailed and specific requirements for wiring distribution, circuit breakers, and grounding to reduce the potential for shocks, fires, and loss of power. This topic is discussed further in the Standards section. It should be obvious that for the electrical system to be safe and dependable, it must be designed and installed properly. In addition, the electrical system should be inspected and tested periodically. This, too, is described in detail in the section on standards of the National Fire Protection Association.

Many of the hazards attendant to the use of medical equipment already have been mentioned. Electric shock has been described in terms of its effects on the body, and it has been shown how patients can be at risk for either macroshock or microshock. Operators can be equally at risk of macroshock—perhaps even more than patients—because they handle more equipment, more often, and under less-controlled conditions. Operators have the additional hazard of a startle reaction to a shock that can lead to a secondary accident as they jerk or jump. Defective equipment—in particular, improperly grounded equipment, poses a serious shock hazard.

Loss of power can immediately threaten a patient if equipment is sustaining his or her life. The best examples are heart–lung machines and ventilators, although compressed gas also can be a power source. The loss of oxygen to an anesthesia machine or ventilator can be just as life threatening as the loss of AC power. AC and compressed gas from a central source are fairly dependable and, at least with life support equipment, usually have some backup source. The same is not necessarily true for equipment that has a self-contained power source. External (temporary) pacemakers and portable ventilators are examples; the former depend on batteries and the latter on oxygen cylinders. Equipment with self-contained power sources can be especially dangerous if power fails because patients may not be under direct observation by clinicians or may be in locations where adequate backup support is not readily available (e.g., transport in an elevator).

A less common hazard is RF interference. Some pieces of equipment generate RF signals that "escape" from their intended circuitry. The electrosurgical unit is the classic example. A powerful RF generator, such as an electrosurgical unit, can conduct RF interference back through the power line and radiate it through the air, much like a radio transmitter. The former can be controlled by circuits called *RF filters.* The latter can be controlled by a combination of circuit design, physical layout, and shielding via the enclosure of subassemblies and the entire device. Devices also can be susceptible to RF interference. Devices with digital circuitry, including microprocessor-controlled devices, are particularly susceptible. Equipment that is susceptible to RF interference will have RF filters built in to protect it. Unless properly designed, a characteristic of simple RF filters is that they allow unacceptable leakage current to ground.[6] Although modern medical equipment incorporates RF filters that do not have this flaw, older medical equipment (especially older physical therapy diathermy units) and any pieces of equipment not intended for medical applications have RF filters that cause high leakage current. An example of the latter is the personal computer. Often, an RF filter can be replaced with one designed for medical equipment. If not, a dedicated isolation transformer may have to be installed—a more expensive and cumbersome solution.

More recently, the extent to which the electromagnetic environment interacts with medical equipment has garnered attention. A variety of malfunctions resulting from electromagnetic interference (EMI) with devices such as powered wheelchairs, apnea monitors, and ventilators have been reported.[24] Television and radio transmission antennas, at some distance from a hospital, can cause erratic behavior of equipment.[25] Miniaturization of electronics has allowed the development of increasingly complex medical devices. They typically consume less power than older equipment but often are more sensitive to EMI. There also has been a concomitant development and proliferation of communications devices, such as cellular telephones and wireless computer links. Unforeseen problems may result from the interactions between communications devices and medical devices.[26] Neither the full extent of the problems nor the appropriate levels of precautions and standards have been completely defined.

Fire and explosion hazards were described first and separately because they were a concern before the use of electrical equipment. They still are hazards that are not limited to electrical equipment. Patients also can receive thermal injuries directly from equipment. Sustained skin contact with a good thermal conductor at 42–44 °C can burn the skin. As the temperature increases, the time required to burn falls rapidly. Hypothermia/hyperthermia machines, blood warmers, and infant radiant warmers are devices intended to help maintain a patient's temperature. All of these should have safety (backup) thermostats, but they can overheat a patient if circuitry fails or if they are set improperly. The patient and the equipment both should be monitored. A malfunctioning heated humidifier in a ventilator circuit can burn a patient's airway or present a fire hazard. A patient also can be burned inadvertently by a laser or an electrosurgical unit. These are not the-

oretical hazards; they occur regularly in operating rooms as a result of even the slightest carelessness.

Moisture in equipment can reduce the insulating properties of wires, components, and printed circuit boards, resulting in a malfunction, a shock hazard, or a fire. The most common cause of moisture entry into equipment is spillage of a container of liquid that had "conveniently" been placed on top of the equipment. Some equipment is built with holes or slots in the top to allow cooling. This is a poor design, usually compounded by a top that is horizontal. It is much better to design equipment so that it does not require holes in the top and so that the top is at any angle to prevent its use as a shelf.

Patients and staff can suffer mechanical injury from equipment. A sharp corner or projection on a piece of equipment is almost a guarantee that someone will run into it. A top-heavy piece of equipment can fall onto a person as easily as onto the floor. A portable IV pole with small casters, a narrow wheel base, and two or three pumps clamped to the upper half can easily be knocked over. Overloaded or poorly installed shelves eventually will fail. Loose brackets or locking assemblies may lead to the collapse of a bed, operating room table, or wheelchair. What this also should indicate is that even if no human injury results, the equipment will be damaged such that the damaged equipment is not available and possibly subject to expensive repair or early retirement.

Hazards of Misuse

Misuse of equipment is given many names that also indicate the breadth of this category: human or operator error, accidental activation, incorrect setting, confusing controls, misinterpreted displays, abuse, and so on. The types of hazards that can result from misuse are essentially the same as those previously described. It is too easy, especially for a clinical engineer, to claim clinicians do not have enough respect for medical equipment. It is more useful to list steps to prevent misuse.

Anyone who operates medical equipment should read the operator's manual and understand the operating principles of the equipment, the function of all controls and displays, and any warnings. A copy of the manual should be available in a known, convenient location (with the equipment, or on an institutional intranet, if possible). An abbreviated instruction label on the instrument often is useful. Operators should receive training, which may have to be repeated periodically, especially if the operators are only "occasional" users. New equipment should have undergone a careful selection process, ideally a comparative evaluation based on existing standards and an objective set of technical and clinical criteria. Trained technicians should periodically inspect and maintain the equipment. Malfunctioning or damaged equipment should be serviced promptly.

For the most critically important equipment, plans or provisions for the eventuality of a failure should be in place. If there is sufficient justification, a backup unit is the best solution. There should be a long-range plan for how and when equipment should be considered for retirement and replacement. Criteria should include not only age and repair costs, but also functionality.

Common sense is most important. Psychologist Edward Titchener said, "Common sense is the very antipodes of science." This negative remark obviously is meant as sarcastic humor. More accurately and more to the point, the physician Peter Latham said, "Common sense is, in medicine, the master workman."

STANDARDS

In a nation of rules, regulations, and recommendations, healthcare (including medical device manufacturers, hospitals, clinics, and other providers) is arguably one of the more regulated aspects of our society. The list of organizations that promulgate or enforce healthcare standards reads like a veritable alphabet soup of acronyms: FDA, NFPA, JCAHO, UL, ANSI, IEC, AAMI, ECRI, and so on. This section covers those organizations that have the most impact on the use of medical equipment. It describes the various groups, their standards, and the differences between their standards.

National Fire Protection Association

The National Fire Protection Association (NFPA) is a nonprofit organization that produces scores of different fire safety-related codes and standards. Interestingly, none of them carry the force of law unless they are adopted by a state or local governing body. The two of most import to electrical safety in hospitals are the *National Electrical Code* (NFPA 70),[3] commonly known as the NEC, and *Standard for Health Care Facilities* (NFPA 99).[4] As with all NFPA standards, these codes are under constant review. Revisions appear, on the average, every 3 years. "Article 517" in the NEC pertains to electrical construction and installation in healthcare facilities. In its seven parts, it prescribes design, installation, and performance criteria of electrical distribution systems for general care, intensive care, and anesthetizing locations (including use of flammable and nonflammable anesthetics); electrical supplies for x-ray equipment; and low-voltage systems for communications, data, fire alarms, and so on. Two of the parts cover applications that are unique to hospitals. Emergency electrical power systems must provide continuous electrical service to specified areas of the hospital in the event of a disruption of normal electrical service. Isolated-power systems are required only in areas designated as hazardous anesthetizing locations (i.e., areas in which flammable anesthetics are used or stored).

Standard for Health Care Facilities combines what used to be 13 separate standards. Its companion, *Health Care Facilities Handbook,*[27] provides guidance and commentary on the standard. This standard addresses fire, explosion, and electrical hazards in healthcare facilities. It covers performance, use, and maintenance of the physical facilities and equipment as they relate to hazards. Chapter 13 on "Hospital Requirements" has several standards that cover electrical, gas, and vacuum systems and equipment; this chapter deals specifically with requirements on anesthetizing locations that are intended to protect against explosion, shock, or mechanical injury hazards associated with the use of inhalation anesthetics. Some changes have occurred in this section during the past few years. In particular, isolated power is no longer required "in facilities that have a written policy prohibiting the use of flammable inhalation anesthetizing agents."

The electrical distribution system includes power to essential areas and functions for which alternate sources of power should be available in the

event of disruption of normal supply. The electrical distribution system in patient care areas is to be tested according to criteria listed. Grounding voltage and impedance are to be tested in new construction before it is accepted and in existing construction before it has been altered (annual inspections are recommended).

Electrical equipment in hospitals includes fixed and portable patient care and non–patient care equipment. Of these, portable patient care equipment deserves the most attention. It is to be tested at least annually in general care areas and semiannually in critical care areas, unless the hospital can justify longer periods based on inspection history. Testing includes and should be in the order of physical inspection, grounding, and leakage current. Equipment should have an appropriate plug, power cord, and strain relief at the chassis. The chassis leakage current of portable patient care equipment was increased from 100 μA to 300 μA in 1993. This change finally occurred after a decade-long debate of patient safety versus a desire to correlate more closely with international standards (Table 27–1). This current was further increased to 500 μA in 2005 with the adoption of the third edition of IEC 60601-1 in the United States and the subsequent withdrawal of AAMI ES-1. Also, leakage current is measured as the RMS value from DC to 1 kHz. Leakage current limits increase to 10 mA proportional to frequency.

There are additional restrictions for equipment used in anesthetizing locations. There must be a storage device (e.g., cord wrap hooks) for the power cord of portable equipment to prevent damage during storage. Switches are not allowed in the power cord, except for splash-proof foot switches. Equipment must be plugged into a fixed receptacle (i.e., not an extension cord). Allowable exceptions to this requirement are multiple-outlet strips permanently attached to a rack, table, or pedestal, and overhead (ceiling-drop) receptacles supplied by a flexible cord.

There are also some important administrative requirements. Only isolated input equipment is allowed to be connected to conductive catheters or pacemaker leads connected to a patient's heart. Equipment purchase orders are to require manuals that include operating, testing, and maintenance instructions. There is to be a scheduled inspection and preventive maintenance program. Electrical equipment for use with oxygen delivery equipment is to be listed for such use.

The hazards with centrally piped medical gas and vacuum systems include gases that intensify combustion (e.g., oxygen and nitrous oxide) being piped throughout the hospital, gas cylinder storage, pipe leaks, cross-connection of gases, and poor performance or failure of the system. Most of these hazards can be prevented by proper design and installation of medical gas and vacuum systems. In particular, care must be taken with oxygen and nitrous oxide, which are used with anesthesia equipment and (oxygen only) with respiratory therapy equipment. For example, after components of the gas supply are serviced, oxygen flowmeters and the oxygen flush valve must be tested to confirm that only oxygen is being delivered. Almost all of the medical gas and vacuum requirements in NFPA 99 apply only to new installations, and all apply exclusively to centrally piped systems.

Joint Commission

The Joint Commission (formerly Joint Commission on Accreditation of Healthcare Organizations [JCAHO]) is another private, nonprofit organization. It was formed in 1951 to improve the quality of healthcare to the public. The Joint Commission develops standards of quality in collaboration with health professionals and others. They publish and annually revise 10 accreditation manuals for different segments of healthcare, including the *Comprehensive Accreditation Manual for Hospitals* (CAMH).[28] Compliance with the requirements of the CAMH is, in principle, voluntary. In practice, compliance is considered virtually mandatory. Medicare and Medicaid, many state health departments, and various other licensure organizations accept or require Joint Commission accreditation as part of their own requirements.

In 2003, the Joint Commission introduced new National Patient Safety Goals, standards that address specific areas of patient safety. These standards are evaluated and updated annually. In 2004, the Joint Commission implemented its latest major changes to their accreditation system, Shared Visions-New Pathways, with even greater emphasis on patient safety and quality of care. Among the many changes was a new survey process based upon a "patient tracer methodology." In 2006, all accreditation surveys became unan-

TABLE 27–1.

Comparison of Electrical Safety Standards, Patient Care Equipment Ungrounded

Specification	ANSI/AAMI 60601-1:2005	NFPA 99	UL 60601-1	IEC 60601-1
Ground impedance, plug to chassis	Not applicable	0.5 Ω	0.2 Ω	0.2 Ω
Leakage current, chassis to ground	300 μA	300 μA	300 μA AC 420 μA DC	500 μA
Leakage current, nonisolated patient connection	100 μA	100 μA	50 μA AC 70 μA DC	500 μA
Leakage current, isolated patient connection	50 μA	50 μA	10 μA AC 14 μA DC	50 μA
Leakage current, line voltage applied to isolated patient connection	50 μA	20 μA	20 μA	50 μA

ANSI/AAMI 60601-1:2005, American national standard, safe current limits for electromedical apparatus; IEC 60601-1, medical electrical equipment; NFPA 99, standard for health care facilities; UL 60601-1, medical electrical equipment, part 1: general requirements for safety; AC, alternating current; DC, direct current.

nounced, emphasizing the need for hospitals to be in continuous compliance with accreditation standards.

The accreditation standards that uniquely pertain to medical equipment appear in the chapter on "Management of the Environment of Care." Standard EC.6.10 describes how hospitals must manage medical equipment risks, and standard EC.6.20 describes how medical equipment must be maintained. However, the Joint Commission standards are interdisciplinary; that is, the roles of many departments and functions affect and are affected by standards throughout the CAMH. Standards that affect medical equipment appear in chapters on leadership, human resources, information technology, human resources, and infection control, as well as in other parts of the chapter on environment of care.[29]

Food and Drug Administration

Government regulation of medical devices is the responsibility of the Food and Drug Administration (FDA). Within the FDA, device regulation is the responsibility of the Center for Devices and Radiological Health (CDRH). The first federal law to protect the public from adulterated or misbranded food and drugs was The Food and Drugs Act, passed in 1906. In 1938, a new law The Federal Food, Drug, and Cosmetic Act established the FDA and expanded the authority to regulate food, drugs, and cosmetics. In May 1976, the Medical Device Amendments established the Bureau of Medical Devices and the Bureau of Radiological Health[30] (In 1982, the FDA combined these two bureaus into the CDRH.) The 1976 amendments gave the FDA specific authority for the regulation of medical devices. Before this, the FDA's ability to regulate medical devices was severely hampered because the FDA had to work within regulations intended for drugs. The 1976 amendments differentiated medical devices from drugs by defining that the latter group works primarily through chemical action, whereas the former does not.

The 1976 amendments also established a classification system for medical devices. Class I ("General Controls") devices require minimal regulation; they do not require performance standards or premarket approval. General controls require that manufacturers register annually with the FDA, follow published Good Manufacturing Practices (GMP) for establishing and documenting quality assurance practices, and comply with other labeling and documentation requirements of the Medical Device Amendments. Class II ("Performance Standards" cleared by premarket notification or 510(k)) devices must meet FDA-established standards that address safety and effectiveness or be compared to devices that were on the market in May 1976 (or devices that have been cleared via this process since then). To date, the FDA has created very few performance standards for specific devices. (Voluntary standards have been established by other organizations, and manufacturers almost invariably comply with them.) Examples of class II devices include ventilators, monitors, and infant incubators. Class III ("Premarket Approval") devices should be demonstrated as safe and effective, typically via clinical testing. They include life support and implantable devices and devices that have a potential unreasonable risk of illness or injury. Examples include implantable pacemakers and heart valves.

The FDA has been actively reviewing consensus standards for optional use by manufacturers to support claims of safety or effectiveness. The document *Recognition and Use of Consensus Standards; Final Guidance for Industry and FDA (2001),* represents the FDA's current thinking on this topic.

The Safe Medical Devices Act of 1990 (SMDA) was signed into law on November 28, 1990. Effective November 28, 1991, users are required by law to report to manufacturers if a device contributed to a patient's or staff member's serious injury or illness. If a device contributed to a death, the user must report to the manufacturer and the FDA. Users include virtually all medical facilities except physicians' offices. A *device* is broadly defined as an apparatus used to diagnose or treat a disease or function of the body. Reports must be submitted within 2 weeks of the time the user became aware of the incident. A serious illness or injury is one that is life threatening, results in permanent impairment, or requires immediate intervention to prevent permanent impairment. This law represents the first time that the FDA has directly regulated users of medical equipment. The user-reporting requirements of the SMDA are only one of the 18 parts of this law. The other sections pertain to new or expanded regulations for manufacturers, including more authority for the FDA to require recalls of products.[31]

Underwriters Laboratories and Nationally Recognized Testing Laboratories

The Underwriters Laboratories (UL) is an independent, nonprofit organization that develops safety standards. It tests materials, devices, and systems against these standards and "lists" (approves) products that meet the standards. The UL probably is the most widely recognized safety testing organization in the United States. It was founded in 1894 as a result of fire insurance companies' (underwriters') concerns for the number of electrical fires occurring at the 1893 Columbian Exposition in Chicago. UL is a Nationally Recognized Testing Laboratory (NRTL). Whereas at one time UL was the only NRTL, today more than a dozen different testing organizations for testing electrical equipment are recognized. Manufacturers seek NRTL listing to independently verify the safety of their products and, in many cases, to reduce their product liability insurance costs. Some areas of the United States require UL listing of products (e.g., Chicago, Oregon, and North Carolina).[32] Hospitals require their electrical equipment to carry NRTL listing so that they can comply with the federal Occupational Safety and Health Administration (OSHA) regulations, that is, so that they maintain a safe workplace.

The original UL standard for electrical medical equipment was UL 544, *Standard for Medical and Dental Equipment*.[8] Its various sections addressed construction, hazards to patients and users, electrical performance characteristics (including grounding impedance and leakage current; Table 27–1), and labeling requirements. It required chassis leakage of 100 μA for patient care equipment.

In 1994, UL adopted UL 2601-1, *Medical Electronic Equipment, Part 1: General Requirements for Safety*.[32] This standard started with International Electrotechnical Commission (IEC) 60601-1 and its two amendments.[33] It was modified in a section of "US Deviations." In general these deviations were from the UL 544 standards, when these standards were more stringent than the corresponding IEC 601-1 standards. For example, the chassis leakage was 300 μA for patient

care equipment, rather than 500 μA of IEC 60601-1, which is used in the rest of the world. In 2005, IEC approved the third edition of 60601-1, and in 2006 the United States adopted it without the 300-μA chassis leakage deviation.[21a]

Association for the Advancement of Medical Instrumentation

The Association for the Advancement of Medical Instrumentation (AAMI) is a private, nonprofit, professional membership organization. Members include engineers technicians, physicians, nurses, and administrators. Membership categories include individual, institutional, and manufacturers. One of the primary activities of AAMI is the writing of voluntary standards for medical devices. These standards are unique in that they include more than safety; they also include performance. To date, the AAMI has published 68 standards and a number of "recommended practices" and "technical information reports." AAMI standards include *Electrosurgical Devices, Diagnostic Electrocardiographic Devices, Electronic or Automated Sphygmomanometers, and Cardiac Defibrillator Devices*.[34] Their standards are developed by a consensus process, in which manufacturers, users, researchers, consultants, and the FDA typically participate. AAMI standards are submitted to the American National Standards Institute (ANSI; see ANSI section) for approval as a national standard. In addition, AAMI represents ANSI in the development of international standards for medical equipment with the IEC and International Organization for Standardization (ISO). It is the intention of the U.S. medical device standards writing organizations—including FDA, ANSI, and AAMI "to adopt IEC and ISO standards if at all possible or to adapt them with minimal changes."

The AAMI's electrical safety standard was ES-1, *American National Standard, Safe Current Limits for Electromedical Apparatus*.[35] It specified four classes of medical equipment: those with isolated patient connection, nonisolated patient connection, likely to contact patient (but no patient connection), and no patient contact. The 1993 revision of this standard increased leakage current limits from the previous editions. The limits were more compatible, although not identical, with the IEC standard (discussed later in International Standards; Table 27–1). The leakage current from a patient care device to ground was raised from 100 to 300 μA, not only to bring the AAMI standard closer to the IEC standard but also based on a study by Levin.[13] The leakage current limits are for frequencies from DC to 1 kHz. From 1 to 100 kHz, the limit increases proportionately to the frequency (i.e., at 100 kHz, the limit is 100 times the 1-kHz limit). Above 100 kHz, the limit remains constant. This standard was withdrawn in 2006 and replaced by IEC 60601-1.[33]

American National Standards Institute

The American National Standards Institute (ANSI) is a private, nonprofit organization that coordinates most other U.S. organizations that promulgate standards, including NFPA, AAMI, and ASTM International. It administers voluntary consensus standards for virtually every type of product. These standards do not carry the force of law unless they are adopted and enforced by some other agency. ANSI also is the official U.S. representative to the IEC and ISO (see International Standards below). Within ANSI, the Medical Device Standards Board coordinates standards approved specifically for medical equipment.

ASTM International

ASTM International (formerly the American Society for Testing and Materials) also is a private, nonprofit organization that promulgates standards. It was founded in 1898 and currently has approximately 134 committees that write standards for materials, products, systems, and services. The F4 Committee writes standards for medical and surgical materials and devices, the F29 Committee writes for anesthetic and respiratory equipment, and the F30 Committee writes for emergency medical devices. Of ASTM's 68 volumes of standards, Volume 13.01 (Medical Devices) contains the ASTM standards for medical equipment, materials and supplies, and services. Examples include tracheal tubes, anesthesia workstations, pediatric trauma facilities, and fixation pins and wires.

International Standards

International standards are assuming increasing importance because of the European Community (EC). A major provision of the EC is the adoption of standards that will replace national standards of member countries. For any manufacturer to be able to market equipment in the EC, it has to comply with these standards. This is important to manufacturers because the EC represents a large market, second only to the United States.

The International Electrotechnical Commission (IEC) writes standards for electrical devices, and the International Organization for Standardization (ISO) writes standards for everything else. The IEC Technical Committee No. 62, which is responsible for standards on electrical equipment, publishes IEC 60601-1 *Medical Electrical Equipment*. Part I, "The General Requirements for Safety," is the starting point for all IEC medical equipment standards. Part II, "Particular Requirements," supplements (and amends as necessary) the general requirements to cover the characteristics of specific types of equipment. There currently are approximately 60 Part II Particular Requirements from IEC and more than 15 from ISO. Like the AAMI standards, the IEC and ISO Particular Requirements cover safety and performance

The leakage current limit from the surface of a patient care device to ground is 500 μA. The upper limits for leakage current pertain to frequencies up to 1 kHz. For frequencies between 1 and 100 kHz, these values are multiplied by the frequency in kilohertz, to an upper limit of 10 mA.

ECRI Institute

Since 1968, ECRI Institute (formerly Emergency Care Research Institute) has been studying the safety and performance of medical equipment. ECRI Institute is a private, nonprofit organization that is the medical equipment analogue of Consumers Union. Their primary publication, *Health Devices*, presents comparative evaluations of equipment and disposables and provides analysis and advice on technology and management issues relevant to healthcare. Although they do not publish standards per se, they develop tests and performance criteria for the devices that they evaluate and for recommended inspection procedures. For years, their publication of these criteria and their direct involvement and interaction with organizations that promulgate standards have had a major impact on medical device standards.

SAFE USE OF EQUIPMENT

Hazards: A Reality Check

The hazards of medical equipment have been described in the previous sections of this chapter. These hazards still exist, and new wrinkles on old types of problems continuously appear as new technologies are introduced. The frequency of equipment-related hazards is reduced with understanding and experience. In addition, as more hospitals obtain the assistance of sophisticated clinical engineering departments, risk management and quality assurance functions improve. The current interest extends beyond risk management and quality control to quality improvement.

The first reported instance of a fatal electric shock caused by a medical device appeared in *Lancet* on April 16, 1960.[7] A patient died on the operating table when he was connected to a faulty cardiac monitor. Descriptions of electrical hazards in hospitals were published throughout the 1960s. Carl Walter, in 1970, claimed that 1,200 patients per year were being electrocuted in U.S. hospitals.[36] This figure gained widespread notoriety when Ralph Nader[37] repeated it in *Ladies Home Journal* in 1971. This figure was never documented. Nevertheless, it led to a period of great, if often misplaced, activity that ultimately resulted in an understanding and appreciation of electrical safety. The design and construction of modern medical equipment combined with the practices used in electrical safety programs have almost eliminated electrical shock incidents. Although electrical safety concerns should not be ignored, perhaps their most important contribution is that engineers and technicians now have regular opportunities to test medical equipment. The most important aspect of equipment inspections is performance testing.

Fires and resulting burn injuries caused by anesthetic gases have been eliminated because flammable anesthetic gases are no longer used in the United States. Fires and burns still occur as a result of the use of electrosurgical units and lasers. Precautions still are necessary. It is important to keep sources of fuel, oxidizing gas, and ignition separated. Most of the time, use of common sense and reasonable caution prevents fires. Additional precautions are necessary, in particular, for head and neck surgery. Basically, these precautions involve using nonflammable materials when possible, preventing the buildup of higher concentrations of oxidizing gases (especially from nasal cannulas), and knowing where electrosurgical sparks or lasers are directed.

Burns also occur as a direct result of electrosurgical currents. Unintended burns may result from carelessness or improper technique with either the active or the return (or "dispersive") electrode. The active electrode should never be left on the patient when not in use. Inadvertent activation of the electrosurgical unit can cause a spark or current through layers of surgical drapes. Some electrosurgical units allow connection of more than one active electrode and may not always provide a means for selective activation. It becomes especially important that one active electrode not be lying on the patient when the other is activated because current will be available from both. Burns at the site of the return electrode occur when there is inadequate electrical contact with the site, which may result if the electrode's conductive gel dries out. Gel can dry out in the package if left open too long before application, or even during a particularly long surgical procedure. (Some return electrodes do not use electrode gel; they use either a conductive adhesive or capacitive coupling to the skin.) Another problem with electrical contact occurs if not enough of the electrode is in contact with the skin. The entire surface should be firmly pressed to the skin. Bony areas should be avoided because they make it difficult to maintain good contact. In addition, wrinkled electrodes, or "tenting" of the electrode over the skin, should be prevented. Poor electrical contact results in higher current densities, which can be sufficient to cause burns. Newer return electrode designs incorporate two separate electrodes to continuously monitor skin-to-electrode impedance to detect poor skin contact.

Burns can occur at alternate sites. Contact with other conductive surfaces, such as ECG electrodes or the operating table, can cause the electrosurgical current to divide between return paths. This contact can be resistive or capacitive. At the frequencies used by electrosurgical units, capacitive coupling can occur, with surfaces that would not appreciably conduct lower frequency currents. Two approaches are taken to prevent this. One is to always place the return electrode as close as possible to the surgical site. The other is, via the design of the electrosurgical unit, to ensure that all of the output current is returned to the electrosurgical unit through the return electrode. This can be accomplished by using an isolated output (analogous to isolated-power distribution systems) that does not allow current to return through alternate paths. Another technique is to compare the output current with the return current. If they are not the same, the electrosurgical unit deactivates the output and alarms (audible and visible).

It may be difficult to identify all contributing factors to a burn or burn-like injury. There often are multiple factors, any one of which by itself would not have caused an injury. Thermal burns can result from direct contact or radiant heat. Hyperthermia units can cause the former, and radiant warmers or high-intensity lights can cause the latter. Ischemia resulting from pressure or surgery can exacerbate the problem because circulating blood is an effective means for dissipating heat. Mechanical injuries can appear to be burns. Shearing forces, which result from changing the position of the operating table, can cause mechanical injury. Chemical burns can result from the application of some skin preparation agents (e.g., acetone, alcohol, iodine, or merthiolate). Injury is more likely if the agent is in constant contact with the skin and if heat or pressure is applied. Ethylene oxide, if not completely aerated from the chambers of a resterilized anesthesia mask or hyperthermia blanket, may cause skin injury, especially if the skin is moist. Electrical burns can result from the unintended flow of electrical current. Not only electrosurgical units, but virtually any device that has an electrical output, can cause a burn if the current density is allowed to get too high. For example, nerve stimulators for testing the degree of muscle paralysis have caused burns when used with inappropriate electrodes.

Outright failure of medical equipment accounts for only a small percentage of patient injuries. Generally, a complete failure is obvious, and the real problem is the lack of availability

of the device. A more insidious problem occurs if the device is inaccurate. This can lead to inappropriate treatment, either directly because of an incorrect output (e.g., defibrillator) or indirectly because of an inaccurate measurement (e.g., pressure monitor).

Although not many device-related patient injuries occur, more result from human error (referred to as *use error*) than device failure. This probably is because when a device fails, an operator is likely to discover it, whereas when use error occurs, it may go unnoticed. Use error can take the form of misinterpretation, oversight, or misapplication. Any of these can result from, at least in part, the equipment design. Confusing or ambiguous controls and indicators increase the opportunities for mistakes. In addition, human error is likely to occur if operators do not receive adequate training or if a variety of models of equipment are used interchangeably for the same applications. A new standard has been developed, IEC 62366:2007, which will require manufacturers to minimize use error.[21a]

Aspects of Equipment Safety

Attention should be given to all aspects of equipment safety to provide the proper measure of safety. Two broad categories should be considered: care of the equipment and care of the users.

Care of equipment requires conscientious application of engineering and management principles. Care of equipment also requires care of physical facilities; the former cannot work properly unless the latter also works properly. To provide this care, clinical and plant engineering departments not only have to do their own jobs, they have to cooperate.

The clinical engineering department typically has responsibility for most electronic and pneumatic equipment that has a role in patient care. The major functions of clinical engineering departments are inspections, repairs, and user assistance. Every clinical engineering department should provide these services. Biomedical equipment technicians are specially and specifically trained to provide these services.

Equipment inspections and preventive maintenance must be done according to appropriate schedules and procedures. Developing the schedule depends on judgment and experience. Consideration is given to the likelihood of problems occurring, the seriousness of the consequences, and the manufacturer's specifications and recommendations. The procedures are developed from a combination of the manufacturer's procedures in the service manual, independently published standards and guidelines, and practical experience. Inspection procedures must include safety (mechanical and electrical) and performance tests. The latter should be considered more important. Performance failures may or may not be more serious than safety failures, but they are more likely to occur. A successful inspection depends on two other aspects as well: appropriate test equipment and cooperative equipment users. The former is obvious; the latter too often is not. To locate equipment and ensure its availability, biomedical equipment technicians should have help from equipment users. New radiofrequency identification (RFID) systems may help locate equipment and track maintenance history. Finally, the inspection program must be documented, including the schedule, procedures, and results.

Medical equipment repair is a technical skill that depends on education and experience. Users can help in two important ways. The first is to take the time to explain the nature of the problem and to make a reasonable assessment of the priority of the equipment. The second is to give the technician time to concentrate on troubleshooting and repair. Documentation of repairs is important to the clinical engineering department in order to track trends with equipment and users. Such documentation also should be available to the users for their review.

Other functions provided by more versatile clinical engineering departments include equipment evaluations, equipment-related incident investigations, in-service education, and design and fabrication of new or modified equipment. These services are best done by engineers or experienced technicians with a demonstrated ability for these functions.

Plant engineering departments also provide inspections, preventive maintenance, and repairs, although they typically do not provide user assistance to clinicians. The equipment for which they are responsible is predominantly nonmedical, but it is just as critical as medical equipment is to clinicians and patients. The medical equipment for which plant engineering departments are responsible may include patient beds, operating tables, operating room lights, nurse call systems, and mechanical items such as stretchers and wheelchairs. However, as this equipment becomes more versatile and more complex, responsibility often is transferred to the clinical engineering department.

Clinical engineering and plant engineering departments must cooperate, particularly in areas where their responsibilities overlap. Examples include the installation of equipment for patient monitoring, dialysis water treatment, and imaging, and for other equipment having unique installation or operational requirements. Likewise, clinical engineering and information technology departments must cooperate.[38] Increasingly, the lines separating their equipment responsibilities is blurring, as medical equipment is networked and data from medical equipment are added to electronic patient records.[39,40]

Arguably the most important facet of the safe and effective use of medical equipment is the end user. The end user usually is a nurse or a physician but may be an engineer, technician, or therapist. The most vital component for user success is training. The end user can be so skilled that he or she can even overcome shortcomings of particular equipment or so unskilled as to make the best of equipment hazardous. Training can and should be available from the manufacturer, directly from its representatives and from its operator's manual, from the clinical engineering staff, and from other knowledgeable users. Users should understand the operating principles of the equipment, the operation of controls and indicators, and the applications for which the equipment is intended. They should observe the setup and preuse checks prescribed by the manufacturer. They have the right and the duty to insist that equipment be properly maintained and in proper working order. Finally, they should be observant and conscientious during the actual use of the equipment.

Another, occasionally overlooked, aspect of medical equipment use is cooperation with others in healthcare who are involved with the acquisition and use of medical technology. The institution's administration is responsible for planning, budgeting, and complying with a myriad of standards

and regulations. They cannot be completely successful without the cooperation of clinicians. Support services, from housekeeping and nutrition departments to plant and clinical engineering departments, cannot successfully complete their responsibilities without cooperation from clinicians. All clinical areas have similar requirements. It often is just as important to share the availability of clinical equipment as it is to share clinical information to provide optimal patient care.

Technology Management

It is an oversimplification, but still useful, to categorize the approximately 40-year history of clinical engineering by decades. The 1960s were primarily concerned with electrical safety, the 1970s with performance assurance, and the 1980s with productivity and quality assurance. The 1990s were concerned with technology management, incorporating quality improvement. Now we are addressing software reliability, firmware upgrades, connectivity of medical devices to the hospital information system, and the absence of standards-based interoperability. The intention is for everyone involved in the acquisition and use of technology to cooperate to improve this process and patient care within the constraints (primarily financial) imposed on healthcare.

Technology management is a complex subject, still in its infancy at least as far as its acceptance and application in healthcare institutions.[41] To bring a measure of order out of what often is a seemingly chaotic situation, technology management can be described as a five-step cycle (Fig. 27–17).

Appropriately enough, the first step is planning. New technology should be approached with equal measures of promise and caution. It takes time and objectivity to determine whether the new technology actually will improve healthcare, what the total cost will be, whether the cost is affordable, and whether the new technology fits properly with the mission and other plans of the individual institution. Replacement of equipment also is involved in planning. Justification for replacement should include consideration of dependability and safety, operating and maintenance factors (including cost), and performance. Another consideration in planning is the quantity of equipment needed to satisfy peak demands and for backup. Related to this is the support for new equipment: trained users, installation requirements, supplies, and maintenance requirements.

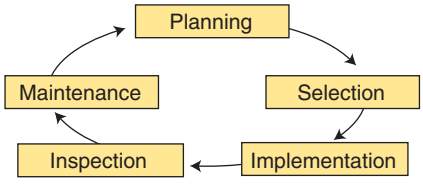

FIGURE 27–17. Cycle of technology management.

If the decision is made to acquire new equipment, the second step is selection. Unless the technology is new, there probably will be more than one source or more than one model or configuration. Technical and clinical criteria should be determined, based on available literature, the experience of other users, and the institution's unique needs. A comparative evaluation should be conducted.[42] An engineer should test equipment samples to compare performance versus the established criteria, any available standards, and the manufacturer's specifications. Acceptable equipment then should undergo a clinical trial that is long enough to expose the equipment to a representative sample of potential uses and users. Current users of each model at other institutions should be contacted for their reactions and opinions. Where possible, the institution should standardize on one model of a particular type of device, especially if users are likely to encounter different pieces of the same type of equipment. Finally, the institution should protect its negotiating position with vendors by not making its final decision (or at least letting it be known) until competitive bids are received and reviewed.

Implementation follows selection. The time to include all requirements and specifications to protect the investment is during order placement. Considerations for inclusion in negotiation and ultimate order are operator and service training, warranty, supplies and accessories, price protection for future purchases, upgrades (especially software), and provision for maintenance, including parts and backups. This also is the time to consider installation requirements such as special space or services, and who will perform to installation. Acceptance of, and payment for, the equipment should be contingent on a successful initial inspection to be provided by personnel of the institution's choosing. Before the new equipment is put into use, users should be trained. Ongoing training, for new users and as reinforcement for others, should be available as needed. The need for training simply cannot be overlooked or overemphasized.

Ongoing use of equipment requires an inspection program. As described previously, an inspection program should be performed according to an established schedule, with procedures and test equipment that cover safety and performance aspects. Some equipment requires routine preventive maintenance (e.g., regular parts replacement or calibration). The inspection program must be properly documented, including the schedule, procedures, and results. Based on trends discovered by analyzing inspection results, it may be appropriate to adjust the technology management program. If the equipment is not meeting expectations, it may be necessary to involve the manufacturer. If something was overlooked in the acquisition, the oversight not only should be corrected, but the selection and implementation processes adjusted to prevent such occurrences in the future. As a result of trends, it may be necessary to increase the inspection frequency or to possibly reduce it.

Ongoing use of equipment requires maintenance. During the warranty period, a final decision can be made about whether service will be provided by the manufacturer, an independent service organization, or an in-house department. Before the warranty expires, arrangements can be made so that there is no lapse in service. Again, documentation is necessary for, among other things, determining whether there are any trends in service problems that could be corrected. In addition, the service history of the equipment should be used to help decide on future purchases (e.g., buying more of the same device and repair or replacement choices). This leads back to step 1—planning.

Technology management is intended to combine and refine individual equipment programs, to make them work more efficiently, and to be directly involved in improving quality in general and patient care in particular (Box 27–1).

CONCLUSION

Medical technology is vital to modern healthcare. Its contributions to patient

BOX 27–1.

Technology Management Program Components

- Equipment control program: documentation, inspection schedule, procedures
- Outside service contracts: negotiate; monitor performance
- Inspection and repair records evaluation: identify problems; advise on inspection schedules and procedures; advise on equipment replacement
- Device evaluations (including disposables)
- Device recalls and alerts program
- Risk management and quality assurance program
- User training program
- Expansion of in-house service (e.g., personal computers, home-care program devices)
- Hazardous materials management program
- Research, design, and fabrication of clinical equipment

care and its rate of progress are awe inspiring. The practice of anesthesiology largely depends on medical technology. Equipment increases the anesthesiologist's ability to fulfill patient responsibilities, but it certainly does not replace it. The anesthesiologist should know how to apply technology safely and effectively as part of these responsibilities.

This chapter provides a background for the principles and requirements of the safe use of medical equipment. Historically, scare tactics were used to convince clinicians to follow specific guidelines for the safe use of medical equipment. The better approach is to explain the problems and the solutions so that guidelines are understood and applied objectively. For example, medical device standards—when used as their originators intended—generally are a help and not a hindrance to providing safe and effective patient care. It also is valuable for clinicians to understand the principle of operation of each device sufficiently to produce a "conceptual model" to aid safe use and troubleshooting.

This chapter provides a review of basic electricity so that electrical hazards to patients can be understood. In response to such hazards, medical device standards have been developed. To apply these standards, electrical safety programs were instituted in hospitals. Experience with electrical safety programs showed the need for other safe practices in the application of technology. Technology management programs currently are being developed to acquire and implement new technology effectively.

Medical technology is remarkable, but so are the people who use it safely and effectively. Two factors may not be intuitively obvious: (1) safe and effective application of medical technology requires cooperation among clinical staff, support services, and administration, and (2) justification for and application of medical technology aims for improvement of the quality of patient care.

PART 4

MANAGING ANESTHESIA CARE

SECTION A

Monitoring the Anesthesia Patient

CHAPTER 28

Perioperative Information Management Systems

J.P. Abenstein, MSEE, MD

In the 1950s and 1960s, digital computers, in the form of mainframe systems, first made their way out of government laboratories and into the corporate world. They soon found their way into hospitals, generally as accounting tools. Over time, computer technology was offered as a solution to many real and perceived problems in the hospital, including medical record keeping, patient data analysis, and materials management to name just a few. In spite of the expenditure of significant resources, both monetary and personnel, few real clinical solutions were successfully introduced. This was disappointing to both investors and computer advocates. The reasons for these failures are many but often were based on the fact that the proposed clinical solutions were more complex and demanding than was technically or fiscally feasible to solve. Often the solution was far more expensive than the problem.

The last 10–15 years have seen truly dramatic changes in computing. Desktop and server hardware are remarkably powerful. Advances in network technology allow for the integration of thousands of machines. Storage solutions make it possible to store and retrieve information stored on hundreds of terabytes. The Internet has demonstrated that large amounts of information can be transmitted and displayed in new and creative ways. Finally, and most importantly, advances in computer science, particularly programming tools and computational theory, now allow for the introduction of clinically important computing technology in the medical environment.

Interest in the perioperative information management system (PIMS) is increasing. This interest is based on a variety of issues, including the following:

KEY POINTS

1. The question of whether medical records will be electronic has been answered. All medical records will be entered and accessed on computer systems, including anesthesia and critical care documentation. Resistance is futile; you will be assimilated.
2. Anesthesiologists can either embrace this new technology and have a say in how it will be manifested in their work environ nment, or they can wait until another physician or administrators decides for them how they will document their clinical care.
3. Configuring and installing a perioperative information management system (PIMS) is a significant task. Careful project management is required. This includes:
   - **a.** Production of a scope document that defines the expected functionality of the PIMS.
   - **b.** Rigid control over the project to prevent scope creep. No additional functionality should be allowed unless it is vital to the overall success of the project.
   - **c.** Contracting the defined functionality in the scope document if that functionality is not critical and proves to be delaying the project.
   - **d.** Departmental leadership must keep ownership of the project. Careful delineation must be made between project decisions (how to program functionality) and practice decisions (how will clinicians use the PIMS). Practice decisions must be made by the leadership, NOT the project.
4. Additional functionality can and should be added to the PIMS after installation. New functionality that focuses on patient safety and practice efficiency is most common.
5. The business case for a PIMS can be made from both direct and indirect benefits. Direct benefits include improved billing, decreased lost charges from incomplete records, and decreased risk from regulatory and payer audits. Indirect benefits include legible records and ubiquitous access to medical information instantly throughout a medical center.
6. Objections to adoption have proved to be unwarranted. These include concerns with cost (see business case), artifacts, and the impact on workflow. In particular, the concern with increased risks during litigation have proved to be completely unfounded. Both the experience at Mayo Clinic and that reported in the literature show that risk during litigation is decreased with a PIMS.
7. The PIMS database can be used for practice management, quality assurance, and research. Use of electronic data to produce information and knowledge is in its infancy.

1. Physiologic data are not recorded in a timely fashion, particularly during critical incidents that demand all of a clinician's attention.[1] The anesthesia provider, either unconsciously or purposely, "smoothes" the physiologic information prior to recording.[2–4]
2. Serious legal consequences may be generated by the lack of accurate records.[5–7]
3. The explosive growth in monitoring devices and laboratory data generates so much data that the process of recording information diminishes a clinician's ability to care for his/her patient.[8]
4. Increasing demands by regulatory agencies for quality assurance (QA) reviews consume too much time and money. The ability to generate a database should allow for automated screening of perioperative records.[9]
5. Use of computer-generated databases will reduce the difficulty in determining the safety and efficacy of new technologies and therapeutic interventions. PIMS has been offered as a solution for these and many other perceived problems.

Counter-arguments opposing the introduction of a PIMS are strong[10–16]:

1. An unacceptable number of artifacts will appear on the official anesthesia record. Artifacts potentially could mislead clinicians as to the course of the anesthetic and potentially generate medicolegal difficulties.
2. The anesthesia provider will be forced to spend too much time generating the anesthesia record and will neglect the patient.
3. The clinician will not look at the current state of the monitors because there is no need to write the values down, thereby leading to a lack of vigilance.[17]
4. The expense and added complexity far outweigh the unproven small improvement in record keeping and practice.

Despite the ongoing controversy over PIMS, the number of institutions installing such systems continues to grow. Initially, these systems were designed and built by the users. Several academic departments have spent substantial resources developing these systems, with mixed results.[18–20] In the last several years, a number of commercial products have been released. These systems vary in their degree of automation, complexity, networking capability, and cost.

Pragmatically, the debate on whether to embrace electronic anesthesia records is essentially over. Not because of any breakthroughs in computing technology or the development of the "perfect" anesthesia system but because of the fact that the decision to use electronic medical records (EMRs) has already been made by hospital systems, external payers, and regulatory groups. Whether or not anesthesiologists accept electronically based documentation, the facilities in which anesthesiologists work, the payers whom they send bills to, and virtually the entire external medical regulatory structure have made it clear that EMRs will not be preferred, they will be required. Therefore, anesthesiologists are left with the decision either to choose and implement a PIMS that best fits their needs or to wait for a physician in another specialty or hospital administrator (i.e., individuals who do not know where the operating rooms are, much less how an operative practice functions) to pick one for them.

Unfortunately, little has been written on the routine use of PIMS. This reflects the small number of systems that have been installed and the difficulty in objectively evaluating the use of automatic record keeping. Therefore, most decisions on purchasing a PIMS are based on preconceived notions and the assurances of equipment vendors. This chapter attempts to delineate the major issues associated with choosing, implementing, and using a PIMS in a clinical practice.

THE MEDICAL RECORD IN CONTEXT

Physicians, nurses, allied health staff, and others are caring for increasingly ill patients undergoing ever more complex and risky procedures in operating and nonoperative procedural suites. The primary tool used to manage these patients is the information found in the medical record. Starting with basic patient demographics (i.e., name, hospital number, height, weight,) the medical record is the repository of information concerning the patient's medical history, current condition, laboratory and diagnostic test results, and all other information associated with the current episode of care. Unfortunately, the vast amount of information about the patient is rarely available in a format that allows caregivers to find the pertinent information in a timely manner. This problem has worsened as patients and the healthcare system that cares for them have grown in complexity. The suggestion that physicians and nurses will continue to search through often random collections of mismatched illegible pieces of paper in order to piece together the current status of a surgical patient is unacceptable. Lost time and information is the rule. Not uncommonly, patients submit to expensive and potentially dangerous diagnostic tests, and the results of those tests are not used by their physicians merely because the results are effectively lost. Today, the paper medical record is broken beyond repair.

In the operating room, rapid access to vital information often can mean the difference between a successful intervention and a disaster. Information technology offers a solution to this problem. A number of centers, including Mayo Clinic, are in the process of developing comprehensive EMRs. From the perspective of the operating suite, a subset of these tools and information is most important:

- Interfacing and display of physiologic monitoring
- Interfacing and display of mechanical support devices
- Periprocedural events (e.g., airway management)
- Medications
- Fluids
  - Input and output calculations
- Infusions
- Stat laboratory results
  - Arterial blood gases (ABGs)
  - Electrolytes
  - Hemoglobin
  - Coagulation studies
- Recent diagnostic studies
  - Cardiac catheterization
  - Echocardiography
  - Laboratory results
  - Radiographic images and interpretation

- Electrocardiographic and electroencephalographic tracings and interpretation
- Recent history and physical examination
  - Patient problem list
  - Current pathophysiologic state
  - Summary of progress notes
  - Current medications
  - Allergies

This information is found in the electronic tool used by an anesthesiology practice to document its patient care activities, the PIMS. With this collection of integrated tools, a collated summary of information is produced that reflects the patient care and response to care during the perioperative period.

Automated anesthesia record keeping systems (AARKS) have been commercially available for a number of years. The total market share of this technology is small but is growing rapidly. Today, a number of commercially available systems have been successfully implemented outside of research and development environments. These companies include (but are not limited to) the following:

- CareFX, Scottsdale, AZ
- Caresuite, Picis, Wakefield, Massachusetts
- Centricity, GE Medical, Fairfield, CT
- CompuRecord, Philips Medical, Andover, MA
- Innovian Anesthesia, Dragger Medical, Germany
- Surginet–Cerner Corporation, Kansas City, MO

I believe that EMRs have reached the "tipping point." Although this technology has downsides, including the substantial cost of implementation, they are outweighed by its benefits. As stated earlier, outside forces are making it next to impossible to avoid EMRs, both in and out of the operating suite.

It is reasonable to extrapolate the success of computer-based anesthesia records to the additional information gathered and recorded in the operating suite. The additional benefit of eliminating multiple, often conflicting, documentation of the same information and the elimination of transcription errors will improve efficiency and distribution of appropriate patient information to all the medical professionals in the operating suite. Finally, the process of introducing this technology can spur medical organizations to rethink what information really needs to be recorded. It is fair to say that a portion of the information we dutifully record each day is never read or used to care for our patients. If it is not used, why enter the information? Manifesting a PIMS in the operating suite is vital to the continued success of this enterprise.

The rest of this chapter focuses on the selection, configuration, implementation, and evaluation of a PIMS in a clinical environment. I will use the Mayo Clinic experience as the basic template for this discussion.

SELECTION OF A PIMS PRODUCT

An automated anesthesia record keeping system had been used in the cardiothoracic and vascular surgery operating rooms at Mayo Clinic since 1983. This system was based on the Hewlett Packard Patient Data Management System (PDMS). It used a minicomputer for processing and interfaced with custom physiologic monitors, mass spectrometer, blood bank, cardiac catheterization laboratory, radiology department, and blood gas laboratory. The user in the operating room entered information via a command-line interface. The anesthesia record was produced in real time with a color X–Y plotter. Over the life of the system, more than 75,000 anesthetics had been recorded and archived.

By early 1996 it became evident that the system was reaching the end of its useful life. Hardware failures were increasing, and the vendors had made it known that spare parts would no longer be available. In addition, the software had reached the limit of functionality, and the ongoing process of modifying the software as the practice evolved was no longer possible. A search was begun to find a replacement for the cardiac system with the intention of expanding the use of automated anesthesia record keeping to the entire anesthesia practice and to incorporate information from preoperative care, intraoperative nursing, procedural data, and postoperative care.

At the 1996 American Society of Anesthesiologists (ASA) Annual Meeting, a team of anesthesiologists and information services staff examined all the PIMS-related products presented at the meeting. Four manufacturers were invited to present their systems in greater depth at Mayo. They were asked to demonstrate the ability of their products to chart both complex (aortic valve replacement and coronary artery bypass graft) and short (myringotomy with tubes) procedures. The systems were evaluated for their clinical utility, ease of use, and completeness, as well as technical compatibility with the installed base of clinical instrumentation and networked information systems. The initial four products where culled to two. Further evaluation was done, including site visits, visits to research and development facilities, detailed technical review by our engineers and programmers, further clinical simulations of detailed anesthetic scenarios, and fiduciary review. After an extensive 6-month evaluation, the decision was made to purchase a replacement system for the cardiothoracic and vascular practice, which consisted of 14 operating rooms, and if successful to expand the implementation to the entire anesthesiology practice of approximately 150 anesthetizing locations, 75 postanesthesia recovery beds, 60 preprocedural waiting beds, potentially the nonoperative procedural practice, and the ICUs.

The initial replacement project was carefully defined to manifest only the functionality of the existing system. Attempting to expand functionality would add too much complexity to the project and could prevent successful implementation prior to failure of the existing system.

A detailed scope document was produced to fully define the expected functionality, the steps necessary to manifest the project, and the project time line. Production of a Gantt chart was an integral part of the scope document. A Gantt chart breaks the project into small parts, with expected time line and dependencies. A simplistic example of a Gantt chart is shown in Fig. 28–1. The importance of the scope document cannot be overstated. Without a scope document, successful management of the project would be impossible. The stated operational philosophy of the project was to design and implement a system that was consistent with the clinical practice. It is considered paramount not to expect the practice to change in order to use

the new system but to modify the system to fit the practice. Another critical project management strategy was the careful delineation of project decisions and practice decisions. Aspects of the new system that would directly impact the clinical practice (e.g., how attending physicians would sign the chart, or whether to block patient transfer if the chart was not complete) were taken to the clinical leadership. Assuring that the clinical leadership had a direct sense of ownership of this project was an important part of the project's success.

The project was strictly managed in order to prevent scope creep (i.e., the addition of new functionality as the project progressed). If proposed new functionality was not in the scope document and the argument could not be made that the new functionality was absolutely vital (e.g., lack of the functionality would led to patient harm, system failure, or regulatory noncompliance), it was not considered. In fact, some expected functionality was deferred when it became apparent that continued development would lead to unacceptable delays in the project. It is vital to carefully define the functionality of the PIMS, document the functionality in a scope document, rigidly stick to the functionality defined in the scope document while implementing the PIMS, and contract the functionality if implementation is negatively impacted by aspects of the defined functionality.

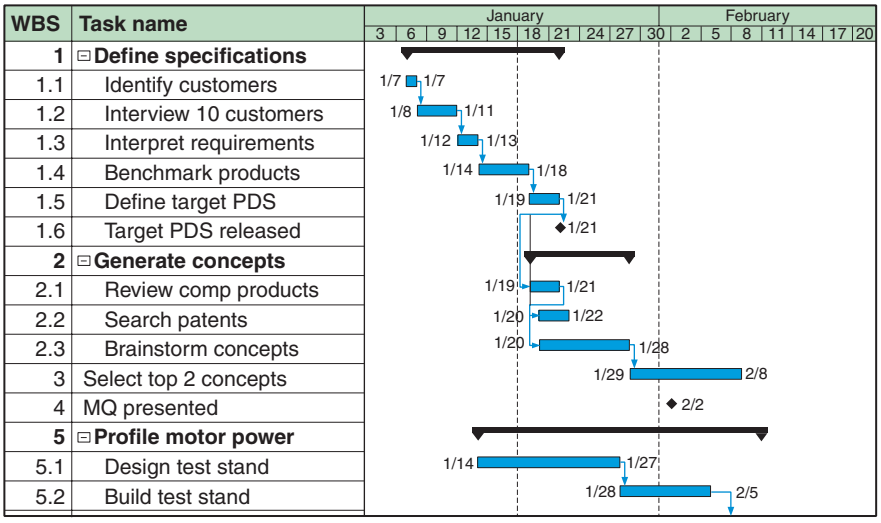

FIGURE 28–1. Simplistic example of a Gantt chart. Note each line item has a start date and an end date. Arrows show dependency. For example, 1.1, "Identify customers," starts and ends on 1/7. 1.2, "Interview 10 customers," requires 1.1 to be complete before this task can begin. When 1.2 is completed then 1.3 begins, and so on. Other tasks can be performed simultaneously.

DESIGN AND CONFIGURATION OF A PIMS

The first part of the project was to configure the software. This consisted of building a variety of database tables that listed every fluid, medication, procedure, personnel, and text-based patient care documentation (i.e., "events"). These lists had already been partially created on the existing system, but because the new product was built around a relational database the tables had to be constructed in more detail than the previous system. The level of detail must be carefully considered. It is attractive to document every possible variation of a clinical activity. For example, an intravenous line placement can include the size, length, specific location, and use of local anesthesia. The events for one IV could then read: 18G, 5 cm, IV, 0.5 cc, 1% lidocaine, left, dorsal, forearm. This would require the clinician to potentially pick as many as seven different events to document the placement of one IV. The number of possible choices for each and every action can quickly add to a very large number. Therefore, when one considers the number of activities done during one case, the decision on the level of detail or granularity that will be documented becomes critical. It is strongly recommended to apply great restraint in filling event, procedure, fluids, and medication lists. An example of an event list is shown in Fig. 28–2. Complete and detailed documentation is attractive, but the system must be useable in a clinical context.

The design of the different screens (e.g., events, flowsheet(s), fluids, medications,...) also had to be configured. The home screen was modified repeatedly. At first, we thought that maximizing the information content of the home screen would be ideal, but when the project team and clinical users interacted with mockups of the system, we realized that the content was

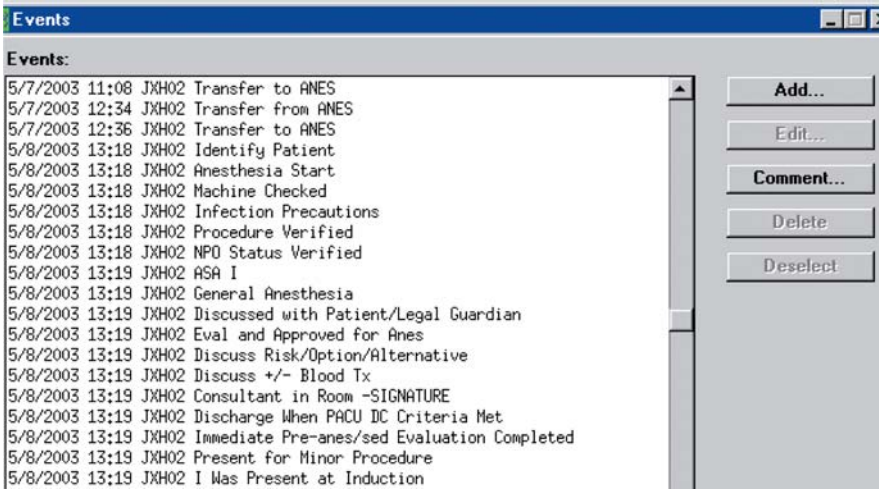

FIGURE 28–2. Example of an event list. Note that each event is timed and dated, and the author is identified by user name (i.e., JXH02). This list consists of events documented at the beginning of a procedure. The event "Consultant in Room—SIGNATURE" is the legal signature of the attending physician and must be documented under the login name and password of an attending physician.

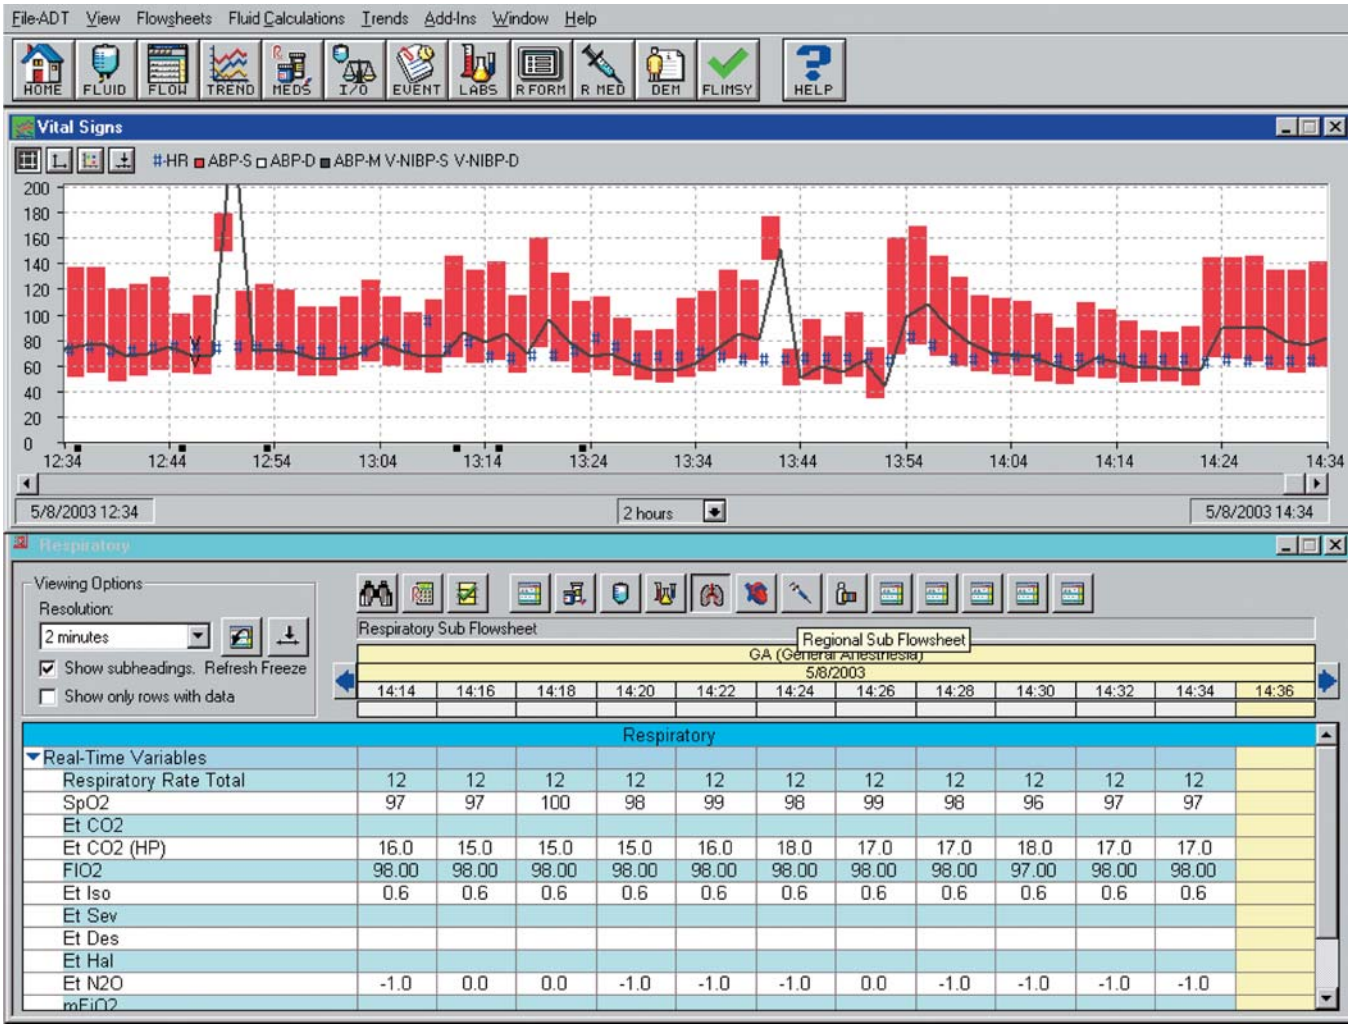

FIGURE 28–3. PIMS home screen. Top. Graphical recording of invasive blood pressure (*red bars*), mean blood pressure (*line*), and heart rate (*plus signs*). Bottom. Numerical output of respiratory parameters (e.g., respiratory rate, end-tidal carbon dioxide).

too complex and information was difficult to visually extract from the screen. The final version of the home screen only presented a graphical representation of the vital signs (i.e., blood pressure and heart rate) and the most recent output of the pulse oximeter and mass spectrograph (i.e., inhaled oxygen, exhaled carbon dioxide, and inhalation anesthetic concentrations; Fig. 28–3). After using this home screen in the clinical setting, the respiratory gas data were decided to be of little use, and the screen was replaced with the events window. Details such as physician signature and other time and security sensitive documentation also were solved. The billing and legal departments were consulted to assure that the electronic documentation would fulfil payer and regulatory requirements.

Macros were programmed to speed documentation of complex portions of the anesthetic, such as induction and emergence. A number of activities (e.g., anesthesia start, on bypass) required the same documentation. In order to decrease the charting workload, a number of preprogrammed charting macros were designed. Some of these subroutines simply accomplished a preset documentation task (e.g., the same events, medications, fluids). Other macros pause and ask the user to pick one or more items (e.g., size of the endotracheal tube, patient position) and then the macro continues. These preprogrammed tasks have the efficiency of the charting process.

The final portion of configuration consisted of designing the printed anesthesia record. This was a complex task because the practice was very focused on retaining an anesthetic record that remained essentially in the same format as the traditional handwritten record. This task was made more difficult by the limitations of font size, readability, and paper size. The final product was very close to the handwritten format, but the minimum size for any anesthetic was two pages. The computer-generated anesthetic record is shown in Fig. 28–4, with detailed close-up views shown in Figs. 28–5 to 28–7.

HARDWARE DESIGN

While the configuration team was doing its work, the project's computer scientists and engineers went about the process of interfacing the system with the clinical instrumentation and networked systems. The system has a thick client–server architecture, meaning that the PIMS software runs on the computer in the operating room and sends data to the central server, in this case, every 5 minutes. The benefit of this architecture is that if the computer in the operating room crashes, even

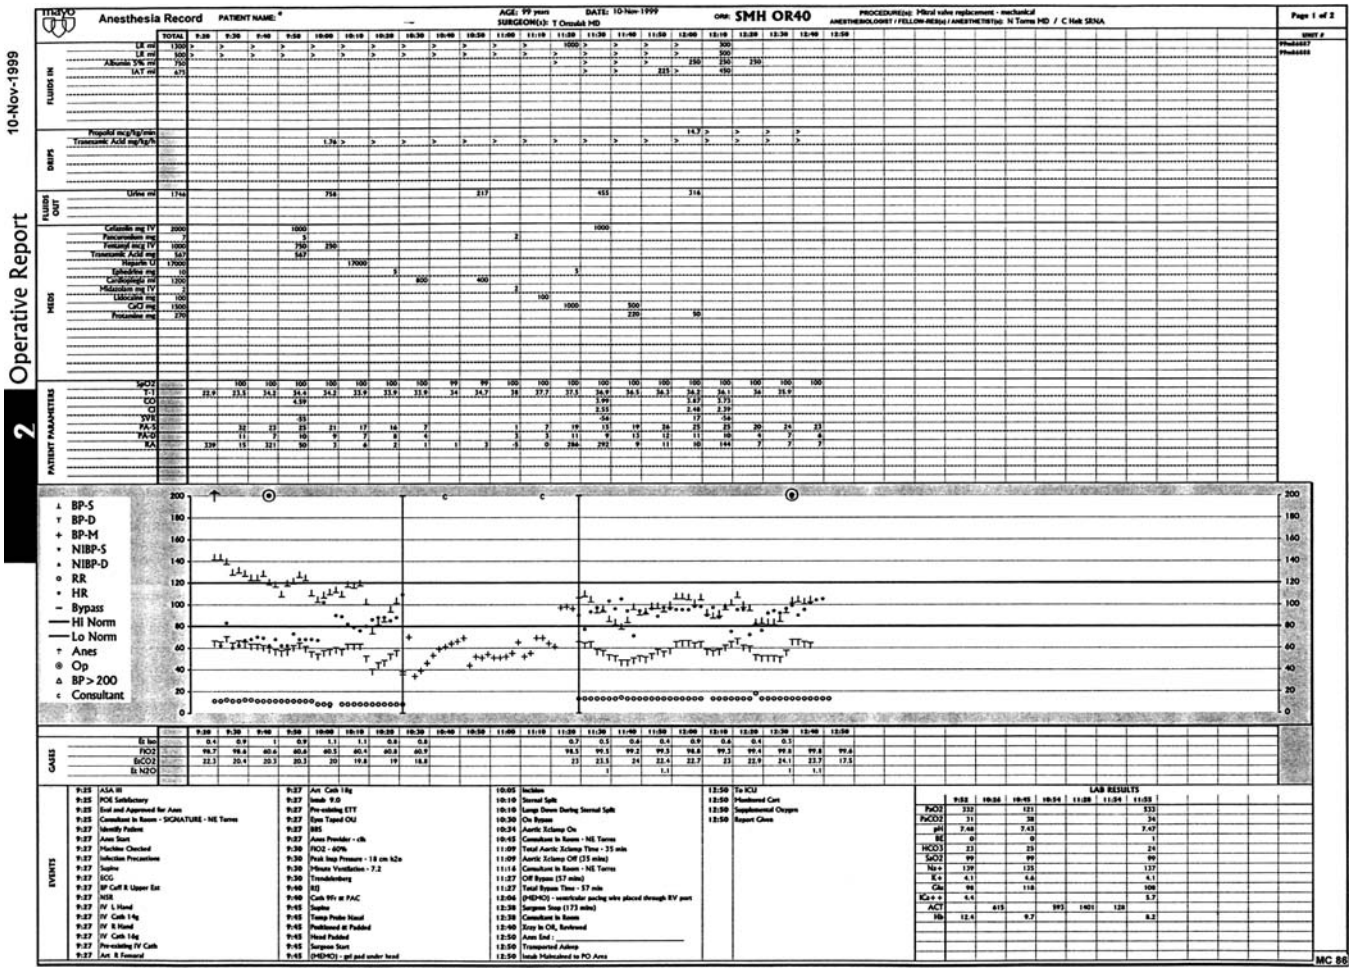

FIGURE 28–4. PIMS paper output—printed anesthesia record. Graphic vital signs with numeric vital signs above (e.g., central venous pressure, cardiac output). Drugs and fluids above vital signs. Text events on bottom left. Blood gas results on bottom right.

with a unrecoverable hard drive failure, all of the anesthetic records, except for the last 5 minutes, are retained on the server. Conversely, if the server goes down, the anesthetic record can continue to be recorded in the operating room. The vendor's architecture was further enhanced by installing fully redundant servers and hard drives. The system runs on two servers that are in geographically separated locations (i.e., across town from each other). Each server has mirrored hard drive arrays. If one server goes down, the entire load is automatically switched to the remaining server. The same hold true for the hard drives. Finally, the entire database is mirrored on a third, nonproduction server that is used for ongoing development and offline database queries. This high-reliability architecture design provides for a stable (i.e., <8 hours of unscheduled downtime per year, measured against a 24-hour-per-day, 7-day-per-week calendar) robust computing environment.

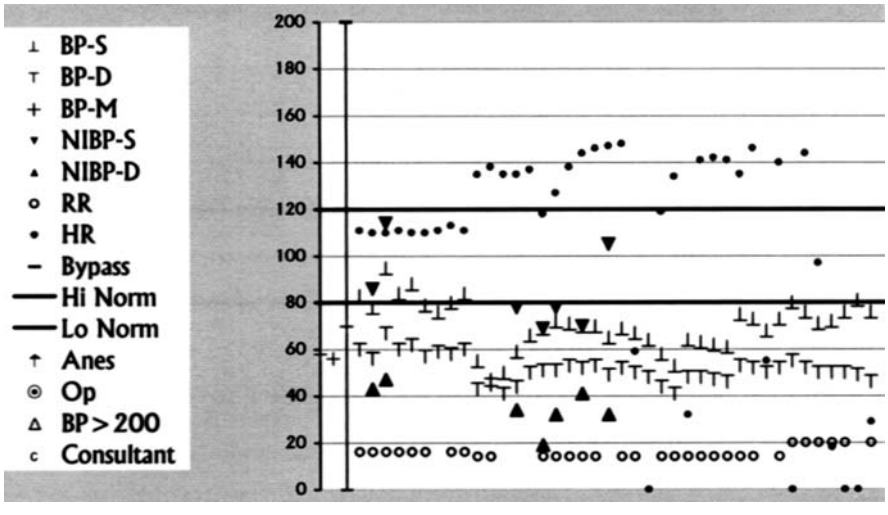

FIGURE 28–5. Close-up of the graphical display of vital signs on the PIMS printout.

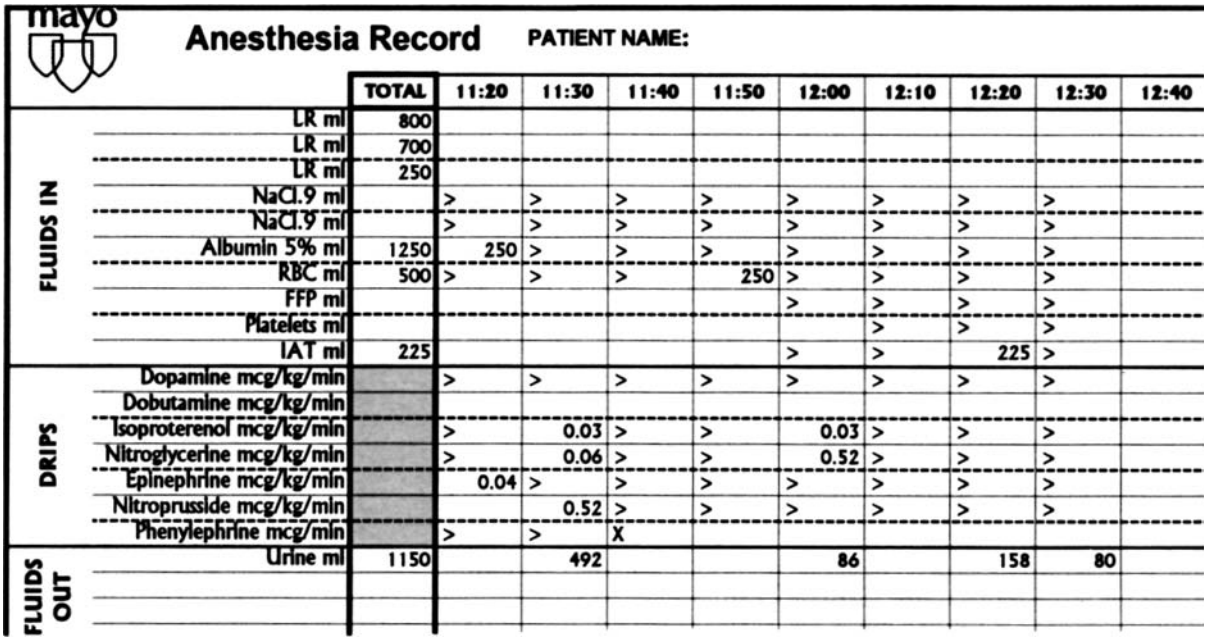
The system also had to be interfaced with the Hospital Information System (HIS). Specifically, patient demographics from the Admit, Discharge, and Transfer System (ADT) had to be forwarded and documented in the PIMS. New laboratory values had to be captured from Laboratory Medicine. This proved to be somewhat difficult because the outputs, for example, from the different ABG analyzers labeled their output values somewhat differently. This initially caused multiple rows containing the same values (e.g., a row labeled as PO_2 and another



mayo

labeled as AO_2) to be generated in the anesthetic record. The project had to implement an application that would translate these differently labeled outputs to only one label per value and then forward these translated results to the PIMS. Each interface with different electronic systems in the hospital had to be developed, debugged, validated, and, at times, had to clean up the forwarded information prior to being recorded on the PIMS.

The initial workstations used in the operating room consisted of Intel P3 processors at 300 MHz and 128 MB of random access memory (RAM). The operating system was Windows NT, v.4.5. The majority of information was transmitted via an Ethernet connection to the institutional network. Information from the operating room was archived to a server every 5 minutes in order to assure data redundancy. The interfacing with the physiologic monitor initially was via a serial card in the operating room computer. This proved to be somewhat unreliable, so the physiologic monitors then were interfaced, via an optical cable, to the institutional Intranet, which then forwarded the information to the operating room computer. This architecture offers the added advantage of being able to see the real-time values and waveforms from any workstation in the medical center. This interface is dependent on fixed computers and monitors; therefore, they cannot be moved from room to room. A number of hardware and software have been upgraded since the initial installation of the system. Currently, the PIMS runs on 3.0-GHz machines running Windows XP.

The placement of the computer system in the operating room was carefully considered. It was recognized early on that the system could not be too far away from the patient in order for the clinician to be able to care for the patient as well as chart on the PIMS.

FIGURE 28–8. Anesthesia cart in the cardiovascular operating room. Physiologic monitor and anesthetic gas analyzer on right. Computer screen and keyboard on left. Computer itself is mounted on the back of the cart.

Because the initial implementation of the system was in the cardiovascular and thoracic operating rooms, we had the luxury of fairly large operating rooms. The previous system had occupied a large cart, which included not only the computer but also the physiologic monitor, respiratory gas analysis, as well as other equipment. Therefore, it was straightforward and consistent with the current practice to replicate this footprint for the new PIMS. This hardware configuration is shown in Fig. 28–8. The luxury of the large cardiovascular operating rooms was not found elsewhere in the practice. Not only did we have to consider the much smaller general operating rooms, but we also had to deal with the fact that the location of the anesthesia equipment commonly changed in many operating rooms. This required as compact a hardware configuration as possible and the installation of multiple Ethernet sockets and sources of A/C power. After a number of false starts, the general operating room configuration decided upon is shown in Fig. 28–9.

FIGURE 28–9. Mounting of the PIMS hardware in general purpose operating room. Flat screen monitor and keyboard mounted via an articulating arm on right of anesthesia machine. Computer is below on a custom shelf affixed to right side of the machine.

VALIDATION AND IMPLEMENTATION OF A PIMS

After design, configuration, system architecture, interfacing, and hardware installations were completed, the system had to be validated prior to implementation. The project would have a short grace period with the clinicians, particularly those who had no involvement with the development of the PIMS. In order to gain acceptance, we would roll out an anesthesia charting system that was

- Accurate—the information on the electronic anesthesia record accurately captures and records information from the physiologic monitors, anesthesia machine, and ventilator, and laboratory and other information from the Hospital Information System and that entered by the clinician.
- Reliable—the PIMS is up and running each and every time an anesthetic needs to be documented (i.e., 24 hours per day, 7 days per week).
- Useable—charting the anesthetic course on the PIMS can be performed simultaneously with caring for a patient. That charting does not degrade the quality of care secondary to either time or concentration demands.
- Readable—the anesthetic record is useable during administration of the anesthetic to track the course of care and facilitate clinical decision making. The anesthetic record is readable and useable after the procedure by both anesthesia and nonanesthesia clinicians.

In order to achieve these goals, validation and implementation of the PIMS was accomplished in well-defined stages.

The first step consisted of the production of a number of clinical scenarios where every step of documentation was scripted. This information was en-

tered into the PIMS, in a remote computer laboratory, when the system was interfaced and gathering data from a networked monitor in an operating room. These clinical scripts were run repeatedly until all the automated and manual information entered was correct and the printed anesthesia record was complete and error free. Once the computer laboratory portion of validation was accomplished, the system was brought into the operating room for further testing. This testing consisted of the computer programmers entering the information into the system, during operative procedures, and then comparing the output to the handwritten record.

While the system was being tested in the computer laboratory, the configuration of the PIMS was also being tested in the usability laboratory. Clinicians who had no involvement in the project were brought to the usability laboratory where a mockup of an operating room, including all the routine anesthesia equipment and the prototype PIMS, was installed. The clinicians were asked to perform a number of charting tasks while a simulated anesthetic was occurring. They were observed via a one-way mirror, videotaped, and their interaction on the computer recorded. They were debriefed after the tasks were completed. The information gathered via the usability laboratory was used to modify the configuration of the PIMS (e.g., screens, icons, lists of events,...) to improve the user interface and usability of the PIMS, particularly in a clinical context.

Once all the bugs were identified and corrected in the computer and usability laboratories, the system was turned over to the clinical staff. After training, the staff first used the system in the "background." One clinician would care for the patient and produce the handwritten record, while another clinician would chart on the computer system. When the project team was satisfied that the electronic record accurately matched that of the handwritten record, the clinical validation process then consisted of charting in the "foreground." The clinician caring for the patient would chart on the computer record while a second clinician would produce the handwritten record for inclusion in the medical record. This last step was considered most important because it was vital to determine, prior to using the PIMS to produce the official anesthetic record, that using the system and simultaneously caring for an anesthetized patient in a manner consistent with the clinical practice was possible.

The final step was implementation of the PIMS as a production system. As with the rest of the project, this was done in an orderly stepwise manner. The entire clinical staff, physicians and nurses, was trained on use of the system. These classes consisted of 4 hours of hands-on training. The go-live process started with only four operating rooms. Each room had a clinical user paired with a "super user" who was part of the project team. The system was used for charting the anesthetic course by the primary clinician while the project team member(s) solved problems and answered questions. After 3 days, the four rooms were successfully implemented, and an additional four rooms were brought online in the same manner. This process continued until all 14 rooms were implemented. Once all 14 rooms were up and running, one to two project team members remained in the operating room suite, during the day, for 2 weeks. They remained available to answer questions and promptly solve problems. In addition, one team member, who had remote access to the operating room computers from home, was on call every night to solve problems with the PIMS. Most of the problems were educational in nature and could be solved remotely.

Postimplementation review determined that the system worked well in the context of the cardiothoracic and vascular anesthesiology practice. As part of the evaluation process, observers recorded the time spent documenting the anesthetic course on handwritten records and, after 3 months of use, on the PIMS. The results showed that the time spent charting the anesthetic course was about the same for the first 90 minutes of a case. After 90 minutes, the time spent charting by hand continued to increase in a linear manner whereas the time spent charting on the PIMS did not increase. Therefore, in short cases, computer charting took no longer compared to hand charting, but for cases longer than 90 minutes charting on the PIMS took less time. These results are shown in Figs. 28–10 and 28–11. These results are consistent with a time-motion study of anesthesia record keeping and transesophageal echocardiography from the University of California–San Diego.[21] This study also observed anesthesia personnel charting an anesthetic record manually and electronically during cardiac surgical procedures. The authors reported that there was no time difference between the two modalities, although when the clinicians charted was different. The authors also noted that little, if any, charting was done at the beginning of a case and that during paper-based charting the physiologic data and other details had to be reconstructed well after the fact. In contrast, the objective data all were recorded contemporaneously with the electronic record. Ours and Weinger's results are consistent with earlier reports.[22,23]

The new system was stable and produced an acceptable anesthesia record. Further refinements were made once the system was fully operational in the cardiovascular and thoracic anesthesiology practice and the

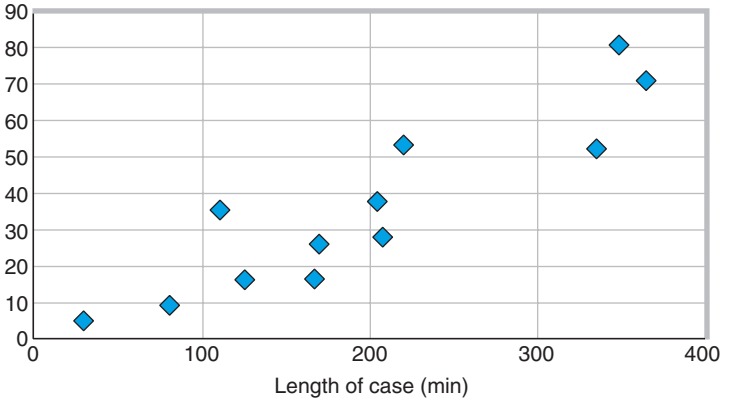

FIGURE 28–10. Results of anesthesia charting timing study for manual charting on a paper record. Time devoted to charting increases as length of case increases.

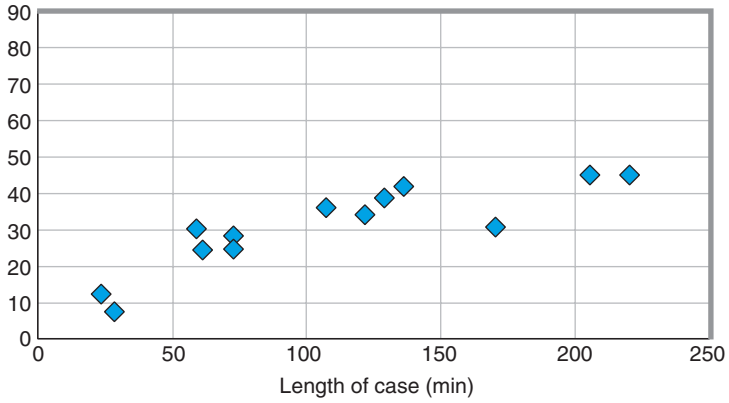

FIGURE 28–11. Results of anesthesia charting timing study for charting on PIMS. Time devoted to charting increases for first hour of anesthesia. For cases lasting >1 hour, charting the anesthesia record takes 30–45 minutes for any length of case.

clinical users had the opportunity to evaluate the system and provide feedback to the project team about any problems encountered or enhancements needed. Based on this experience, the decision was made to expand the use of the system to the entire anesthesia practice at Mayo Clinic.

Further configuration was needed to incorporate the specific documentation needs of the rest of the practice. This was particularly true for procedure listing and patient care events. As with the cardiothoracic and vascular rollout, further implementation was done in a planned stepwise process. Currently, 105 operating rooms, 85 nonoperative procedural rooms (e.g., cardiac catheterization laboratory, invasive radiology, GI laboratory), 10 recovery rooms, and 24 ICU and stepdown units are using the PIMS software that has been configured for the specific use of a procedural suite or critical care practice.

EXPANDING FUNCTIONALITY

Almost immediately after the PIMS was installed, there were demands for improvements. In the more than 7 years since the PIMS has been used in the clinical setting, the demands for changes and refinements have not slackened. What has become clear is that a project of this nature and scope is never completed because of the constant change in the clinical practice (e.g., new medications, fluids, procedures) and the fact that the system is being used by bright people who are constantly thinking of how to do their job more effectively and efficiently. The demands for additional functionality outstrips available resources (i.e., programmers, administrative, clinical support, and engineers). This is consistent with our experience with the original cardiovascular anesthetic record, other parts of the Mayo EMR, and reports from other institutions that also have embraced electronic charting. To successfully manage these demands required the development of a change management process. All requests for added functionality must be documented (i.e., a phone call expressing a want is not adequate). The requests are first evaluated by the technical team to determine how much work (e.g., programmer time, other technical resources) and money the request will require. The clinical team evaluates the request for its importance to the practice and assigns a priority. The impact on current projects is assessed. The technical team projects how much delay there will be in other projects time lines by adding the new request to the workload (i.e., more work to be done by a fixed number of personnel). This information is brought to the project management team, which reviews the request, decides whether to move forward on the request, and if so whether to add it to the current active projects or to add it to the queue of pending projects. If the request is added to the queue, a 1–5 priority score is assigned to guide the team as to when to activate a queued request. Finally, the clinical leadership (i.e., department and division chairs) is kept informed as to the decisions of the project group, and at times the practice will overrule the decisions of the project team (e.g., the practice may decide that a newly requested change in the PIMS takes priority over currently pending projects).

Projects to Improve Usability and Charting Accuracy

As soon as the PIMS was rolled out beyond the confines of the cardiovascular practice, there were demands for automated charting aids. This was particularly true in those parts of the practice that delivered anesthesia services for very short procedures (e.g., electroconvulsive therapy [ECT], bone marrow transplant, pediatric surgery). Users reported difficulty in documenting the anesthetic while caring for patients during these short procedures. The solution was to produce a set of icons that, when selected, would document a predefined set of charting actions. The image of the icons would change after they were selected to remind the user that this set of documentation had already been accomplished. Fig. 28–12 shows an example of this icon/button set that is used in the ECT suite. The first three icons—start, treat, and stop—document those events associated with the start of the anesthetic, beginning of treatment, and end of treatment. The last icon—transfer—charts the events associated with the end of the anesthetic course and transfers the patient's chart to the postanesthesia care unit (PACU). In addition to these icons, each practice area had its most commonly used fluids and medications automatically added to each anesthetic record when the case was started. These additions to the PIMS improved its functionality.

Documentation of perioperative procedures (e.g., regional anesthetics, placement of invasive catheters, and airway management) demands signifi-

FIGURE 28–12. Close-up of part of the icon bar in PIMS as used in the electroconvulsive therapy (ECT) suite. When these icons are selected, a predefined set of charting actions is triggered. "Start" documents the beginning of the anesthetic. "Treat" documents the beginning of the ECT treatment. "Stop" documents the end of the ECT treatment. "Trans" documents the end of the anesthetic and transfer of the patient to the recovery room.

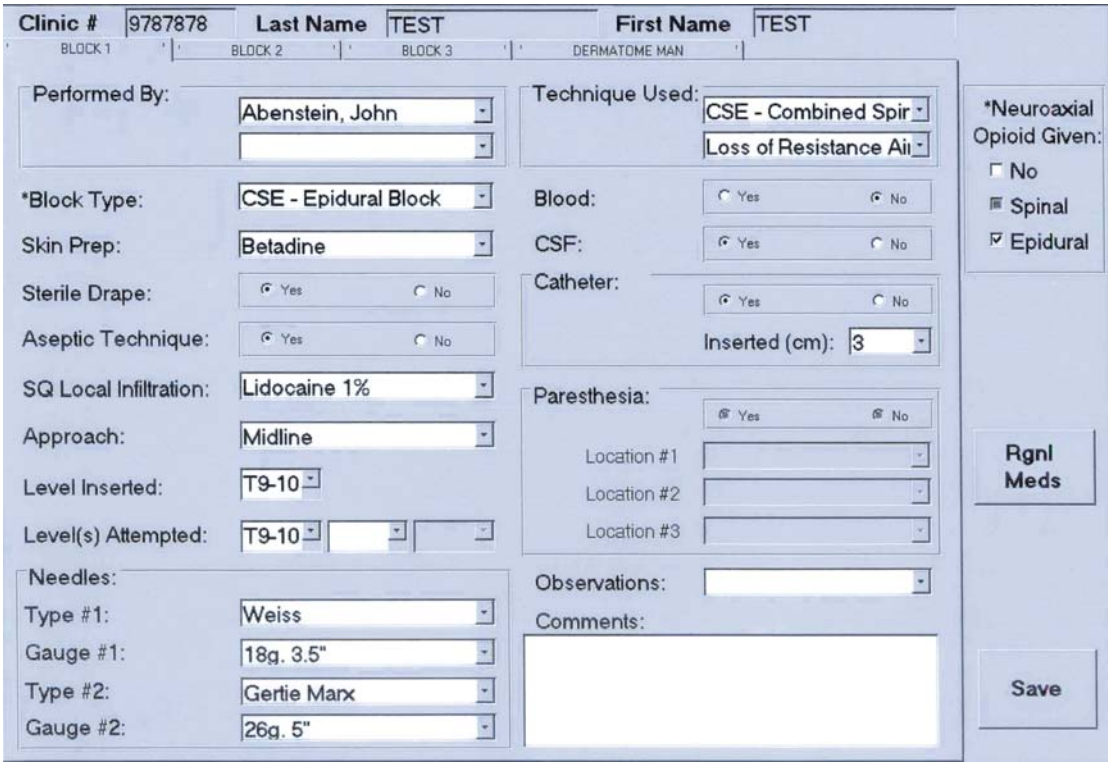

FIGURE 28–13. PIMS regional anesthesia form. Instead of picking from a long event list (Figure 28–2), the clinician chooses from short pull-down menus (e.g., CSE-Epidural Block, Betadine) or clicks on radio button. This form allows for rapid documentation with more granularity than offered by event lists.

cant granularity in order to accurately and completely document what was done to the patient. In addition, specific documentation is required by third party payers for reimbursement (e.g., that the regional anesthesia block was placed for postoperative pain management). Choosing from a long event list became problematic for charting these procedures, and the consequence was an unacceptable rate of incomplete charts and delivered services that were unbillable. The solution was to create electronic forms that could be completed in a more timely manner and could mandate completion of required documentation. Fig. 28–13 shows the regional anesthesia form. It is completed by selecting items by clicking on radio buttons or selecting items from short pull-down menus. The information is stored in the same database with the rest of the PIMS data, making queries straightforward. When the anesthetic record is printed, this documentation is in a separate section of the record and not stuck in the middle of a long list of events.

The same strategy was used for documenting the placement of invasive lines (e.g., arterial catheters, central lines, pulmonary artery catheters). This project was completed several years after the regional anesthesia project and was programmed using Microsoft's .NET technology. The programming effort required to manifest this form was much less than for the regional anesthesia form. As shown in Fig. 28–14, this form requires only one click for each data element. When a selection is made, the next list is opened, which can be different depending on a previous selection. When the documentation is saved, the information is stored in the PIMS database, documented on the anesthesia record, and forwarded as structured text to the hospital progress notes. This facilitates passing the information to other caregivers. For example, when the critical care service is determining when a central line must be replaced to prevent line sepsis, it is much faster to review sequential progress notes than to decipher an anesthetic record.

Projects to Improve Billing and Regulatory Compliance

In the paper environment, only a manual audit process assures that documentation is complete, that it fulfils billing requirements, or that it has all the details demanded by different regulatory agencies. The PIMS has the ability to automatically query the anesthesia record to determine if all the necessary documentation is present.

One of the early additions to the PIMS functionality was to automate documentation of anesthesia time. As with most anesthesia practices, there had been variability among clinicians as to how anesthesia start and stop were documented. With the initiation of the PIMS project, we were able to standardize this documentation. When the patient comes into the operating room and the PIMS is launched, the event "anesthesia start" is documented. At the end of the case, the patient is transferred electronically out of the operating room, and the patient is transported to the next unit, generally the recovery room or intensive care unit. When the patient is admitted to the receiving unit, the system documents "anesthesia end." If the clinician spends an extended amount of time rendering care in the receiving unit, he or she can edit "anesthesia end" to reflect this additional time. With the introduction of this electronic charting tied to admission and discharge, we now have reproducible and defendable anesthesia time documentation.

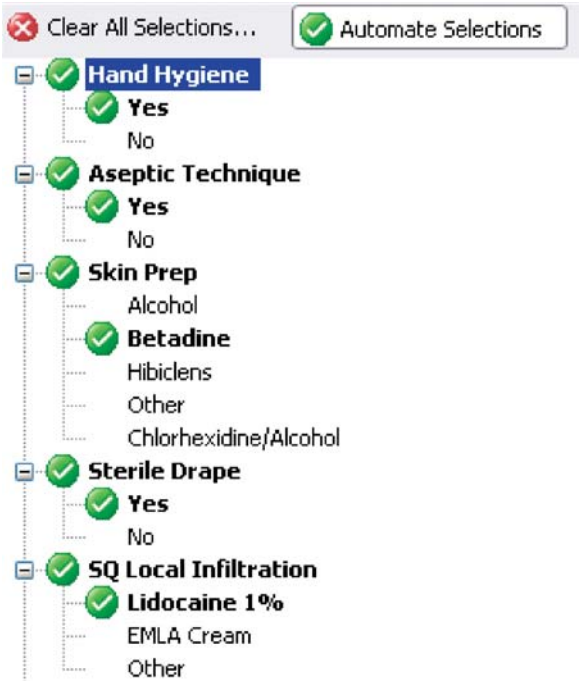

FIGURE 28–14. PIMS invasive monitoring form. In contrast to the regional anesthesia form (Figure 28–13), this form was produced using Microsoft.NET technology. This allows for rapid form development and decreases maintenance. The clinician picks from a short event list (e.g., picks Betadine in the skin prep list). This action automatically opens the subsequent list. As with the regional anesthesia form, this form allows for rapid documentation with the required granularity.

With paper record keeping, billing information had to be documented separately from the anesthesia record. The content of these forms was commonly different from what had been documented on the anesthesia record. At times, billing forms were lost or simply not filled out by busy clinicians. We added electronic billing and QA to the PIMS. At the end of a procedure, triggered by patient transfer, a subset of the anesthetic record is electronically generated and forwarded to the billing and QA offices. The only way to enter billing or QA information is via the anesthetic record; there is no possibility of conflicting information between the medical record and what is being billed. The same holds true with the QA data. With the introduction of this process, lost billings are a thing of the past. This one process change has improved anesthesia billing 5–10%.

Completeness of critical documentation is required by the Medicare program and other payers. At the end of the procedure, also triggered by the transfer process, the PIMS electronically reviews the documentation and determines whether the required events (i.e., anesthesia start and stop, procedure start and stop, attending physician signature, and ASA physical status) have been entered into the record and are in the correct order. Fig. 28–15 shows the screen that informs the user whether the required documentation is complete and correct. Only when the documentation is complete will the PIMS allow for the transfer. This process has also improved the accuracy of our record keeping. We must be careful not to make the number of required documentation events too long because this complicates the charting process, particularly at the busiest time of the case, which can lead to "crashed" records when users force quit the application, thereby bypassing the chart check process.

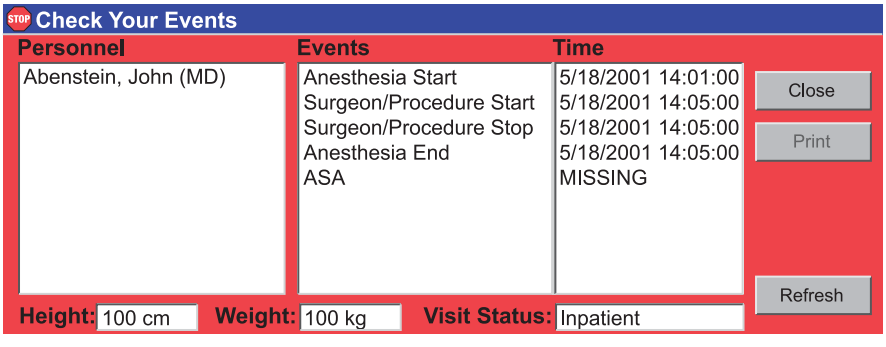

FIGURE 28–15. PIMS chart completeness screen. This application is launched at the end of an anesthetic course when the clinician chooses to transfer the patient's anesthesia record. The application determines if the required documentation (i.e., anesthesia start, procedure start, procedure end, attending signature, and American Society of Anesthesiologists [ASA] status) has been entered into the record. In the example shown, ASA status is missing.

Projects to Improve Patient Safety and Quality of Care

One of the most exciting aspects of a PIMS is the potential to use computer-based tools to directly improve patient safety and quality of care. Initially, we held the view that simple reminders (i.e., warning windows) would be a straightforward means by which to accomplish this goal. It soon became evident that clinicians found these electronic alerts to range from being annoying to interfering with their ability to get their work done. When the clinicians were observed in the operating room, they routinely clicked on the "OK" button in the warning window, took no action, and continued on with the current task. We saw no measurable improvements in safety but noted unnecessarily expended resources, and we began to alienate the clinical staff.

Instead of depending on warning windows to remind clinicians of what they should do, we changed direction and focused on transmitting information in a reliable manner. In addition, we tried to decrease dependence on human beings, who have a remarkable ability to see and hear what they expect to see and hear and to use computer-based processes that reliably produce the same output when given the same input.

Our initial projects were consistent with our general strategy—small. For example, feedback from the critical

FIGURE 28–16. Close-up of events on the PIMS printout. Note that all the events are documented in time order except for the first event, which is always intubation difficulty. This event is also printed in a larger font, which is bolded. This was considered an important patient safety feature.

care service made it clear that teasing out difficult intubations from the anesthetic record, which could have >100 documented lines of text, proved difficult. In the paper environment, intubation difficulty was documented in a specific location on the anesthesia record, and the clinician circled a "0," "1," or "2." This linear analog score had proved useful over the years and was replicated in the electronic record, but it now was just one more event in what appeared to be an endless list of events. The solution was to force intubation difficulty to the top of the event list (Fig. 28–16). In addition, if a difficult intubation was documented on the preoperative assessment, this would be carried forward to all subsequent evaluations (i.e., it would be automatically documented as a difficult intubation on every future preanesthetic evaluation), and a warning window would be displayed when the assessment was opened. Unfortunately, this safety solution was short lived because the PIMS migrated away from printing a paper anesthetic record to the information being available only electronically. The solution to this problem was found with the use of another electronic form, very similar to the invasive line form discussed earlier (Fig. 28–14). An airway management form was developed that not only has the advantages of additional granularity to more fully document how the patients airway was managed, but when the documentation is complete and saved, the system generates a structured text message that is forwarded to the electronic progress notes. This way, every clinician can easily find and read the details of airway management during the patient's anesthetic course by merely accessing the progress notes. This has proved very useful for downstream users, particularly the critical care service when they are deciding on when to wean and extubate a patient.

A more difficult problem was seen with spinal and epidural opioids. Initially, the regional anesthesia form (Fig. 28–13) required that the clinician document whether neuraxial opioids were administered and, if so, via what route (Fig. 28–17). The regional anesthesia form cannot be saved or exited without documentation of whether neuraxial opioids were delivered and, if so, by which route. This was then printed, always in the same location, on the anesthesia record. Unfortunately, some patients who had received neuraxial opioids were missed by the service and/or nursing, received additional parenteral narcotics, and had respiratory depression requiring intervention. Several solutions were attempted, including changing the location of the information on the anesthesia record and automated e-mails triggered by patient transfer. None of these solutions worked. Finally, a hospital-specific Internet site was created that listed every patient who had received opioids in the last 48 hours and included the patient's medical identification (ID) number and the time, date, and route of administration. This site is accessed throughout the day by the acute pain service, and it is their responsibility to see every patient and ensure that appropriate pain medication orders are written. This example highlights the fact that although computer-based solutions can be very powerful, they will not work unless they are coupled with achievable policies and procedures and that the solutions are evaluated to determine whether they are working (i.e., postimplementation review).

A major problem in all medical centers is difficulty errors in correctly identifying patients, particularly in environments where patients cannot speak for themselves. This is particularly true in the operating room where the patient not only is unable to answer questions but, after surgical preparation and draping, cannot even be visually identified. The traditional solution is to place an armband on the patient, but this solution is only as good as the individuals who are comparing the armband to another piece of documentation. Another safety project made use of a bar code reader and the addition of a bar code on the patient's armband. Currently, prior to entry into the operating room, the PIMS is launched, and the patient's name and medical ID number are entered into the system. The software compares the entered name and ID number via an interface with the hospital information system to determine if the name and number match. If the name and number are correctly linked, the PIMS starts recording vital signs and other objective data, but no charting may be done. When the patient arrives in the operating room or procedure room, a bar code reader inputs the information on the armband bar code, which consists of the patient's medical ID number (Fig. 28–18). If the medical ID number on the armband matches the information that had been entered into the system, the PIMS launches the anesthesia record and documents anesthesia start, and

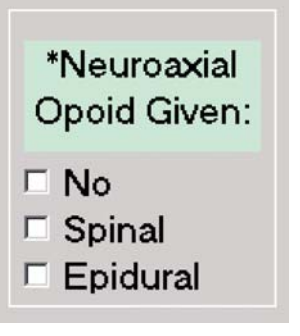

FIGURE 28–17. Close-up of the regional anesthesia form (Figure 28–13), which documents whether neuraxial opioids were administered and, if so, by which route (i.e., spinal or epidural). One of the three choices must be picked before the form can be saved and the clinician returned to the PIMS.

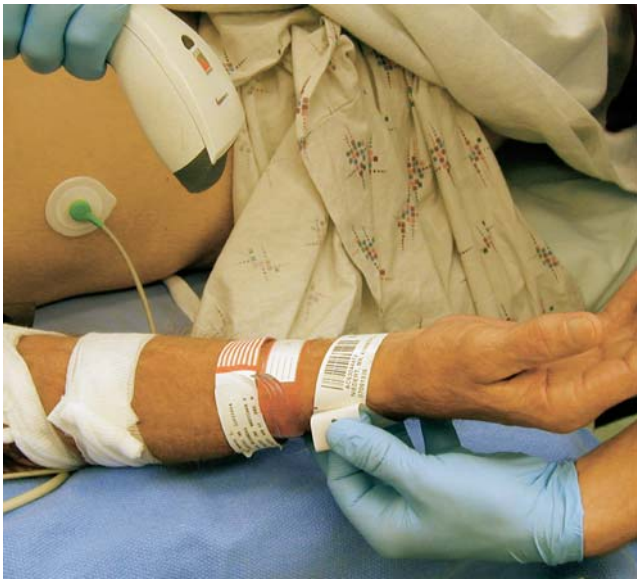

FIGURE 28–18. Bar code identification of the patient. When the patient enters the operating room, the bar code, which consists of the patient's medical ID number, is read with a hand-held device. This number is compared to the medical ID number the clinician entered earlier, which was confirmed to match the patient's name.

FIGURE 28–19. Bar code identification of blood products. The clinician reads the bar code on the blood product bag, which consists of the medical ID number of the intended recipient, with a hand-held device. This is compared to the confirmed medical ID number of the patient on the operating room table.

charting is enabled. This process ensures that the EMR on the computer is actually that of the patient on the operating table.

Unfortunately, this process does not always work. Some patients come to the operating room from the emergency department without identification. Some armbands are unreadable because the ink has worn off. Sometimes the patient has taken the armband off. These are just a few examples of how the system can be defeated. Therefore, the system allows the clinician to bypass the bar code identification but requires the user to document the reason for the bypass and to attest to the fact that he or she used other reliable means of identifying the patient. This bypass proved to be the source of several incorrect patient identifications, usually when there was a rush of getting the patient into the room, the bar code was not working for whatever reason, and the anesthesia personnel was assured of the

FIGURE 28–20. Screen displayed by the PIMS if the bar code identification of a blood product matches that of the patient on the operating room table.

identity of the patient. After a few near misses, the bar code ID bypass was refined. The system now has two requirements: (1) the clinician who is in the room must sign in with his/her name and password and document as performed previously, and (2) an anesthesia supervisor, either an attending physician or senior nurse, must enter the operating room and document that correct identification has been done.

A similar process was added to the PIMS for positive blood product identification. The blood identification process also makes use of bar code identification. When blood products are brought into the operating room, the clinician scans a bar code on the blood product bag (Fig. 28–19). Like the patient's armband, the bar code on the blood product bag contains the intended recipient's medical ID number. The system compares the ID number on the blood product bag to that of the patient, who had been identified earlier via a bar coding process. If the medical ID number of the patient matches that of the blood product, the system clearly informs the clinician of the fact, both via text and color (i.e., green; Fig. 28–20). If there is a mismatch between the patient and the blood product, the clinician is also informed via text and color (i.e., red; Fig. 28–21). Since the bar code blood product identification system was installed, no patient has received an incorrect unit of any blood product, although the rare near miss (i.e., wrong blood product is brought into the operating room) does occur.

The various patient safety projects demonstrate the fundamental fact that the failure to correctly communicate (i.e., transfer information from one clinician to another) is commonly the

FIGURE 28–21. Screen displayed by the PIMS if the bar code identification of a blood product does not match that of the patient on the operating room table.

foundation upon which error and, at times, patient harm occur. The various safety projects that a PIMS allows decrease the opportunity for those errors of communication to occur. For example, if the patient in the operating room is not the same patient the clinician believes was brought in to the OR (i.e., the patient the clinician initially entered into the PIMS), the system does not allow charting to occur, clearly communicating that the wrong patient is in the operating room. Part of the solution to these kinds of medical errors is taking the human brain out of the process, because human neurophysiology is structured to draw rapid conclusions based on incomplete datasets, thus leading clinicians to see what they expect to see (e.g., patient and blood ID). These procedures are a subset of the ongoing efforts to leverage the electronic environment to decrease the opportunities for clinicians to draw wrong conclusions that lead to errors and harm.

RETURN ON INVESTMENT

There is an understandable concern that EMRs broadly, and PIMS specifically, may not be worth the cost. These systems are expensive, with estimates between $20,000–$40,000 per bed. This cost includes the software, hardware, interfacing, furniture, and so on. The return on this investment can be difficult to tease out of the complex dynamics within a medical facility. Nonetheless, we can point to a number of significant benefits associated with the introduction of EMRs.

One of the most obvious benefits of EMRs is availability. With paper records, the paper chart must accompany a patient arriving on the ward or in the operating suite. In the context of an inpatient episode of care, the current chart commonly is placed on a clipboard or other device that holds the pieces of paper together. When the patient is moved, it is a simple task to merely place the chart on the gurney or to have the patient hold the record on his/her lap while th wheelchair is pushed. This becomes more complicated in an outpatient context and even more difficult when the patient has pertinent medical records from a previous episode of care. When the record is not with the patient, it must be sent for. This generates a time delay as well as an expense. The internal estimates at Mayo Clinic assessed a $7 cost every time a record was sent for or moved (i.e., cost of having a clerk find the record and then transport it), and it was twice as expensive to access a radiology image. If the chart is not in the expected location but instead is on another physician's desk (e.g., to be summarized or reviewed for research purposes), the time delay often can be substantial, if the record can be found at all. The consequence of these delays not only is less efficient care delivery but also possibly less effective care. Depending on the medical situation of the individual patient as well as the time demands on the clinician, decisions may be made without access to important medical information. When we analyzed our critical care practice more than a decade ago, we concluded that as much as 25% of laboratory and radiographic results were never seen by clinicians because they either could not find the results or were unaware that the studies had been done.

Once a fully integrated EMR is installed, there is virtually no delay in accessing current and historic medical information, although there is a transition period when the legacy, paper chart will be accessed. The access to old records decreases fairly rapidly over time as their value erodes and the electronic records increasingly contain historic information. Instead of having to call for a chart or waiting until a colleague has completed his/her charting task, all a clinician has to do is access a computer terminal, enter his/her ID information, and then access the patient's medical record. This ready access also assists in the direct delivery of care because clinicians can discuss cases while they have access to the record. The clinician who receives a phone call from an ICU nurse is not constrained by what the nurse sees on the record or the monitor. The clinician can access the record from a distant location and discuss the patient's management while having access to the patient's real-time physiologic data. Although we initially had worked very hard to produce a printed anesthesia record that was as similar as possible to the handwritten record, once the rest of the medical center was up and running, we were able to abandon the printout entirely. The advantages to the anesthesia team of having complete access to a patient's medical record, particularly previous anesthesia records, everywhere in the medical center are substantial.

Having this kind of ready access to medical information is associated with a real economic advantage. An immediate cost savings is associated with not having to store and transport paper records. The efficiencies gained from virtually immediate access to medical information can be translated into improved access to medical care and the ability to evaluate and treat more patients per day. Not only does an electronic record provide near immediate access, anywhere in the medical center, to the patient's medical record, it provides that information in a legible form. Fig. 28–22 shows an example of a handwritten record. It is both difficult (some would say impossible) and time consuming to obtain information from handwritten records. At times the difficulty in reading a handwritten record is an even greater barrier to understanding a patient's medical history than is the impact of a delay in obtaining the record. For an anesthesiology department, rapid electronic access to legible medical information means faster and more comprehensive preanesthesia assessments. It also increases the likelihood that preexisting conditions that could complicate the perioperative course (e.g., difficult intubation, pseudocholinesterase deficiency) are identified and the associated complications prevented. New findings in an electronic format are available more rapidly. For example, digital radiology can makes images available as soon as they taken. Preventing periop-

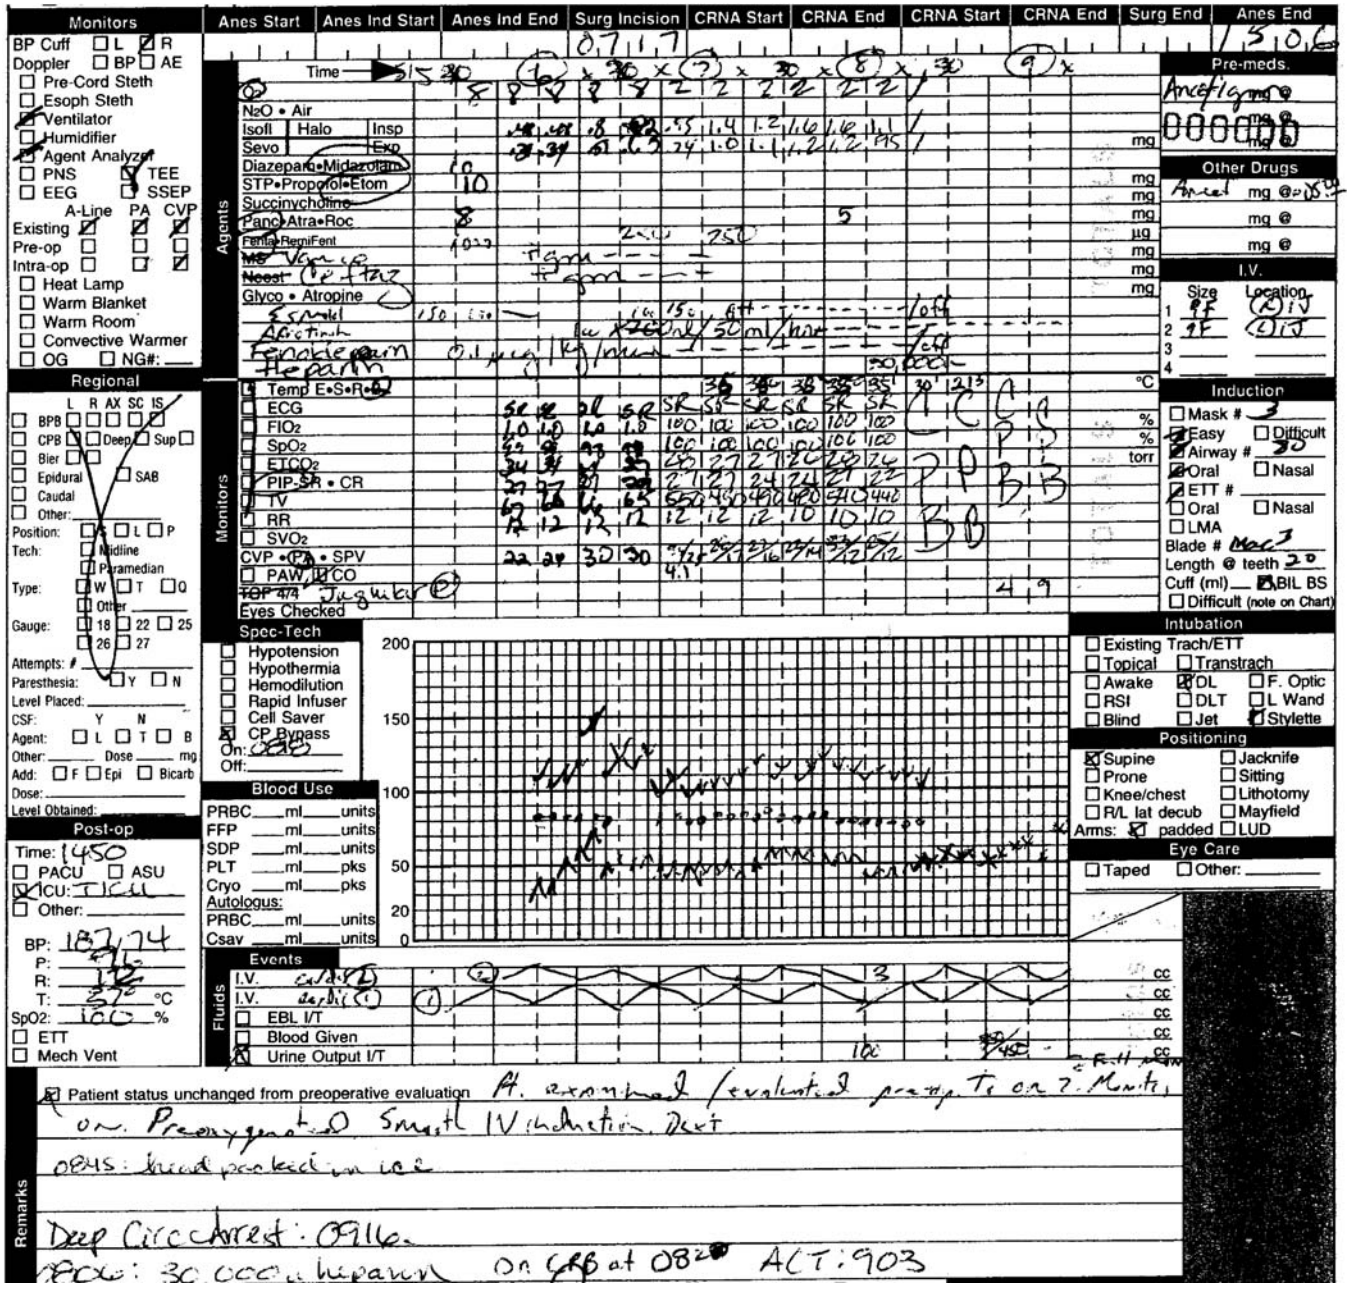

FIGURE 28–22. Example of a handwritten anesthesia record.

erative complications offers significant cost savings, and holding down costs is imperative in an environment of bundled pricing for procedures.

As noted earlier, the PIMS communicates directly with the billing office at the end of every anesthetic procedure. The information forwarded is a subset of the anesthetic record, and the system determines whether all the required information for billing has been provided. If any required item is missing or incomplete, the system blocks transfer of the patient until the required documentation has been entered. Our estimate is that anesthesia billing has increased 5–10% with this electronic process. Billing for reimbursable procedures (e.g., central line placement, postoperative regional analgesia) has also improved with the addition of electronic forms that ensure that these procedures are documented with adequate granularity, thereby allowing for appropriate billing and reimbursement. This process decreases opportunities for incomplete documentation, which has given us confidence that we not only are complying with the various billing requirements but we also are compliant with regulatory requirements. This substantially reduces the economic risks associated with regulatory audits. Considering the fact that each incidence of noncompliance could be fined as high as $10,000, the value of mitigating such a risk is significant.

These are just a few examples of the business case for a PIMS. Rapid access to a patient's medical information that is presented in a legible form is of unquestionable value. EMRs decrease costs by eliminating the need to store and transfer paper records. Care is delivered in a more efficient manner because there are no delays in accessing information. Care is delivered

more effectively because all information about a patient is available and legible. System design facilitates the clinician's ability to identify critical information, thereby decreasing the likelihood of avoidable perioperative complications, whether secondary to misidentifying the patient, blood products, previous complications, or critical underlying pathophysiology. A PIMS allows for electronic transfer of billing information that is complete and comprehensive. This allows the organization to receive reimbursement for all delivered services. Finally, the PIMS ensures that the records are complete with regard to regulatory requirements. Therefore, an EMR, including a PIMS, decreases the costs of delivering care, increases productivity, increases revenues, and mitigates regulatory risks.

BARRIERS TO ADOPTION

One of the most important issues hindering adoption of a PIMS is cost. As discussed earlier, the business case can clearly be made and the return on investment can be substantial, depending on the specific issues a PIMS can improve in the medical center. Nonetheless, the capital costs are substantial. As a general statement, a PIMS almost always will be part of a larger EMR project that is supported and funded at the institutional level. Although some anesthesiology practices may decide to go it alone in order to obtain the benefits of an electronic record for their practice, this model will be the exception and not the rule. The benefits of a standalone project can make a PIMS project worth pursuing (e.g., mitigation of litigation and regulatory risks, improved billing), but a more comprehensive project allows for greater benefit and broadens the risk across the medical facility.

Concern with artifacts is a common reason for opposing a PIMS. Physicians and nurses express the fear that inaccurate recordings of physiologic parameters (e.g., blood pressure, oxygen saturation) not only will produce an inaccurate record that may mislead clinicians carrying for the patient but also could put them at increased risk during litigation. We have found these concerns to be unfounded. Although artifacts do occur (e.g., arterial blood pressure >300 when arterial line is flushed), they almost always are obviously artifactual and of no concern. The reason these incorrect data are transparently artifactual is human physiology. The PIMS records information every minute and records in the database every 30 seconds. For example, it is impossible for the blood pressure to be steady at 120/70 for many minutes, then briefly >300 (flushing) or <10 (transducer open to air), and then instantly return to 120/70, all the while with no change in heart rate, oxygen saturation, or end-tidal carbon dioxide concentration. At times, information that does not reflect the patient's physiologic state is recorded. If the information is of brief duration, the PIMS data can be manually corrected, and users will commonly enter the correct information. More commonly, the physiologic data on the monitor is incorrect (e.g., low blood pressure or oxygen saturation secondary to low perfusion state). This situation is best handled by writing a memo into the PIMS or progress note explaining the clinical situation. In a study of a clinical information system used in an ICU setting, Ward[24] reported a <0.1% error rate for verified vital signs (i.e., oxygen saturation, heart rate, and respiratory rates).

There is also objection to a PIMS because of concerns that computer-based record keeping will take the clinician away from the patient's bedside, and critical events will be missed. As discussed earlier and as reported by Weinger et al.,[21] the time dedicated to electronic charting is no worse than that for paper record keeping. An added advantage of PIMS is that the system records monitored data in real time; this negates the requirement with paper records keeping to recreate, from faulty memory, what had occurred in the past. This allows clinicians to concentrate on patient care and to document during low-intensity maintenance periods of the procedure. The potential problem with automated record keeping is not taking the clinician away from the patient, but that the PIMS may take the clinician away from the record. Except for the beginning and end of a procedure, there is very little to do in terms of record keeping during the bulk of a procedure. Therefore, there is no need to examine the record every 5 minutes, as required for paper record. This could lead to the missing of trends. Although we have no identified incidences, we are examining whether processing of real-time data to identify adverse trends and to warn clinicians would be a value-added to the PIMS in the operative setting.

Finally is the concern commonly voiced that PIMS will significantly increase litigation risk. The reasons given include documentation of artifacts, erroneous entry secondary to typographic errors, purposeful misunderstanding of the content of automated records, and the risk associated with accurate documentation of vital signs (e.g., hypotension and tachycardia during induction of anesthesia). The issue of artifacts was discussed earlier. Incorrect manual documentation is just as likely with an electronic record as with a paper record. Because computer-based medical record keeping is, by definition, legible, it seems more likely that fewer errors will occur with a PIMS as compared to a paper record because an illegible entry is effectively an error or even missing information. Although increased variations of vital signs are noted on a PIMS, this merely reflects the normal increase and decrease of blood pressure, heart rate, and other physiologic parameters that occur during an anesthetic procedure. It is well documented that clinicians smooth vital signs on a paper record.[1–4,25] Therefore, if questions arise as to the variability of the vital signs during a procedure, accessing the literature as well as other anesthetic records to establish the fact that the observed variability is normal and expected is a straightforward process. Litigation concerns that a PIMS accurately records the vital signs hopefully reflects the views of a minority within the medical community. If the purpose of the medical record is not to document what had occurred during a procedure but instead is to obfuscate the patient's medical care, then a PIMS certainly could put a clinician at increased risk. The literature as well as our experience clearly shows that PIMS records are much more accurate and complete records compared to the paper paradigm.

In contrast to the concerns expressed regarding litigation risk, our experience has been quite different. Since the introduction of the PIMS, first in the cardiovascular and thoracic operating rooms in the early 1980s and then wall to wall in the late 1990s,

every time we have been challenged by litigation the electronic documentation has served to bolster our defense. During legal review, no challenges were made regarding documentation of artifacts, physiologic variability, or unsmoothed data. The fact that the objective data (e.g., physiologic parameters, laboratory results) were recorded electronically without the possibility of human interference added weight to their veracity. The completeness of the records gave confidence that the record reflected what really occurred. The legibility of the medical record has decreased opportunities for disagreements on what the record meant. We now are confident that the PIMS is a critical element of accurate record keeping that will aid us in the event of legal challenge. Our experience is consistent with that reported by Feldmanm,[26] who surveyed 55 anesthesia departments regarding their experience with electronic record keeping and malpractice cases. Twenty-four departments reported a total of 41 malpractice events where the anesthetic record was documented electronically. In none of these cases did the respondents claim that the electronic record caused problems with their defense. Thirty of the cases were dropped prior to trial, and 11 either were settled or went to litigation. Eighteen departments believed that their PIMS helped with their risk management, and three departments believed that the PIMS was a critical element to this endeavor. Based on our experience and the results of Feldman's survey, it is reasonable to conclude that a PIMS would decrease the risk of adverse legal review.

When the details of most objections to a PIMS are examined, it is clear that the objections are not well grounded. Although the capital expenditure is nontrivial, over time improved billing, more efficient and effective medical care, decreased complications, and decreased regulatory risk will substantially make up the expense. Concerns with artifacts and the associated time required to chart on an electronic record are, in fact, nonissues. Artifacts will occur, but they are transparently obvious, are correctable (although our experience shows this is rarely done), and have not been demonstrated to be problematic, either during the course of care or afterward. PIMS has been shown to, at worst, demand the same time for charting activities as a paper record, but it has the advantage of automatically charting much of the objective information automatically while the clinician is engaged in patient care activities. Objections that an electronic system will chart what really occurred and that this could put the clinician at risk are correct, but the purpose of a medical record is to document what occurred and not to serve as an obfuscating shield to protect clinicians. Finally, our experience and that of other facilities has shown that a PIMS helps, not hinders, the defense in a medical malpractice case. In summary, the objections commonly offered to the installation of a PIMS are not supportable.

PRACTICE MANAGEMENT

One of the many claims made by proponents of a PIMS is that the collected data from many patients, records can be used to generate new medical knowledge. It is widely believed that electronic records will allow researchers to determine which medical strategies work and which do not. Unfortunately, until now these claims have been thinly demonstrated.

Once information about the patient, the course of care, and resource utilization is entered into a database, it can be processed and displayed as a tool to improve both the quality and the efficiency of practice in the operating suite. This kind of analysis is a major value-added with the implementation of a PIMS. For example, examining the relationship of a variety of physiologic variables to adverse outcomes can identify easily solvable problems. Close attention to the economic as well as the medical impact of new pharmacologic agents can assist in the appropriate use of new drugs. Analysis of laboratory testing with practice decisions helps to identify which tests are really needed for clinical management. Comparing the practices of physicians to that of their peers allows for identification of "best practices" as well as problematic issues. The ability to carefully examine one's practice offers the possibility of accelerating practice improvements and improving patient outcomes.

In our experience, the data made available by the PIMS has been used primarily for practice management purposes. We have created a number of automated reports to assist the management of our clinical and education enterprise, including the following:

- Productivity reports, tracking the cases of each physician and nurse.
- After hours reports, tracking both emergency and scheduled procedures performed after hours.
- Concurrency reports, tracking the number of concurrent cases each anesthesiologist is responsible for and the status of the clinician being supervised (i.e., resident physician, anesthesiologist assistants, nurse anesthetist, or student nurse anesthetist).
- QA reports, tracking anesthesia morbidity and mortality. These reports are broken down by clinical area (e.g., neurosurgery, cardiac catheterization laboratory), clinician, patient comorbidity, and so on.
- Education reports, tracking the number, kind of cases, invasive lines, and regional anesthetics of resident physicians. Similar reports are generated for the nurse anesthesia program.

The demands for practice management reports are ongoing. As with requests for changes to the PIMS, the reports must be prioritized. Currently, the work to produce these reports falls on the shoulders of the information technology team of programmers who must put aside work to upgrade the PIMS in order to generate these reports. The system currently is at the point where we are examining whether we can transfer responsibility for report generation and maintenance to another group, possibility an expanded research group that has the necessary technical and statistical skills.

The literature is beginning to see the results of different groups of investigators making use of the data available in their respective PIMS databases. These reports include the following:

An investigation from the Mount Sinai School of Medicine in New York, which examined the relationship between postinduction hypotension and the patient's preoperative history and pharmacologic management.[27] The authors reviewed more than 5000 electronic records and showed that propofol was associated with clinically significant hypotension in patients who were older than 50 years and had

an ASA physical status greater than II. This hypotension was associated with greater length of stay and higher mortality rates.

Investigators at Duke University reported that they used the data generated from their electronic anesthesia record to determine the cost of anesthetic medications used on a per case and per clinician basis.[28] This information was used as feedback to the clinical staff, and the department saw an associated cost saving in excess of $1 million per year.

The University of Miami reported that use of a PIMS in conjunction with education, workflow integration, and user feedback improved their QA completion rate from a baseline of 48% to 94%.[29]

Researchers at the University Hospital in Giessen, Germany, analyzed the data in their PIMS database to determine if certain patient characteristics could predict significant hypotension after spinal anesthesia. Using sophisticated statistical analysis, the authors reported a statistically significant association between post–spinal anesthesia hypotension and chronic alcohol consumption, emergency procedures, and a history of hypertension.[30]

The same investigators examined their data for an association between patient and anesthetic characteristics and antiemetic rescue treatment. They reported that patients who were smokers, female, younger than 40 years, or had received opioids, nitrous oxide, or propofol were at increased risk.[31]

These are early examples of the potential use of data in a PIMS database to improve the quality of patient care. It is too early to predict the degree to which this kind of analysis will be used to change how anesthesia care is delivered. However, it appears reasonable that as PIMS gains a greater share of the anesthesia marketplace, investigators will make increasing use of the data and hopefully will discover information within the sea of data.

MANAGEMENT OF AN ESTABLISHED PIMS

Installation of a PIMS requires a dedicated staff. In our project, we assigned a full-time nurse anesthetist, 20% of a physician's time, five to seven information technology staff, and three administrative staff. This does not include the significant time and effort of the clinical and administrative staff in the department of anesthesiology that also contributed to making the project a success. Although this allocation of personnel may appear to be overly generous, it is not inconsistent with what other institutions have used to configure and install their systems, particularly when scaled to the size of the respective institutions. Some manufacturers include configuration and installation of their system as part of the cost of their software, but experience has shown that significant institutional resources are required to successful install such a system.

After the go-live period is complete and the PIMS appears to be stable and functioning, the project team's job has just begun. Ongoing issues include PIMS support for the clinical staff. This consists of onsite support during the workday, help desk support, and 24-hour-per-day, 7-day-per-week on-call support from programming and engineering staff. As the system expands to a greater number of clinical sites, a greater demand is placed on the network and the different servers supporting the system.

The complex issue of user expectations and demands must be engaged. The ongoing demands for added functionality and customization are an expected outgrowth of computer-based documentation. A formal process to review these requests and to determine which changes are appropriate and cost-effective, and when and to what degree to develop the requested added functionality must be developed. With this process in place, the PIMS is positioned to evolve with the clinical practice.

Such a process requires ongoing dedicated personnel to the PIMS project, including clinical, information technology, and administrative staff. The business software systems that a hospital administration must use for accounting, inventory control, and human resources require in-house information technology staff support to ensure the systems are up and running and are upgraded to meet ever changing requirements. Clinical systems must have similar support. Without the ability to update or add refinement to a PIMS, the usefulness of the system will rapidly degrade. This issue should be considered nonnegotiable. If a medical organization is considering moving its medical records from a paper format to an electronic system, information technology staff must be part of the package. Too many facilities have failed in their attempt to introduce an EMR because they were unwilling to hire the necessary support staff. When time constraints and intensity of clinical tasks are considered, the need for information technology staff is more important with a PIMS than with almost any other clinical system. Appropriate personnel—clinical, information technology, and administrative—must be part and parcel of a PIMS, for configuration, installation, and maintenance.

SUMMARY

After a relatively slow start, particularly when compared to other industries, computer technology is beginning to be used at the patient bedside, broadly referred to as the electronic medical record (EMR). One important part of the EMR is the perioperative information management system (PIMS). The PIMS consists of the electronic tools used to document the preanesthetic evaluation, the intraprocedural anesthetic record, and the postanesthesia care. It also consists of a database that stores all the data on perioperative care. This database then can be used to reconstruct an individual's record for medical or administrative purposes (e.g., billing or regulatory review). It also can be used to evaluate aspects of rendered care to a large number of patients (e.g., track how many cases have been done, determine which proportion of patients with coronary disease received β-blockers).

There are many reasons to move from a paper to an electronic record. Some of the most important issues addressed by a PIMS are the realities that paper records are sometimes illegible and inaccurate, are time consuming to produce and maintain, and generate difficulties with payers, regulators, and during legal review. EMRs solve most of these problems. Paper records can be lost or spoiled. Electronic records allow clinicians in a medical facility virtually instant access to a patient's medical record. Electronic record keeping has downsides, particularly the ex-

pense and complexity of such a project. Certain objections to a PIMS have proved to be unfounded, including concerns with artifacts, which are easily identified and discounted; that electronic charting is too time consuming, which has been shown to be no worse than paper record keeping; and that a PIMS-generated record could put clinicians at increased risk during litigation, which in our experience and that of others has shown no increased risk—in fact, an electronic record may decrease litigation risk.

Currently a number of companies offer a PIMS. These include CareFX, Picis Caresuite, GE Centricity, Philips CompuRecord, Dragger Innovian, and Cerner Surginet. As expected, each vendor has its advantages and proponents. In my opinion, which product an organization chooses is less important than how the organization manifests and manages the system. It is clear that the medical specialty of anesthesiology will have to embrace EMRs, and most likely will be in the best interest of individual groups to actively engage such a project. Waiting for one's institution to make a decision, or delaying institution of electronic records as long as possible, will put an anesthesiology department at risk for having the decision made for them by individuals with little or no knowledge of an operative practice. It is better to retain control of a department's clinical tools. With regard to electronic record keeping, taking a proactive stance will make it more likely that the department will retain control of its medical records.

The process of configuring and manifesting a PIMS can be complex. The entire process of patient care must be analyzed and broken into its component parts. The first step in the process should be the creation of a scope document that details the expected functionality of the PIMS and the various tasks that must be accomplished in order to accomplish such a project. The scope document then becomes the project's bible, and fairly rigid management is required to prevent scope creep. Once the PIMS functionality is agreed to, no additional functionality should be allowed until after the system is installed, unless a serious error is identified. The project team must continue to engage the department's leadership for decisions that impact the clinical practice. Decisions such as mandatory documentation should be made by the clinical leadership and not by the PIMS project team. This keeps the leadership engaged in the project, ensures that the leadership retains ownership of the project, and prevents the PIMS team from becoming marginalized.

The necessary steps of configuring and installing a PIMS include detailing every aspect of the process (e.g., lists of medications to be documented, size of intravenous lines that may be placed), interfacing the different devices (e.g., monitors and ventilators) that will feed information into the PIMS, and installing computer systems in each anesthetizing location. As the PIMS takes shape, each aspect must be tested and verified. Most of this work can be done in a testing site outside of the clinical spaces. It is vitally important to ensure that the PIMS works as expected prior to use by the clinical staff.

Once the project team is reasonably sure that the system is ready for clinical use, the system must be tested in the clinical setting. For the first few locations, it is prudent to consider charting on the PIMS in parallel with manual documentation. The two records can be compared and the accuracy of the electronic record clinically validated. The next step is to determine whether the PIMS can be used by clinicians concurrently with patient care tasks. A paper record should be recorded during this testing, and again the PIMS should be validated. Finally, once the clinical accuracy and usability of the PIMS have been demonstrated, a staged rollout process should occur. This stepwise approach allows the practice to be assured that the new record-keeping system will not interfere with the practice's ability to care for patients and that their record will accurately reflect the clinical care they delivered.

When the PIMS is installed, the project team will be faced with endless requests for refinements to make charting easier, added functionality, and various database reports. Examples of postimplementation projects include bar code identification of patients and blood products, charting shortcuts for rapid turnover cases, increased charting granularity by use of forms for regional anesthesia and invasive line placement, mandatory charting for billing and regulatory compliance, and forwarding of clinical information, such as neuraxial opioids, to downstream clinicians. The large number of requests requires the development of a change management process. Request for changes and additions to the PIMS must be documented and then reviewed and prioritized by the project team. Disagreements are adjudicated by the departmental leadership. This process has allowed steady but controlled improvements to the PIMS that do no disrupt the clinical practice.

An anesthesiology practice will see positive returns on its investment in a PIMS in terms of time and money. Because billing information is electronically generated in the PIMS, no forms can be inaccurately filled out or lost. It is not unreasonable to expect a 5–10% improvement in billing with an integrated PIMS. Clinically, the utility of electronic access to all patients' medical information is a clear benefit. Avoiding complications secondary to missing information can be expected to lower costs. The PIMS facilitates regulatory compliance, including concurrency issues and pay-for-performance demands. Improved patient safety is an external demand of payers and regulators. It is also a growing expectation of patients. A PIMS will improve the economics of delivering anesthesia care and decrease the risks associated with the practice.

A PIMS is an integral part of modern practice management. It can be used to track productivity, complications, and drug administration. The literature is beginning to publish reports of a PIMS database used to improve the management of an operating suite, to improve a QA program, or to determine the best way to handle specific medical conditions. Our understanding of the downstream utility of these electronic tools is just in its infancy, and it is reasonable to expect that this knowledge base with grow rapidly as more systems are installed.

There is no question that EMRs and PIMSs will become ubiquitous. The only question is when any one particular practice will embrace this new technology. Although complex and expensive, the advantages of electronically based documentation far outweigh the disadvantages. Improvements in access to medical information secondary to legible and available charts, accuracy of documentation, billing, payer, and regulatory compliance, patient

safety and quality of care, and decreased litigation risks are just a few of the advantages of these systems. Perioperative information management is in the future of every anesthesiology practice.

CHAPTER 29

Hemodynamic Monitoring

Shahar Bar-Yosef, MD,
Rebecca A. Schroeder, MD,
and Jonathan B. Mark, MD

One can ascribe the birth of hemodynamic monitoring to the British anesthesiologist Joseph T. Clover, MD (1825–1882), who has emphasized the need to have one's finger on the pulse when giving chloroform anesthesia (Fig. 29–1).[1] The word *monitor* originated in the Latin word *monere*, meaning "to warn." Indeed, one of the more commonly associated roles of monitoring devices is to alert the anesthetist of changes in patient's conditions. However, an additional goal of "monitoring" relates to regulation and control: the anesthetist uses information gleaned from the monitors to modify therapeutic interventions, and then uses the monitors again to gauge the effect of these interventions, and so on in a continual feedback-control loop.[2] It becomes clear, then, that for the patient to gain benefit from the monitor used, several conditions must be fulfilled. First, the data needs to be correctly interpreted; both the technical and physiologic aspects of the monitor need to be perfectly understood by the physician-user. Second, effective clinical interventions should exist to treat the underlying problem. Third, risks associated with the monitor itself should be recognized and minimized. It is important to emphasize that physiologic information not followed by effective interventions will not benefit the patient and information that is mistakenly interpreted can even lead to patient harm by prompting wrong interventions.[3]

This chapter describes the technical and physiologic principles behind the more commonly used monitors in the perioperative period, presents existing data regarding their accuracy and usefulness, and suggests a cognitive framework for employing these monitors to answer specific clinical questions.

ARTERIAL BLOOD PRESSURE MONITORING

Blood pressure is the vital sign that describes the driving force for perfusion of all tissues and is the major determinant of left ventricular afterload. Accurate, reliable, and timely measurement of arterial blood pressure (ABP) is crucial for the responsible care of critically ill patients and those undergoing surgical procedures. ABP can be measured accurately with invasive and noninvasive methods, but both are subject to artifacts that could lead to inappropriate therapy and patient injury unless correctly identified and interpreted.

Noninvasive Arterial Blood Pressure Measurement

Current auscultatory methods for measuring ABP are based on the work of Korotkoff, who described the series of distinct sounds produced by the return of blood flow through the artery during cuff deflation. This method has a variety of limitations, including its reliance on pulsatile blood flow and its tendency to significantly underestimate blood pressure in states of extreme vasodilatation, or overestimate blood pressure in cases of severe arterial vasoconstriction.[4]

Automated noninvasive ABP measurement has been based on the oscillotonometric technique, in which the point of maximal cuff pressure fluctuation corresponds to mean arterial pressure (MAP).[5] The technique whereby systolic and diastolic pressures are determined varies somewhat between device manufacturers, but in general, systolic and diastolic pressures correspond to the points of rapidly increasing and decreasing oscillations, respectively (Fig. 29–2). Unfortunately, when compared to direct ABP measurement, oscillotonometry tends to overestimate ABP during hypotension and underestimate it during hypertension.[6]

Invasive Arterial Blood Pressure Measurement

Theory and Background

Direct ABP measurement remains the gold standard despite its increased cost and the additional expertise and

KEY POINTS

1. When interpreting invasive hemodynamic pressures, consideration should be given to technical aspects including the zero reference level, dynamic response of the monitoring system, and the effects of changes in intrathoracic pressures.
2. Much diagnostic information can be gleaned from the analog waveform of directly measured pressures, both arterial blood pressure and cardiac filling pressures.
3. The interpretation of filling pressures like central venous pressure (CVP) and pulmonary artery occlusion pressure (PAOP) is confounded by many variables, notably changes in ventricular compliance, valvular abnormalities, and positive pressure ventilation.
4. Use of the pulmonary artery catheter for monitoring without a structured therapeutic intervention protocol has generally been found not to be beneficial in most perioperative and critical care settings. It might still be justified in very-high-risk patients or in critically ill patients who do not respond to empiric therapy.
5. There are no accepted "gold standards" for cardiac output measurement. With this in mind, it is more clinically useful to follow trends in cardiac output rather than consider absolute values.
6. Functional indices based on respiratory variation in hemodynamic parameters are better predictors of fluid responsiveness compared to static filling pressures or volumetric indices.
7. Metabolic indices like lactate, base excess, and venous oxygen saturation should be included in the hemodynamic monitoring of the critically ill patient.
8. Preemptive goal directed therapy, aimed at optimization of hemodynamic goals before and during surgery, has been found to decrease mortality in high-risk surgical patients and decrease morbidity in moderate-risk patients.

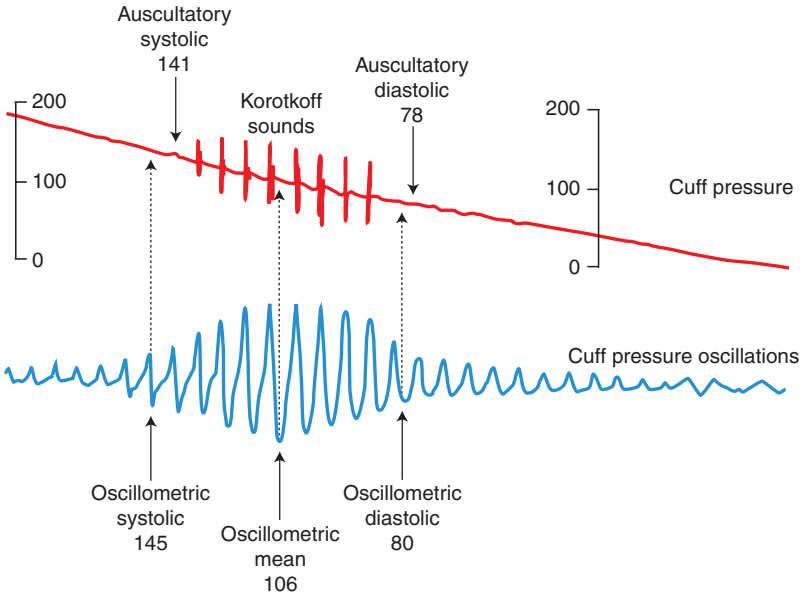

FIGURE 29–2. Noninvasive measurement of blood pressure. In the auscultatory method, systolic and diastolic pressures are decided based on the beginning and end of Korotkoff sounds. In the oscillometric technique, the mean blood pressure is the primary measured variable, determined as the point of maximal oscillations in cuff pressure. The exact algorithm used to decide upon the systolic and diastolic pressures varies. (Reproduced with permission of the author from Geddes LA. Cardiovascular Devices and Their Applications. New York: John Wiley, 1984: Fig. 3–6.)

risk involved. A small catheter is placed within an arterial vessel and connected through fluid-filled tubing to an electromechanical transducer. The dynamic response of this system is best characterized by two physical properties: natural frequency and damping coefficient. Natural frequency describes how rapidly a system oscillates after it is set in motion, and the damping coefficient refers to how rapidly it comes to rest after such a disturbance. With a low natural frequency, the system will resonate and pressure waves displayed on the monitor will be greatly exaggerated versions of the true ABP, a phenomenon known as overshoot or ringing. Underdamped systems exaggerate high- and low-pressure values and produce artifactual peaks and troughs in the displayed waveform. In contrast, overdamped systems display waveforms devoid of detail with attenuated peaks and troughs.

The dynamic response of the monitoring system can be quickly assessed with the "fast flush test" (Fig. 29–3).[7] Although accurate quantitative evaluation of natural frequency and damping coefficient is possible, in clinical use a satisfactory flush test will appear as one large and one small oscillation and then a return to baseline. Based on the fast-flush test, one can determine whether changes in the monitoring system (e.g., reducing the length of extension tubing, removing stopcocks, removing clots or air bubbles) would likely improve natural frequency and decrease resonance of the system. For all invasive pressure monitoring systems, a zero reference value should be set, usually at the upper border of the heart estimated as 5 cm below the sternal border in the fourth intercostal space in a supine patient.[8]

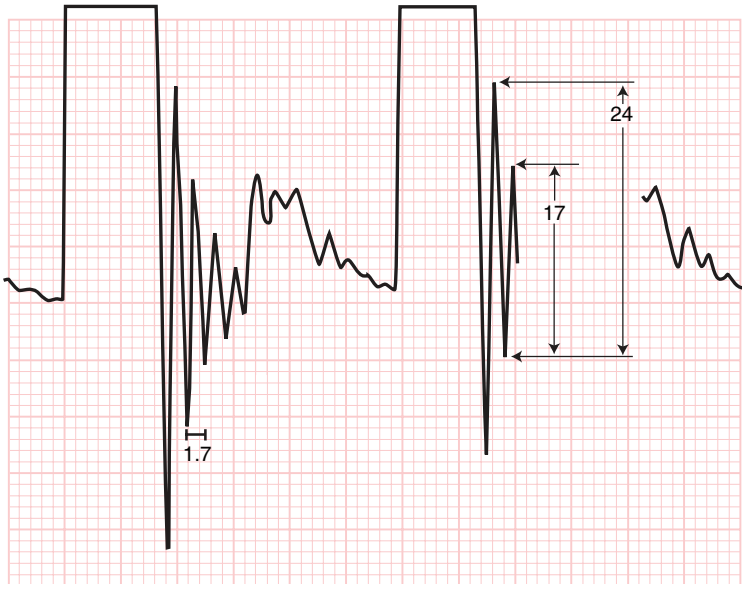

FIGURE 29–3. The "flush test" used to estimate natural frequency and damping coefficient of an invasive pressure monitoring system. A square-wave artifact is created by temporarily opening the flushing system, then allowing the monitoring system to return to "resting" state. Natural frequency is calculated as the recording paper speed (25 mm/sec) divided by the length of 1 cycle between two adjacent pressure oscillation peaks (1.7 mm in this example, resulting in a natural frequency of 14.7 Hz). The damping coefficient is reflected by the ratio between the amplitude of two adjacent oscillation peaks—the higher the ratio, the smaller the amount of damping exists. (Modified with permission from Gardner RM. Direct blood pressure measurement-dynamic response requirements. Anesthesiology 1981;54(3):227–236.)

The Arterial Blood Pressure Waveform

The systemic arterial pressure waveform results from forceful ejection of blood from the left ventricle during systole, runoff into the peripheral vessels during diastole and reflectance of waveform energy from the peripheral circulation (Fig. 29–4).[9] As a consequence, ABP waveform morphology differs as the monitoring site moves distally, a phenomenon known as distal pulse amplification. Compared with aortic pressure waveforms, more distal site tracings show wider pulse pressure, delayed upstroke, delayed, slurred dicrotic notch, and more prominent diastolic wave. Beyond these normal physiologic variations, large gradients may exist between central and peripheral sites in patients in shock and following cardiopulmonary bypass, when central ABP is greater than peripheral ABP.[10,11]

Specific waveform patterns have been described and may provide useful diagnostic information in several pathologic states (Fig. 29–5). Additional information that can be gleaned from the arterial waveform includes systolic pressure variation, an important indicator of hypovolemia.[12,13]

Insertion Technique

The most common site for monitoring ABP in clinical practice is the radial artery because of its ease of access and low complication rate. The process of cannulating any palpable peripheral artery is similar. The site is immobilized so the extremity is secure but the pulse is still palpable. In the case of the radial artery, the hand is mildly dorsiflexed perhaps with the thumb extended. The skin is prepared with alcohol or chlorhexidine, and a local anesthetic is injected into the skin and around the artery, both to anesthetize the site and reduce the risk of arterial spasm. Integrated needle-guidewire-catheter assemblies are frequently used in adults. The angle of needle entry should be shallow and in line with the course of the artery. When blood flows into the reservoir, the wire is advanced into the artery, and the catheter then passed over the wire. The wire should thread with no resistance, and the catheter should pass smoothly and painlessly. Some practitioners prefer to place arterial lines without the use of a guidewire, threading the catheter directly into the vessel upon appearance of the flash through the needle hub.[14] If

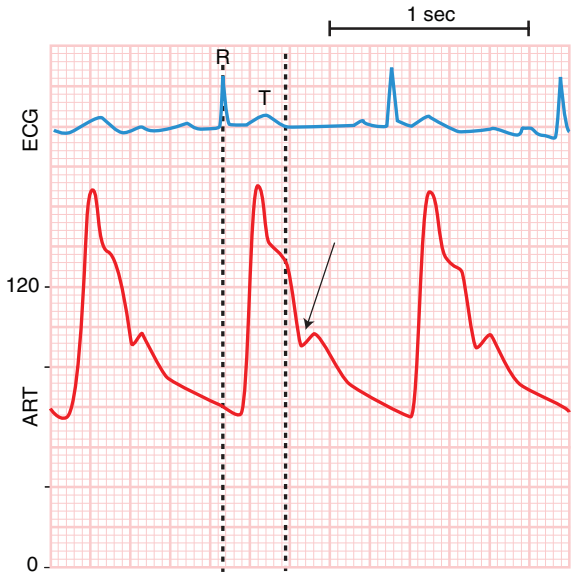

FIGURE 29–4. Normal arterial pressure waveform with sharp systolic upstroke, a peak and a well-defined dicrotic notch (*arrow*). Note that the upstroke follows the R-wave on the electrocardiogram (ECG) trace as a result of the short delay between electrical and mechanical systole.

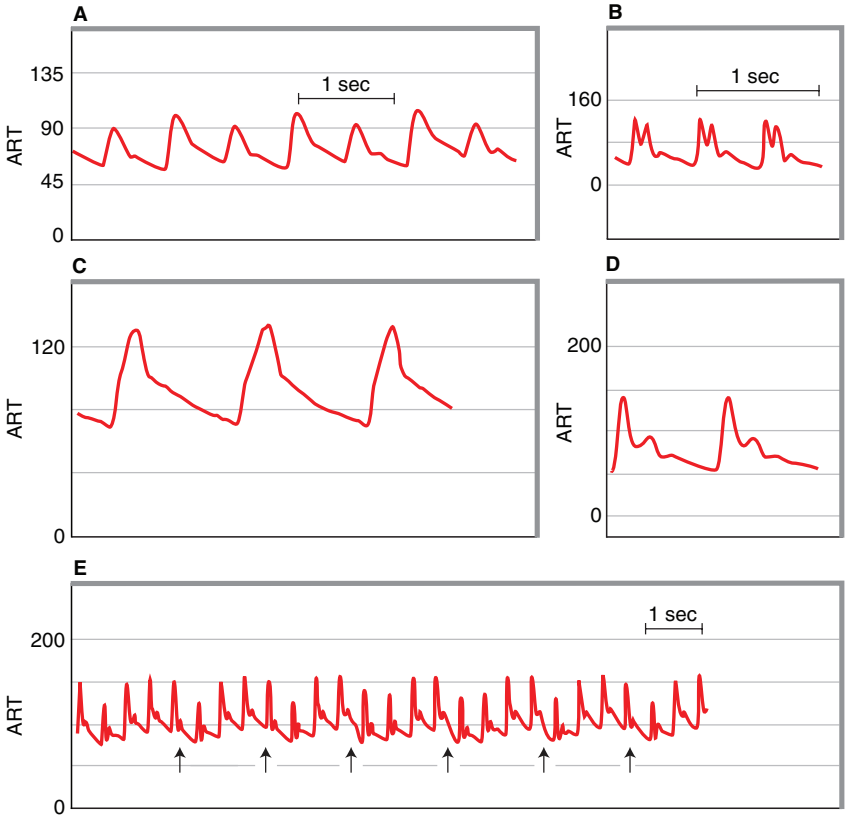

FIGURE 29–5. Pathologic arterial waveforms. **A.** *Pulsus alternans*—alternating higher and lower systolic peaks, commonly associated with large pericardial effusion or severely depressed ventricular function. **B.** *Pulsus bisferiens*—characterized by a double systolic peak, low diastolic pressure, and a wide pulse pressure, usually indicating severe aortic regurgitation. **C.** *Pulsus tardus*—slurred upstroke with a delayed systolic peak, characteristic of severe aortic stenosis. **D.** *Spike-and-dome configuration* characteristic of hypertrophic obstructive cardiomyopathy, with a normal systolic upstroke but wide, delayed dicrotic notch and prolonged ejection phase. **E.** *Pulsus paradoxus*—cycles of increasing and decreasing systolic blood pressure correlating to respiratory cycle (*arrows* point to spontaneous breaths). In this example, the degree of variation is approximately 35–40 mm Hg. (Reproduced with permission from Mark JB. Atlas of Cardiovascular Monitoring. New York: Churchill Livingstone, 1998: Figs. 17.22, 17.24, 18.10.)

smooth passage into the vessel lumen does not occur, a through-and-through method may salvage the procedure. The needle-catheter assembly is advanced through the back wall of the vessel, the needle removed, and the catheter pulled back slowly until brisk pulsatile flow is obtained through the catheter. At this point, the catheter may be advanced into the artery or a guidewire inserted and a catheter advanced over the wire. Gentle spinning or rotation of the catheter facilitates advancement into the vessel. If the radial artery cannot be cannulated successfully, an alternative site must be sought. One should be extremely cautious using the ipsilateral ulnar artery. Many have raised concerns about cannulation of the brachial artery owing to the lack of collateral circulation to the arm, but this has not been confirmed by clinical studies.[15] Other possible targets include the dorsalis pedis, axillary, and femoral arteries.

Indications for Invasive Arterial Blood Pressure Monitoring

Current standards for intraoperative monitoring require measurement of the blood pressure at least every 5 minutes.[16] Despite traditional teaching that intraoperative blood pressure liability does not result in worse outcome following elective surgery, some clinical evidence indicates that, especially in longer surgery, intraoperative deviations greater than 20% from preoperative levels are associated with postoperative complications.[17,18]

Direct invasive monitoring of ABP is indicated in cases when large moment-to-moment blood pressure changes are anticipated, or when coexisting medical conditions, abrupt blood loss, or large fluid shifts are likely to cause sudden cardiovascular changes. Occasionally, invasive ABP monitoring is performed when noninvasive methods are unreliable or technically difficult. These situations include morbid obesity, burn or trauma patients who have no suitable site for cuff placement, or a patient whose dysrhythmias preclude adequate function of automated noninvasive blood pressure devices. A frequent need to measure arterial blood gases is another indication for invasive arterial cannulation.

Complications of Blood Pressure Monitoring

Even a monitoring modality as seemingly innocuous as noninvasive ABP measurement is not without risk although reported complications are relatively rare. Most complications have followed high frequency or prolonged periods of cuff cycling, or have occurred in patients receiving anticoagulation therapy, and have resulted in either local trauma or impaired perfusion to the distal extremity.[19] Likewise, peripheral arterial cannulation has been shown to be relatively safe, with a risk of ischemic complications of less than 0.1%. The Allen test, which examines the integrity of the ulnar collateral circulation, is not considered a reliable positive or negative predictor of ischemic complications.[20] Other possible complications include air or catheter embolism, blood loss from tubing disconnection, and inadvertent arterial injection of drugs.[21]

CENTRAL VENOUS PRESSURE MONITORING

Theory and Background

Central venous pressure (CVP) provides an indicator of intravascular volume, and the waveform details can provide additional information about specific cardiac pathology and dysrhythmias. By understanding the physiologic phenomena responsible for these waveforms, one can appreciate the mechanisms underlying other hemodynamic waveforms (hepatic vein, pulmonary artery), and their relation to Doppler ultrasound spectral velocity patterns obtained with echocardiography.

The Normal CVP

Central venous pressure, or right atrial pressure (RAP), is ideally measured at the junction of the superior vena cava (SVC) and the right atrium (RA), and reflects the balance between intravascular volume, venous capacitance, and right ventricular (RV) function. In a healthy, spontaneously breathing subject, normal mean CVP ranges between 1 and 7 mm Hg. Figure 29–6 displays a normal CVP waveform. It is comprised of three waves and two descents: the c wave, x descent, and v wave occur during cardiac systole, and the y descent and a wave occur during cardiac diastole (Table 29–1). Identification of each wave is easiest when the CVP trace is aligned with the electrocardiogram and the electrocardiogram (ECG) R wave is marked to indicate the end of diastole. Use of the ABP trace to identify the CVP waves may lead to confusion as a result of the delay between electrical depolarization and onset of the systolic upstroke. Note that flow from the vena cavae into the RA is greatest when RAP is the lowest (i.e., during the x and y descents). This relationship is responsible for the pattern seen when the hepatic veins are examined with spectral Doppler echocardiography. A similar relationship between left atrial pressure and pulmonary venous flow velocity also exists for the left side of the heart.

The Abnormal CVP

Analysis of the CVP waveform can assist in identification of a variety of clinical diagnoses. Specific dysrhythmias cause unique patterns that are easily interpreted when the underlying physiologic disturbance is kept in mind (Fig. 29–7). Atrial fibrillation is recognizable by the absence of the a wave and a prominent c-v wave. Atrioventricular (AV) nodal rhythms can result in cannon a waves that result from retrograde conduction of the cardiac impulse from the AV node to the atrium, producing contraction of the atrium against a closed tricuspid valve during ventricular systole. Similar cannon waves may be detected during any form of AV dissociation, including ventricular pacing. Effective restoration of AV synchrony with atrial or AV pacing can be confirmed by documentation of a normal CVP trace.

Disorders of the tricuspid valve can also affect the CVP waveform (Fig. 29–8). Severe tricuspid regurgitation results in a broad, tall, systolic c-v wave (often termed a regurgitant v wave), resembling a RV pressure waveform. In contrast, tricuspid stenosis produces a tall, end-diastolic a wave and an attenuated, early diastolic y descent.

In combination with data from the pulmonary artery catheter, the CVP waveform is also useful for diagnosis of other conditions, including right ventricular ischemia, cardiac tamponade, and constrictive pericarditis.

Insertion Technique

Cannulation of the central veins is necessary for measurement of CVP and for placement of a pulmonary artery catheter or transvenous pacing wire. A variety of sites are available, including femoral, subclavian, internal and external jugular, and even the

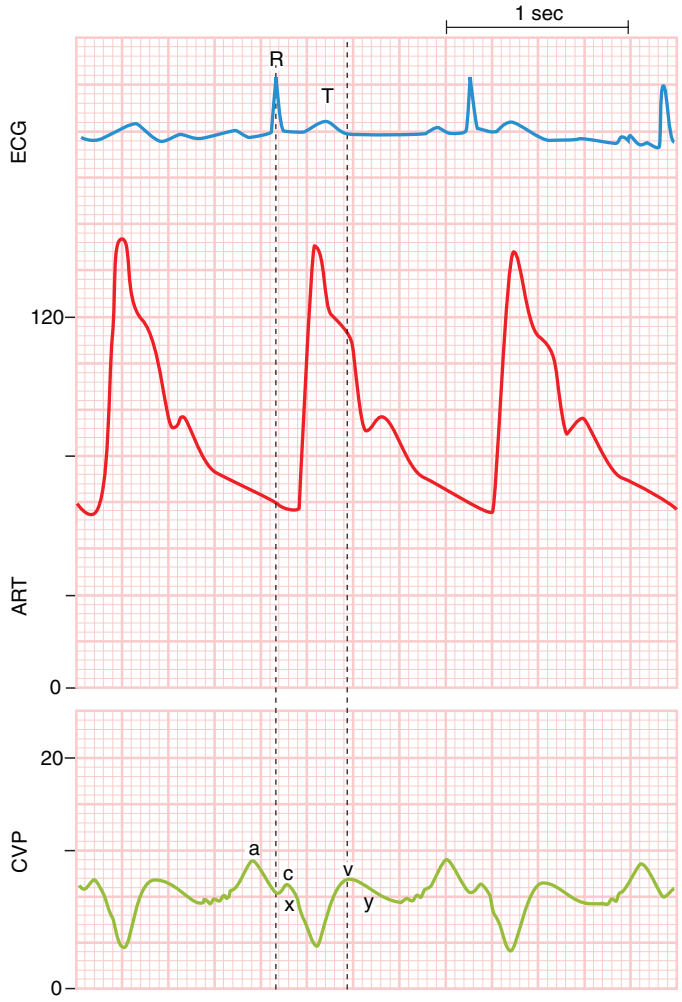

FIGURE 29–6. Normal central venous pressure (CVP) and arterial pressure waveforms. The systolic (a and c waves, x descent) and diastolic (v wave, y descent) components of the CVP waveform are noted. Clear identification of the a and v waves is aided by the electrocardiogram (ECG) waveform as the electrical R wave immediately follows the CVP a wave. (Reproduced with permission from Mark JB. Atlas of Cardiovascular Monitoring. New York: Churchill Livingstone, 1998: Fig. 2.5.)

large antecubital veins. Amongst anesthesiologists, the internal jugular vein (IJV) approach is the most common because of its ease of access in the operating room and its optimal positioning for placement of a pulmonary artery catheter. In contrast, the subclavian vein approach is often preferred for long-term access or in the intensive care unit because of increased patient comfort and lower infection rate.[22]

During IJV cannulation, one must rely on either superficial anatomical landmarks or imaging techniques to locate the vessel, which usually lies lateral and slightly superficial to the carotid artery. To approach the right IJV, the patient is positioned supine, with mild Trendelenburg tilt, and with the head turned slightly to the left. Ultrasound studies have shown that rotation of the head greater than 40° increases overlap of IJV and carotid artery, increasing the risk of arterial puncture.[23] Appropriate aseptic technique is important with a wide preparation area; full body draping for the patient, and mask, gown, gloves, and cap for the operator.[22]

There are a variety of approaches to the IJV, with the anterior being the most common and reliable.[24] The carotid artery is palpated with the fingertips of the left hand. The skin is then anesthetized near the apex of the triangle formed by the two heads of the sternocleidomastoid muscle. A small-bore finder needle may be used to locate the vessel, beginning at the apex of the triangle, angled at approximately 30° to the skin, and directed toward the ipsilateral nipple. It is important to keep the carotid pulsation under the left fingertips, but to avoid compression of the pliable jugular vein. If no blood flash is obtained on forward motion of the needle, it should be withdrawn slowly with constant, gentle aspiration. It is common to get the "flash" of blood on withdrawal of the needle rather than on forward movement as a result of compression of the vessel by the advancing needle. If the vein is not located on the first pass, it is reasonable to make a small number of repeat attempts, as long as the carotid pulsation remains medial to the path of the needle. However, the needle should be withdrawn periodically to check patency and to reassess the anatomy.

After locating the vein with the finder needle, the vein is approached with an 18-gauge thin-walled needle attached to a syringe, directed along the same trajectory, with constant aspiration. On entering the vessel, the syringe is removed, a guidewire is inserted through the needle, and the needle removed. The electrocardiogram should be monitored for dysrhythmias during wire manipulation that may cause atrial or ventricular

TABLE 29–1.

Components of the Normal Central Venous Pressure Waveform

Waveform Component	Cardiac Cycle Phase	Causative Mechanical Event
a wave	End diastole	Atrial contraction
c wave	Early systole	Isovolumic ventricular contraction
x descent	Mid systole	Atrial relaxation and descent of the base of the heart
v wave	Late systole	Systolic filling of the atrium
y descent	Early diastole	Opening of the atrioventricular valve

Modified with permission from Mark JB.[40]

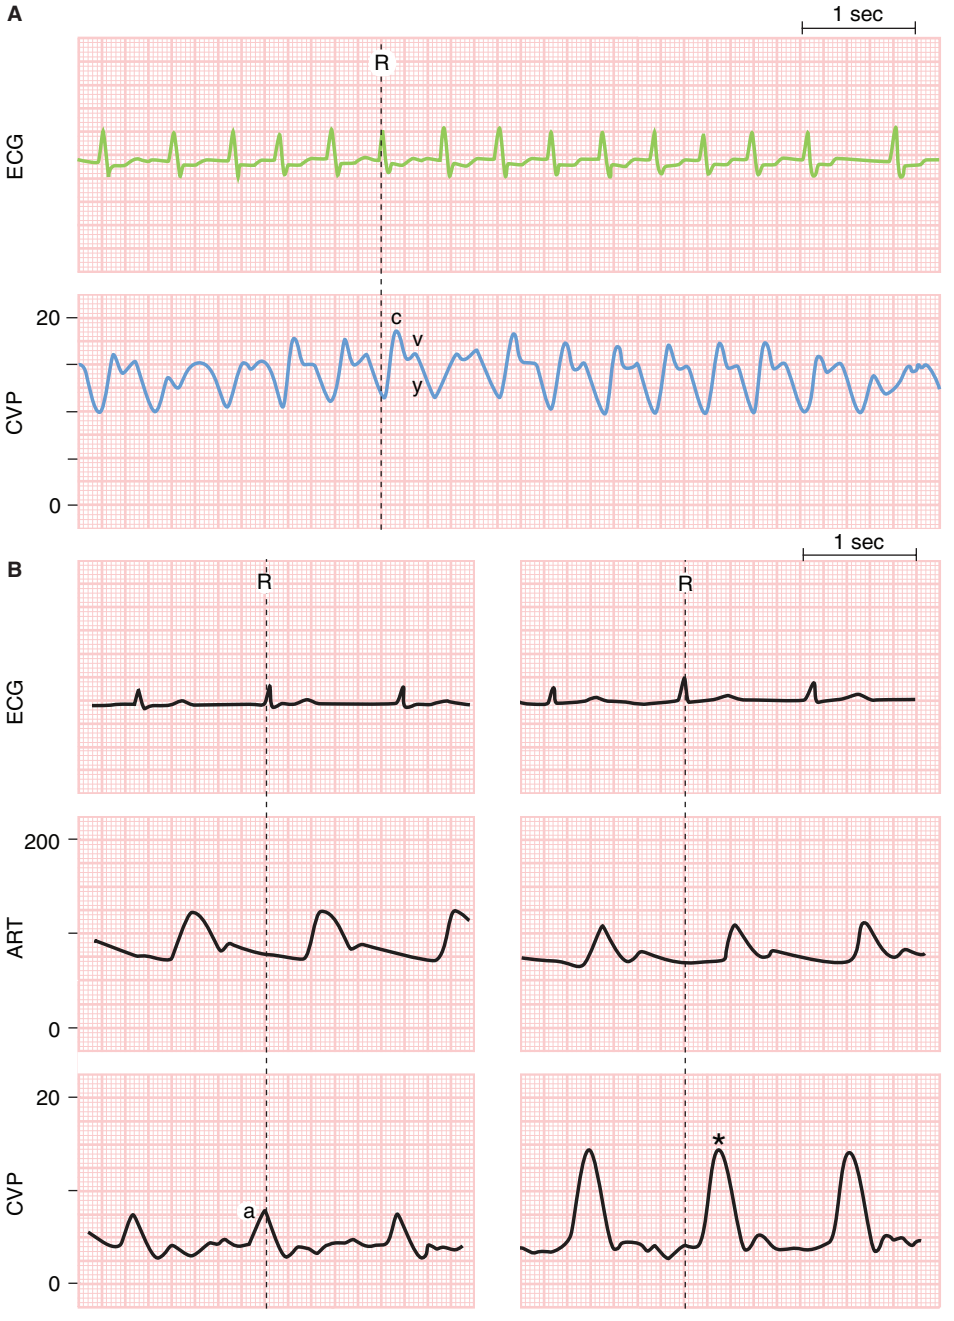

FIGURE 29–7. Effect of dysrhythmias on the central venous pressure (CVP) waveforms. **A.** *Atrial fibrillation*—irregular R-R interval leads to an inconsistent CVP value and while there is no a wave there is a prominent c-v–wave complex. **B.** *Atrioventricular dissociation*—early systolic cannon a waves (marked by *) result from atrial contraction against a closed tricuspid valve. (Reproduced with permission from Mark JB. Atlas of Cardiovascular Monitoring. New York: Churchill Livingstone, 1998: Figs. 14.1 and 14.5.)

irritation. As an alternative to the thin-walled needle, a 2-inch 18-gauge catheter may be used to enter the vessel. With this technique, the catheter is threaded into the vessel, the needle removed, and the guidewire inserted through the catheter. Confirmation of venous rather than arterial cannulation may be accomplished in one of several ways. Detection of pulsatile blood through the thin-walled needle identifies unintended cannulation of an artery. In addition, when using the 18-gauge catheter to cannulate the IJV vein, attachment of a length of intravenous tubing to measure the intravascular pressure prior to placement of the guidewire is a common and effective safety check.

After confirmation of venous cannulation, the skin, subcutaneous tissues, and vessel opening are dilated, and the catheter is placed. A small skin incision eases passage of the catheter itself and prevents damage to its leading edge. However, care should be taken with passage of the vessel dilator, as it is large, stiff, and capable of perforating or tearing the vessel.

The most recent innovation in central venous cannulation has been the development of small portable ultrasound devices for vessel localization. These devices have made it possible to image the great veins of the neck either prior to or during line place-

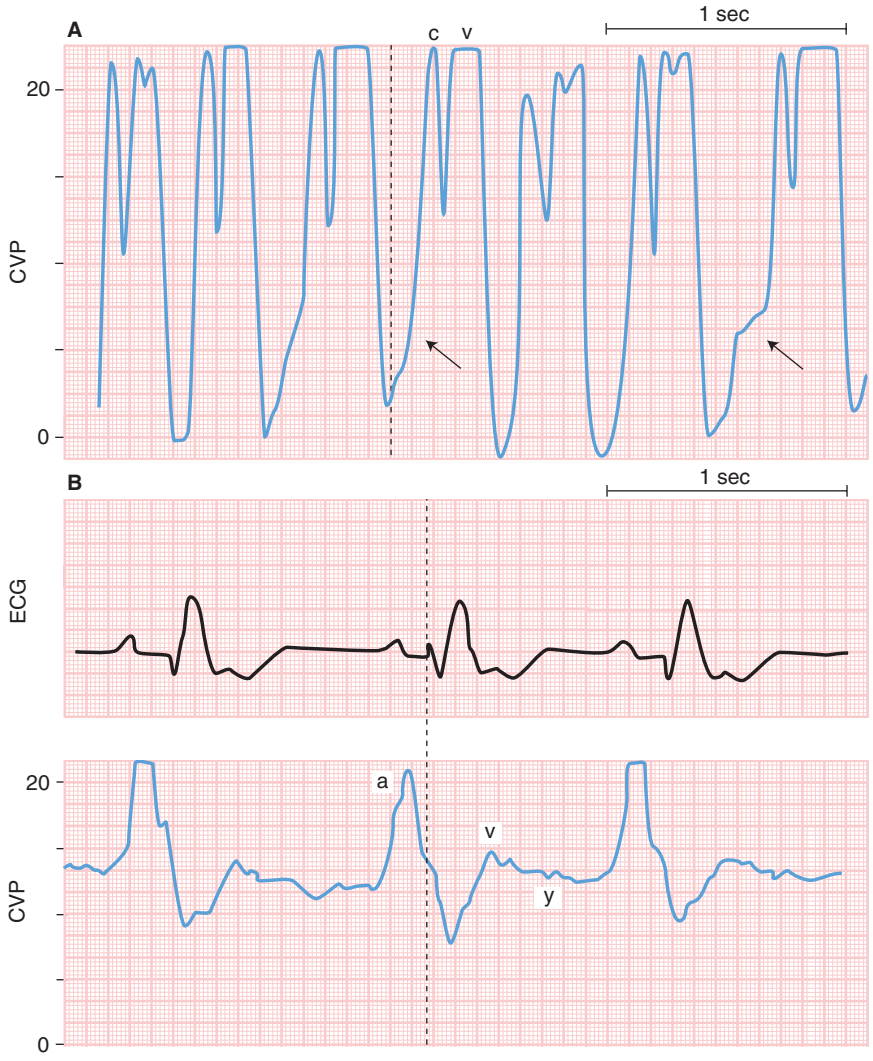

FIGURE 29–8. Effect of tricuspid valve pathology on the central venous pressure (CVP) waveform. **A.** *Tricuspid regurgitation*—high mean CVP with tall c-v–wave complex (*arrows*), minimal x descent, and sometimes absent a wave as a consequence of the presence of atrial fibrillation. **B.** *Tricuspid stenosis*—high mean CVP but with prominent a wave and deep x descent with minimal v wave or y descent. ment. A variety of studies show that their use decreases the incidence of failed catheter placement, as well as the complication rate.[25,26] Routine use has been recommended, although the importance of maintenance of skills and training in the traditional landmark method has been emphasized by some authors.[25] Obese patients and patients with neck scarring might be especially suitable candidates for using ultrasound guidance.

Indications for Central Venous Catheterization

Box 29–1 lists the indications for central venous catheterization. The main indication for monitoring CVP is as a guide for volume status assessment and fluid resuscitation. Once in place, it may be used for additional purposes such as for obtaining repeated blood samples.

Complications of Central Venous Catheterization

Complications arising from a central venous catheter can generally be separated into those arising from the placement of the catheter itself and those that develop while the catheter is in place and in use (Box 29–2). Type of complication will vary somewhat between locations. For example, pneumothorax is more common when using the subclavian vein approach. However, for all central vein cannulation sites, vascular injury is the most common complication and can result in a wide range of clinical sequelae, ranging from undetectable hematoma to life-threatening cardiac tamponade following perforation of the intrapericardial portion of the superior vena cava or right atrium. Risk for this complication can be minimized by ensuring the catheter tip is located at the

BOX 29–1.

Indications for Central Venous Line Placement

Monitoring
- Central venous pressure monitoring
- Pulmonary artery catheterization

Therapeutic Intervention
- Hemodialysis
- Temporary transvenous pacing
- Aspiration of air emboli (e.g., sitting position craniotomy)
- Infusion of vasoactive drugs or total parenteral nutrition
- Need for repeated blood sampling
- Cannulae placement (e.g., veno-venous bypass, portosystemic shunt)
- Inadequate peripheral venous access (obesity, burns, postchemotherapy)

BOX 29–2.

Complications of Central Venous Catheterization

Secondary to catheter placement:
- Airway or lung injury (pneumothorax, subcutaneous or mediastinal emphysema)
- Bleeding (subcutaneous hematoma, hemothorax)
- Chylothorax
- Arterial injury/cannulation
- Air embolism
- Nerve injury
- Catheter shearing/embolism
- Dysrhythmias

Secondary to in-situ catheter:
- Dysrhythmias
- Hydrothorax/hydromediastinum
- Thromboembolism (superior vena cava syndrome, pulmonary embolism)
- Infections (cellulitis, bacteremia, sepsis, endocarditis)
- Vascular/cardiac perforation (arteriovenous or venobronchial fistula, cardiac tamponade)

BOX 29–3.

Recommended Measures to Decrease Catheter-Related Infections

- Adequate training of physicians and nurses.
- Avoiding femoral vein catheterization.
- Use of full sterile technique for catheter insertion (including cap, mask, gown, sterile gloves and drapes).
- Chlorehexidine rather than povidone-iodine for skin preparation.
- Use of heparin-bonded catheters.
- Removal of catheters as early as possible.

TABLE 29–2.

Hemodynamic Parameters Measured by the Pulmonary Artery Catheter

Measured Parameter	Normal Values	Normal Values Indexed to Body Surface Area
Cardiac output	4–6 L/min	2.8–4.2 L/min/m²
Central venous pressure	2–7 mm Hg	n/a
Pulmonary artery pressure (systolic/diastolic)	15–30/6–15 mm Hg	n/a
Pulmonary artery occlusion pressure	5–12 mm Hg	n/a
Right ventricular ejection fraction	40–60%	n/a
Mixed venous oxygen saturation	70–75%	n/a

n/a, Not applicable.

level of the carina or higher on a chest x-ray.[27] Delayed presentation of aortovenous and even aortobronchial fistulas have been reported, although rare.[28] Inadvertent placement of any large-bore catheter into a central artery should prompt evaluation by a vascular surgeon for management to avoid a variety of long-term complications. Respiratory compromise can develop from several sources, including embolism of air or clot, pneumothorax, direct airway injury from the advancing needle, or airway compression from arterial bleeding and expanding hematoma. Catheter-related infectious complications range from local site infection to life-threatening sepsis and endocarditis. In an attempt to decrease infectious complications, specific recommendations have been published by the Centers for Disease Control (Box 29–3).[22] Routine scheduled replacement of central venous catheters, either on guidewire or to a new site, does not decrease the infection risk. Rather, central catheters should be removed as early as clinically feasible. The incidence of many of these complications can be decreased with use of ultrasound technology prior to or during central line placement.[25,26]

THE PULMONARY ARTERY CATHETER

A landmark article in 1970 described the clinical use of a balloon-tipped, flow-directed pulmonary artery catheter (PAC) for treatment of patients with acute myocardial infarction.[29] Use of the PAC rapidly spread as an important monitoring tool for treatment of high-risk surgical and critically ill patients. Various modifications of the PAC allow measurement of intracardiac pressures, cardiac output, mixed venous oxygen saturation, and RV ejection fraction (Table 29–2 lists normal values). From these measured values, various hemodynamic indices can be calculated, including systemic and pulmonary vascular resistances (SVR and PVR), stroke volume (SV), right and left ventricular stroke work indices, right ventricular end-diastolic volume, and shunt fraction (Table 29–3). It should be emphasized that calculated parameters inherit measurement inaccuracies of each of the constituent directly measured parameters; consequently, these calculated indices may have magnified errors. Numerous studies show that standard clinical measurements such as heart rate, blood pressure, and urine output do not always allow early identification of inadequate perfusion states; moreover, experienced clinicians are often wrong in their assessment of the circulatory profile of critically ill patients.[30] Therefore, monitoring using the PAC often reveals new information that should be helpful in diagnosis and management of various hemodynamic disturbances, guiding fluid and vasoactive drug therapy. However, continuous debate still exists regarding the clinical usefulness of the PAC and whether its use improves patient outcome.[31,32]

Monitoring cannot be expected to benefit patient outcome unless the clinician collects the data accurately and interprets and applies it correctly. This has proven especially problematic for the PAC; studies have demonstrated deficiencies in interpretation of the raw hemodynamic waveform even by experienced physicians.[33] Other studies have found that even when given the processed PAC data, different intensivists make different, sometimes opposing or even harmful, choices for therapeutic interventions.[3,34] These studies have led to increasing emphasis on training requirements by the American Society of Anesthesiologists (ASA), Society of Critical Care Medicine, and the National Institutes of Health.[35–37] Widespread difficulties with interpretation and application of PAC data confounds evaluation of PAC clinical outcome studies and might explain in part the discrepant results and failure to show benefit in many trials.[32] Correct insertion technique, awareness of indications and possible complications, and understanding of the physiologic principles involved, are all prerequisites for gaining any clinical benefit from the use of the PAC.

Insertion Technique

The current PAC for use in adult patients is 110 cm in length, contains 3 or 4 lumens, and has an embedded thermistor and a 1.5-mL balloon at the tip. The long and pliable catheter has a relatively low natural frequency, which might contribute to error in measuring transmitted pressures when the damping coefficient is unusually high or low. The catheter is inserted through a one-way valve on a large-bore introducer placed into a central vein.

The right internal jugular vein affords the most direct path for inserting the PAC into the right-heart chambers. The left subclavian vein is an alternative choice as the catheter fol-

TABLE 29–3.

Hemodynamic Calculations Derived from Pulmonary Artery Catheter Measurements

Parameter	Formula	Normal Values	Normal Values Indexed to BSA
Stroke volume	$\frac{\text{Cardiac output}}{\text{Heart rate}}$	60–90 mL	40–60 mL/m²
Systemic vascular resistance	$\frac{(\text{MAP} - \text{CVP}) \times 80}{\text{Cardiac output}}$	900–1500 dyne × sec/cm⁵	1600–2400 dyne × sec × m²/cm⁵
Pulmonary vascular resistance	$\frac{(\text{mPAP} - \text{PAOP}) \times 80}{\text{Cardiac output}}$	150–200 dyne × sec/cm⁵	225–320 dyne × sec × m²/cm⁵
Left ventricular stroke work	(MAP – PAOP) × stroke volume × 0.0136	60–110 g × m	50–68 g/m
Right ventricular stroke work	(mPAP – CVP) × stroke volume × 0.0136	8–16 g × m	5–10 g/m
Right ventricular end-diastolic volume	Stroke volume/right ventricular ejection fraction	100–160 mL	60–100 mL/m²
Oxygen delivery	Cardiac output × CaO_2 × 10	850–1050 mL/min	500–600 mL/min/m²
Oxygen consumption	Cardiac output × (CaO_2 – CvO_2) × 10	200–250 mL/min	120–160 mL/min/m²
Pulmonary shunt fraction	(Pulmonary capillary oxygen content – CaO_2)/(Pulmonary capillary oxygen content – CvO_2)	<5%	n/a

lows the natural curve of the brachiocephalic vein into the superior vena cava. Other routes, including more peripheral sites such as the femoral vein, or even a large arm vein, can be used, but catheter positioning might be more difficult and limited intraoperative access will hinder needed adjustments. Once the catheter is inserted through the introducer to a depth of 20 cm, the balloon at the tip is filled with 1.5 mL of air to help float the catheter into the pulmonary artery. Although catheter guidance depends both on balloon flotation and blood-flow direction, the former is by far the more important.[38] Consequently, patient positioning can influence the ease with which the catheter passes through the heart. A combination of head elevation with patient tilt to the right places the right ventricular infundibulum and pulmonary valve in a nondependent position, and aids flotation across the valve.[39] The catheter tip also has a curve that can help in maneuvering across the tricuspid and pulmonary valves. Optimizing patient positioning and direction of the catheter curve are more important in clinical situations in which the right atrium or ventricle are enlarged or cardiac output is low.

Identification of correct catheter positioning depends primarily on monitoring changes in pressure transduced from the distal port of the PAC (Fig. 29–9). When the PAC is introduced from the right internal jugular vein, the right atrium is encountered at 20–25 cm from the edge of the introducer's hub, right ventricle at 30–35 cm, pulmonary artery at 40–45 cm, and the wedge position at approximately 50 cm.[40] By keeping these estimated distances in mind, the clinician can avoid excessive catheter insertion that may lead to catheter coiling or knotting within the heart.

The PAC balloon should not be kept inflated for more than a few seconds at a time because of the risks of pulmonary infarction or pulmonary artery rupture. If the pulmonary artery occlusion pressure (PAOP) waveform appears when less than 1 mL of air is added to the balloon, the PAC tip has migrated into a small pulmonary artery branch and the catheter should be immediately withdrawn to a point where this does not occur.

Fluoroscopy has been used to aid PAC insertion and localization in difficult cases, or when using the femoral or arm veins as entry sites. More recently, the use of transesophageal echocardiography (TEE) has been described to help with visualizing the PAC during insertion.[41] The midesophageal right ventricle inflow–outflow view is especially suitable for this purpose (Fig. 29–10).

PAC-Derived Pressure Measurements

Once the PAC is in place, several physiologic parameters can be measured, calculated, and derived (Tables 29–2 and 29–3). The most important measurements are cardiac output, an index of global perfusion, and PAOP, an index of left ventricular (LV) preload. Additional useful pressure recordings are measured from the right atrium (CVP) and pulmonary artery. Right ventricular pressure can be measured as the catheter tip is advanced or retracted. To measure PAOP, the balloon is slowly inflated so that pulmonary blood flow carries the catheter to a "wedged" position. At this point, the balloon obstructs forward blood flow through a medium-sized pulmonary artery branch, and a static column of blood is created, connecting the catheter tip to a junction point where flow resumes in the pulmonary veins near the left atrium.[42] Because resistance to flow in the large

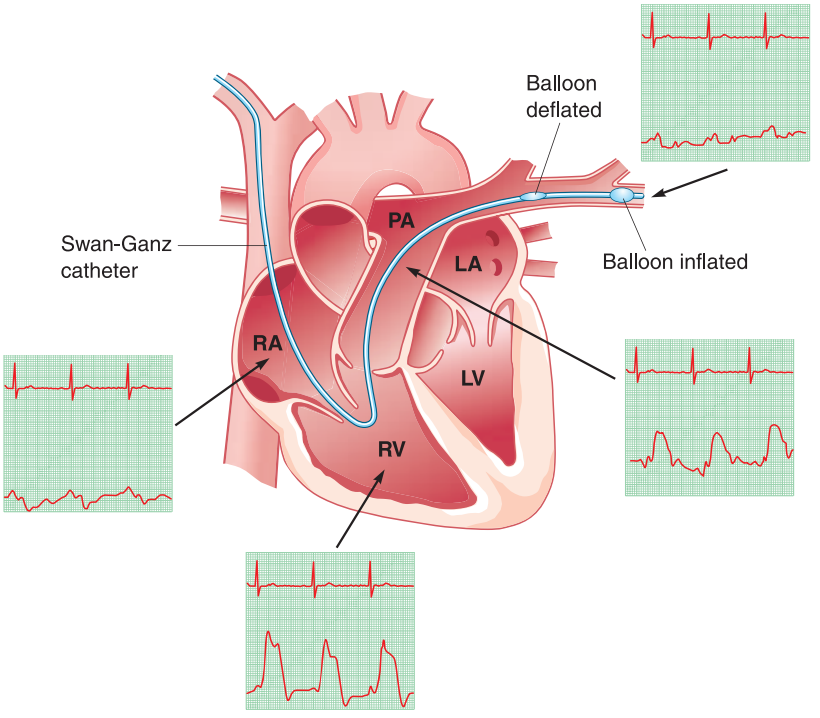

FIGURE 29–9. Pressure waveforms measured by the pulmonary artery catheter. As the catheter is advanced from the venous cannulation site, the first waveform recorded will be the central venous pressure trace. Passage of the catheter from the right atrium (RA) into the right ventricle (RV) is accompanied by marked increase in "systolic" pressure. As the catheter tip enters the pulmonary artery (PA), a dicrotic notch may appear in the systolic wave and the diastolic pressure will increase in magnitude and will be down-sloping, in contrast to the up-sloping diastolic pressure in the right ventricle. With further advancement of the catheter, the balloon will occlude blood flow and the tip will record the pulmonary artery occlusion pressure, characterized by disappearance of the "systolic" pressure wave and reappearance of venous a, c, and v waves. (Modified with permission from Mark JB. Atlas of Cardiovascular Monitoring. New York: Churchill Livingstone, 1998: Fig. 3.1.)

pulmonary veins is low, the PAOP should provide an accurate estimate of left atrial pressure (LAP). Similar in morphology to the CVP trace, the PAOP waveform has a and v waves that reflect a LAP waveform that is slightly delayed and damped by the interposed pulmonary vascular bed. Although the PAOP is usually reported as a single mean value, the PAOP a wave, which just follows the ECG R wave, better reflects left ventricular end-diastolic pressure (LVEDP), particularly in patients with left ventricular dysfunction,[43] and is therefore a more accurate predictor of left ventricular preload. The mean PAOP, however, is a better estimate of the hydrostatic back pressure that influences pulmonary edema formation. Even though the terms PAOP and pulmonary capillary pressure (PCP) are sometimes used interchangeably, these pressures do not reflect the same physiologic measurement. Because direction of blood flow is from the pulmonary capillaries to the pulmonary veins and thence to the left atrium, true PCP is slightly higher than PAOP and may be significantly higher when either pulmonary venous resistance is elevated, as in acute respiratory distress syndrome (ARDS), or when blood flow is increased.[42]

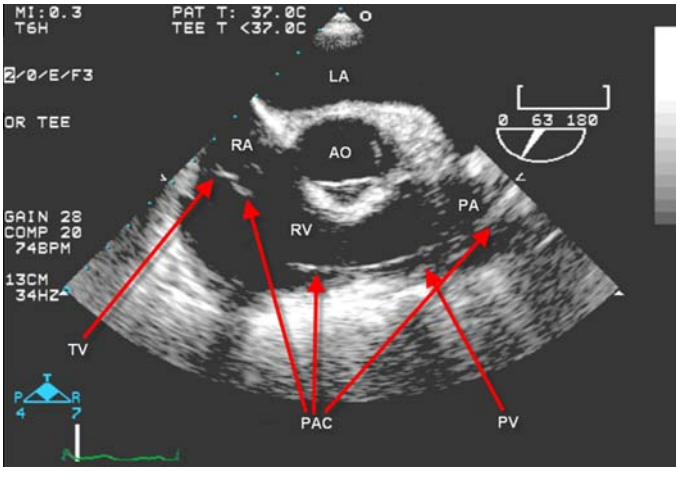

FIGURE 29–10. Midesophageal right ventricle inflow–outflow transesophageal echocardiography view demonstrating the pulmonary artery catheter (PAC) in the right atrium (RA), right ventricle (RV), and pulmonary artery (PA), traversing the tricuspid valve (TV) and pulmonary valve (PV). Also shown are the left atrium (LA) and aorta (AO).

Factors Affecting Data Validity and Interpretation

A primary reason for PAC monitoring is to provide an estimate of left ventricular preload. Physiologically, true preload is the length of the ventricular muscle sarcomere at end-diastole. In the three-dimensional heart, left ventricular end-diastolic volume (LVEDV) can be considered a global measure of LV preload; however, measurement of this parameter is not readily available clinically. LVEDP can be measured by left-heart catheterization, although its relationship to LVEDV depends on left ventricular compliance. Under normal physiologic conditions, upstream pressure measurements of LAP, PAOP, and pulmonary artery diastolic pressure (PADP), should provide accurate surrogates for LVEDP. Use of PAC-derived pressures (PAOP and PADP) to estimate preload is predicated on these assumptions. However, there are many pathophysiologic conditions in which these surrogate measures of LVEDV are subject to error. These are discussed below and are summarized in Table 29–4.[42,44]

Artifacts Motion of the PAC tip from ventricular contraction or valve leaflet movements can produce artifactual spikes or troughs in the pressure waveform, termed *catheter whip*. "Overwedging" appears when balloon inflation produces a gradually rising, nonpulsatile pressure, which results from the catheter tip being forced against the

TABLE 29–4.

Factors Causing Under- and Overestimation of Left Ventricular End-Diastolic Volume

Condition	Site of Discrepancy	Cause of Discrepancy
Underestimation		
Decreased left ventricular compliance	LVEDV < LVEDP	Change in pressure–volume relation
Aortic regurgitation	LAP < LVEDP	Ventricular filling continues after mitral valve closure
Decreased pulmonary vascular bed	PAOP < LAP	Balloon inflation significantly decreases right ventricular blood flow
Pulmonic regurgitation	PADP < PAOP	Bidirectional runoff for pulmonary artery blood flow
Right bundle-branch block	PADP < PAOP	Delayed pulmonary valve opening allows continued fall of PADP
Overestimation		
Positive pressure ventilation	LVEDP > transmural EDP	Ignoring intrapericardial pressure
Mitral stenosis/left atrial myxoma	LAP > LVEDP	Obstruction to flow across mitral valve
Mitral regurgitation	Mean LAP > LVEDP	Retrograde systolic v wave
Ventricular septal defect	Mean LAP > LVEDP	Antegrade systolic v wave
Tachycardia	PADP > PAOP = LAP > LVEDP	Short diastole creates pressure gradients
Positive end-expiratory pressure	PAOP > LAP	Expansion of West lung zones 1 or 2
Overwedging	PAOP > LAP	Occlusion of distal catheter lumen
Pulmonary venous hypertension	PADP > PAOP	Increased pressure gradient over pulmonary circulation

EDP, end diastolic pressure; LAP, left atrial pressure; LVEDP, left ventricular end-diastolic pressure; PADP, pulmonary artery diastolic pressure; PAOP, pulmonary artery occlusion pressure.

arterial wall, occluding the distal lumen of the PAC.

Ventricular Compliance Because the pressure-volume relationship of the left ventricle is curvilinear, the same change in ventricular volume can produce either a small or large change in LVEDP, depending on the position on the compliance curve over which the left ventricle is operating. Also, conditions causing a marked shift in the compliance curve may result in pressure and volume changing in opposite directions, that is, increased LVEDP associated with decreased LVEDV (Fig. 29–11). In the perioperative period, myocardial ischemia, right ventricular failure causing interventricular septal shift, and inotropic drug effects, can all induce rapid changes in ventricular compliance.

Catheter-Tip Position West et al. divided the lung into three zones according to gravity-dependent differences in perfusion and ventilation that affect the relationship of pulmonary arterial pressure (Pa), alveolar pressure (Palv), and pulmonary venous pressure (Pv).[45] The PAC tip needs to reside in zone 3 (Pa > Pv > Palv) so that a continuous column of blood exists and the pressure measured by the catheter tip will reflect vascular rather than alveolar pressure. In a supine, spontaneously breathing subject, this is rarely a problem. However, with hypovolemia (low Pv) or positive-pressure ventilation (high Palv), zone 2 or zone 1 conditions might appear. This may be suspected when the PAOP trace demonstrates excessive respiratory variation in the pressure waveform (Fig. 29–12).[46]

Changes in body position will also influence the distribution of lung blood flow and the anatomic locations of the different lung zones. This may be an important consideration in a patient who has a PAC inserted while supine, but later is positioned in the lateral, prone, or steep head-up or head-down positions.

Ventilatory Pressure Influences With large cyclic variations in intrathoracic pressure, as occurs during labored

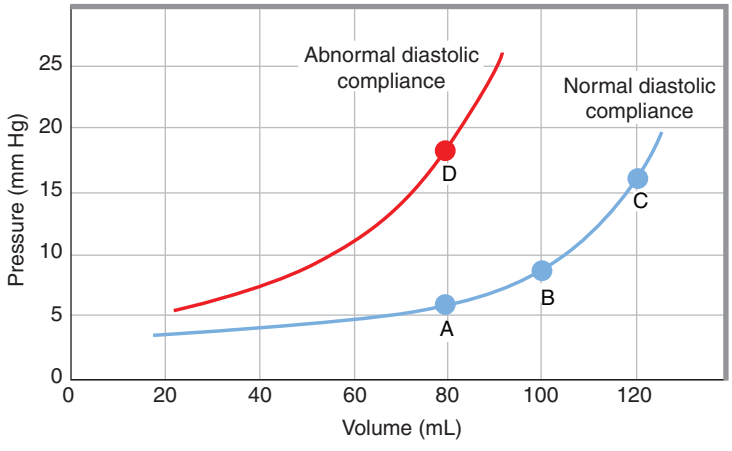

FIGURE 29–11. The effect of change in left ventricular compliance on pressure–volume relationship. The normal relationship (*light blue curve*) is curvilinear. Depending on the starting point, the same change in the true preload, that is, end-diastolic volume, will cause a markedly different change in left ventricular end-diastolic pressure, and hence in the pulmonary artery occlusive pressure (A to B vs. B to C). When ventricular compliance decreases (*red curve*), an increase in filling pressures (from A to D) does not necessarily reflect increased end-diastolic volume. (Modified with permission from Mark JB. Atlas of Cardiovascular Monitoring. New York: Churchill Livingstone, 1998: Figs. 15.1 and 15.2.)

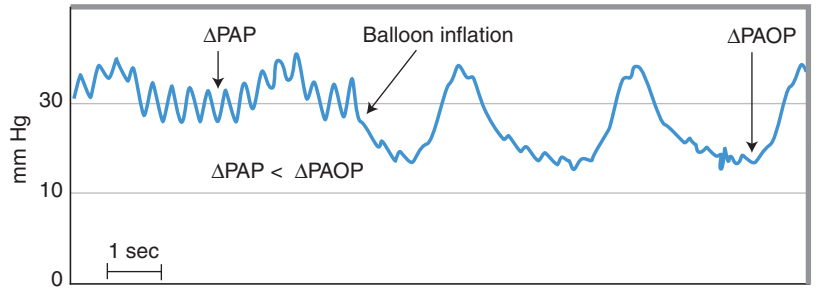

FIGURE 29–12. Pressure trace recorded during positive pressure mechanical ventilation from a pulmonary artery catheter located in West lung zone 1. Pressure swings in the pulmonary artery occlusion pressure (ΔPAOP) reflect changes in airway pressure and are significantly higher then swings in pulmonary artery pressure (ΔPa), which result from changes in pleural pressure. (Modified with permission from Teboul JL, Pinsky MR, Mercat A, et al. Estimating cardiac filling pressure in mechanically ventilated patients with hyperinflation. Crit Care Med 2000;28(11):3631–3636.)

respiration, coughing, Valsalva maneuver, or positive-pressure ventilation, both intracardiac and intrapericardial pressures are affected. The PAC will reflect the increased intracardiac pressures, although the true transmural pressure which determines cardiac preload, has not been changed.[47] Consequently, the PAOP should be measured at end-expiration, a time point when intrathoracic pressure approximates atmospheric pressure, whether the patient is breathing spontaneously or mechanically ventilated. Visual inspection of the waveform display is more accurate than reliance on digital display for identifying end-expiratory pressures. During spontaneous breathing, inspiratory pressures are negative and the end-expiration point corresponds to the higher vascular pressure values. The opposite is true under positive-pressure ventilation.

Application of positive end-expiratory pressure (PEEP) will also alter intrathoracic pressure and hence PAOP measurements at end-expiration. The magnitude of these effects depends on the level of PEEP used and the pulmonary and chest wall compliance.[42] As a simple rule of thumb, the increase in measured PAOP is usually less than one-half the value of the PEEP applied. As lung compliance deteriorates, however, the transmission of airway pressure to the pleural space is attenuated. Therefore the effect of high PEEP, commonly employed in these situations, is minimized.[48]

Diagnostic Use of the PAC-Derived Pressure Waveform

In addition to the quantitative hemodynamic data provided by pressure measurements and cardiac output, the analog pressure waveform can be diagnostic of several pathologic cardiovascular conditions. Although echocardiography has mostly supplanted the PAC for clinical diagnosis of most of these disorders, initial clinical clues can be provided by PAC monitoring (Fig. 29–13).[49]

Complications of PAC Monitoring

Complications associated with PAC arise from central venous cannulation (Box 29–2), initial PAC placement and positioning, and from continued presence and use of the catheter within the body. Frequency varies greatly between various reports and most complications have been described only in case reports or small case series.[35] Although minor complications occur in up to 50% of cases, recent practice guidelines concluded that the incidence of serious life-threatening complications is much lower, and estimated to be 0.1–0.5%.[35] Two large, prospective registries of PAC complications in surgical patients support this estimated risk, showing major morbidity in 0.12–0.16% and mortality of 0.016% of catheterized patients.[50,51] Factors suggested as important to minimize complications include the expertise and experience of the attending physician, close supervision of trainees, and attention to detail during pulmonary artery catheterization and usage.

Dysrhythmias

Transient dysrhythmias, most commonly premature ventricular contractions (PVCs), accompany passage of the PAC through the heart in up to 70% of patients.[50] PVCs can also occur during removal of the catheter. Clinically significant dysrhythmias, such as complete heart block, ventricular tachycardia and ventricular fibrillation, are much rarer—approximately 3% of patients.[50,52]

Transient right bundle-branch block occurs in up to 5% of patients during PAC insertion.[53] Therefore, patients with preexisting left bundle-branch block are at risk of developing complete heart block.[54] In these patients, a margin of safety can be provided by using a PAC with a pacing port, having transcutaneous pacing readily available, or, rarely, a prophylactic placement of a transvenous pacing wires.

In patients with severe aortic stenosis and other conditions associated with severe left ventricular hypertrophy, effective external cardiac massage is hard to achieve. When cardiac surgery is performed in these patients, many anesthesiologists delay flotation of the PAC until after sternotomy, which enables open cardiac massage to be performed in the event of a life-threatening dysrhythmia.

Catheter Knotting

Possible risk factors for looping and knotting of catheters within the heart include low cardiac output states, right-heart dilation, and excessive length of catheter inside the heart.[55] The PAC might also become entangled with intracardiac pacing wires or anatomic structures such as chordae tendinae.[56,57] If knots occur, they can usually be disentangled under fluoroscopic guidance. Alternatively, the knot may be pulled tight and the catheter removed with its sheath.[58]

Thromboembolism and Pulmonary Infarction

Minor thrombi associated with the PAC were almost universal in the past, but became uncommon with the use of heparin-coated catheters.[59] Major pulmonary embolism associated with PAC use has been reported in 0.9% of patients receiving PAC versus none in the control group.[60] Pulmonary infarction following PAC can also result from prolonged balloon inflation or distal catheter migration.[61]

Catheter-Related Infections

For central venous catheters and PACs alike, catheter-related infections usually result from skin organisms colonizing the introducer sheath.[22] Heparin-coated PACs and regular central venous catheters carry a similar risk of

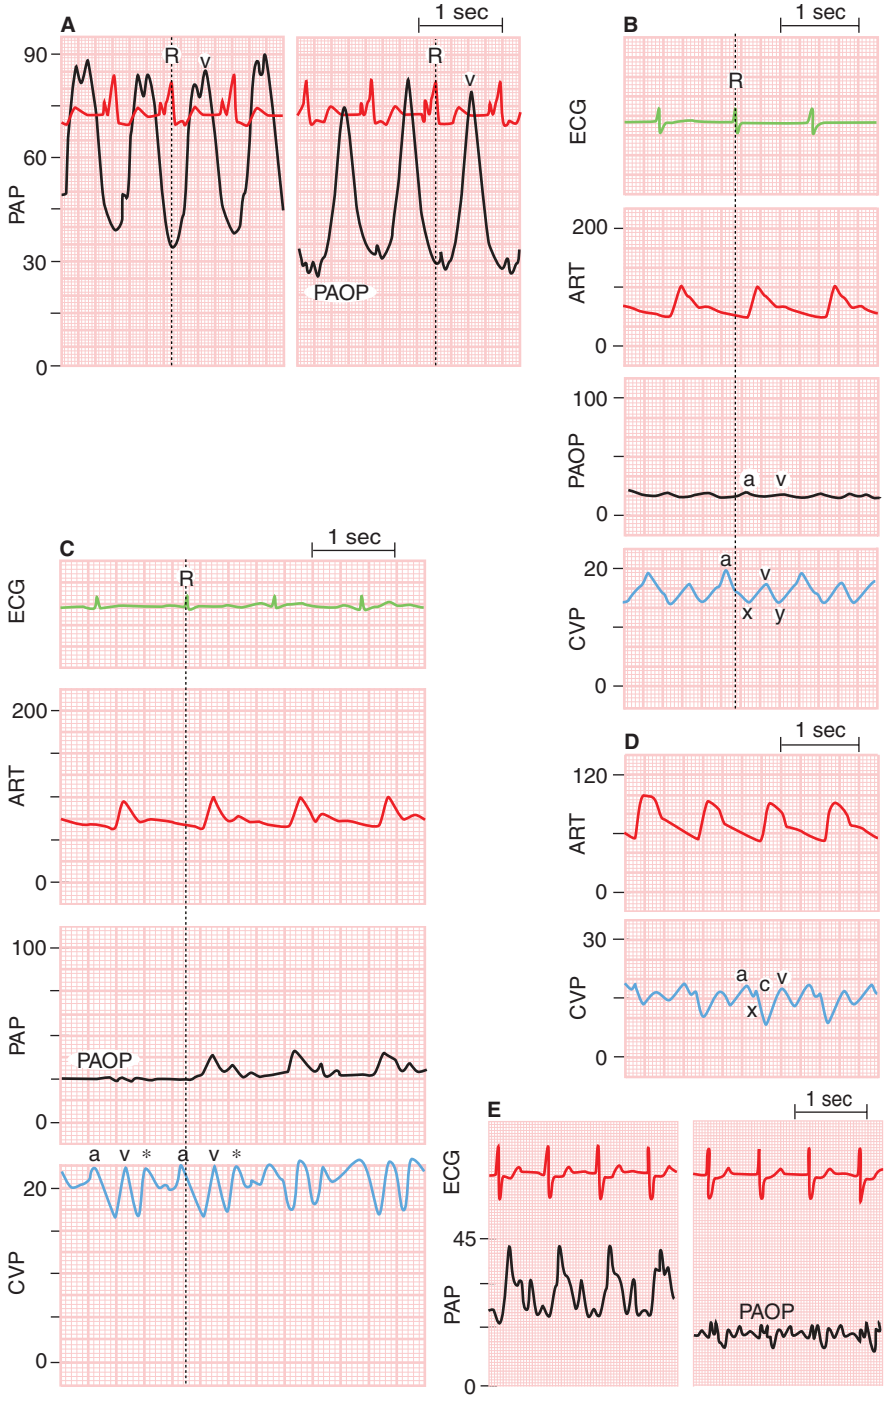

FIGURE 29–13. Pressure waveforms morphology in various clinical situations. **A.** *Acute mitral regurgitation*—giant v waves are seen in the pulmonary artery occlusion pressure (PAOP) trace, as well as distorting the nonwedged pulmonary artery pressure (PAP) trace. While the wedged (PAOP) pressure can be mistaken to be a PAP trace, the timing of the main pressure wave relative to the electrocardiographic T wave can help in correct identification. **B.** *Right ventricular infarction*—note prominent CVP waves with increased mean value (16 mm Hg) almost equal the PAOP pressure (18 mm Hg). **C.** *Constrictive pericarditis*—equilibration of end-diastolic pressures across the heart: PAOP, diastolic Pa, and CVP a wave, all about 25 mm Hg. Also note the W-shaped CVP trace with the mid-diastolic plateau wave (marked by *). **D.** *Cardiac tamponade*—relatively low blood pressure (84/55 mm Hg) and elevated CVP with dominant x descent but attenuated y descent. **E.** *Pulmonary hypertension*—increased pulmonary pressure (42/20 mm Hg) with markedly lower PAOP (13 mm Hg), caused by increased pulmonary vascular resistance. (Reproduced with permission from Mark JB. Atlas of Cardiovascular Monitoring. New York: Churchill Livingstone, 1998: Figs. 17.11, 12.15, 18.1, 18.5, and 6.11.)

infectious complications (2.6 infections per 1000 catheter days), whereas non–heparin-coated PACs carry a 2-fold increased risk.[22] Leaving the PAC in place for more then 5–7 days also increases the risk of infection.

Valvular Damage and Endocarditis

Case reports have described PAC-associated injury of the tricuspid valve[62] and the pulmonary valve,[63] but these injuries appear to be very rare events. The PAC balloon must be completely deflated prior to catheter withdrawal to avoid valvular injury. Even with proper catheter management, endocarditis, either septic or thrombotic, has been described in autopsy studies, probably representing occult endocardial injury.[64]

Pulmonary Vascular Injury

Pulmonary vascular injury and pulmonary artery rupture are rare, life-threatening complications of pulmonary artery catheterization. Pulmonary artery rupture has an incidence of 0.02–2.0% but carries a mortality of 40–70%.[60,65,66] Risk factors for this catastrophic complication include patient characteristics (advanced age, female gender, hypothermia, anticoagulation therapy, and pulmonary hypertension) as well as operator errors (overdistension of the balloon, unrecognized distal migration of the catheter, and balloon inflation when the catheter tip is wedged).[65,66] In patients with risk factors, consideration should be given to using the PADP as an estimate for PAOP and avoiding repeated balloon inflation.

Sudden hemoptysis is the most common presentation of pulmonary artery rupture. Other signs include hemothorax, hypoxemia, and cardiovascular collapse.[65,66] Maintaining oxygenation and achieving rapid control of bleeding are initial therapeutic goals. Endobronchial intubation with a double-lumen tube or intentional mainstem intubation allows selective lung ventilation and isolation of the bleeding segment.[67] Ancillary treatment includes lowering pulmonary artery pressure, reversing anticoagulation, and performing bronchoscopy for endobronchial toilet and identification of the bleeding site. Definitive control of bleeding may be achieved by transcatheter selective pulmonary artery embolization,[68] but surgical lung resection is required when more conserva-

BOX 29–4.

Common Indications for Pulmonary Artery Catheterization

- Hemodynamic monitoring in high-risk patients undergoing major surgery, including preoperative optimization
- Differential diagnosis and management of shock (hypovolemic, septic, cardiogenic)
- Diagnostic evaluation of major cardiopulmonary disorders (e.g. myocardial ischemia, pulmonary hypertension, intracardiac shunt, pulmonary edema)
- Titration of therapy in unstable hemodynamic conditions (e.g. hypervolemic therapy in subarachnoid hemorrhage, management of eclampsia)
- Optimization of ventilatory support (PEEP titration)

tive treatments fail or if life-threatening bleeding develops.[65,66]

Indications for Use and the Controversy Surrounding Pulmonary Artery Catheterization

Box 29–4 summarizes the common indications for the PAC. However, studies show that factors other than medical indications affect the decision to use the PAC, including institutional, geographical, organizational, demographical, and individual preferences.[69,70]

In 1996, Connors et al., in a retrospective study in critically ill patients, concluded that PAC use is associated with a 20% increased mortality.[71] This study ignited a major controversy regarding the role of the PAC in clinical medicine.[31,32] Although earlier studies shared problems of inadequate methodology, unequal case mix and small sample size,[35,36] several more recent, large, well-designed clinical trials have been published and have helped to better define the role of the PAC in perioperative medicine. In patients undergoing major noncardiac surgery, a large observational study showed that PAC use was associated with a 2.2-fold increase in risk of cardiac complications,[72] and a large randomized study found no benefit for PAC-guided goal-directed therapy compared to standard care without PAC.[60] In moderate-risk vascular surgery, both randomized controlled studies[73] and a meta-analysis[74] demonstrated no benefit associated with routine use of the PAC. Lastly, a large prospective randomized trial in patients undergoing coronary artery bypass surgery compared routine use of PAC versus CVP monitoring, and showed no difference in outcome.[75]

Several recent, large, randomized studies also have been performed in nonsurgical populations, including patients with severe congestive heart failure,[76] patients with acute lung injury,[77] and ICU patients with early shock or multiorgan failure.[52,78,79] All found no therapeutic advantage for use of the PAC.

However, most randomized studies have looked at the routine use of the PAC in large sequential cohorts of patients with relatively moderate risk of death.[80] In most of these clinical trials, specific therapeutic protocols were not mandated and management was left to the physician's discretion. Patients whose physicians considered them to be too sick to avoid having a PAC placed were also usually excluded.[81] In contrast, several recent large, nonrandomized studies suggest that PAC use may benefit especially high-risk patients characterized by age > 65 years, significant physiologic disturbances (i.e., large base deficit) and a high level of disease acuity or injury severity.[82–84] In addition, use of the PAC as a "rescue" monitor in patients who remain hemodynamically unstable despite empirical therapy has received little investigation.

Several expert panels have been convened to provide guidelines to help standardize clinical practice.[35–37] Specifically focused on the perioperative period, the ASA task force practice guidelines for PAC use suggest that preemptive PAC insertion in patients deemed at high-risk is a justifiable practice because of the delay associated with PAC placement once complications have developed, as well as possibly increased vascular and infectious complications related to hasty catheter insertion under suboptimal clinical conditions.[35] The guidelines emphasize the role of operator's experience in preventing PAC-associated complications, and underscore the importance of training and education to improve physician's knowledge and understanding of cardiopulmonary physiology. According to the ASA guidelines, the use of the PAC is considered necessary only in high-risk patients undergoing high-risk surgery, and even then is contingent upon a favorable practice environment (i.e., knowledgeable and experienced physicians and ICU nurses). The term *high-risk patient* generally refers to an ASA class 4 or 5 patient with significant cardiovascular disease, pulmonary dysfunction, renal insufficiency, sepsis, or trauma. High-risk surgery includes procedures commonly associated with large fluid shifts or hemodynamic derangements and high predicted mortality. As new monitoring modalities become clinically available, the need for PAC is expected to decrease even further.

Special Types of Pulmonary Artery Catheter

Pacing Pulmonary Artery Catheter

Two types of PAC have pacing capability. One has 5 electrodes incorporated in the catheter that allow bipolar atrial, ventricular, or atrioventricular sequential pacing. A second type has an extra lumen through which a pacing wire can be placed into the right ventricle. An obvious target population for these catheters are patients undergoing cardiac surgery using cardiopulmonary bypass, where pacing is frequently required postoperatively for a short period. Other candidates are patients with left bundle-branch block, in whom placing a PAC puts them at risk of developing complete heart block. Successful pacing with these catheters is usually achieved intraoperatively in anesthetized patients,[85] but capture becomes less reliable when patients start to move postoperatively. As a result, these catheters are not widely used.

Continuous Mixed Venous Oximetry

Measurement of mixed venous oxygen content in the pulmonary artery blood provides an assessment of the balance between total body oxygen supply and consumption.[86] Assuming the contribution of dissolved oxygen is negligible, the mixed venous oxygen saturation can be expressed by rearrangement of the Fick equation (Box 29–5). This relationship highlights that venous saturation increases when arterial oxygen saturation, hemoglobin concentration, and cardiac output increase, and decreases when oxygen consumption increases.

BOX 29–5.

Mixed Venous Oxygen Saturation

$$SvO_2 = SaO_2 - \left(\frac{\dot{V}O_2}{CO \times 1.36 \times Hgb}\right) \times 100$$

Where	
SvO_2	= mixed venous oxygen saturation (%)
SaO_2	= arterial oxygen saturation (%)
$\dot{V}O_2$	= oxygen consumption (mL O_2/min)
Hgb	= hemoglobin concentration (g/mL)
CO	= cardiac output (mL/min)
1.36	= the amount of oxygen carried by hemoglobin (mL/g)

Hence, under conditions where oxygen consumption, hemoglobin concentration, and arterial oxygenation remain stable, mixed venous oxygen saturation continuously reflects changes in cardiac output.

Mixed venous oxygen saturation can be measured intermittently using a PAC by sampling blood from the distal pulmonary artery lumen. Cooximetry should be used to directly measure saturation rather than calculate it from the blood oxygen partial pressure owing to the steep hemoglobin–oxygen saturation curve at partial pressures normally seen in venous blood. Continuous measurement of mixed venous saturation can be achieved using oximetric PACs that employ "reflectance spectrophotometry": transmitting light through a fiberoptic bundle, measuring the light reflected from the blood, and calculating the amount of light absorbed by the hemoglobin. Similar to plethysmography, this technique is based on the differential absorption of various wavelengths of light by oxyhemoglobin and deoxyhemoglobin. Oximetric PACs have several technical limitations that should be recognized. They may show a drift artifact, requiring recalibration every 24 hours with a pulmonary artery blood sample, and they may be inaccurate at venous oxygen saturations below 50%. Other technical problems include thrombus formation on the catheter tip or excessive proximity to the vessel wall that may result in inaccurate readings. Most systems will warn of a reduction in light signal quality under these conditions. Last, if the catheter is wedged, arterialized blood with high oxygen saturation will be sampled rather than mixed venous blood.

Although continuously monitoring venous oximetry can reliably reflect changes in cardiac output during cardiac surgery,[87] this is not the case in situations associated with rapid changes in oxygen consumption, like graft reperfusion during liver transplantation,[88] aortic cross-clamp removal,[89] and high-dose therapy with catecholeamines.[90]

Two recent studies, performed in patients with early sepsis[91] and in patients undergoing cardiac surgery,[92] demonstrated that therapeutic interventions aimed at achieving venous oxygen saturation above 70% result in improved outcome. This contrasts with negative results of an older study performed in critically ill patients,[93] supposedly emphasizing the importance of early monitoring and therapy.

Recently developed oximetric central venous catheters allow continuous measurement of central venous oxygen saturation in the superior vena cava. Because the brain normally is the major oxygen consumer, central venous oxygen saturation (70–75%) is usually slightly lower than mixed venous oxygen saturation (75%).[86] With hypoperfusion, splanchnic blood flow suffers before cerebral blood flow, and oxygen saturation in the inferior vena cava decreases first. Under these situations, central venous saturation will be higher than mixed oxygen saturation by approximately 5–8%.[94] Despite these complicated relationships, central venous oximetry does correlate with severity of injury and blood loss in trauma patients with otherwise stable hemodynamic parameters,[95] and has been used successfully to guide therapy in early sepsis.[91] Experience with this type of catheter in the perioperative period has been very limited to date.

Right Ventricular Ejection Fraction PAC

This modification of the PAC allows measurement of right ventricular ejection fraction (RVEF) using a fast-response thermistor that measures beat-to-beat changes in pulmonary artery blood temperature.[96] Similar to the continuous cardiac output PAC, the RVEF PAC incorporates a heating filament that delivers a thermal bolus into the bloodstream. Distal temperature is measured in the pulmonary artery, and from the beat-to-beat temperature decay curve and successive diastolic temperature plateaus, RVEF is computed. Right ventricular end-diastolic volume (RVEDV) can be calculated from RVEF and stroke volume, and this derived variable has been used as an index of cardiac preload. Studies demonstrate acceptable accuracy of the thermal technique for RVEF measurement compared to radionuclide ventriculography.[97]

Right ventricular dysfunction may result from right ventricular ischemia or acute pulmonary hypertension. These events are not rare during cardiac surgery, especially after weaning from cardiopulmonary bypass (CPB) and protamine neutralization of heparin. Indeed, RVEF monitoring in patients following CPB can identify patients with significant right ventricular dysfunction.[98] In patients with septic shock, depressed RVEF better predicts prognosis than does cardiac output or cardiac filling pressures,[99] as well as indicating the need for inotropic support rather than fluid resuscitation alone.[100]

CARDIAC OUTPUT MONITORING

Cardiac output is determined by cardiac preload, afterload, contractility, and heart rate. As such, cardiac output is a global index of circulatory status. Using cardiac output and other hemodynamic measurements, a variety of useful parameters can be derived, including vascular resistances, oxygen delivery to the tissues, and oxygen consumption (Table 29–3). Measurement of cardiac output and its response to therapeutic interventions are commonly employed therapeutic protocols in critically ill patients. While thermodilution cardiac output (TDCO) using the PAC is generally considered the gold standard in both clinical medicine and research, studies comparing it with the Fick method have not shown good agreement.[101] For clinical purposes, however, the absolute cardiac output might be less important than changes in cardiac output and assessing its adequacy in terms of oxygen supply and demand.[102]

Even though TDCO measurement remains the reference method, other less invasive cardiac output measurement techniques are gaining in popularity.[103] Like the PAC, each of these newer

BOX 29–6.

The Modified Stewart-Hamilton Equation for Calculation of Cardiac Output

$$CO = \frac{V_I \times (T_B - T_I) \times K}{\int_0^\infty \Delta T_B(t)dt}$$

Where CO = cardiac output (L/min)
V_I = injected volume (mL)
T_B = blood temperature
T_I = injectate temperature
K = computation constant
$\int_0^\infty \Delta T_B(t)dt$ = integral of temperature change over time

The computation constant adjusts for characteristics of the injectate (volume, specific heat capacity, and density) and catheter (specific heat capacity, dead space).

monitoring modalities requires education and training for effective use.

The Thermodilution Technique

TDCO measurement is based on the indicator dilution principle, wherein a known amount of substance is injected into the circulation and its concentration measured over time at a downstream site. For TDCO, a thermal bolus is used as the indicator and a thermistor incorporated into the catheter 4 cm proximal to the tip measures the change in pulmonary artery blood temperature. Based on these measurements, cardiac output is calculated using the modified Stewart-Hamilton equation (Box 29–6).[104] TDCO, therefore, measures right ventricular output, which, at steady-state conditions and in the absence of intracardiac shunts, equals left ventricular output.

The computation constant adjusts for characteristics of the injectate (volume, specific heat capacity, and density) and catheter (specific heat capacity, dead space).

In clinical practice, 10 mL of room temperature saline or D_5W (0.15 mL/kg in children)[105] is injected rapidly and uniformly through the proximal port of the PAC into the SVC or right atrium. The injectate temperature should be measured at the point of injection, to obviate the influence of injectate rewarming in the syringe. The results from 2–3 consecutive measurements are usually averaged, deleting measurements varying more than 10%. The reproducibility of the TDCO technique is not high; therefore at least 15% change in cardiac output between two time points is required to be considered clinically significant.[104] When comparing TDCO results derived with different cardiac output computers, the measurement variability is even higher, in the range of 20%.[106]

Right and left ventricular loading conditions, as well as pulmonary artery blood temperature, all vary considerably during the respiratory cycle.[107] While synchronizing cardiac output measurement to end-inspiration or end-expiration might decrease measurement variation and increase reproducibility, a more truly representative mean value for cardiac output is obtained by averaging multiple measurements performed throughout the respiratory cycle.[108] Similarly, while using ice-cold rather than room-temperature injectate can increase the signal-to-noise ratio of the thermal bolus, this has not been shown to be clinically significant.[109]

Technical errors during TDCO measurement are common and may go unrecognized. A real-time display of the pulmonary artery blood temperature curve is an important aid to identify spurious measurements (Fig. 29–14).[104] Fluid boluses, given either peripherally or through the PAC introducer sheath, behave as additional positive or negative thermal sources and will affect TDCO measurement accuracy.[110] In the immediate postcardiopulmonary bypass period, both a rapid drift and an exaggerated respiratory variation of the pulmonary artery blood temperature can introduce clinically significant errors in TDCO measurement.[111,112] Right-sided valvular regurgitation, especially tricuspid regurgitation, can have a significant and unpredictable effect on the accuracy of TDCO measurement by causing recirculation of the thermal bolus.[113] Because positive pressure ventilation with high levels of PEEP can either induce or exacerbate tricuspid regurgitation,[114] this may limit the accuracy of TDCO measurement in a large group of critically ill patients. It is also important to remember that intracardiac shunts invalidate TDCO as a measure of systemic cardiac output, because under these conditions right and left ventricular outputs are not equal. Additionally, either recirculation (in left-to-right shunts) or injectate bypassing the thermistor (in right-to-left shunts) will introduce errors in the calculation of cardiac output. Lastly, in low flow states, TDCO might overestimate true cardiac output owing to excessive heat loss from slow transit of the injectate.[115]

Notwithstanding its limitations, the TDCO technique is simple to perform repeatedly and quickly, does not require blood sampling, and uses a nontoxic, nonrecirculating, and nonaccumulating indicator. For these reasons, TDCO is extensively used as the preferred method in a variety of clinical settings. However, because TDCO measurement requires pulmonary artery catheterization, it is a highly invasive monitoring technique.

Transpulmonary Thermodilution Cardiac Output Measurement

Transpulmonary thermodilution replaces the PAC with a special thermistor-tipped arterial catheter that measures blood temperature change in the systemic circulation (either femoral or axillary artery) following bolus administration of ice-cold injectate through a central venous line.[116] Unlike standard TDCO measurement, this technique requires iced injectate owing to higher thermal noise and greater thermal loss from the longer path that the thermal bolus must traverse from venous injection to systemic arterial detection. Compared to TDCO, this measurement is made over a longer time period, which eliminates the problem of respiratory variation in cardiac output.[117] Both in patients after cardiac surgery and in critically ill patients, transpulmonary thermodilution cardiac output agreed well with standard TDCO, although the transpulmonary values tended to be about 0.3–0.5 L/min higher, possibly reflecting loss of heat during transfer through the lungs.[118,119]

Lithium Dilution Cardiac Output Measurement

Another indicator dilution technique employs intravenously injected ionized lithium as the indicator. The dilution curve is built by drawing blood from a standard arterial line over a lithium-sensitive electrode.[120] Similar to transpulmonary thermodilution, respiratory influences are eliminated with this method because cardiac output is measured over several respiratory cycles. Another advantage of this technique is that the injection

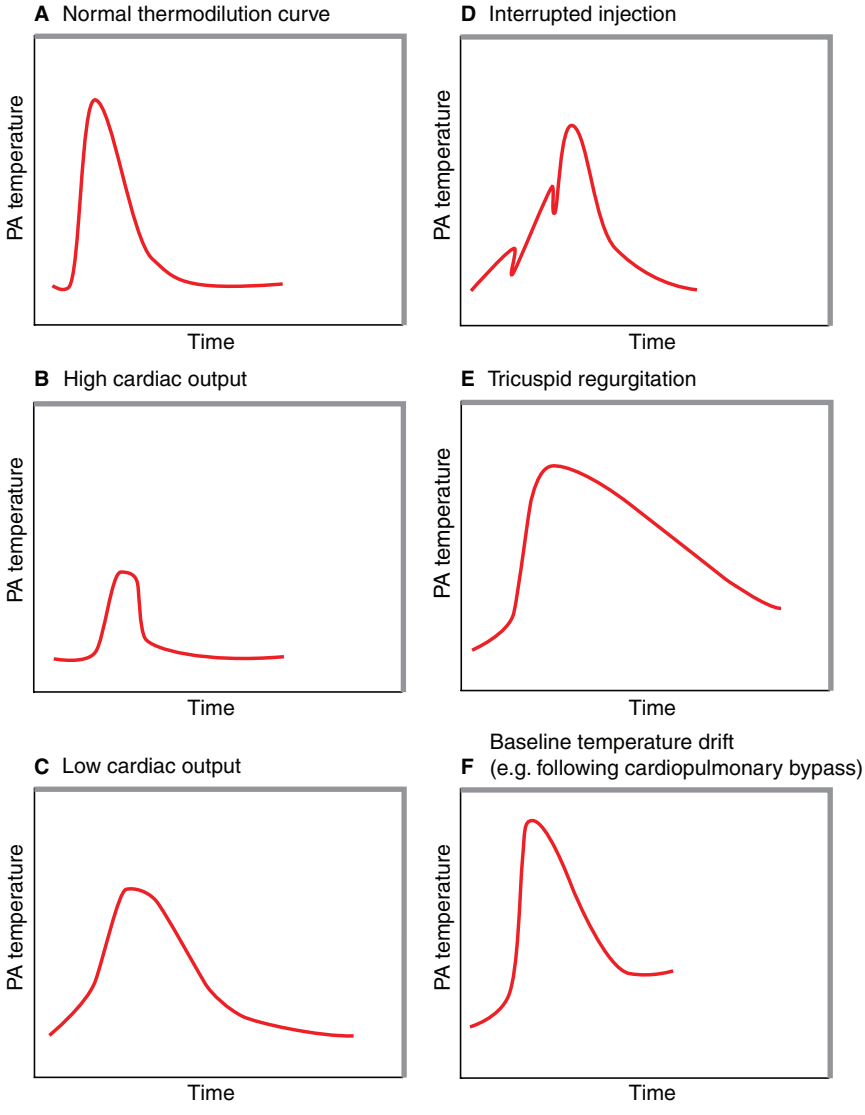

FIGURE 29–14. Thermodilution curves recorded from the thermistor at the tip of the pulmonary artery catheter after injection of cold saline. Because the injectate temperature is usually colder than body temperature, the temperature along the y axis is decreasing. The cardiac output is inversely related to the area under the curve, as demonstrated by curves *A* to C. Curve *D* shows the effect of a nonsmooth injection. In tricuspid regurgitation (curve *E*), incomplete mixing of the indicator within the right ventricle and subsequent recirculation between the right atrium and right ventricle will distort the descending limb of the thermodilution curve, usually leading to an increased area under the curve and underestimation of cardiac output. After discontinuation of cardiopulmonary bypass (curve *F*), blood temperature gradually decreases as blood flow resumes to body parts that are cold (e.g., the lungs). The drift in baseline temperature will decrease the area under the curve and lead to an overestimation of cardiac output.

of the lithium indicator can be done through a peripheral vein, removing even the requirement for central venous catheterization.[121] In small children, lithium-dilution cardiac output compares favorably with transpulmonary thermodilution cardiac output.[122] In several studies that compared lithium-dilution cardiac output with TDCO in postoperative patients in the critical care unit, a good agreement was found, although the lithium-dilution technique tends to underestimate TDCO by 0.2–0.5 L/min.[120,121]

The lithium-dilution technique has several limitations. It cannot be used in patients who are allergic to or receiving lithium. Nondepolarizing neuromuscular blocking agents can interfere with the lithium electrode, which requires a 15–30-minute wait period before measuring cardiac output.

Partial CO_2 Rebreathing

This noninvasive method employs a modification of the Fick principle to measure cardiac output in mechanically ventilated patients. In the modified Fick partial rebreathing method, CO_2 production and end-tidal CO_2 are measured at baseline and during brief periods of rebreathing, which allows calculation of pulmonary capillary blood flow.[123] The rebreathing is achieved by intermittently diverting exhaled gas through a loop connected to the ventilatory circuit. While this technique does not involve invasive vascular catheterization, it generally requires a tracheally intubated, mechanically ventilated patient. It provides a semicontinuous cardiac output measurement, as the rebreathing period can be automatically repeated. A major theoretical drawback of the technique is that it only measures blood that participates in gas exchange, ignoring shunted blood. To account for this, the CO_2 rebreathing measurements can be adjusted by estimating shunt fraction based on FiO_2 (fraction of inspired oxygen) and either arterial oxygen partial pressure or saturation.

Clinical studies of the partial rebreathing method in surgical patients have been mainly limited to patients undergoing or recovering from coronary artery bypass grafting (CABG). These small trials have generally shown acceptable bias and precision compared to TDCO,[124] although accuracy at higher cardiac output is reduced.[125] Newer software versions allow use of the partial rebreathing method in modes of ventilation that allow spontaneous breathing and might improve its performance in patients in the intensive care unit.

Because arterial PCO_2 increases 2–5 mm Hg during each rebreathing measurement period, the use of the CO_2 rebreathing technique is relatively contraindicated in neurosurgical patients who have increased intracranial pressure.

Continuous Thermodilution Cardiac Output Measurement

The continuous thermodilution PAC incorporates a thermal filament around the right ventricular portion of the catheter, approximately 20 cm from the tip. This filament is intermittently warmed to about 111.2°F (44°C), and a thermodilution curve is recorded by the thermistor at the tip of the PAC in

the pulmonary artery. Because this warm thermal signal is much smaller than the cold thermal signal of standard TDCO measurement, a stochastic system controls filament heating, switching it on and off with pseudorandom timing, thereby enhancing the signal-to-noise ratio.[126] The displayed cardiac output is updated every 30 seconds and represents the averaged measurement over the previous 3–6 minutes, eliminating respiratory variations. Current commercial systems have a "fast" mode that displays the result of each measurement cycle as it is performed, allowing earlier detection of acute changes, but at the price of accentuated random variations and errors. Because of the very small thermal signal involved, this method is more susceptible to interference by other sources of heat, such as rapid intravenous fluid infusion or the temperature changes that occur immediately following cardiopulmonary bypass.[127]

Continuous thermodilution has been quite extensively validated against standard TDCO, mainly in patients undergoing cardiac surgery.[119,128] Although this method is termed *continuous thermodilution*, current devices only provide semicontinuous measurement that is averaged over a several-minute interval, and therefore have an obligate delay of approximately 10 minutes in identifying acute hemodynamic changes.[129] However, compared to TDCO measurements performed only every several hours, continuous thermodilution might still allow earlier recognition of hemodynamic problems.[130] Thus far, no studies have demonstrated that patient outcome is improved by using these more expensive continuous cardiac output catheters.

Pulse Contour-Derived Cardiac Output

Pulse contour methods calculate stroke volume from the area under the arterial pressure waveform. The pressure waveform as measured in the large arteries is a combination of a forward pressure wave produced by the contraction of the heart and a backward pressure wave reflected from arterial branch points and arterial–arteriolar junctions. The magnitude of wave reflection is affected by changes in arterial resistance and compliance and needs to be taken into account in the calculation algorithm.[131,132] Available commercial devices are based upon different models of the circulation, and generally require intermittent (every 4–8 hours) calibration with a cardiac output reference to establish accurate monitoring in an individual patient, by accounting for differences in vascular resistance, compliance, impedance, and wave reflectance.[133] While the pulse contour method only requires an arterial line for monitoring, the needed calibration methods might require additional invasive procedures. Reliable pulse contour measurement requires a reasonably well-defined arterial pressure waveform, in part because the dicrotic notch is often used to identify end-systole. Conversely, it appears that pulse contour cardiac output monitoring remains accurate across arterial pressure-monitoring systems that have a wide range of dynamic response characteristics.[134] Other limitations of this technique include the presence of frequent dysrhythmias or severe tachycardia leading to a variable or low stroke volume, respectively. Some investigators have shown that large fluctuations in systemic vascular resistance affect vessel compliance and wave reflectance and require recalibration to maintain accuracy of the pulse contour measurements,[134] whereas other studies have shown preserved accuracy despite acute changes in systemic vascular resistance.[135]

Notwithstanding these shortcomings, the pulse contour method provides a true continuous beat-to-beat measurement of cardiac output, which has acceptable agreement with TDCO and a small mean bias of 0.1–0.3 L/min.[119,132,134] In addition, pulse contour methods can calculate the beat-to-beat variation in stroke volume induced by positive pressure ventilation, which can be used to evaluate volume status.

Esophageal Doppler

Ultrasound waves reflected from a moving target change their frequency, which allows calculation of the direction and velocity of movement using the Doppler equation (Box 29–7). For cardiac output calculation, circulating red blood cells are used as the moving target.

Current Doppler cardiac output technique employs an esophageal probe, similar in size to a standard orogastric tube, which is inserted into the lower esophagus, approximately 35–40 cm from the incisor teeth.[136] This position provides a suitable acoustic window to the descending thoracic aorta, because the aorta and esophagus are almost parallel at this anatomic location. With this method, descending thoracic aorta blood flow is calculated from the area under the velocity–time curve and the aortic cross-sectional area. The latter is either derived from a nomogram or continuously measured during the cardiac cycle with a dedicated M-mode echo transducer incorporated into the probe to measure aortic diameter. As might be expected, measuring the aortic diameter gives more accurate results than using the nomogram.[137] Because the flow in the descending aorta is only a proportion of total cardiac output, some devices report an estimate of total cardiac output that is derived by multiplying descending thoracic aortic flow by an empirical constant of 1.4.[136] In addition to providing a minimally invasive, continuous beat-to-beat estimate of cardiac output, Doppler cardiac output monitors can provide valuable information regarding cardiac preload, contractility, and afterload, all derived from the shape of the velocity–time spectral Doppler waveform (Fig. 29–15).[136] The respiratory variation in aortic blood flow velocity can also be used to evaluate preload, similar to systolic blood pressure variation.[138]

One shortcoming of the esophageal Doppler monitor is its restriction to tracheally intubated, deeply sedated patients. Relative contraindications include patients with esophageal pathology or severe coagulopathy. In addition, frequent repositioning of the Doppler probe is needed, particularly in ICU patients who are not paralyzed,

BOX 29–7.

The Doppler Equation

$$V = \frac{\Delta f \,.\, c}{2 f_o \,.\, \cos q}$$

Where V = blood velocity
Δf = change of ultrasound frequency
f_o = transmitted ultrasound frequency
θ = angle between the ultrasound beam and velocity vector
c = velocity of ultrasound in blood (1540 m/sec)

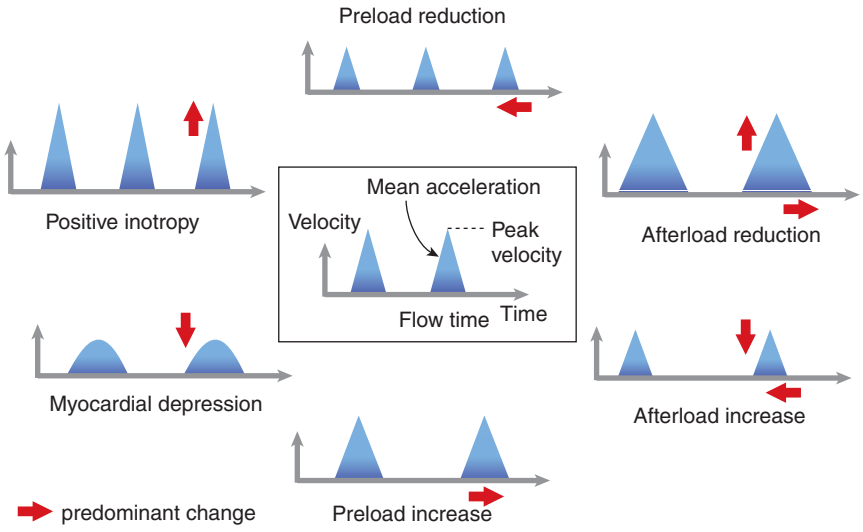

FIGURE 29–15. Spectral Doppler tracings of descending aorta blood flow recorded using esophageal Doppler cardiac output monitoring. Changes in the velocity–time waveform shape result from alterations in contractility (mainly affect peak velocity and mean acceleration), preload (mainly affect systolic flow time corrected for heart rate [FTc]), and afterload (which affect FTc, mean acceleration and peak flow velocity). (Modified with permission from Singer M. Esophageal Doppler monitoring of aortic blood flow: beat-by-beat cardiac output monitoring. Int Anesthesiol Clin 1993;31(3):99–125.)

anesthetized, and immobile. Additional concerns involve the underlying assumptions on which the technique is based: a fixed ratio between descending aortic blood flow and total cardiac output, a constant thoracic aortic cross-sectional area during systole, a uniform flow profile across the aorta, and absence of significant diastolic antegrade aortic flow. It is unsurprising that esophageal Doppler cardiac output measurements tend to underestimate total cardiac output measured by other methods, although in some trials, the bias was small enough to be clinically insignificant and generally changes in cardiac output over time were reliably tracked.[139]

Despite all the theoretical concerns regarding the accuracy of the technique, Doppler-derived cardiac output monitoring is one of the few monitoring modalities that have been tested and found to be clinically effective for resuscitating critically ill and surgical patients. Several studies, both in cardiac and noncardiac surgery, used esophageal Doppler monitoring to guide fluid therapy for maximizing cardiac output, and have shown a reduced incidence of perioperative complications and a shorter hospital length of stay.[140–144]

Gastric Tonometry

Gastric tonometry is a unique monitoring modality, which instead of directly measuring total cardiac output, measures gastric PCO_2, serving as a surrogate measure of regional blood flow and tissue perfusion. As gastric mucosal blood flow decreases, CO_2 clearance is reduced. With further reduction in blood flow and oxygen delivery, CO_2 production increases from titration of H^+ ions generated by anaerobic metabolism.[145] Increased mucosal tissue levels will be reflected by increased CO_2 levels in the gastric lumen because CO_2 diffuses freely across membranes. The gastric tonometer monitor consists of a modified gastric tube with a balloon at the tip, which is filled with either saline or air. Carbon dioxide in the balloon equilibrates over time with the gas in the gastric lumen, and samples are intermittently aspirated for measurement using either an arterial blood gases machine (for saline tonometry) or infrared spectroscopy (for air tonometry).[146] Calculating the gap between gastric PCO_2 and arterial PCO_2 controls for the effect of respiratory acidosis on gastric CO_2. Most devices can also calculate gastric pH (intracellular hydrogen ion concentration [pHi]) when the arterial bicarbonate level is measured and entered into the monitor. A pHi value below 7.32 is considered abnormal, but the PCO_2 gap (gastric PCO_2 – arterial PCO_2) is currently considered to be a better measure of tissue perfusion.[147]

During low perfusion states, splanchnic blood flow is the first to be compromised, as the body diverts blood flow to the brain, heart, and kidneys.[148] Consequently, gastric PCO_2 has been considered to be an early monitor of hypoperfusion. Studies of experimental graded hemorrhage,[149] as well as clinical studies in trauma patients,[150] support this concept. The effects of gut ischemia may be protean, as it can contribute to bacterial translocation, inflammatory response, and the development of multiorgan failure, independent of the mechanism that caused the ischemia in the first place.[151] Indeed, intraoperative gastric hypercarbia was shown to correlate with increased complications, length of stay and mortality after both cardiac and noncardiac surgery.[152,153] Lastly, several studies in ICU patients and in patients undergoing noncardiac surgery suggest that therapy guided by gastric PCO_2 can reduce morbidity and mortality.[154,155]

Gastric tonometry is contraindicated in patients with esophageal abnormalities and the measurements might be affected by feeding, gastric insufflation or suctioning and the use of H_2 blockers. Finally, not all studies have found gastric tonometry to be useful.[156,157]

PROBLEM-ORIENTED HEMODYNAMIC MONITORING

For clinicians, monitoring choices should always stem from a clinical diagnostic or therapeutic question. Consequently, it is essential to discuss and compare the various existing monitoring modalities in terms of their usefulness in answering specific clinical questions.

Assessment of Acute Ischemia

Several studies confirm the association of perioperative myocardial ischemia with postoperative cardiac complications, mainly myocardial infarction and cardiac death.[158,159] This highlights the importance of early diagnosis of ischemia in the surgical patient. The most commonly used methods to diagnose ischemia perioperatively are ECG monitoring and echocardiography. Some physicians, however, advocate the use of the PAC to monitor for ischemia.[160]

Myocardial ischemia typically impairs diastolic relaxation, which leads

to decreased ventricular compliance and increased ventricular end-diastolic pressure.[161] This leads to an increased amplitude of the a wave of the PAOP, reflecting left atrial contraction against a nonrelaxed ventricle. Less prominent increases in mean PAOP and PADP can also be seen. When systolic dysfunction occurs, reduced stroke volume, left ventricular stroke work, and arterial blood pressure may ensue. If acute mitral regurgitation occurs as a result of either ischemia-induced geometric changes in the left ventricle or papillary muscle dysfunction, a tall c-v wave can be observed in the PAOP trace.

The main limitation of using PAC monitoring for diagnosis of ischemia is that no threshold values have been set as diagnostic criteria. In a study where ischemia was defined as wall motion abnormalities seen on TEE, mean PAOP increased by 3.5 ± 4.8 mm Hg.[162] However, a threshold of 3 mm Hg had only a 25% sensitivity and a 15% positive predictive value for ischemia. Another study in patients undergoing CABG used myocardial lactate production to diagnose ischemia and found that a 5-mm Hg increase in mean PAOP had almost 100% specificity, but only 1.6% sensitivity.[163] Interestingly, ECG monitoring had only 17.5% sensitivity, demonstrating the lack of a clinically reliable and useful ischemia monitor. Given the numerous factors that can affect PAC pressure measurements, these results are unsurprising. Also, ischemia in small areas of the myocardium might not induce a large enough change in global myocardial compliance to be detected by the PAC. Lastly, the PAOP cannot be continuously monitored because of the risk of pulmonary infarction.

To summarize, PAC monitoring should probably not be employed for the sole purpose of diagnosing perioperative ischemia. However, other currently available monitors, namely ECG and TEE, are also limited in their diagnostic usefulness. Information collected from the PAC can help to corroborate the diagnosis of ischemia, evaluate its hemodynamic significance and guide therapy.

Assessment of Pulmonary Edema

Pulmonary edema results from the interplay of two different processes: increased pulmonary capillary hydrostatic pressure and increased pulmonary capillary permeability. The critical forces driving edema formation are described by the Starling equation (Box 29–8). Pulmonary edema formation is reduced as pulmonary capillary hydrostatic pressure is lowered (e.g., by diuresis), but at a certain point left ventricular preload reduction will reduce cardiac output without any further benefit in terms of pulmonary edema. In normal alveolar–capillary permeability states, a pulmonary capillary pressure of 18–20 mm Hg is considered to be the threshold beyond which alveolar flooding is promoted.[164] Accordingly, pulmonary edema in the presence of a PAOP below 18 mm Hg has traditionally been classified as noncardiogenic edema.[165]

The Usefulness of the PAOP

Clinical reliance on absolute PAOP values such as these can be, however, misleading. First, increased hydrostatic pressure might be transient, as in acute ischemic left ventricular dysfunction or acute neurogenic pulmonary edema. Following such an event, by the time the PAOP is measured, it might already be significantly lower. Second, the PAOP is used as a surrogate for pulmonary capillary pressure, assuming negligible pulmonary venous resistance. However, in conditions of increased cardiac output or increased pulmonary venous resistance (e.g., pulmonary fibrosis, late-stage ARDS, high-altitude pulmonary edema, vasopressor therapy), true pulmonary capillary pressure might be significantly higher than the measured PAOP.[166] In these patients, pulmonary vasodilators might be beneficial for treating pulmonary edema. Third, positive-pressure ventilation may increase the PAOP while simultaneously increasing the interstitial tissue pressure, resulting in no net increase in the filtration pressure gradient. Last, in patients with acute lung injury and increased capillary permeability, the Starling equation indicates that pulmonary capillary pressure might play even a greater role in edema formation because as K_d decreases, protein concentration in the interstitium increases and the oncotic pressure gradient decreases (Box 29–8). Under these conditions, pulmonary capillary pressures less than 18 mm Hg might still promote formation of pulmonary edema. Indeed, pulmonary capillary pressure is a major determinant of fluid flux across the alveolar capillary membrane regardless of the degree of capillary permeability. The "safe" level of PAOP in patients with increased alveolar capillary permeability remains elusive.[167] However, a large randomized study in patients with acute lung injury has found some clinical advantage to a restrictive fluid therapy (aiming at PAOP < 8 mm Hg or CVP < 4 mm Hg) compared to liberal fluid management (PAOP 14–18 mm Hg or CVP 10–14 mm Hg).[168]

BOX 29–8.

Starling's Equation for Fluid Flux across Membranes

$$\text{Fluid flux} = K_{fc} \times (P_{capillary} - P_{interstitium}) - K_d \times (\pi_{capillary} - \pi_{interstitium})$$

Where: P = hydrostatic pressure
π = oncotic pressure
K_{fc} = capillary filtration coefficient
K_d = reflection coefficient

Measuring Extravascular Lung Water

A different approach to assess pulmonary edema involves quantification of extravascular lung water (EVLW), which can be measured using transpulmonary thermodilution.[169] Studies conducted in critically ill patients demonstrate that EVLW has prognostic value.[170] Also, trials in patients with acute lung injury found that compared to care guided by PAOP monitoring, therapy guided by EVLW monitoring results both in a reduction in the amount of administered fluid and in an improvement in clinically significant end points such as ventilator days, ICU length of stay, and mortality.[167] A more recent study suggests that monitoring EVLW can be used to guide fluid challenges in septic patients at risk for pulmonary edema.[171] Only little data, however, exist regarding EVLW monitoring during the perioperative period, and its usefulness in the operating room remains uncertain.

Assessment of Ventricular Contractility

Contractility, the force of muscle contraction, can be defined as the velocity of myocardial fiber shortening during systole. Together, contractility, pre-

load, afterload, and heart rate are the four determinants of cardiac output.

Direct assessment of intrinsic ventricular contractility, independent of loading conditions, is possible under laboratory or research conditions, but is not easily available clinically. Instead, several indices of integrative "pump" function can be used, attempting to take into consideration the effects of loading conditions. Under a range of loading conditions, these indices can still give reasonably accurate estimate of ventricular contractility.[172]

Cardiac Function Curve

A classical study on the use of the PAC in the setting of myocardial infarction defined cardiogenic shock as the combination of low cardiac index (< 2.2. L/min/m^2) and high PAOP (>18 mm Hg).[173] As a rough guide, this combination is commonly used clinically to decide upon the need for inotropic support, for example, following weaning from cardiopulmonary bypass. However, significant ventricular dysfunction may be present in a variety of clinical conditions when measured cardiac output is in the normal range, yet inadequate for the bodily needs. Also, cardiac output might be preserved despite low stroke volume because of increased heart rate, or stroke volume might be preserved despite reduced contractility because of reduced afterload. Similarly, PAOP can be abnormally increased from a variety of other causes besides systolic left ventricular dysfunction. Rather than focusing clinically on absolute values for PAOP or stroke volume, "fluid responsiveness" might serve as a better indicator of ventricular function. When a fluid bolus does not lead to a significant increase in stroke volume, while at the same time the PAOP does rise significantly, this can be construed as a sign of a failing left ventricle that is operating on the "flat portion" of its Starling curve (Fig. 29–16).[174] Obviously, a flat portion also exists in a normal ventricle, however at a relatively very high stroke volume.

Ventricular Stroke Work

Another measure of pump function is ventricular stroke work, which is the energy consumed by the ventricle while transferring the stroke volume from the atrium to the pulmonary artery or aorta.[175] The higher the pressure differential between the filling pressure and the mean arterial blood pressure (pulmonary or systemic), the higher is the ventricular work. A failing ventricle, as a result of a contractility–afterload mismatch, will display a smaller stroke work index.[176]

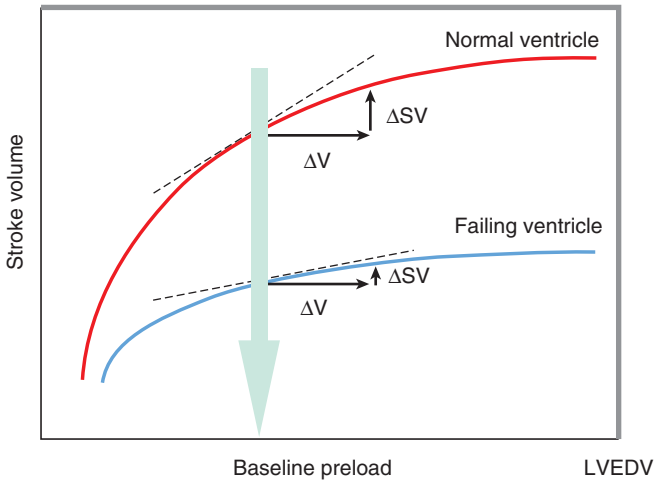

FIGURE 29–16. Lack of fluid responsiveness as a marker of ventricular dysfunction. Starting from the same left ventricular end-diastolic volume (LVEDV, *yellow arrow*), a similar preload augmentation (ΔV) leads to a much smaller increase in stroke volume (ΔSV) in the failing ventricle, operating on a much flatter Starling curve (the slope is marked by the *dotted line*). Therefore, assessment of baseline preload, whether in pressure terms (e.g., pulmonary artery occlusion pressure) or in volume terms (LVEDV) cannot predict the cardiac output response to preload augmentation. (Modified with permission of Springer Science and Business Media from Michard F, Reuter DA. Assessing cardiac preload or fluid responsiveness? It depends on the question we want to answer. Intensive Care Med 2003;29(8):1396.)

Echocardiography

Echocardiography has become a widely used monitor to evaluate ventricular function.[177] The most widely used index for assessing left ventricular function is the ejection fraction, usually estimated from the observed change in ventricular two-dimensional cross-sectional area, although techniques do exist for more accurate calculation. Regardless of calculation technique, it, again, should be emphasized that the ejection fraction is both preload and afterload dependent. Because of the nongeometric shape of the right ventricle, calculation of right ventricular ejection fraction is usually abandoned in favor of a more qualitative evaluation of contractility, based mainly on inward movement of the ventricular wall during systole.

The rate of pressure rise during systole, dP/dt, is classically measured using intraventricular pressure manometers. In patients with mitral regurgitation, a similar parameter can be measured using echocardiography from the mitral regurgitation jet Doppler envelope. As this index is measured during the isovolumic contraction phase, it is afterload independent, although it is still preload dependent.

Newer Monitors

Newer monitoring modalities offer new indices of contractility. From the esophageal Doppler time–velocity waveform, the peak flow velocity as well as the slope of the velocity–time envelope (i.e., mean acceleration) can be calculated (Fig. 29–15).[178] These are analogous to the dP/dt index mentioned previously.

The transpulmonary thermodilution supplies the cardiac function index, defined as the cardiac index divided by the global end-diastolic volume index, which is a preload index. The resulting quotient is supposed to be a preload-independent index of contractility.[179]

Right ventricular ejection fraction can be directly measured using the RVEF PAC. In the presence of right ventricular dysfunction, as a result of either ischemia[98] or sepsis,[100] fluid loading may cause further hemodynamic deterioration by increasing right ventricular end-diastolic volume, inducing leftward shift of the interventricular septum, thereby decreasing left ventricular compliance and preload.[180] This might be diagnosed by

RVEF PAC monitoring, prompting inotropic support of the right ventricle.

Assessment of Volume Status

Fluid management is a major responsibility of the anesthesiologist or critical care physician in the perioperative period. Goals for fluid administration are maintenance of effective intravascular volume and optimization of tissue perfusion and cellular oxygenation. Inadequate intravascular volume resuscitation initially impairs nonvital organ perfusion, but eventually leads to a state of shock with inadequate oxygen delivery to all tissues. Volume expansion is expected to increase stroke volume and cardiac output. However, excessive volume administration can result in pulmonary and intestinal edema, exacerbation of cor pulmonale, hemodilution and functional anemia, hyperchloremic acidosis from administration of normal saline, and coagulation abnormalities, all of which may increase morbidity and mortality.[181]

The inflammatory response to surgical trauma, ischemia/reperfusion injury or sepsis increases vascular permeability, greatly increasing fluid losses from the vascular space.[182] Even without additional pathology, general anesthesia alone has been shown to increase interstitial fluid three-fold compared to conscious controls.[183] Hence, perioperative and critically ill patients are often relatively hypovolemic. Unfortunately, not always is volume expansion able to improve organ perfusion; several investigators have shown that up to one half of critically ill patients fail to respond to fluid administration.[184,185] The challenge for resuscitation of critically ill patients is to identify individuals who are hypovolemic and who will respond favorably to volume expansion.

Clinical Evaluation

Most commonly, and in the absence of invasive monitors, standard clinical signs and symptoms are used to guide fluid administration in the operating room. Formulae for calculating volume deficits are based on the length of fasting period, estimates of insensible losses during the operation, blood loss, and third-spacing of fluid. Tachycardia and hypotension are most considered to indicate hypovolemia. Assessing peripheral perfusion including capillary refill and tactile warmth of the extremities can add information. Several laboratory findings may suggest hypovolemia, including inappropriately high hematocrit, hypernatremia, high levels of blood urea nitrogen (BUN), increased ratio of BUN to creatinine, or elevated base deficit (i.e., metabolic acidosis). In patients with relatively normal renal function, urine output and composition (osmolarity, fractional excretion of sodium) can provide some information concerning intravascular volume. However, many of these signs actually evaluate perfusion, which may be inadequate despite normal or even increased volume status, for example, in face of severe vasoconstriction or cardiogenic shock. Additionally, many other processes common in the perioperative period can affect these signs, including hypothermia, anxiety, increased antidiuretic hormone or hyperchloremic metabolic acidosis. Several studies show the lack of sensitivity or specificity of the clinical examination and laboratory indices to assess volume status.[186,187]

One of the best methods to determine the adequacy of volume resuscitation is to administer a fluid challenge and assess the desired physiologic response, such as improved blood pressure, increased urine output, or clearance of a metabolic acidosis: 250–500 mL of crystalloid or colloid solution are given over 30 minutes and the response is monitored. Even simpler, passive leg raising can induce transient autotransfusion and increase blood pressure in patients who are volume responsive.[188] In contrast to respiratory variation-based dynamic indices, the passive leg-raising test is also useful in patients with dysrhythmia or spontaneous breathing.[189] In severely hypovolemic patients, however, the amount of blood in the legs might be too low to significantly change hemodynamics. In patients who have failed to respond to these simple measures, or in whom a fluid challenge carries greater risk, more sophisticated assessment requires additional hemodynamic monitoring.

The Usefulness of Filling Pressures

Static pressure measurements, mainly CVP and PAOP, traditionally have been used as preload indicators to guide fluid administration. However, the relationships between intravascular blood volume, end-diastolic ventricular volumes, and cardiac filling pressures are complex and affected by many factors. Both right and left ventricular compliances are frequently abnormal in critically ill patients. Nonlinear ventricular diastolic compliance (Fig. 29–11) also confounds the direct pressure–volume relationship, as do myriad other factors, including changes in pulmonary vascular resistance, decreased chest wall or abdominal compliance, increased pericardial pressure, increased intrathoracic pressure from mechanical ventilation or auto-PEEP, and the use of vasoactive drugs. In fact, even in healthy volunteers no predictable relationship between CVP or PAOP and volumetric measures of preload or cardiac performance can be demonstrated.[190] In a critical review of 12 studies, marked overlap in CVP or PAOP measurements did not allow identification of patients who would respond to volume expansion.[184] Because PAOP, and not end-diastolic ventricular volume, represents the hydrostatic force for development of edema in the lung, monitoring PAOP during fluid resuscitation can still be important, especially in patients who are at risk for development of pulmonary edema.[171]

One approach to trying to cope with the lack of predictive ability of baseline filling pressures is to administer a fluid challenge and evaluate the change in pressures. An increase of no more than 3 mm Hg in the CVP or in the PAOP indicates a state of hypovolemia, and additional fluid challenges are given until a higher increase in pressures is observed. In a goal-directed therapy study in patients with femoral neck fractures, volume was infused to achieve sustained increases of CVP of ≥3 mm Hg in order to maintain blood pressure within 20% of baseline. This was associated with improvements in postoperative outcomes, demonstrating the possible usefulness of such an approach.[141] Another type of dynamic test involves the decrease in CVP that accompanies spontaneous, negative pressure inspiration: a decrease of more than 1 mm Hg was found to predict fluid responsiveness.[191]

Volumetric Indices

Another approach for assessing preload involves volumetric measurements. Fast-response RV ejection fraction PAC are able to calculate RVEDV. As a direct measure of right ventricular preload, it has been found to be a

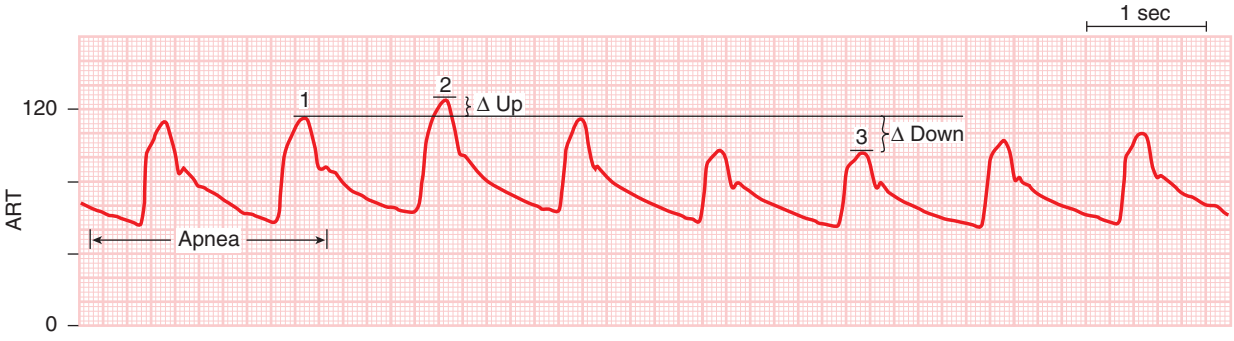

FIGURE 29–17. Systolic pressure variation visible on an arterial pressure trace. Note that Δup and Δdown are measured from an apneic baseline. In this example, Δup is approximately 9 mm Hg, whereas Δdown is approximately 18 mm Hg, for a total SPV of 27 mm Hg.

better index of fluid responsiveness than PAOP,[192,193] though some studies found the opposite.[194] RVEDV monitoring might be especially useful in patients requiring mechanical ventilation, where elevated intrathoracic pressures confound interpretation of cardiac filling pressures.[195]

The transpulmonary thermodilution technique allows measurement of a parameter called global end-diastolic volume (GEDV) which represents the volume of blood inside both right and left heart chambers at end-diastole. From the GEDV, another parameter, intrathoracic blood volume, can be calculated. Several small studies in septic patients,[196] and during cardiac[197] or lung transplant surgery,[198] have found these indices better indicators of volume status compared to pressure measurements.

Echocardiography can be used to measure and derive a number of cardiac volumes and parameters that can help to evaluate preload. Not surprisingly, ventricular end-diastolic area has been found a better index of preload compared to filling pressures.[199] In healthy volunteers, echocardiographic volume indices also correlated with cardiac output response to volume expansion;[190] interestingly, however, studies in patients could not generally identify threshold values able to predict response to volume challenge.[184,185]

In contrast, the degree of superior or inferior vena cava collapsibility during inspiration in ventilated septic patients was found predictive of the increase in cardiac output in response to volume infusion.[200,201] Unfortunately, the time, training, cost, and equipment involved in use of bedside echocardiography in the critical care setting often limit its use and effectiveness.

Respiratory Variation-Based Dynamic Indices

As an alternative to static preload measurements, a variety of dynamic measures have been proposed to identify hypovolemic patients who will respond to volume expansion by increase in cardiac output. These are based on the cyclic changes in left ventricular preload induced by changes in intrathoracic pressure during positive-pressure mechanical ventilation. In fluid-responsive (i.e., preload-dependent) patients, cyclic changes in stroke volume and blood pressure will ensue.[202]

Systolic Pressure Variation Increases in systolic pressure variation (SPV; Fig. 29–17) beyond 8–10 mm Hg have been found to reflect the degree of blood loss and consequent hypovolemia, as well as to correlate with response to volume infusion.[12,203] SPV has two distinct components. An early systolic increase of 2–4 mm Hg immediately follows the end-expiratory pressure baseline and is caused by blood squeezing out of the lungs during inspiration,[204] and from decreased left ventricular afterload.[205] The second component is a pressure decrease of approximately 5–6 mm Hg which reflects a decrease in venous return to the heart caused by positive pressure.[206] The second pressure change is termed the delta-down component (Δdown), and may be a more sensitive indicator of volume responsiveness compared to total SPV.[185]

Pulse Pressure Variation Pulse pressure variation (PPV) is defined as the difference between the maximal and the minimal pulse pressure values during a single mechanical breath, divided by the mean of these two values (Fig. 29–18). Some clinical data suggest that PPV might be a more accurate predictor of fluid responsiveness compared to SPV,[207,208] although both are affected by both Δup and Δdown, and therefore might be misleading in conditions of hypervolemia or cardiac failure.

Stroke Volume Variation Stroke volume variation (SVV) is defined analogously to PPV, and can be calculated from arterial pulse contour cardiac output monitors. A SVV greater than 10% is a good predictor of fluid responsiveness in patients undergoing neurosurgical or cardiac procedures.[209,210] A major theoretical concern regarding the use of SVV is whether the changes in arterial tone and impedance induced by positive-pressure ventilation affect its accuracy.[211]

Respiratory variation in peak blood flow velocity in the descending aorta can be measured using esophageal Doppler. A variation in excess of 18% identified those patients who would benefit from volume infusion.[138]

Limitations of Dynamic Indices Dynamic preload indices are simple to use, minimally invasive, and accurately reflect the cardiac output response to fluid loading. However, they require the patient to be intubated and ventilated using a controlled mode of ventilation to ensure uniform tidal volume, generally larger than 8 mL/kg.[13,212] The arterial pressure waveform should be inspected and the signal optimized if needed.[213] Dynamic indices cannot be used in patients with significant dysrhythmias, notably atrial fibrillation, because nonuniform diastolic filling time will induce its own beat-to-beat stroke volume variation.

The respiratory systolic variation test has been suggested to eliminate the effects of Δup and tidal volume variation on SPV (Fig. 29–19).[214] A

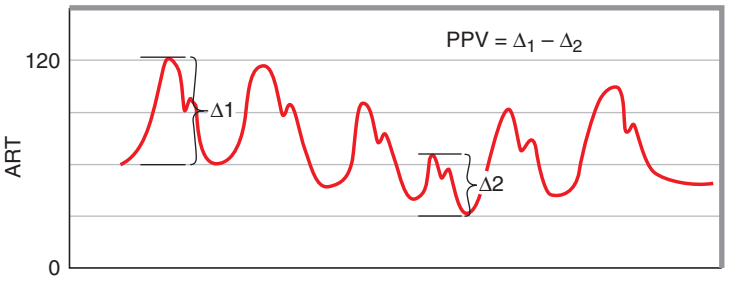

FIGURE 29–18. In this example of pulse pressure variation, maximal pulse pressure is approximately 62 mm Hg, while minimal pulse pressure is near 36 mm Hg. The resulting PPV of 26 mm Hg is larger than 12% of the mean of the two values (49 mm Hg), and as such indicates fluid responsiveness or hypovolemia.

slope greater than 0.5 mm Hg/cm H_2O was found to have the best predictive power for fluid responsiveness.[214] The usefulness of this test in patients with abnormal lung compliance has not been addressed yet.

Summary

A conclusion that may be drawn from the review of these techniques and clinical trials is the superiority of dynamic measures over static measures in identifying patients who would benefit from volume expansion.

There are, however, two important issues to consider. First is the idea that preload, as measured by either volume or pressure variables, is fundamentally different from fluid responsiveness. Hypovolemic patients might fail to respond to volume expansion for a host of reasons like right or left ventricular failure (Fig. 29–16) or increased venous or arterial compliance. Also, fluid administration causes hemodilution and thereby decreases left ventricular afterload. This can increase stroke volume as a consequence of a decreased left ventricular end-systolic volume with no or minimal change in end diastolic volume.[215]

A second important issue is defining the clinical goal. Simply being fluid responsive does not necessarily indicate that fluid should be administered. Actually, fluid responsiveness is a characteristic of normal cardiovascular physiology.[190] The primary question the physician should ask himself is whether hypoperfusion exists, and only if the answer to this question is positive, should evaluation of preload responsiveness be performed and acted upon.[213]

Assessment of Perfusion

Ensuring adequate perfusion of major body organs is the main hemodynamic goal of the anesthesiologist in the perioperative period. Tissue hypoperfusion is the defining characteristic of circulatory shock, but can occur long before other signs and symptoms become apparent. Unfortunately, most currently employed monitoring modalities provide only indirect measures of organ perfusion. Regional perfusion variability adds to the monitoring challenge since some organs, like the splanchnic bed, might be hypoperfused while more vital organs, like the brain and heart, remain adequately perfused.[216]

Clinical Evaluation

A variety of traditional clinical indices have been used to judge the adequacy of tissue perfusion. These clinical signs and symptoms include the level of consciousness, urine output, heart rate, capillary refill, and skin temperature and color. All, however, may be unreliable in the perioperative period owing to the many confounding effects encountered during this time; as a result, hemodynamic monitors were developed to fill this patient care need.

Pressure-Based Indices

The simplest of these monitors are pressure-based measurements, mainly systemic blood pressure and cardiac-filling pressures. Perfusion of major body organs is pressure independent over a wide range of pressures, because of autoregulation. In addition, compensatory mechanisms help to defend blood pressure, so that in many circumstances, arterial hypotension is a late sign of hypovolemia or shock.[149] Studies in different patient populations demonstrate the coexistent of normal vital signs despite occult shock as demonstrated by continuing anaerobic metabolism.[217]

Flow-Based Indices

The next level of hemodynamic monitoring involves flow-based measurements, namely cardiac output, stroke volume, and oxygen delivery. Several studies suggest that these indices do

FIGURE 29–19. Positive Randomized Controlled Studies of Goal-Directed Therapy in the Perioperative Period

Study	Patient Population	Number (n)	Monitoring Modality	Therapeutic Goals	Interventions	Mortality (Control vs. Treatment Group)[a]
Bishop, 1995[241]	Severe trauma	115	PAC	CI >4.5 L/min/m² DO_2 >600 mL/min/m² VO_2 >170 mL/min/m²	Fluids, blood, dobutamine	37% vs. 18%
Boyd, 1993[242]	High-risk noncardiac surgery	107	PAC	DO_2 >600 mL/min/m²	Dopexamine	22.7% vs. 5.7%
Wilson, 1999[243]	Major elective noncardiac surgery	138	PAC	PAOP >12 mm Hg Hb >11 g/dL SaO_2 > 94% DO_2 >600 mL/min/m²	Fluid, blood, oxygen, adrenaline/dopexamine	17% vs. 3%
Lobo, 2000[244]	Major elective surgery	37	PAC	DO_2 >600 mL/min/m²	Dobutamine	50% vs. 15.7%
Berlauk, 1991[245]	Peripheral vascular surgery	89	PAC	CI >2.8 L/min/m² SVR <1100 dyne*s/cm⁵ PAOP 8–15 mm Hg	Fluid, afterload reduction, positive inotropes	9.5% vs, 1.5% (p borderline significant at 0.08)
Polonen, 2000[92]	Cardiac surgery	403	PAC	SvO_2 >70% Lactate <2 mmol/L	Fluids, dobutamine	3% vs. 1% (p nonsignificant, but significantly shorter hospital stay and fewer complications)
Pearse, 2005[246]	High-risk noncardiac surgery	122	Lithium dilution	Maximize stroke volume DO_2 >600 mL/min/m²	Fluids, dopexamine	9.7% vs. 10% (p nonsignificant, but significantly shorter hospital stay and fewer complications)
Mythen, 1995[142]	Cardiac surgery	60	Esophageal Doppler	Maximize stroke volume	Fluids	Not reported, but significantly shorter hospital stay and fewer complications
Sinclair, 1997[143]	Femur neck fracture	40	Esophageal Doppler	Maximize stroke volume	Fluids	10% vs. 5% (p nonsignificant, but shorter hospital stay)
Gan, 2002[140]	Noncardiac surgery with estimated blood loss >500 mL	100	Esophageal Doppler	Maximize stroke olume	Fluids	Not reported, but shorter hospital stay

CI, cardiac index; DO_2, oxygen delivery; Hb, hemoglobin concentration; PAC, pulmonary artery catheter; PAOP, pulmonary artery occlusive pressure; SaO_2, arterial oxygen saturation; SvO_2, mixed venous oxygen saturation; SVR, systemic vascular restistance; VO_2, oxygen consumption.
[a]For all results, p is significant at 0.05 levels unless stated otherwise.

have a prognostic value,[218] and many studies of goal-directed therapy demonstrate their clinical usefulness (Table 29–5). However, these studies also demonstrate that the "optimal" level of cardiac output or oxygen delivery in the perioperative period is not necessarily the "normal" level. With the changes in oxygen requirements resulting from anesthesia on the one hand, or the systemic inflammatory response on the other hand, the same oxygen delivery might be too high, too low, or just right. The development of "oxygen debt" after major surgery is associated with both survival and the incidence of complications.[219]

Metabolic Indices

Considering the shortcomings of flow-based monitoring methods, metabolic indices might supply the required information about the adequacy of oxygen delivery or cardiac output. These metabolic markers include either global measures such as base excess, blood lactate level, and venous oxygen saturation, or regional perfusion measures, such as cerebral oximetry and gastric tonometry.

Lactic Acidosis Elevated blood lactate and metabolic acidosis indicate anaerobic metabolism, presumably related to hypoperfusion leading to tissue ischemia. Indeed, various studies

confirm the prognostic significance of serial lactate and base deficit measurements,[220,221] and the potential of using lactate level as a guide for directing therapy.[92,222] Several pitfalls need to be acknowledged. Lactate levels may increase as a consequence of isolated organ damage such as limb ischemia or mesenteric thrombosis, where surgical intervention, rather than medical therapy to increase oxygen delivery, is warranted. Also, because there are various other etiologies for both hyperlactatemia and metabolic acidosis, lactic acidosis is probably a more specific index for hypoperfusion than either measure alone.[223]

Venous Oximetry Because increased oxygen extraction can initially compensate for reduced oxygen delivery, anaerobic metabolism usually does not occur before venous oxygen saturation has decreased to 30–40%.[224] Therefore, monitoring venous oximetry, in either mixed pulmonary or central venous blood, might allow early detection of hypoperfusion before tissue ischemia develops. Reduced venous oxygen saturation better predicts adverse outcome after cardiac surgery than does cardiac output or oxygen delivery,[225] while treating low cardiac output in patients with a normal venous oxygen saturation might be counterproductive.[226] Indeed, venous oxygen saturation may be one of the more important monitors for judging the adequacy of the hemodynamic status and determining whether the measured pressure- and flow-based indices are acceptable, in the context of the individual patient's oxygen requirements.[227]

Regional versus Global Perfusion A major drawback of lactate, base deficit, and venous oxygen saturation is their global nature. Lactate production and increased oxygen extraction induced by ischemia in an isolated organ might be diluted and therefore masked when whole-body lactate or mixed venous oximetry are measured. Consequently, a place exists for also monitoring regional perfusion, the best example being gastric tonometry. Other regional monitors include jugular bulb oximetry, sublingual capnography, near-infrared light spectroscopy, tissue oxygen electrodes, and cytoscan imaging.[228,229]

To summarize, a systematic approach to hemodynamic monitoring that combines relatively easily measured metabolic indices with classical hemodynamic measurements might allow early detection of tissue hypoperfusion and undertaking of appropriate corrective measures (Fig. 29–20).

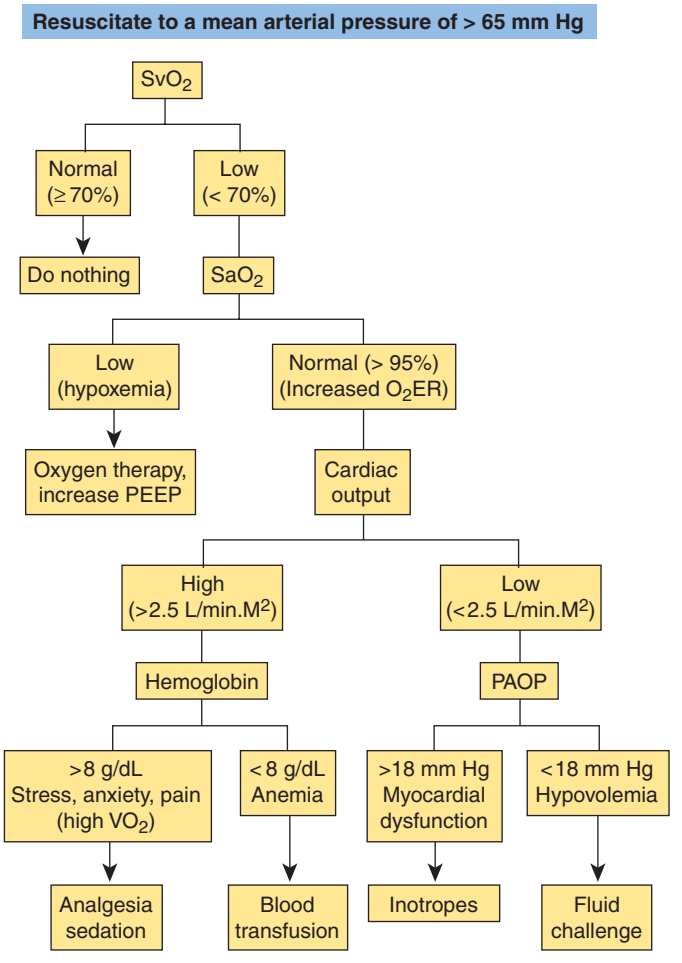

FIGURE 29–20. A systematic approach to assessment and treatment of hypoperfusion. Perfusion assessment by measuring mixed venous oxygen saturation (SvO_2) starts after restoration of perfusion pressure (which can be done using fluids and vasopressors). O_2ER, oxygen extraction ratio; SaO_2, arterial oxygen saturation; VO_2, systemic oxygen consumption. (Reproduced with permission from Pinsky MR, Vincent JL. Let us use the pulmonary artery catheter correctly and only when we need it. Crit Care Med 2005;33(5):1119–1122.)

Preemptive Goal-Directed Therapy

Monitoring alone cannot influence patient outcome unless it is used to guide effective therapeutic interventions. Usually, these interventions are ill-defined and highly variable between practitioners, contributing to the difficulty in assessing the usefulness of various monitoring modalities, most notably the PAC.[3,32] The "goal-directed therapy" approach, in contrast, defines a priori a set of interventions aimed at achieving specific values for monitored physiologic parameters. In an early retrospective trial in high-risk surgical patients, mostly trauma victims, survivors were found to achieve higher levels of cardiac output (>4.5 L/min/m^2), oxygen delivery (>600 mL/min/m^2), and oxygen consumption (>170 mL/min/m^2) compared to nonsurvivors.[218] This was followed by a successful prospective interventional trial aimed at treating patients to achieve these "supranormal" values preoperatively through use of fluids, blood transfusion, and vasoactive drugs.[230] Many similar trials followed, and most of them confirmed a significantly decreased morbidity and mortality in the goal-directed treatment group (Table 29–5). However, a recent, large, multicenter, randomized study tested early goal-directed therapy in surgical patients and did not find any benefit.[60] This study, however, included relatively low-risk patients (mortality in the control group was

only 7.7%), the goals chosen differed from those in previous positive studies, most patients did not achieve the therapeutic goals prior to surgery, and the interventions were not rigorously defined.

In contrast to perioperative management of surgical patients or treatment of patients in early stages of sepsis,[91] goal-directed therapy has been less successful when applied to critically ill medical and surgical patients who have an established systemic inflammatory response syndrome, sepsis, or multiorgan failure.[93,231] The main early pathophysiologic disturbance in trauma and perioperative patients is occult hypovolemia, which can be ameliorated with fluids alone.[232] In contrast, the pathophysiologic disturbances in critically ill septic patients with multiorgan failure may be much more profound and involve abnormalities at the level of the microcirculation and mitochondria. These critically ill patients might not be able to increase oxygen use regardless of oxygen delivery.[233,234]

Goal-directed therapy in the perioperative period is still an area of ongoing research and considerable uncertainty. Several retrospective studies suggest that the large fluid volumes required for increasing cardiac index and oxygen delivery to supranormal values might result in congestive heart failure[72] and increased abdominal pressure leading to gastric hypoperfusion and acute renal failure.[235] Positive inotropic agents might increase systemic oxygen consumption owing to their thermogenic effect, hence paradoxically decreasing venous oxygen saturation despite increased cardiac output.[90] Increasing myocardial oxygen consumption might also trigger acute ischemic events.[72]

For perioperative goal-directed therapy to have a beneficial effect on mortality, treated patients need to be at a very high-risk group (at least 15–20% predicted mortality, according to a recent meta-analysis[236]). Older patients (above 65 years) with coexisting cardiorespiratory diseases may be one such group.[237] A low anaerobic threshold on preoperative cardiopulmonary exercise testing or a clinical assessment of the ability to climb 2 flights of stairs might also help identify patients who will not be able to increase oxygen delivery perioperatively without aggressive therapeutic interventions.[238,239] Patients with lower mortality risk might still benefit from goal-directed therapy by having a reduced complication rate or shortened hospital length of stay.

To provide any benefit, hemodynamic goals must be achieved early, either pre- or intraoperatively. In most patients, optimization of volume status is all that is required. Patients with known cardiac dysfunction may require inotropic therapy in addition to fluid resuscitation, guided either by cardiac output or venous oxygen saturation. Clinical attention to development of fluid overload and increased oxygen consumption may reduce potential complications of goal directed therapy. When performed properly and applied to appropriate patient cohorts, perioperative hemodynamic optimization may not only improve outcome, but also may prove to be a cost-effective intervention as the reduction in complications compensates for the increased monitoring costs and ICU use.[240]

Discrepant Clinical Data and Troubleshooting Monitoring Problems

One of the more important roles played by the anesthesiologist in the care of the critically ill patient is to determine that the monitored data are accurate and, based on these data and the rest of the patient's history, physical findings, and testing results, to arrive at a clinical diagnosis. A common challenge arises when monitoring results provide discrepant data or are otherwise inconsistent with the clinical condition of the patient and the working clinical diagnosis. In these circumstances, a methodical approach is helpful, one that is based upon a good understanding of monitoring equipment and patient physiology. Box 29–9 summarizes the recommended steps in the evaluation of discrepant data. These steps can be performed rapidly and some even simultaneously. Although less common, there are certainly clinical situations wherein apparently normal monitored values are in fact spurious. Recognition of these problems begins with knowledge of the clinical condition of the patient and the clinical context in which the monitored value is observed.

BOX 29–9.

Standard Steps for Troubleshooting Unexpected Monitored Values

- Recognize clinical urgency
- Address technical considerations
- Confirm digital values with accompanying waveforms
- Confirm measurements using another technique
- Cross validate measurements with another monitored variable
- Consider physiologic and pathophysiologic explanations
- Consider iatrogenic causes

Ravi Bissessar, MD, and
Solomon Aronson, MD

Intraoperative echocardiography now is considered an essential part of modern cardiac surgery. It can be performed using transesophageal, epicardial, epiaortic, and transthoracic approaches. Its clinical applications are numerous, including assessment of left ventricular (LV) and right ventricular (RV) function, assessment of preload, measurement of cardiac output, detection of myocardial ischemia, assessment of valvular function, detection and assessment of various congenital heart diseases, and evaluation of aortic atheromatous disease prior to cannulation. Intraoperative echocardiography serves as an important diagnostic tool, as well as a monitor, for cardiac surgical patients.

INDICATIONS FOR PERIOPERATIVE TRANSESOPHAGEAL ECHOCARDIOGRAPHY

Since 1996, when evidence-based practice guidelines for perioperative transesophageal echocardiography (TEE) initially were published (see Fig. 30–1), support for the superiority of intraoperative TEE over other techniques (e.g., electrocardiograms or pulmonary artery catheters) for specific diagnostic information has steadily increased. The indications for a TEE examination should be based on each patient's condition rather than a specific surgical procedure. In addition, the dynamics of each case should dictate when a TEE examination may reduce critical diagnostic work or distract from it. Table 30–1 provides some published recommendations.

LIMITATIONS TO AND CONTRAINDICATIONS FOR TEE

One of the most important limitations to performing an intraoperative TEE examination is the expertise or attention of the physician. Substantial patient harm can result from inappropriate fixation of the anesthesiologist's attention on the TEE examination rather than on the patient. Although performing a useful TEE examination while simultaneously caring for the patient often is possible, a more appropriate practice would be having a colleague perform the TEE examination while the primary anesthesiologist focuses on caring for the patient (especially if a more comprehensive TEE examination is desired or the patient is unstable).

There are few absolute contraindications to performing a TEE examination in an anesthetized patient. A history of dysphagia, esophageal varices, severe gastroesophageal reflux disease, odynophagia, unstable cervical spine injuries, prior mediastinal radiation, and upper airway pathology should be sought prior to probe insertion and are considered relative contraindications. Although TEE has been proven safe, it should be undertaken only by experienced operators in cases with a clear indication for TEE use. In anesthetized patients, the probe can be inserted blindly or with laryngoscopic visualization. It is helpful to have an assistant support the probe during insertion. A bite guard should always be used to protect the patient as well as the probe. Proper insertion of the probe requires skill and judgment. Major complications of TEE are rare (0.2–0.6% of insertion attempts in prospective studies),[1–3] and most examples are based on published case reports. The transducer should never be forced through resistance upon entry into or during passage through the esophagus. Insertion and manipulation of the TEE probe can result in oral, esophageal, or pharyngeal trauma and arrhythmias. Another important danger of performing a TEE examination is misrepresenting a finding as abnormal when it is actually a normal variant (Table 30–2). Understanding the normal variants will enable better diagnostic accuracy when detecting abnormal structures. Significant clinical experience is required for the echocardiographer to be able to confidently make this distinction.

TERMINOLOGY

Table 30–3 lists the terminology used to describe probe manipulation, with the patient lying supine, with reference to the heart.

BASIC PRINCIPLES OF ECHOCARDIOGRAPHY

Two-dimensional (2D) echocardiography displays the intensity of reflected ultrasound waves as brightness along the axis of the scan plane to reconstruct a representative 2D image. This is useful for identifying tissue structures but does not allow for full assessment of hemodynamics.

Doppler ultrasound, however, can be used to assess hemodynamics. Doppler ultrasound uses the principle of

KEY POINTS

1. TEE is an essential component of cardiac anesthesia care.
2. A complete diagnostic examination should include the standard set of views (at a minimum) suggested by the ASE/SCA guidelines.
3. Intraoperative evaluation of acute persistent and life threatening hemodynamic disturbances in which ventricular function is uncertain and unresponsive to treatment is a Category I indication for TEE.

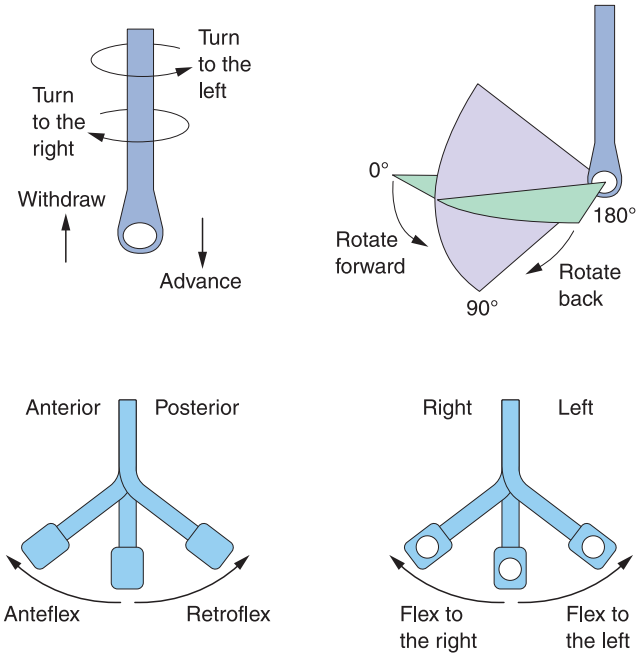

FIGURE 30–1. Probe manipulation of guidelines modified from "ASE/SCA guidelines for performing a comprehensive intraoperative multiplane transesophageal echocardiography examination: recommendations of the American Society of Echocardiography Council for Intraoperative Echocardiography and the Society of Cardiovascular Anesthesiologists Task Force for Certification in Perioperative Transesophageal Echocardiography."[4]

Doppler effect to display the velocities of moving structures (red blood cells or myocardium). When ultrasound is reflected from a moving target, the ultrasound frequency is slightly changed from the transmitted frequency (i.e., Doppler shift). Red blood cells moving toward the probe return a slightly increased frequency of ultrasound waves, and those moving away from the probe return a slightly decreased frequency of ultrasound waves. The magnitude of Doppler shift is proportional to the velocity of the moving structure. These velocity measurements can be translated into the pressure differences that generate them (Bernoulli equation), allowing for hemodynamic assessments.

Modified Bernoulli:

$$\Delta P = 4(V_2^2 - V_1^2).$$

Simplified Bernoulli:

$\Delta P = 4V_2^2$ (assuming $V_1 < 1.5$ m/s).

Because the Doppler effect only measures the velocity component moving directly toward or away from the probe, oblique angles will underestimate the true velocity. Therefore, all Doppler measurements should be made with the sampling beam as parallel as possible to the assumed blood flow. This necessitates using specific views to obtain accurate measurements, as will be described.

Color flow Doppler (CFD) displays the mean velocity of the red blood cells in a sample area according to a color map, assigning different shades of color to their respective velocities and different colors to different directions. This velocity information is overlaid on top of the 2D image, allowing the echocardiographer to visualize the velocity flow patterns of blood through the various structures. The velocity data for the CFD sample area is actually made up of many pulsed-wave Doppler (PWD) areas, which reduces the frame rate of the image displayed. Decreasing the lateral area covered by CFD will result in less PWD sampling and a faster frame rate.

PWD displays the mean velocity of a much smaller sample area versus time, resulting in velocity waveforms of that sample. This allows more accurate measurement of velocity waveforms in specific areas with a high sampling rate but without the 2D structural information. Because of the pulsed nature of this Doppler, it can measure velocities only within a given range determined by how long the transducer listens for ultrasound reflections before repeating the pulses. Velocities outside this given range are assigned incorrect velocities, termed *aliasing*. The aliasing velocity (the highest velocity accurately displayed) often can be increased by decreasing the pulse repetition frequency, but this degrades the temporal resolution. Of course, because PWD is used to construct CFD images, CFD suffers from the same velocity and temporal resolution limitations.

Continuous-wave Doppler (CWD) displays all the blood velocities along a beam of ultrasound rather than at a particular location. The continuous nature of this mode allows for display of the complete range of velocities at the highest temporal resolution. However, this mode cannot determine where along the ultrasound beam the particular velocities originated. This limitation of CWD is termed *range ambiguity*. Often, the echocardiographer will be able assume where the peak velocities should be originating (e.g., a narrowed valve orifice).

SYSTEMATIC APPROACH TO A TEE EXAMINATION

The American Society of Echocardiography and the Society of Cardiovascular Anesthesiologists have suggested a set of standard views and the nomenclature for those views.[4] This nomenclature should be followed whenever possible to minimize confusion. Generally, a combination of these views will allow for a complete diagnostic examination. However, deviation from these standard views may be necessary to obtain images appropriate to the individual patient. It is beneficial to be flexible about the order the views are obtained to allow focusing on a specific clinical question in a timely manner. Each echocardiographer should develop a systematic order for routine diagnostic TEE. This not only allows for increased speed and efficiency but also ensures that an important finding will not be missed simply because a view was forgotten.

Many echocardiographers prefer to order the examination such that they collect multiple views focusing on many different structures from each probe position or depth prior to moving to the next probe location. This

TABLE 30–1.

Recommended Indications for Transesophageal Echocardiography

Category I Indications: Supported by the strongest evidence or expert opinion: TEE is frequently useful in improving clinical outcomes in these settings and is often indicated, depending on individual circumstances (e.g., patient risk and practice setting).	Category II Indications: Supported by weaker evidence and expert consensus; TEE may be useful in improving clinical outcomes in these settings, depending on individual circumstances, but appropriate indications are less certain.	Category III Indications: Little current scientific or expert support; TEE is infrequently useful in improving clinical outcomes in these settings, and appropriate indications are uncertain.
• Intraoperative evaluation of acute, persistent, and life-threatening hemodynamic disturbances in which ventricular function and its determinants are uncertain and have not responded to treatment	• Perioperative use in patients with increased risk of myocardial ischemia or infarction	• Intraoperative evaluation of myocardial perfusion, coronary artery anatomy, or graft patency
• Intraoperative use in valve repair	• Perioperative use in patients with increased risk of hemodynamic disturbances	• Intraoperative use during repair of cardiomyopathies other than hypertrophic obstructive cardiomyopathy
• Intraoperative use in congenital heart surgery for most lesions requiring cardiopulmonary bypass	• Intraoperative assessment of valve replacement	• Intraoperative use for uncomplicated endocarditis during noncardiac surgery
• Intraoperative use in repair of hypertrophic obstructive cardiomyopathy	• Intraoperative assessment of repair of cardiac aneurysms	• Intraoperative monitoring for emboli during orthopedic procedures
• Intraoperative use for endocarditis when preoperative testing was inadequate or extension of infection to perivalvular tissue is suspected	• Intraoperative evaluation of removal of cardiac tumors	• Intraoperative assessment of repair of thoracic aortic injuries
• Preoperative use in unstable patients with suspected thoracic aortic aneurysms, dissections, or disruption who need to be evaluated quickly	• Intraoperative detection of foreign bodies	• Intraoperative use for uncomplicated pericarditis
• Intraoperative assessment of aortic valve function in repair of aortic dissections with possible aortic valve involvement	• Intraoperative detection of air emboli during cardiotomy, heart transplant operations, and upright neurosurgical procedures	• Intraoperative evaluation of pleuropulmonary diseases
• Intraoperative evaluation of pericardial window procedures	• Intraoperative use during intracardiac thrombectomy	• Monitoring placement of intraaortic balloon pumps, automatic implantable cardiac defibrillators, or pulmonary artery catheters
• Use in intensive care unit for unstable patients with unexplained hemodynamic disturbances, suspected valve disease, or thromboembolic problems (if other tests or monitoring techniques have not confirmed the diagnosis or patients are too unstable to undergo other tests)	• Intraoperative use during pulmonary embolectomy	• Intraoperative monitoring of cardioplegia administration
	• Intraoperative use for suspected cardiac trauma	
	• Preoperative assessment of patients with suspected acute thoracic aortic dissections, aneurysms, or disruption	
	• Intraoperative use during repair of thoracic aortic dissections without suspected aortic valve involvement	
	• Intraoperative detection of aortic atheromatous disease or other sources of aortic emboli	
	• Intraoperative evaluation of pericardiectomy, pericardial effusions or evaluation of pericardial surgery	
	• Intraoperative evaluation of anastomotic sites during heart and/or lung transplantation	
	• Monitoring placement and function of assist devices	

TEE, Transesophageal echocardiography.
Modified from Daniel et al.[31]

allows for increased efficiency and decreases the total probe manipulation necessary for a complete examination. Alternatively, the echocardiographer may focus on one structure or chamber at a time. This results in duplicated views, as many structures usually can be seen within single views, and increased probe manipulation, as each structure is interrogated from different vantage points and angles.

Left Atrium

Because the left atrium (LA) lies just anterior to the esophagus in most patients, the LA can be seen in the near field (i.e., at the top) of most midesophageal (ME) images of the heart (probe tip is approximately 35 cm from teeth and anteriorly oriented). Evaluation of the LA usually starts from an ME four-chamber view (Fig. 30–2A; multiplane angle at 0–20° with transducer slightly

TABLE 30–2.

Normal Structures That May Be Mistaken for Abnormal Cardiac Masses

Left atrium	Tissue ridge between the superior pulmonary vein and left atrial appendage ("Coumadin ridge")
	Atrial suture line after cardiac transplant
Left ventricle	Papillary muscle
	Chordae variant (redundancy)
	Prominent apical trabeculation
Right atrium	Chiari network
	Eustachian valve
	Crista terminalis
	Lipomatous hypertrophy of interatrial septum or lateral tricuspid valve annulus
	Right atrial appendage trabeculations
	Pulmonary artery catheter, pacer wire
Right ventricle	Moderator band
	Pulmonary artery catheter, pacer wire
Aortic valve	Nodules of Arantius
	Lambl excrescences
Mitral valve	Myxomatous mitral valve tissue
	Lambl excrescences
Pericardium	Epicardial adipose tissue

TABLE 30–3.

TEE Probe Manipulation

Terminology	Definition
Superior	Toward the head
Inferior	Toward the feet
Anterior	Toward the sternum
Right and left	Patient's right and left sides
Advancing the transducer	Pushing the tip of the probe deeper into the esophagus or the stomach
Withdrawing the transducer	Pulling the tip of the probe up the esophagus toward the head.
Turning to the right	Moving the tip of the probe clockwise within the esophagus (scan plane moving toward the patient's right if the transducer is oriented anteriorly)
Turning to the left	Moving the tip of the probe counterclockwise
Rotating forward	Rotation of the multiplane angle from 0° toward 180° (using the electronic toggle switch)
Rotating back	Rotation of the multiplane angle in the opposite direction toward 0°
Anteflexing	Flexing the tip of the probe anteriorly (clockwise rotation of the large control wheel when oriented anteriorly)
Retroflexing	Flexing the tip posteriorly (counterclockwise rotation)
Flexing to the right	Laterally flexing the tip of the probe to the patient's right (clockwise rotation of the small control wheel). (Fig. 30–1)
Flexing to the left	Flexing the tip to the patient's left. (Fig. 30–1)

retroflexed from the neutral position). It can be evaluated further as the multiplane angle sweeps from 0–120°. Within the LA, a tissue ridge ("Coumadin ridge") separates the LA appendage and left upper pulmonary vein (Figs. 30–2B and 30–2C). This atrial tissue can accumulate fat, creating a mass-like appearance. Because the majority of LA thrombi are located within the LA appendage, this structure should always be interrogated. The normal LA appendage is lined with ridges of pectinate muscle, which may be difficult to differentiate from small thrombi. Thrombi are generally more rounded and often fill the appendage.

LA thrombus usually is associated with high-risk structural and functional heart disease, most commonly atrial fibrillation, mitral stenosis, mitral valve (MV) prosthesis, or LA enlargement resulting from LV dysfunction. These structural and functional cardiac abnormalities tend to be associated with blood stasis within the LA, which facilitates thrombus formation. Mitral regurgitation (MR) may decrease LA stasis and protect against LA thrombus formation. Aortic stenosis (AS), or an aortic prosthesis, usually does not result in significant LA stasis unless accompanied by LV dysfunction. Thrombus usually is homogeneous in appearance, more echogenic than the underlying myocardium, appears in multiple imaging planes, and moves in concert with the underlying myocardium.

TEE is superior to transthoracic echocardiography for detection of LA thrombus. This is partly because of the large percentage of LA thrombi that are found in the LA appendage, which can be well delineated by TEE. LA appendage thrombi can be evaluated by keeping the atrial appendage centered in the image and rotating the multiplane angle from 0–180°. Spontaneous echo contrast, seen as a slowly swirling "smoke" pattern, indicates low-flow velocities. It is strongly associated with LA thrombus. Doppler interrogation of the LA appendage also may be helpful, as lower blood flow velocities identify patients at higher risk.

Right Atrium

Evaluation of the right atrium (RA) can be approached from the ME four-chamber view, ME bicaval view (Fig. 30–3A; probe turned to patient's right with multiplane angle of 110–120°), ME RV

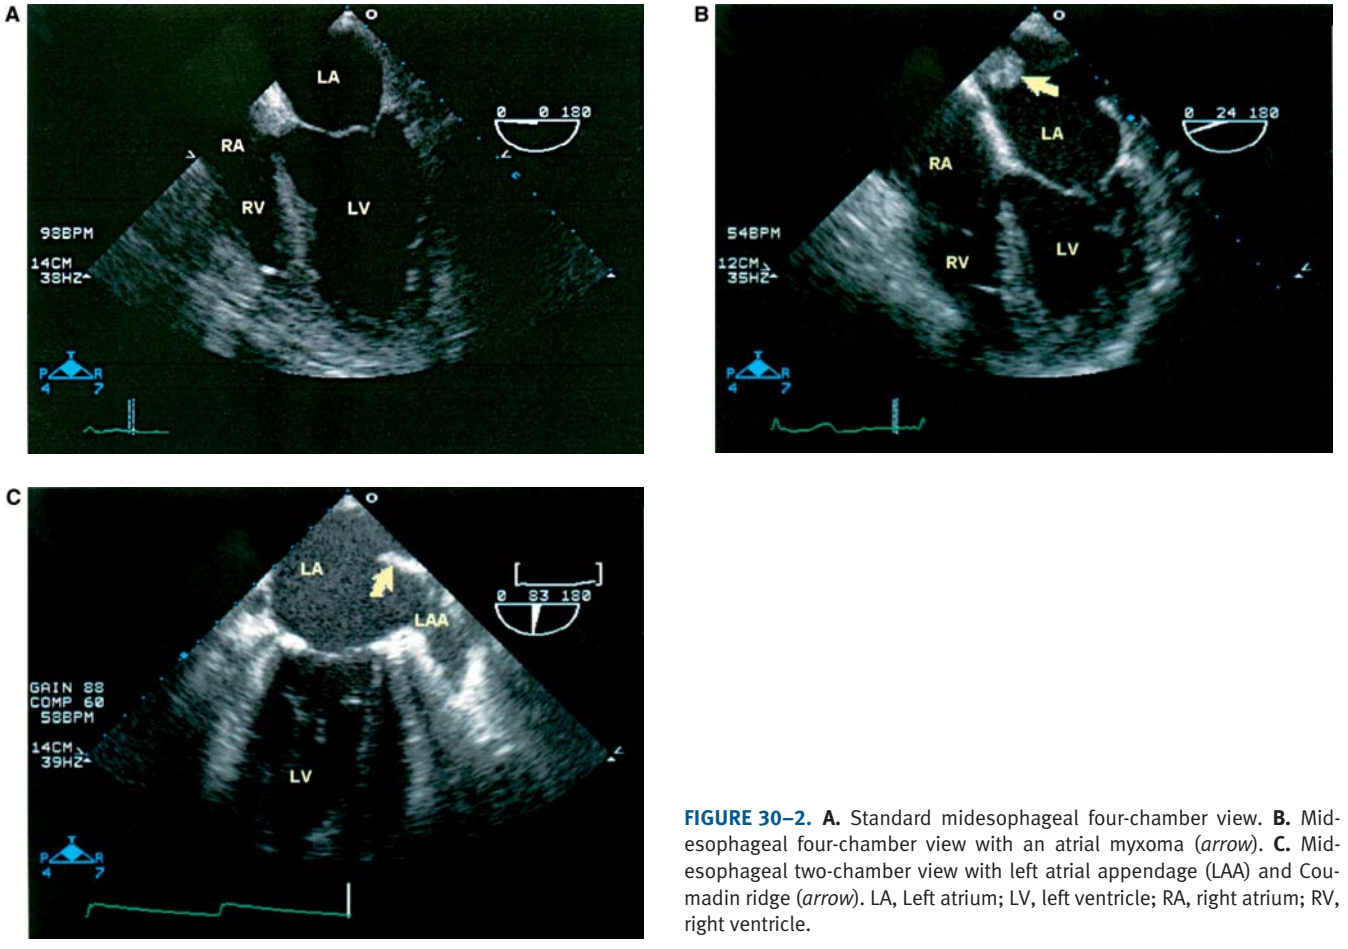

FIGURE 30–2. A. Standard midesophageal four-chamber view. **B.** Midesophageal four-chamber view with an atrial myxoma (*arrow*). **C.** Midesophageal two-chamber view with left atrial appendage (LAA) and Coumadin ridge (*arrow*). inflow–outflow view (Fig. 30–3B; 40–60˚), and transgastric (TG) RV inflow view (rotating the angle to 90˚ and turning the probe to the right from the TG short-axis [SAX] view). The RA is a thin-walled structure. The superior vena cava (SVC) and inferior vena cava (IVC) entering the RA posteriorly and medially, respectively. Remnant embryonic structures should be distinguished from thrombi and other masses. The eustachian valve is an elongated, membranous projection at the junction of the RA and IVC. The Chiari network, a delicate, mobile structure often arising from the eustachian valve and stretching to the interatrial septum (IAS), may be misdiagnosed as an atrial mass. The crista terminalis is a vertical ridge of muscle originating at the junction of the RA and SVCl It runs toward the IVC and has also been misinterpreted as an intracardiac mass. Central venous catheters, pulmonary artery catheters, and pacing wires often can be seen as they course through the right heart and should not be confused as pathologic masses. RA thrombi typically are associated with indwelling catheters or pacemaker leads.

Interatrial Septum

The IAS consists of the thin fossa ovalis centrally and thicker limbus regions anteriorly and posteriorly. The IAS should be examined with CFD to detect interatrial shunts.

Structural atrial septal defects can be divided anatomically into defects at the fossa ovalis (ostium secundum type), defects occurring inferior to the fossa ovalis (ostium primum type), and defects occurring superior to the fossa ovalis (sinus venosus type). The most common defect is the ostium secundum type, in which the posterior atrial wall may be totally absent. The ostium primum type usually can be seen inferior to the fossa ovalis in the ME four-chamber view. It is associated with other endocardial cushion defects, such as ventricular septal defects, atrioventricular canal defects, and tricuspid or MV abnormalities. The sinus venous type of atrial septal defect lies superior to the fossa ovalis close to the opening of the SVC. It may be best seen from an ME bicaval view.

A patent foramen ovale (PFO) is a flap-like opening between the atrial septa primum and secundum at the location of the fossa ovalis that persists after age 1 year. In utero, the foramen ovale serves as a physiologic conduit for right-to-left shunting. PFO is a common functional secundum atrial septal defect that results from failure of the septa primum and secundum to completely fuse (Fig. 30–4A), allowing an interatrial shunt to occur under certain hemodynamic conditions. TEE is the diagnostic standard for detecting PFO, which is present in approximately 20% of adults. The ME bicaval view often is best for detecting this lesion. CFD interrogations of the IAS and contrast echocardiography both have high sensitivity and specificity for detecting PFO. Intravenous injection of agitated saline often is used intraoperatively to produce a contrast effect (Fig. 30–4C). Simultaneous release of a breath-hold-

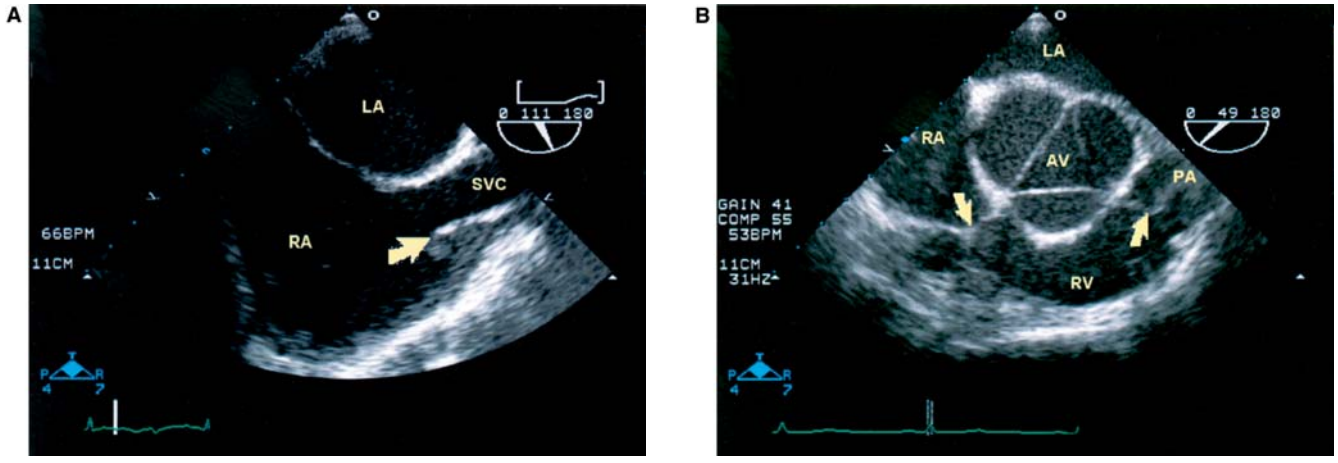

FIGURE 30–3. **A.** Standard midesophageal bicaval view with crista terminalis (*arrow*) visualized. **B.** Standard midesophageal right ventricular inflow–outflow view in a patient with a large aortic valve. ing maneuver will increase RA pressures relative to LA pressures and may open a functionally closed PFO.

In the presence of an atrial septal defect with left-to-right shunting, the LA usually appears normal while the RA and RV enlarge from volume overload. As pulmonary hypertension occurs, the RV wall becomes hypertrophied. With an atrial septal defect, the pulmonary vasculature dilates and can be as wide as the aorta.

An atrial septal aneurysm is an outpouching of thin, mobile, redundant tissue in the region of the fossa ovalis (Fig. 30–4C). The atrial septum is considered to be aneurysmal when a portion at least 15 mm wide has an

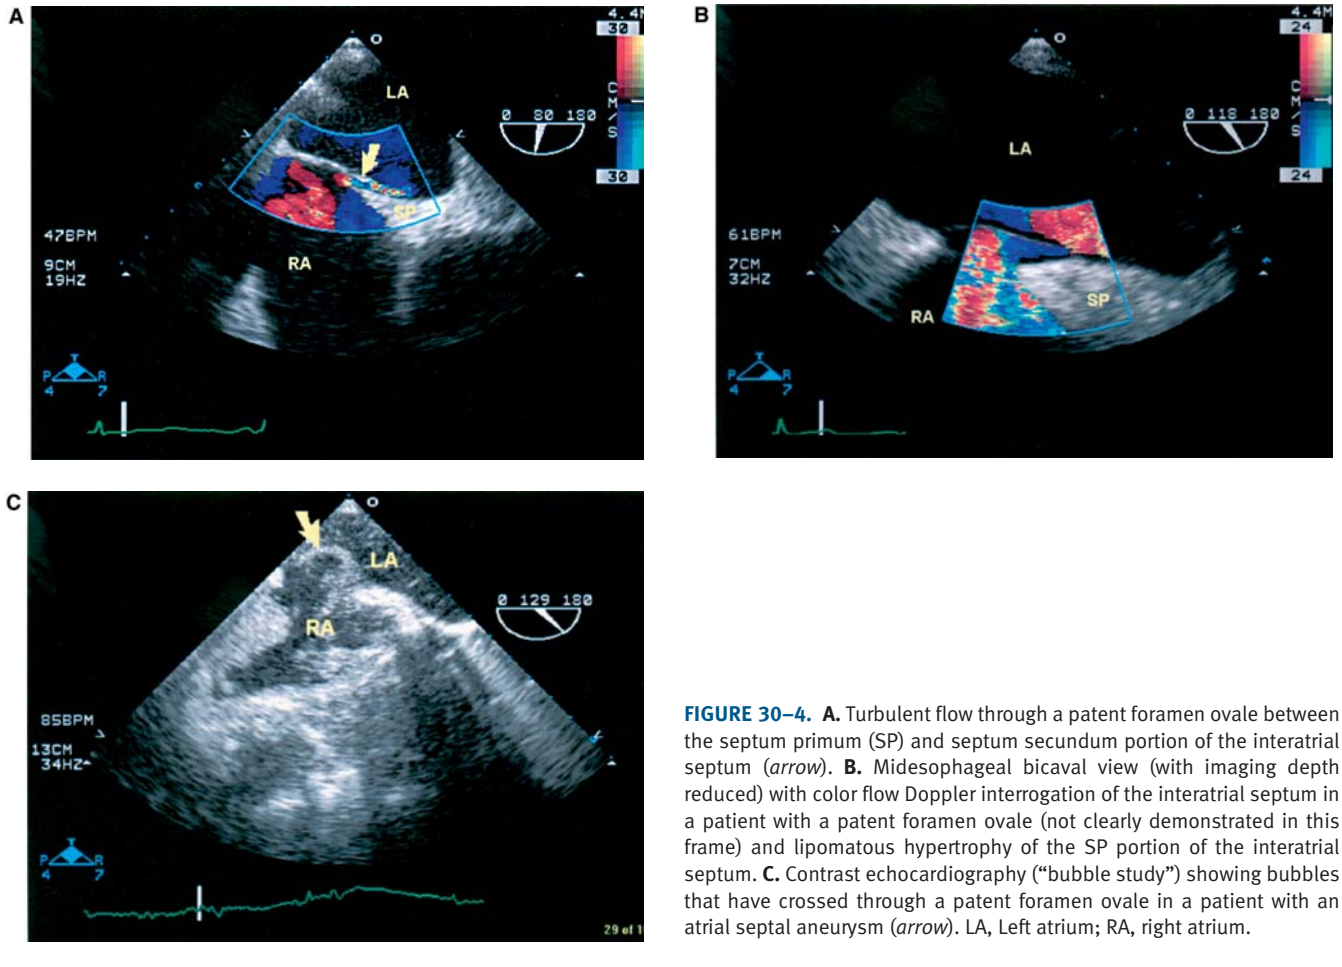

FIGURE 30–4. **A.** Turbulent flow through a patent foramen ovale between the septum primum (SP) and septum secundum portion of the interatrial septum (*arrow*). **B.** Midesophageal bicaval view (with imaging depth reduced) with color flow Doppler interrogation of the interatrial septum in a patient with a patent foramen ovale (not clearly demonstrated in this frame) and lipomatous hypertrophy of the SP portion of the interatrial septum. **C.** Contrast echocardiography ("bubble study") showing bubbles that have crossed through a patent foramen ovale in a patient with an atrial septal aneurysm (*arrow*). LA, Left atrium; RA, right atrium.

interatrial excursion of at least 15 mm. Atrial septal aneurysm formation may be secondary to raised interatrial pressure gradients, producing a bulging septal shift toward the low-pressure side. An atrial septum aneurysm must be considered in the differential diagnosis of atrial cysts and tumors and has been related to atrial arrhythmias, systemic and pulmonary embolism, MV prolapse, and atrial septal defect.

Lipomatous hypertrophy of the atrial septum is a peripherally thickened septum surrounding the thin fossa ovalis (Fig. 30–4B). It results from fat deposits in the atrial septum and should not be confused with intraatrial masses such as myxomas.

Cardiac Tumors

Metastatic cardiac tumors are more common than primary cardiac tumors. Metastatic disease may result from contiguous extension, lymphangitic spread, or hematogenous spread from the primary tumor. It tends to involve the pericardium and myocardium rather than the valves and endocardium. Extension of tumor thrombus via the IVC into the RA is a well-recognized complication of advanced renal cell carcinoma.

Myxomas, the most common primary cardiac tumors, account for approximately 50% of all primary cardiac tumors. Myxomas can cause obstruction and embolization, making prompt surgical removal mandatory. Myxomas usually are solitary and are found most commonly within the LA (Fig. 30–2A), originating from the IAS (often the fossa ovalis). Myxomas characteristically have hemorrhagic cystic spaces and possibly areas of calcification.

Left Ventricle

Systolic Function

Assessment of regional and global systolic LV function often is the primary indication for perioperative echocardiography. TEE is well suited to providing accurate evaluation and monitoring of ventricular filling and systolic function during hemodynamic instability. For purposes of identifying wall-motion abnormalities, the American Society of Echocardiography divides the LV into 17 segments (Fig. 30–5).[5] The basal and midlevels of the LV each have inferior, inferolateral (formerly termed posterior), anterolateral, anterior, anteroseptal, and inferoseptal segments. The apical level has inferior, lateral, anterior, and septal segments. The apical cap is the final segment. All segments (except the apical cap) can be visualized from either an ME or TG probe location. If wall-motion abnormalities are observed, the typical blood supply patterns (or actual blood supply patterns from a previous angiogram) to these segments can help identify the compromised coronary artery or graft.

A wall-motion description should be assigned for each segment. *Mild hypokinesis* refers to a decrease in inward wall movement and a 10–30% increase in endocardial systolic thickening (normal is >30%). *Severe hypokinesis* refers to only slight wall movement and <10% thickening. *Akinesis* refers to lack of both movement and endocardial thickening (indicating severe ischemia or infarct). *Dyskinesis* refers to outward wall movement and endocardial thinning during systole (indicating old infarct). As movement may be passive because of contraction of adjacent segments or translational movement of the heart, thickening is believed to be more reliable than wall movement in determining wall-motion abnormalities. If scaled scores are assigned to each type of wall-motion abnormality, the average of those scores from each segment provides a semiquantitative assessment of global ventricular function, termed the *wall-motion index*. The wall-motion index can be converted in order to estimate ejection fraction (EF) and results in good agreement with other measures of EF.[6]

Many other measures of global ventricular function can be made; only the most common are discussed here. Fractional area change (FAC) can be

FIGURE 30–5. obtained from the TG SAX view ("donut view"). It is simply the proportion of diastolic area of the LV chamber in the midpapillary SAX view (Fig. 30–6B) that is reduced during systole:

FAC% = (End-diastolic area – End-systolic area)/End-diastolic area * 100.

Although FAC often is estimated visually, the chamber circumference can be traced in both systole and diastole to provide the areas for more accurate calculation. Because FAC is measured in only one plane, it may miss significant wall-motion abnormalities outside that plane and therefore has limited accuracy in the assessment of overall ventricular function. Oblique planes of view also may reduce accuracy.

EF, which includes the volume change of the whole ventricle rather than the area change of a EF% = (End-diastolic volume – End-systolic volume)/End-diastolic volume * 100.

Normal EF is 55–75%.

Generating accurate three-dimensional (3D) volumes from 2D echocardiography can be a source of error. Multiple geometric methods have been developed that assume the ventricle fits a stereotypical ellipsoidal shape. They include the single-plane ellipsoid method, cylinder–hemi-ellipsoid method, and area–length method; all of these methods estimate volume from diameter and length measurements in one or two planes. These geometric assumptions limit the accuracy of EF estimation when segmental wall-motion abnormalities or unusual ventricular shapes are present. If the plane of measurement does not include the true apex, termed a *foreshortened view,* then the volumes and EF will be unreliable.

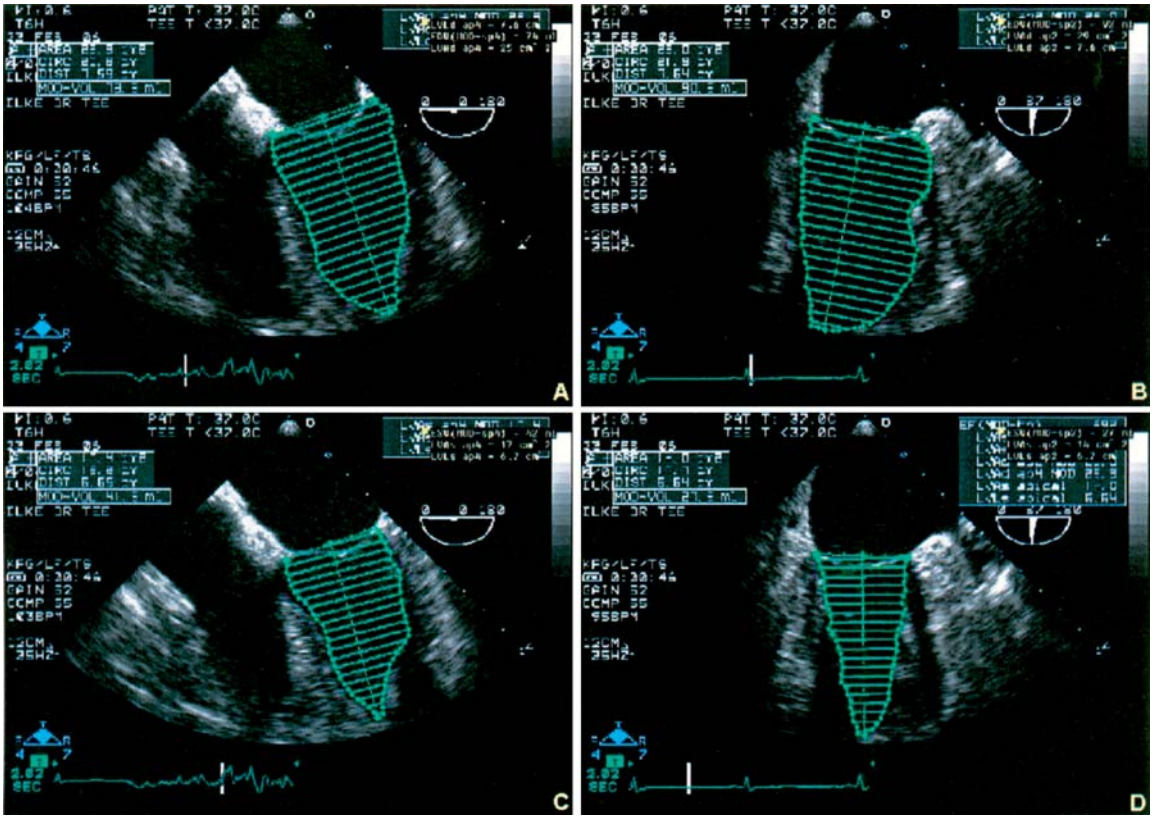
The modified Simpson method, also known as the *disk summation method,* is considered the best method for deriving ventricular volumes and EF from 2D echocardiography. For this method, the endocardial border is traced in two orthogonal planes (e.g., ME four-chamber and two-chamber views). Computer software then models the ventricle as a series of 20 or more stacked elliptical disks (Fig. 30–7). The volume of each disk then is calculated from the thickness of the disk and the diameters of each ellipsoid disk (Fig. 30–7C), and all of the individual disk volumes are summed to yield the total volume of the ventricle. Similar cylindrical disks or rotating ellipsoid models can be generated from a single tomographic view, but with reduced accuracy. This biplane disk summation method allows for variably shaped ventricles. It also can account for significant regional wall-motion abnormalities but still may be limited by image quality or foreshortened views. To reduce foreshortening errors, the two orthogonal views should not be combined if the chamber lengths appear to differ by >20%.

In clinical practice, simple visual estimation by the echocardiographer often is the source of the reported EF. The reliability of visual estimation of EF by an experienced echocardiographer appears to be similar to wall-motion index and EF calculations using the Simpson rule.[6] New image processing modes, such as secondary harmonic imaging, Doppler tissue imaging, and contrast agents, can help delineate subendocardial borders and improve the image. Volumes may soon be obtained from real-time 3D echocardiography with automated border detection programs.

Neither FAC nor EF is a pure index of myocardial contractility because both are dependent upon loading conditions, especially at the extremes of preload and afterload.

Attempts have been made to measure load-independent indices of ventricular function. Generation of pressure–volume loops at different loading conditions results in a linear end-systolic relationship, the slope of which is termed *end-systolic elastance.* The area within pressure–volume loops is *stroke work,* which can be plotted against the corresponding end-diastolic volumes to obtain preload-recruitable work. These measures are much more complex and include measuring intraventricular pressures or their surrogates and thus are principally used for research purposes at this time.

Less load-dependent measures that are easier to obtain, although rarely reported, include the peak systolic pressure-end systolic volume ratio and cardiac power. *Mean cardiac power* is the product of stroke volume, mean arterial pressure, and heart rate. Peak instantaneous power also can be calculated. These measures can be corrected for end-diastolic volume to make them load independent. If MR is present, dP/dt of the MR jet is a relatively load-independent measure of



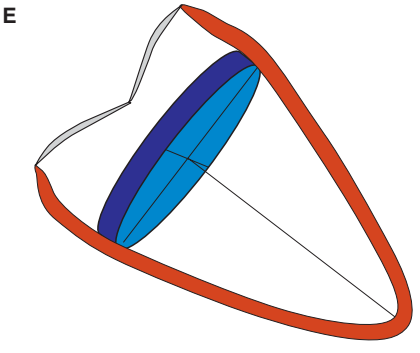


FIGURE 30–7. Ejection fraction calculated using the disk summation method from four-chamber end-diastole (**A**), two-chamber end-diastole (**B**), four-chamber end-systole (**C**), and two-chamber end-systole (**D**) tracings. **E.** Depiction of a single Simpson disk with elliptical diameters measured from midesophageal four-chamber and two-chamber views. Using the software package of the transesophageal echocardiography machines, the volume of each theoretical disk is automatically calculated separately in this way and then summed together to obtain the left ventricular volume in both end-diastole and end-systole, allowing for calculation of ejection fraction.

contractility, which is otherwise difficult to assess when ventricular work is lost into the lower-pressure LA. *Myocardial performance index* is the sum of isovolumic contraction time and isovolumic relaxation time, divided by ejection time. It combines systolic and diastolic function into one easily obtainable and reproducible index that has good prognostic value.[7] All of these measures have the benefit of being independent of ventricular geometry and the subjective determination of endocardial borders.

Diastolic Function

Diastole is divided into four distinct phases: isovolumic relaxation, early rapid filling, diastasis, and atrial contraction (Fig. 30–8). Isovolumic relaxation begins with closure of the aortic valve (AV). The chamber relaxes, and the pressure within the chamber decreases. Once the pressure falls below the pressure in the atrium, the MV opens, ending the period of isovolumic relaxation. Isovolumic relaxation is an active, energy dependent process; therefore, abnormalities in systolic function usually are accompanied by abnormalities in isovolumic relaxation. Blood flowing through the MV initiates the early rapid filling phase. The rapid filling of the chamber (early diastole) is dependent on both LV relaxation (an active process) and chamber compliance (a passive property). As volume fills the ventricle, the pressures between the atrium and the ventricle equalize, and the flow begins to slow. This period is referred to as *diastasis* because there is little blood flow between the chambers. The MV leaflets remain in an open position, and the duration of diastasis is dependent on heart rate and chamber compliance. With the onset of atrial contraction, atrial pressures become greater than ventricular pressures, so again there is a net flow of blood into the ventricle. In normal individuals, atrial contraction contributes approximately 20% to the end-diastolic ventricular volume. The atrial contraction phase is dependent on the chamber compliance, LA function, and the electrical conduction system.

From the preceding discussion, one can conclude that flow is driven primarily by pressure gradients between

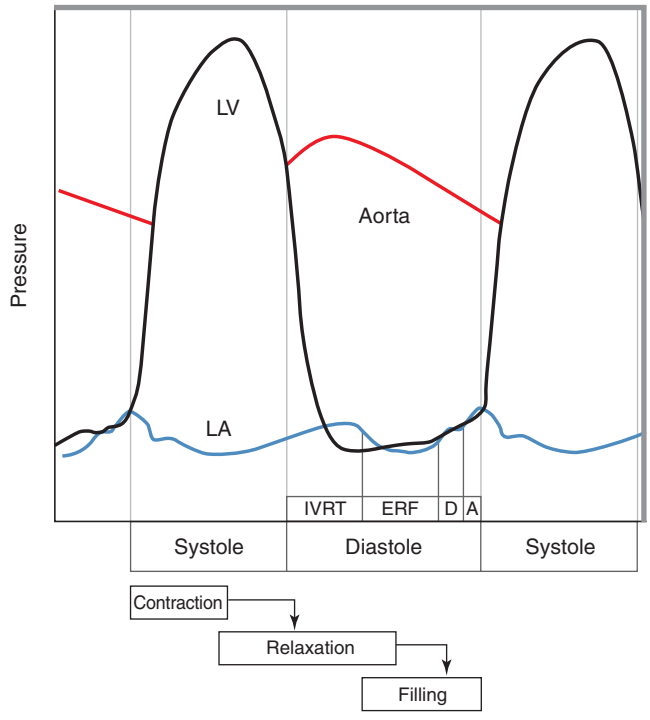

FIGURE 30–8. Pressure tracings from a normal cardiac cycle. Pressure differences (which cannot be measured directly by transesophageal echocardiography) between chambers drive the corresponding flow velocities (which we measure with transesophageal echocardiography to calculate pressure differences). A, Atrial contraction; D, diastasis; ERF, early rapid filling; IVRT, isovolumic relaxation time; LA, left atrium; LV, left ventricle.

the atrium and the ventricle. For a given pressure, if LV relaxation is brisk, the result is a large, early pressure gradient (often even a suction effect) that drives filling during early diastole. This results in less filling in late diastole. On the other hand, if ventricular relaxation is sluggish, early diastolic filling declines and a greater proportion of diastolic filling is seen in late diastole. In the latter situation, there is a greater dependence on atrial contraction for filling.

It follows, then, that a decrease in LV relaxation and/or compliance will lead to a compensatory increase in LA pressures to maintain end-diastolic ventricular volume. Because the rate of LV relaxation and increase of LA pressures is a continuum, many different transmitral pressure gradients and LV filling patterns are possible. This leads to a challenge in quantifying diastolic dysfunction over the continuum of varying patient conditions.

Doppler echocardiography, by virtue of its ability to evaluate flow patterns across valves and in large blood vessels, allows the clinician to diagnose diastolic dysfunction. Two-dimensional echocardiographic inspection of the ventricular systolic function may provide an alternative cause for a patient's heart failure or suggest that diastolic dysfunction is likely. For example, if a patient with the clinical picture of heart failure is found to have normal ventricular systolic function and volumes but LV hypertrophy (end-diastolic wall thickness >1.1 cm) is present, diastolic heart failure is likely. Combined systolic and diastolic failure may be present, or a patient may have ventricular hypertrophy without measurable diastolic abnormalities. Therefore, 2D findings are neither sensitive nor specific for diastolic dysfunction, and further investigation is warranted. Two-dimensional echocardiography, then, is most useful in helping to quantify systolic function and to differentiate isolated diastolic dysfunction from combined systolic–diastolic dysfunction. To fully assess diastolic function, use of Doppler echocardiography techniques is necessary.

The period required for isovolumic relaxation (first phase of diastole) is the isovolumic relaxation time (IVRT). IVRT is measured as the time interval from closure of the AV to opening of the MV. IVRT can be obtained from the deep TG long-axis (LAX) view (multiplane angle at 90°) with a PWD sample at (or CWD through) the junction of the MV inflow and the LV outflow tract (LVOT). Normally, IVRT lasts 60–90 msec and reflects the rate of myocardial relaxation. Impaired relaxation delays the drop in ventricular pressure below that of the atrium, resulting in prolonged IVRT. It probably is the most sensitive Doppler index for detecting impaired relaxation because it is the first to become abnormal, but it is dependent on afterload and heart rate.

If a PWD sample is acquired near the coaptation point of the MV leaflets, transmitral flow velocities can be mapped and measured, corresponding to early diastolic filling. Flow at this time is directed away from the transducer (below the baseline). This wave is the *early* or *E wave.* The time required for the flow velocity to return to zero (from the peak of the E wave back to the baseline) is the *deceleration time.* For a brief time, there is no flow across the MV, and the velocities will remain zero (diastasis). Soon after, the LA contracts, and flow once again begins. Plotting these velocities versus time will yield the *atrial* or *A wave.* The total duration of the A wave (from the end of diastasis to the return of zero flow) is termed *A-wave duration* (A_{dur}).

Normally, most diastolic filling occurs in early diastole so that the E/A ratio is >1 (Fig. 30–9A). However, mitral flow velocity curves vary with loading conditions, age, and heart rate. In healthy young patients, the E/A ratio may be as high as two. As people get older, LV relaxation slows; there is a gradual decrease of the peak E-wave velocity and an increase of the A-wave component. In most individuals, E and A become approximately equal in the sixth decade of life. Because relaxation is impaired beyond what is "normal" for age, early diastolic filling decreases.

With diastolic dysfunction, the volume that remains in the atrium at the end of the early filling phase increases, and a progressively vigorous compensatory atrial contraction ("atrial kick") occurs. This results in a reversed E/A ratio (E/A <0.75, delayed relaxation pattern). In this case, deceleration time is increased (>220 msec) and IVRT is increased (>100 msec).

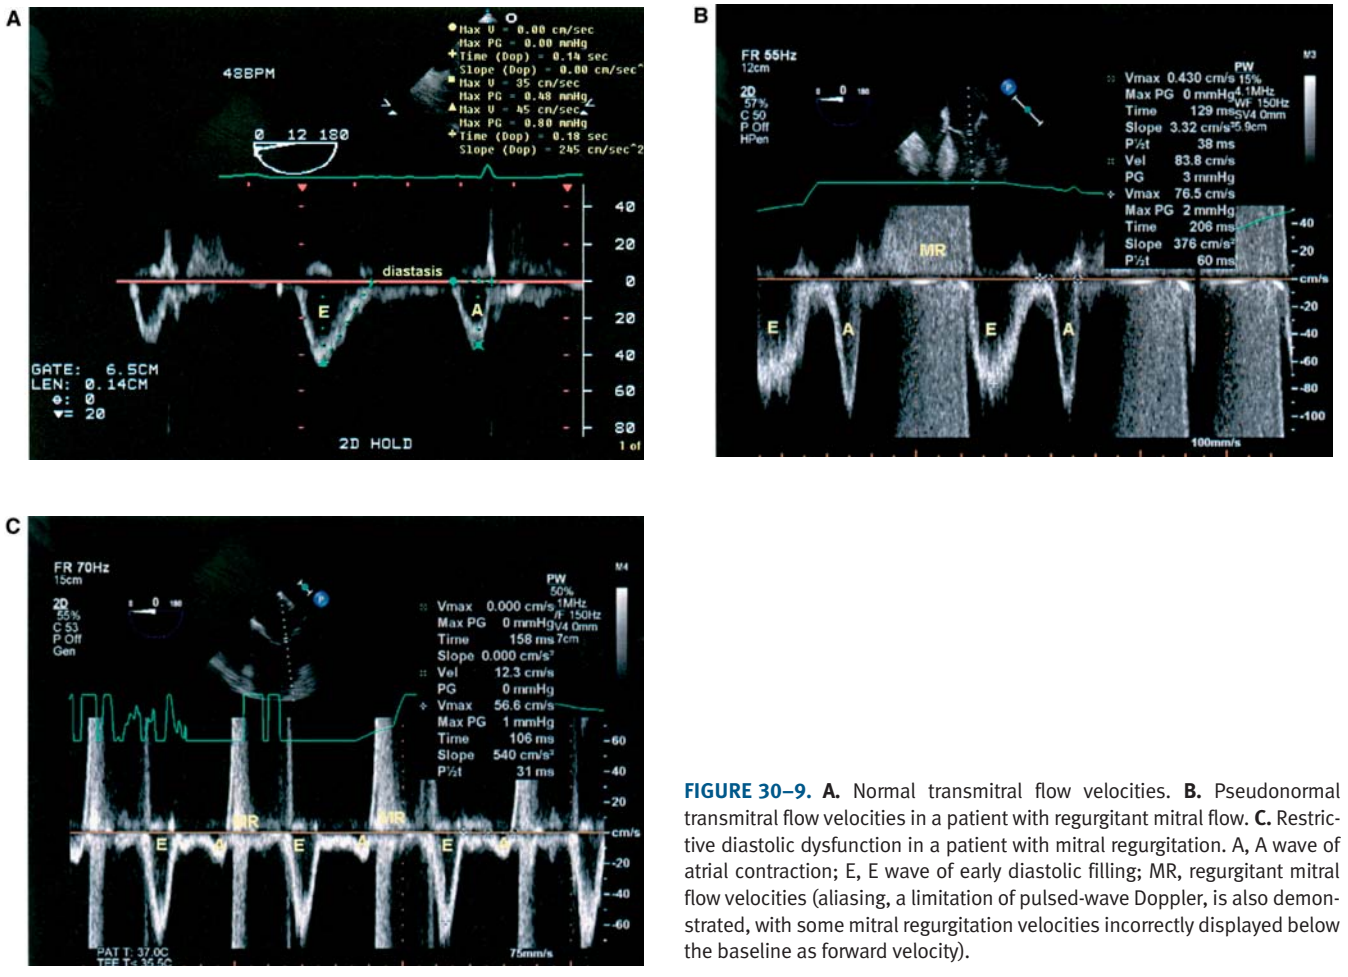

FIGURE 30–9. A. Normal transmitral flow velocities. **B.** Pseudonormal transmitral flow velocities in a patient with regurgitant mitral flow. **C.** Restrictive diastolic dysfunction in a patient with mitral regurgitation. A, A wave of atrial contraction; E, E wave of early diastolic filling; MR, regurgitant mitral flow velocities (aliasing, a limitation of pulsed-wave Doppler, is also demonstrated, with some mitral regurgitation velocities incorrectly displayed below the baseline as forward velocity).

With further diastolic dysfunction, LV compliance is even lower, and filling pressures begin to increase. This leads to a compensatory increase of LA atrial pressure that results in increased early filling velocities despite impaired relaxation. The filling pattern appears relatively normal (termed *pseudonormalization*), and the E/A ratio returns to approximately 1 (Fig. 30–9B). Pseudonormalization represents abnormalities of both relaxation and compliance and can be distinguished from normal filling by a shortened deceleration time.

In patients with severely decreased LV compliance, LA pressure is markedly elevated and drives vigorous early diastolic filling velocities despite impaired relaxation. This restrictive filling pattern (E/A >1.5) is consistent with an abnormal rise in LV diastolic pressure and an abrupt deceleration of early diastolic flow (deceleration time <150 msec) with little additional filling during mid-diastole and atrial contraction (Fig. 30–9C). In the extreme case, the change in pressure in the ventricle exceeds LA pressure so that MR in mid-diastole may occur.

Analysis of pulmonary venous filling patterns provides additional information about LV diastolic function. PWD is used to sample pulmonary venous flow approximately 1.5–2.0 cm within the left upper pulmonary vein (or alternatively the right upper pulmonary vein). Flow from the pulmonary veins into the LA atrium occurs in three phases: systolic phase (S wave), diastolic phase (D wave), and retrograde flow with atrial contraction (A wave). Under normal conditions (LA pressure is normal and the MV is competent), most of the flow into the atrium occurs during ventricular systole (S-wave velocity > D-wave velocity) as the MV annulus is pulled downward (Fig. 30–10A). During diastole, additional blood flows from the pulmonary veins into the LA, which is simultaneously emptying into the LV. During atrial contraction, blood is ejected into the LV, with a small amount of retrograde flow into the pulmonary veins. The smaller A wave is in the opposite direction to the S and D waves.

As pressure in the LA increases (compensating for advancing diastolic dysfunction), systolic flow decreases (decreased S-wave velocity) and flow occurs predominantly in diastole (increased D-wave velocity; Fig. 30–10B). The absolute values of the S and D waves do not necessarily provide any additional information. Because they are dependent on the volume status of the patient, the absolute values of the S and D waves can vary significantly even under normal conditions.

Pulmonary venous flow patterns help to differentiate normal transmitral filling patterns from pseudonormal patterns. In the pseudonormal pattern, the atrium contracts against an increased afterload in the LV due to an elevated diastolic filling pressure and a stiff LV. More blood will be ejected along the "path of least resistance" back into the pulmonary veins. As a result, the A wave in pseudonor-

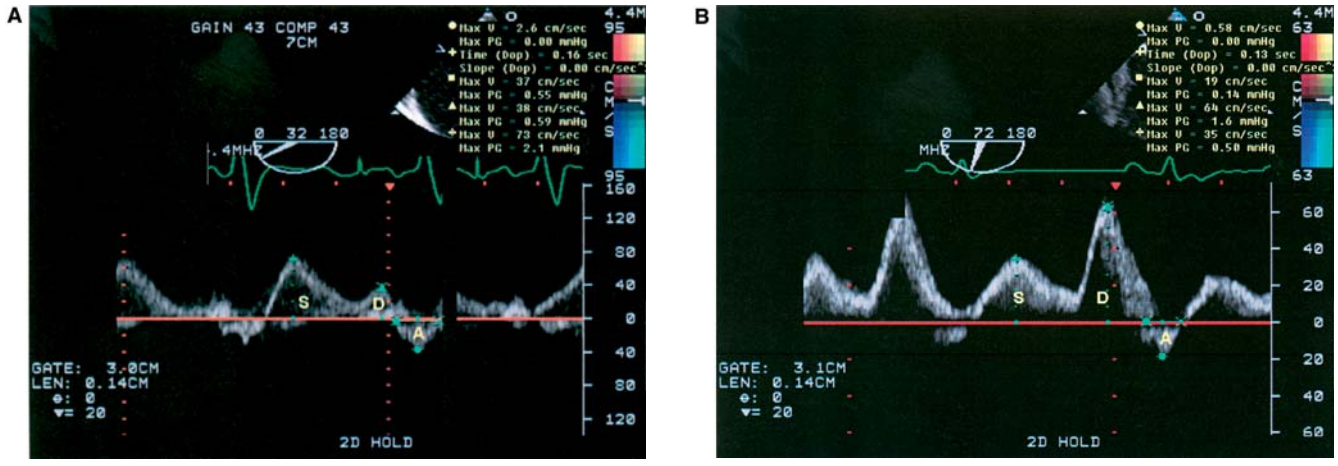

FIGURE 30–10. **A.** Normal pulmonary venous flow velocities (S wave › D wave). **B.** Abnormal pulmonary venous flow velocities (D wave › S wave) from diastolic dysfunction. A, Retrograde atrial flow wave; D, diastolic phase wave; S, systolic phase wave.

mal diastolic dysfunction is tall (often >0.35 m/s) and prolonged.

Both transmitral and pulmonary venous flow patterns are affected by the patient's volume status. Color M-mode Doppler echocardiography is a relatively new modality that can be used to assess diastolic function in a preload-independent manner. When using color M-mode, an "ice pick" scan line is used to display color Doppler velocity information versus time. By placing the scan line through the mitral inflow jet of the LV, two distinct flow profiles are obtained. The displayed profiles correspond to the E and A waves from PWD. The slope of the first (E) wave's aliasing velocity is the propagation velocity (Vp), which is an indication of the velocity at which blood travels from the mitral annulus to the apex during early ventricular filling (Fig. 30–11). Vp correlates to the degree of diastolic dysfunction and is independent of preload and heart rate. Another advantage of color M-mode Doppler echocardiography is that it provides a superior combination of temporal, spatial, and velocity resolution. Propagation velocities <45 cm/s are consistent with diastolic dysfunction in older (>30 years) persons, whereas Vp <55 cm/s is abnormal in younger patients.

Doppler tissue imaging is another relatively new ultrasound imaging modality that measures the velocity of the actual myocardium during the cardiac cycle. Myocardial tissue Doppler shifts typically are higher in amplitude and lower in frequency than the traditional blood flow measurements. PWD tissue imaging provides the capability of recording the low velocities of a moving wall structure with a relatively high sampling rate. A PWD sample is taken at the lateral MV annulus, and the peak early diastolic myocardial velocity (E') is measured. In contrast to blood flow velocity profiles that are below the baseline (away from the TEE transducer), Doppler tissue imaging profiles are above the baseline as the MV annulus recoils toward the transducer in diastole.

During diastole, motion of the mitral annulus shows two distinct movements toward the atrial side in patients with sinus rhythm (Fig. 30–12A). During the early diastolic period, the onset of E' coincides with the beginning of mitral inflow. The E' peak velocity precedes the peak velocity of the transmitral E wave. Unlike transmitral inflow velocities, where measured parameters are preload dependent, E' is a good index of LV relaxation and appears to be less sensitive to alterations in preload.

E' <8 cm/s is consistent with diastolic dysfunction (Fig. 30–12B). In addition, a peak early transmitral inflow velocity to peak early diastolic myocardial velocity ratio (E/E') >10 is consistent with diastolic dysfunction. E/E' then can be used to differentiate normal from pseudonormal transmitral flow pattern. E/E' >15 has been shown to be highly specific for elevated LA pressures, whereas E/E' <8 is highly sensitive for normal LA pressures (Fig. 30–13 and Table 30–4).

Mitral Valve

The MV lies in close proximity to the esophagus and is separated from the

TEE probe by the excellent acoustic window offered by the blood-filled LA. The MV is attached to a fibrous ring and consists of two leaflets, one anterior and one posterior. Although morphologically different, the surface areas of the anterior and posterior MV leaflets are nearly identical and together exceed the area of the mitral annulus in a >2:1 relationship.[8,9] The mitral annulus is a 3D, saddle-shaped, ellipsoid structure that changes shape and decreases in area as it descends during systole (Fig. 30–14). Coaptation of the two leaflets is curvilinear, and both leaflets join at the anterolateral and posteromedial commissures (Fig. 30–15).

The subvalvular apparatus consists of two papillary muscles and chordae tendineae. The anterolateral papillary

muscle supplies chordae to the anterior aspect of both the anterior and posterior mitral leaflets; the posteromedial papillary muscle supplies chordae to the posterior aspect of both valve leaflets. Three groups of chordae exist, named in accordance with their insertion points on the MV leaflets (Figs. 30–16 and 30–17). *First-order chordae* attach to the free edge of the leaflets, *second-order chordae* attach to the body of the leaflets, and *third-order chordae* attach near the base of the posterior leaflet only.[10] More than 120 chordal tendons subdivide as they project from each papillary muscle to attach to the free edge and body of both MV leaflets.[8] The subvalvular apparatus is responsible for maintaining valve integrity during systole and plays a crucial role in preserving the overall structure–function relationship of the LV. The MV shares a close anatomic, and at times pathophysiologic, relationship with the AV. In particular, the fibrous skeleton of the heart that gives rise to the anterior MV annulus is intimately associated with both the left and noncoronary cusps of the AV.

In order to accurately diagnose MV pathology, it is crucial to be able to relate TEE images of this valve to specific anatomic regions. Three approaches to 2D examination of the MV by TEE have been published. Although these approaches all have strengths and limitations, they all emphasize the importance of concise, systematic 2D evaluation of the MV in multiple scan planes and from multiple points of view.

Mitral Regurgitation

In the early 1980s, Carpentier introduced a functional classification of mitral insufficiency (Fig. 30–16).[11] Type I MR has normal motion of the leaflets, with MR due to leaflet perforation, usually from endocarditis, or annular dilation, often accompanying LV dysfunction. Type II MR has increased leaflet motion, typically from myxomatous change, leading to either leaflet prolapse or a flail leaflet. Leaflet prolapse, a result of leaflet redundancy and chordal elongation, is defined as doming of the leaflet body above the level of the mitral annulus in systole with the leaflet tip still directed toward the LV. With myxomatous change, the annulus often is significantly dilated in addition to the defect in leaflet tip coaptation. This regur-

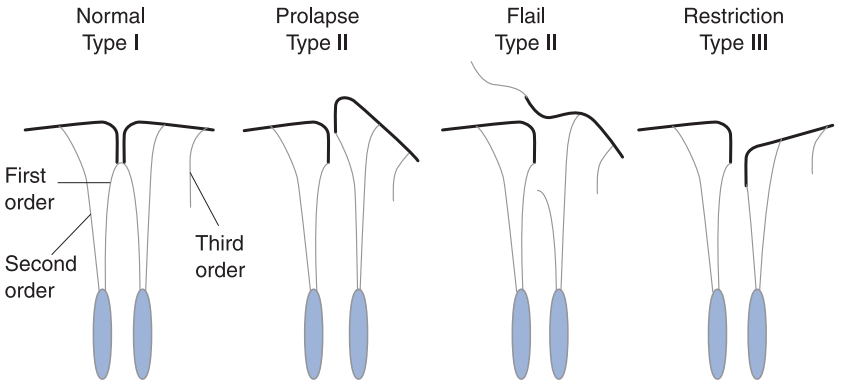

FIGURE 30–16. Normal, prolapsed, flail, and restricted mitral leaflets. The classification of chordae tendineae is also shown.

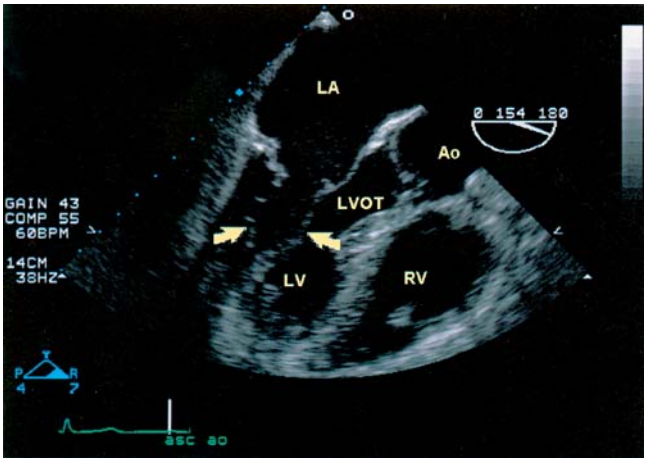

FIGURE 30–17. Midesophageal long-axis view showing subvalvular chordae (*arrows*). Ao, Aorta; LA, left atrium; LV, left ventricle; LVOT, left ventricular outflow tract; RV, right ventricle.

gitant lesion usually evolves slowly and ranges in scale from trivial to severe. A flail leaflet has a leaflet tip directed toward the LA throughout systole. This regurgitant lesion usually is severe with abrupt onset and is poorly tolerated by the patient. Type III MR is characterized by restricted leaflet motion. Type IIIa dysfunction involves restricted leaflet motion during diastole and systole due to rheumatic changes. Type IIIb dysfunction correlates to restricted leaflet motion during systole secondary to papillary muscle displacement in ischemic or dilated cardiomyopathy.

Mitral insufficiency due to global LV dysfunction appears to result from a distorted geometric relationship between the MV leaflets and the papillary muscles. At the gross level, the LV is seen to transform from its usual ellipsoid shape into that of a sphere, causing widening of the interpapillary angle and restriction or tethering of leaflet motion.[12] The valve may appear morphologically normal on 2D imaging, but with loss of the usual systolic leaflet overlap or with a visible coaptation defect. With dilated cardiomyopathy, the regurgitant jet usually is central (Fig. 30–18). Dilation of the annulus may contribute to regurgitation, most notably in the region of the P2 segment, but in most cases is not the major mechanism of regurgitation.

With ischemic MR, dilation of specific areas of myocardium may lead to asymmetric tethering and an eccentric regurgitant jet. Papillary muscle rupture, which most frequently affects the posteromedial muscle, is an occasional complication of myocardial infarction and can result in severe bileaflet regurgitation. The papillary muscle and chordae tips can often be seen flinging into and out of the LA. In hypertrophic obstructive cardiomyopathy, the regurgitant jet usually is directed posteriorly as the anterior leaflet is pulled into the LVOT (systolic anterior motion of the anterior leaflet), resulting in a coaptation defect (Fig. 30–19).

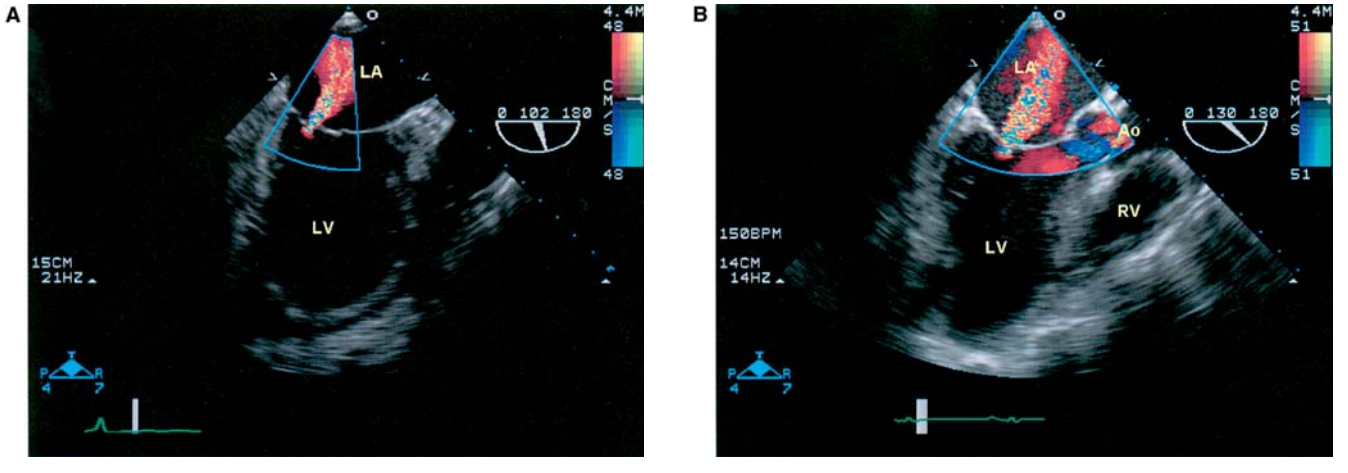

FIGURE 30–18. **A.** Midesophageal two-chamber view with color flow Doppler showing mild mitral regurgitation from left ventricular dilation. **B.** Midesophageal long-axis view with color flow Doppler showing moderate mitral regurgitation. FIGURE 30–19. Midesophageal long-axis view with color flow Doppler revealing mitral regurgitation caused by hypertrophic obstructive cardiomyopathy. Ao, Aorta; IVS, interventricular septum (hypertrophied); LA, left atrium; LV, left ventricle; RV, right ventricle.

MV endocarditis can affect native valves and result in regurgitation because of perforation or deformation of the valve leaflets (Fig. 30–20). Vegetations commonly arise on the upstream side of a valve, which are generally areas of slower flow and therefore are usually seen in the LA. The finding of MV endocarditis mandates careful inspection of the other heart valves to rule out their involvement. Leaflet perforation is identified by the appearance of one or more regurgitant jets that do not seem to arise from the coaptation line. A clue to this particular pathology is the presence of multiple convergence zones on color Doppler.

Echocardiographic examination of the insufficient MV should involve inspection of other structures in the heart that may be altered as a result of the regurgitant process. LA dilation is commonly found in chronic MR of at least moderate severity but is not a feature of acute MR. Left-to-right bowing of the IAS due to elevated LA pressure often can be appreciated in the ME four-chamber or ME bicaval view. Signs of pulmonary hypertension, such as RV and RA enlargement, often accompany progressive MR.

As a significant portion of the systolic volume is unloaded into the LA with severe MR, normal systolic function should appear like a hypercontractile LV. Therefore, an LV with apparently normal systolic function may actually have significant systolic dysfunction. Spherical enlargement of the LV with eccentric hypertrophy signifies long-standing MR in which the compensatory processes of the ventricle are failing.

The severity of MR can be assessed with TEE in a number of ways. One caveat that must be emphasized is that such severity often can be difficult to interpret in the intraoperative period because of the relatively deranged hemodynamic profile of the patient undergoing general anesthesia. Altered loading conditions and cardiac contractility can lead to varying degrees of MR that may be different from those seen in the awake, physiologically normal state. Furthermore, application of severity estimation methods is dependent on the technical expertise of the imaging staff, the complexity involved with the measurement technique, associated limitations with the individual method, and time constraints.

A number of grading systems using CFD have been described, including regurgitant jet length, jet area, jet area as a percentage of LA area, and width of the vena contracta (narrowest diameter of the regurgitant jet at the site of jet formation). The vena contracta is considered the most useful CFD grading system because it effectively estimates the diameter of the regurgitant jet orifice.[13] A vena contracta ≥ 6 mm identifies angiographically severe MR with sensitivity of 95% and specificity 98%. Eccentric regurgitant jets imaged by CFD commonly appear to occupy less overall area compared to jets of similar flow rates directed centrally within the LA.[14] An eccentric jet has a different observed morphology compared to free jets secondary to limited expansion because of impingement of the jet along the atrial wall. Consideration of jet morphology in the CFD assessment is important to avoid underestimating the degree of regurgitation.

A proximal isovelocity surface area (PISA) may be seen on the LV side of the MV during systole as blood flow accelerates toward the regurgitant orifice, causing aliasing with CFD. The product of PISA and the aliasing velocity provides the flow rate through the valve during the measurement. According to the continuity principle, dividing the peak flow rate by the peak regurgitant velocity, as measured by CWD, provides quantitative assessment of the effective regurgitant orifice (ERO):

$ERO = PISA_{MR} * (\text{Aliasing velocity})/(\text{Peak regurgitant velocity})$,

where $PISA_{MR} = 2Pi*r^2$, and r = radius of semicircular shell of color change at the set Nyquist limit.

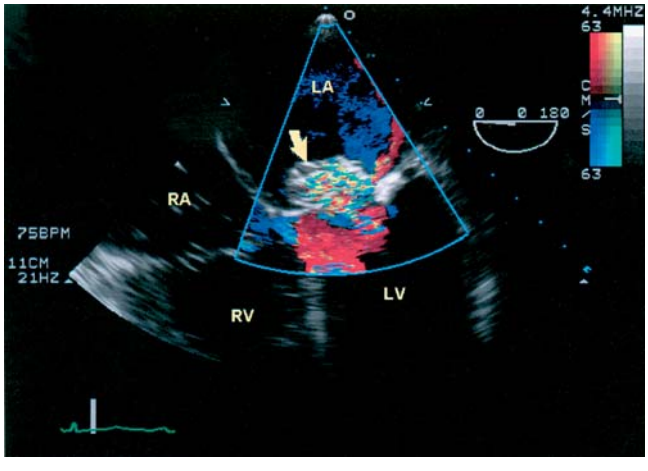

FIGURE 30–20. Midesophageal four-chamber view with color flow Doppler demonstrating mitral regurgitation caused by mitral valve endocarditis (*arrow*). LA, Left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

The continuity principle also can be used to derive regurgitant fractions by determining stroke volumes through various other sites in the heart (notably the LVOT, AV, and pulmonic valve). Stroke volume is calculated as the product of the velocity–time integral (VTI) through an orifice and the calculated orifice area at the same location.

Alterations in the pulmonary venous Doppler profile are useful in quantifying the severity of MR. Trivial or mild regurgitation is generally associated with a normal flow velocity pattern (peak S wave > peak D wave), moderate regurgitation is associated with systolic blunting (peak S wave < peak D wave), and severe regurgitation is associated with S-wave reversal (S wave directed away from transducer as regurgitant blood flows retrograde into the pulmonary vein).[15] It is advisable to interrogate at least one pulmonary vein from each side of the LA because regurgitant jets may preferentially affect the pulmonary venous profile of one side over the other.

Peak E-wave velocity is another parameter that can be used to qualitatively assess the degree of MR. When the degree of MR increases, the added regurgitant volume across the MV increases the pressure gradient between the LA and the LV. This increase in pressure gradient subsequently increases early mitral inflow velocity. E-wave velocity >1.2 m/s identified patients with severe MR with sensitivity of 86%, specificity 86%, positive predictive value 75%, and negative predictive value 92%.[16]

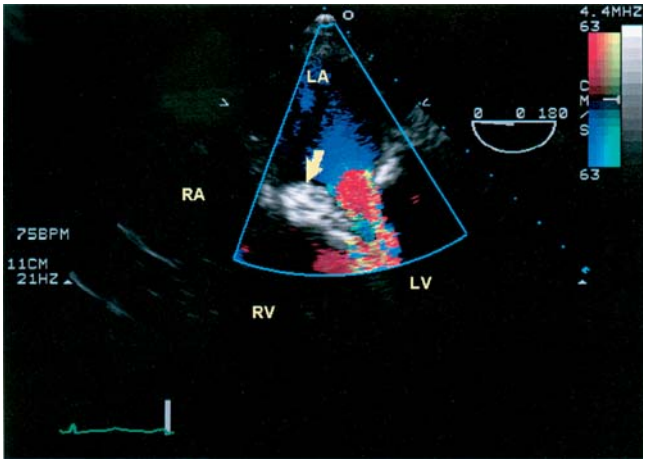

FIGURE 30–21. Midesophageal four-chamber view with color flow Doppler demonstrating mitral stenosis from mitral valve endocarditis (*arrow*). LA, Left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

Mitral Stenosis

Most cases of hemodynamically significant native MV stenoses are due to rheumatic heart disease. Uncommon causes include severe mitral annular calcification, obstructing lesions such as LA tumors and endocarditis vegetations (Fig. 30–21), and congenital deformities such as parachute MV or cor triatriatum. Surgical correction can involve either open commissurotomy or valve replacement. In addition to confirming the severity of the stenosis, it is equally if not more important to evaluate the heart for evidence of LA thrombus (particularly within the LA appendage), RV and LV function, presence and severity of tricuspid regurgitation (TR), and degree of residual stenosis or regurgitation following valve repair or replacement.

Common echocardiographic findings of rheumatic MV stenosis (Fig. 30–22A) include leaflet thickening and calcification, leaflet restriction, and subvalvular involvement (shortening, tethering, and calcification of the chordae). The resulting failure of leaflet coaptation causes a regurgitant jet that is directed toward the side of the lesion (Fig. 30–22B). These leaflet changes are best seen in the ME four-chamber and long-axis (LAX) views. Subvalvular involvement usually is best visualized from the TG two-chamber view. The TG basal SAX view may reveal calcification in the region of the commissures. Rheumatic heart disease also may involve the pericardium, myocardium, and other heart valves.

Associated findings in mitral stenosis include atrial dilation, pronounced

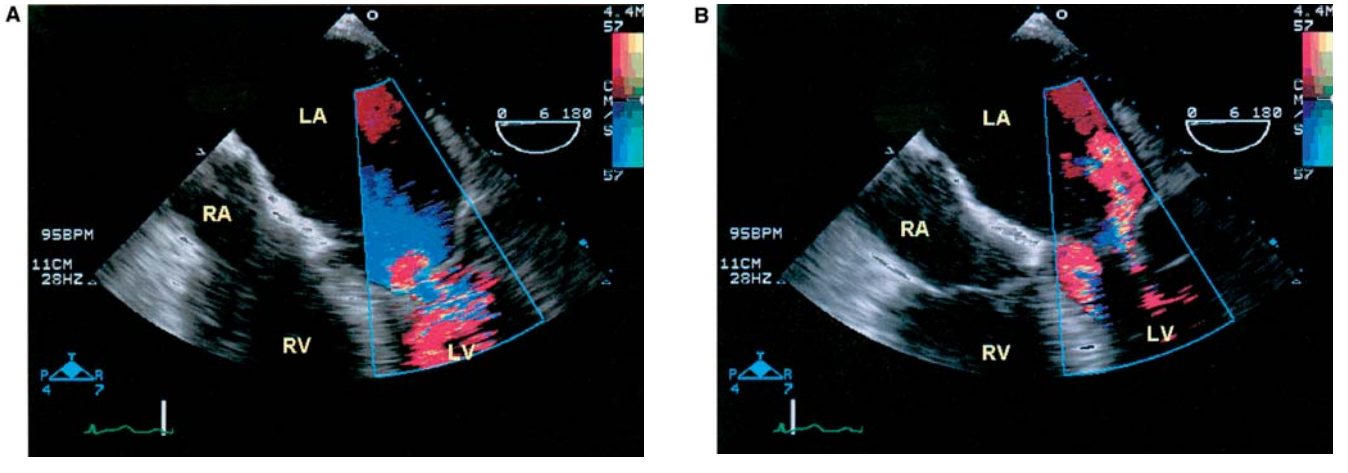

FIGURE 30–22. **A.** Midesophageal four-chamber view with turbulent flow through a stenotic rheumatic mitral valve. **B.** Midesophageal four-chamber view with color flow Doppler demonstrating mitral regurgitation in a patient with rheumatic heart disease. LA, Left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

left-to-right bowing of the IAS, spontaneous echo contrast in the LA (with or without atrial thrombus), and signs of pulmonary hypertension (right-heart dysfunction).

A number of methods are available to the echocardiographer for assessing the severity of mitral stenosis. Mean transmitral pressure gradients are easily estimated from the transmitral CWD profiles using the simplified Bernoulli equation:

Mean pressure difference = 4(Mean transmitral velocity)^2.

Severe MV stenosis is associated with mean transvalvular gradients >12 mm Hg.

The pressure half-time denotes the rate of diastolic pressure decline across the MV, specifically the time required to reach 50% of the peak pressure gradient. Normally the diastolic E wave undergoes rapid deceleration due to the abrupt fall in transmitral pressure gradient as the LV fills during early systole. However, in mitral stenosis, the pressure gradient is sustained much later in diastole, giving rise to a greatly prolonged E-wave deceleration and thus longer pressure half-time. Angiographic experiments have shown that an MV area of 1 cm^2 corresponds to a pressure half-time of 220 ms; thus, the area of the stenotic orifice can be estimated by dividing 220 by the pressure half-time in milliseconds.[17]

The continuity equation can be used in conjunction with the peak transmitral E-wave velocity and PISA measurements to estimate the stenotic orifice area. Providing there is no significant aortic or pulmonary regurgitation or interventricular shunts, the continuity equation also can use stroke volumes of the LVOT, AV or pulmonary valve, and the measured VTI of transmitral inflow to estimate the area of the stenotic mitral orifice.

Aortic Valve

High-resolution images of the AV are provided by TEE because the valve and probe are separated by the LA, which acts as an excellent acoustic window. The AV is composed of three leaflets or cusps that are suspended from the aortic wall along three crescent-shaped lines. The junctions of the free edges of the cusps are called the *aortic commissures.* Behind each leaflet is the respective sinus of Valsalva, a pouch-like dilation of the aortic root. The leaflets and sinuses are named according to the adjacent coronary artery (i.e., left, right, and noncoronary cusps and sinuses).

Four standard views allow examination of the AV and LVOT. Beginning with the imaging depth set at 10–12 cm, the ME AV SAX view is obtained by advancing or withdrawing the probe with a multiplane angle of 30–50° until the AV appears in the center of the screen (Fig. 30–23). All three cusps should be seen symmetrically by rotating the multiplane angle and slightly anteflexing the probe. The general morphology of the AV (bicuspid, tricuspid) is noted as well as the thickness and mobility of the leaflets. CFD is applied to detect flow disturbances indicating aortic regurgitation or stenosis. The AV orifice may be traced to measure valve area.

The ME AV LAX view is obtained by rotating the multiplane angle forward 90° from the ME AV SAX to visualize the LVOT, AV, and proximal ascending aorta in long axis (Fig. 30–24). The AV leaflets appear as two thin lines opening parallel to the aortic walls. The right coronary cusp, being farthest from the probe, is visualized toward the bottom of the display. The left or noncoronary cusp (depending on the imaging plane), located closer to the probe, is seen toward the top of the display. The diameters of the LVOT, aortic annulus, sinotubular junction, and ascending aorta can be measured in this view. The annulus is measured where the leaflets insert into the aorta. The proximal ascending aorta should be evaluated for calcification, atheroma, intimal flap or dissection, and aneurysmal dilation. CFD is again applied to detect the flow pattern through the LVOT, AV, and ascending aorta. Turbulent LVOT flow in this view should prompt further evaluation for hypertrophic obstructive cardiomyopathy or another obstruction to LVOT flow. Systolic anterior motion of the MV (often a fluttering motion into the LVOT, but sometimes apparently occluding the LVOT), associated MR, premature AV closure, and thickened interventricular septum (>1.2 cm, disproportionate from the free wall) confirm hypertrophic obstructive cardiomyopathy.

The deep TG LAX view can be obtained by advancing the probe tip deep into the stomach and then anteflexing to create an imaging plane originating from the LV apex with the AV appearing in the far field. Alternatively, the TG LAX view is obtained from the TG midpapillary SAX view by rotating the angle forward to 90–110° until the AV comes into view in the far field to the right side of the image. Both of these TG views allow for parallel alignment of the ultrasound beam through the AV, making them most useful for measuring Doppler flow velocities through the LVOT and AV rather than visualizing anatomy. Positioning the PWD sample volume in the center of the LVOT allows Doppler flow measurement in the outflow tract. Flow velocity through the AV is measured with CWD. Either or both of these TG views may be difficult to obtain in some patients, and a severely stenotic AV may make Doppler interrogation difficult. CFD may be helpful in detecting

flow through the stenotic orifice, facilitating appropriate placement of the Doppler beam.

Aortic Insufficiency

Acute or chronic regurgitation may result from abnormalities of the AV and the aortic root (Fig. 30–23). Aging, rheumatic heart disease, endocarditis, or congenital bicuspid or unicuspid AV all may lead to aortic regurgitation. Dilation of the aorta resulting from connective tissue diseases (Marfan syndrome, Ehlers-Danlos syndrome), sinus Valsalva aneurysm, aortic root abscess, and hypertension are other causes of aortic insufficiency (AI).

Two-dimensional imaging should be applied in the ME AV SAX and LAX views to detect congenital abnormalities or acquired defects such as myxomatous degeneration and vegetations. The aortic root should be assessed for dilation, and measurements of the LVOT, AV annulus, sinotubular junction, and ascending aorta should be obtained. The area of the end-diastolic gap between the aortic cusps, measured by planimetry, correlates with the severity of AI (mild <0.2 cm^2, moderate 0.2–0.4 cm^2, severe >0.4 cm^2).

The vena contracta should be measured by CFD in the ME LAX view with the imaging depth reduced. A vena contracta <0.3 cm indicates mild AI, whereas a value >0.6 cm signifies severe AI. The ratio of the regurgitant jet area to the LVOT area also can be measured by CFD in the ME LAX view. Similarly, the width of the regurgitant jet can be compared to the width of the LVOT. Values $>60\%$ and $>65\%$ for area and width, respectively, indicate severe AI.

The pressure half time (PHT), described previously to grade mitral stenosis, can be applied to grade the severity of AI. The more severe the AI, the shorter the PHT because the aortic diastolic pressure gradient declines more rapidly. PHT is best obtained in the TG LAX or deep TG LAX views with CWD. PHT >500 msec indicates mild AI, whereas PHT <200 msec is compatible with severe AI. PHT measurements can be misleading in patients with elevated LV end-diastolic pressure (diastolic dysfunction). In these instances, the gradient will dissipate rapidly, and the true severity of regurgitation may be overestimated.

Early diastolic flow reversal in the descending aorta, measured with PWD, may be a normal finding. However, holodiastolic flow reversal in the proximal abdominal aorta/distal thoracic aorta indicates severe AI.

Aortic Stenosis

Calcific degeneration of the AV, the most common cause of AS, is characterized by restricted leaflet motion and calcification along the free edges of the leaflets. Patients with calcific degeneration usually become symptomatic in their sixth to seventh decade of life.

Rheumatic AS typically is seen in middle-aged immigrants. The tips of the leaflets are thickened and calcified and the commissures are fused, producing a characteristic "doming" during systole. The orifice may become circular instead of the normal triangular shape. Rheumatic AS almost always is associated with rheumatic involvement of the MV.

Congenital abnormalities of the AV may lead to AS. Bicuspid AV is the most common form, occurring in approximately 2% of the normal population, and symptoms usually occur in the fourth to sixth decades of life. The bicuspid AV orifice is elliptical, and a calcified raphe is often present on one of the leaflets, giving the false impression of a trileaflet valve (Fig. 30–25).

TEE interrogation should start with 2D imaging in the ME AV SAX and LAX views. Thin and mobile AV leaflets without calcification usually exclude severe AS. Thickening, calcification, and restricted leaflet motion are seen in all cases of AS. Commissural fusion is seen in rheumatic valvulitis. Poststenotic dilation of the aortic root and the proximal ascending aorta may be present. The AV area can be measured by planimetry in the ME AV SAX view using the zoom mode to magnify the frozen image. The inner edges of the distal leaflets should be traced in systole during their greatest excursion. Severe thickening and calcification of the leaflets, shadowing, accentuated cardiac motion, and the inability to obtain a true SAX view near the leaflet tips all may make planimetry difficult and inaccurate. In the ME AV LAX view, leaflet morphology, mobility, calcification, and thickening also can be evaluated. The LVOT can be examined for subaortic pathology.

Turbulent, high-velocity flow can be seen in the proximal ascending aorta with severe AS. Pressure gradients and transvalvular velocity should be measured. To accomplish this, the CWD

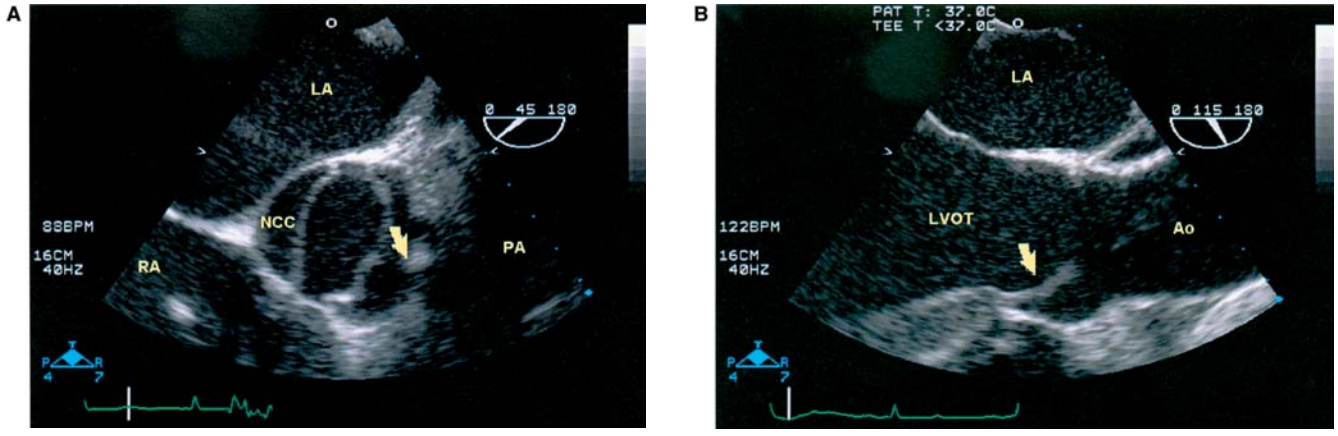

FIGURE 30–25. **A.** Midesophageal aortic valve short-axis view showing the elliptical opening of a bicuspid aortic valve. Arrow indicates calcification along raphe where right and left aortic valve cusps appear fused into a single cusp. **B.** Midesophageal aortic valve long-axis view showing bowing of the restricted bicuspid aortic valve leaflet (*arrow*). beam is positioned across the AV in the TG LAX or deep TG LAX views (Fig. 30–26), and the edge of the spectrum is traced to obtain the peak and mean pressure gradients and flow velocities. Severe AS corresponds to a peak velocity >4 m/s (Fig. 30–27A). The VTI of the traced spectrum is calculated and corresponds to the distance traveled by a column of blood during the stroke cycle. This allows use of the continuity principle to calculate the effective AV cross-sectional area (CSA_{AV}). The continuity principle is based on the conservation of flow over time between two conduits within a closed circuit (AV and LVOT in this example). Because flow is the product of the cross-sectional area of the conduit and the VTI through the conduit:

$$CSA_{LVOT} \times VTI_{LVOT} = CSA_{AV} \times VTI_{AV},$$

where $CSA = \pi r^2$, and r = radius of the respective conduit.

The radius of the LVOT can be measured in the ME LAX view. VTI_{LVOT} can be obtained in the TG LAX or deep TG LAX views using PWD. VTI_{AV} can be directly measured with CWD from the deep TG view. Alternatively, a "double-envelope" technique can be used to simultaneously measure LVOT and AV VTIs by CWD in the TG LAX or deep TG LAX views (Fig. 30–27C). Because the velocity of flow through the smaller AV must accelerate from that of the larger-diameter LVOT, the larger envelope must correspond to the VTI of the AV, and the smaller, but denser, envelope represents the VTI of the LVOT.

Aorta

The aorta is the largest artery in the body with a normal diameter up to 3.5 cm. It is divided anatomically into four segments: ascending aorta, transverse aortic arch, descending thoracic aorta, and abdominal aorta. The ascending aorta begins at the level of the aortic annulus and the aortic valve. Just distal to the aortic annulus, the ascending aorta dilates to form a segment known as the *aortic sinus of Valsalva,* which includes the respective left coronary, right coronary, and noncoronary sinuses. Distal to the aortic sinuses, the aorta has a brief segment with a reduced diameter called the *sinotubular junction.*

In adults, the ascending aorta is approximately 5 cm in length. After originating from the AV annulus, the ascending aorta extends rightward around the main pulmonary trunk and crosses the right pulmonary artery anteriorly. It then ascends rightward and anteriorly until it meets the aortic arch at the origin of the innominate artery (at the level of the second intercostal space). The proximal or near aortic arch is poorly visualized with TEE because of the anatomic interposition of the trachea between the esophagus and the aorta at this level. Whereas the innominate and left common carotid arteries are in close proximity to the trachea, the left subclavian artery lies to the left of the trachea and can be visualized more easily with TEE.

The descending thoracic aorta begins distal to the left subclavian artery at the level of the ligamentum arteriosus. This is an area of narrowing referred to as the *aortic isthmus.* The ligamentum arteriosus is a fibrous connection between the pulmonary artery and the aorta, a remnant of the ductus arteriosus during fetal life. Inferior to the isthmus, the descending aorta courses to the left lateral side of the body of the fourth thoracic vertebrae. The descending aorta is relative-

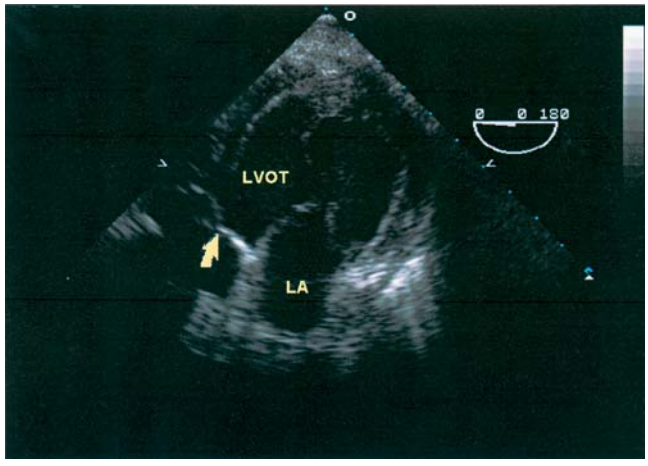

FIGURE 30–26. Deep transgastric long-axis view with aortic valve leaflets (*arrow*) seen on the left. LA, Left atrium; LVOT, left ventricular outflow tract.

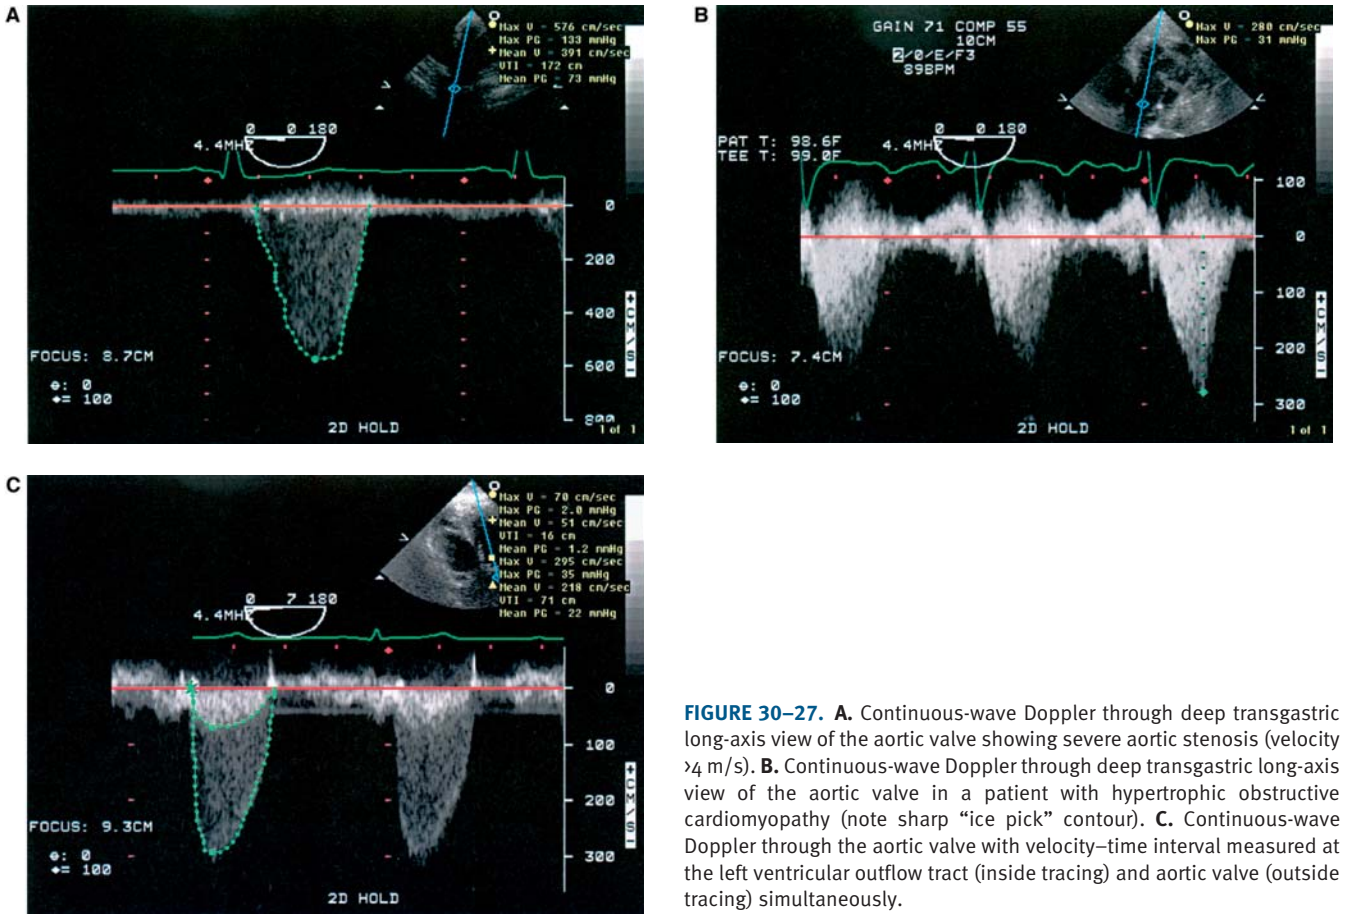

FIGURE 30–27. **A.** Continuous-wave Doppler through deep transgastric long-axis view of the aortic valve showing severe aortic stenosis (velocity >4 m/s). **B.** Continuous-wave Doppler through deep transgastric long-axis view of the aortic valve in a patient with hypertrophic obstructive cardiomyopathy (note sharp "ice pick" contour). **C.** Continuous-wave Doppler through the aortic valve with velocity–time interval measured at the left ventricular outflow tract (inside tracing) and aortic valve (outside tracing) simultaneously.

ly transfixed to the vertebral column here. Therefore, deceleration injuries often occur at the level of the isthmus. The descending aorta continues along a slightly anterior and rightward path as it approaches the diaphragm, where it lies directly posterior to the esophagus. Therefore, at the level of the lower esophageal sphincter, the heart and the aorta are on opposite sides of the esophagus.

The Society of Cardiovascular Anesthesiologist and the American Society of Echocardiography have defined six views for interrogating the thoracic aorta by TEE.[4] Multiple imaging planes from within similar views may be necessary to accurately define aortic pathology.

The ME ascending aorta SAX view is obtained in the 0–30° imaging plane with the probe approximately 25 cm from the lips. In this view, an SAX view of the ascending aorta along with the main pulmonary artery, right pulmonary artery, and SVC is obtained. Qualitative analysis of the aortic anatomy and wall thickness can be obtained in this view.

The ME ascending aorta LAX view is obtained between 110° and 140°. This view is easily obtained after starting with the ME AV SAX view ("Mercedes-Benz" view), which is easily recognized at the ME level with the multiplane angle at 20–50°. Once the "Mercedes-Benz" view is obtained, rotating the imaging plane forward an additional 90° and withdrawing the probe slightly yields the ME ascending aorta LAX view (Fig. 30–28). This view is useful in defining wall thickness, aortic dimensions, and blood flow patterns in the ascending aorta.

From the ME ascending aorta views, turning the probe to the left with a multiplane angle of 0° produces an SAX image through the descending aorta. Once the aorta is visualized, the depth of the image should be optimized so that the aorta is in the center of the screen. Inserting the probe to the level of the diaphragm (where the image disappears) and then slowly withdrawing the probe allows scanning of the entire descending thoracic aorta. The SAX view is useful for defining wall thickness, determining atherosclerotic severity, and measuring aortic dimensions (Fig. 30–29A).

From the SAX view, rotating the plane to 90° produces an LAX view of the descending aorta (Fig. 30–29B). These views are useful for defining spatial relationships of SAX findings, interrogating aortic flow patterns, and identifying branch vessels.

With the scan plane at 0°, withdrawal of the probe following the aorta to an upper esophageal window with a rightward rotation produces an LAX view of the aortic arch. This view is used to define aortic dimensions, wall contour, and branch vessels. Advancing the multiplane angle to 90° in the upper esophagus produces an SAX view of the arch. At the proximal arch, the main pulmonary artery and right pulmonary artery may be seen if the depth is sufficient (Fig. 30–33A). At the distal arch, multiple views of the arch and its branch vessels may be obtained.

Even using all of these views, TEE does not image the entire thoracic aorta. A "blind spot" in the distal ascending/proximal arch is created by the trachea. The aorta also is subject to echocardiographic artifacts and dropout caused by calcifications. With every image, the examiner should describe the morphology, dimensions, and integrity of the aortic wall. Evalu-

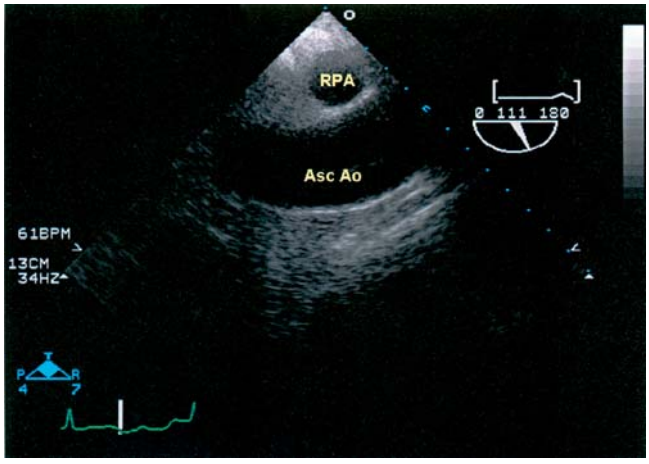

FIGURE 30–28. Midesophageal ascending aorta long-axis view. Asc Ao, Ascending aorta; RPA, right pulmonary artery.

ation for spontaneous echocardiographic contrast or turbulent flow also is recommended. Any fluid collection should be noted.

The association between atherosclerosis of the aorta and systemic embolization is prevalent in the literature. Katz et al.[18] showed a link between the severity of atherosclerotic atheroma and the incidence of perioperative stroke. In addition, atherosclerosis of the ascending aorta is an independent predictor of long-term neurologic outcomes and morbidity following cardiac surgery.[19] If atheroma is not detected by TEE examination of the aorta, then significant atheroma in the ascending aorta (where cannulation, cross-clamping, and most aortic manipulation occurs for cardiopulmonary bypass) is unlikely.[20] Conversely, if significant atheroma is found in the thoracic aorta upon TEE examination, then there is a 34% chance of significant atheroma in the ascending aorta, and epiaortic scanning should be strongly considered.

Many different classification systems for aortic atheroma severity have been proposed. The most widely used system was proposed by Katz et al.,[18] consisting of a five-grade classification system. A grade I atheroma has minimal or no intimal thickening. A grade II atheroma has severe intimal thickening without a protruding element. A grade III atheroma has intimal thickening protruding <5 mm into the lumen. A grade IV atheroma protrudes >5 mm into the lumen. A grade V lesion is any atheroma with a mobile component. Although currently there is no consensus as to the size of plaque that should warrant alteration of the surgical procedure, large atheromas and atheromas with mobile elements should warrant discussion with the surgeon.

Direct ultrasound of the aorta via a high-frequency probe placed directly on the aorta (epiaortic scanning) can be used to gain additional information during procedures that use a sternotomy. An epiaortic probe is guided into a sterile sleeve on the operating field. Gel or water is used to create a standoff from the probe to the aorta in order to visualize the anterior wall of the aorta. The aorta is best visualized in both the LAX and SAX views. The image should be optimized so that the aorta is in the center of the screen. The cross-clamp site and antegrade cardioplegia site should be interrogated. These sites often fall in the region of the aorta that is difficult to image with TEE because of the interposed trachea. If atherosclerotic lesions that could be embolic sources are present, manipulation of these areas should be avoided.

TEE is useful for diagnosis and classification of thoracic and abdominal aneurysms (Fig. 30–30). An aneurysm of the aorta involves an increase in the luminal diameter of all three layers of the aorta. A pseudoaneurysm involves an interruption of the intima and media at the level of the aneurysmal sac and its communication with the native aorta. An ascending aortic diameter >4 cm, descending thoracic aneurysm >6 cm, or abdominal aortic aneurysm >5 cm in diameter is considered an indication for surgical intervention.

Dissection of the aorta is a process in which the intima separates from the adventitial layer. It is characterized by the presence of an intimal flap and resulting false and true lumens. Aortic dissection can result from intimal rupture followed by cleavage formation and propagation of the dissection into the media. Additionally, aortic dissec-

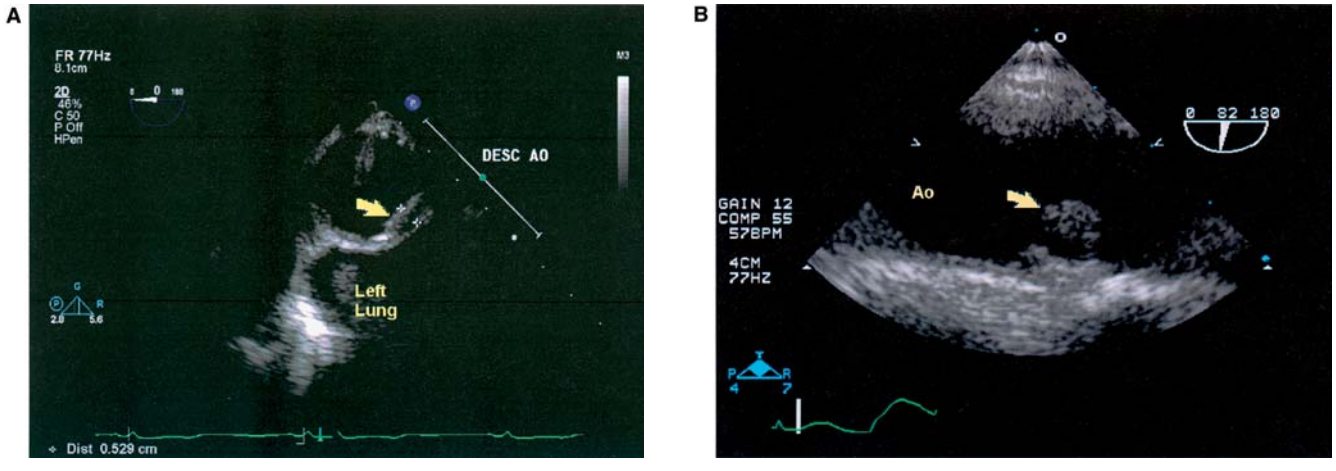

FIGURE 30–29. **A.** Descending aorta short-axis view with atheroma (*arrow*). **B.** Descending aorta long-axis view with atheroma (*arrow*). Ao, Lumen of aorta.

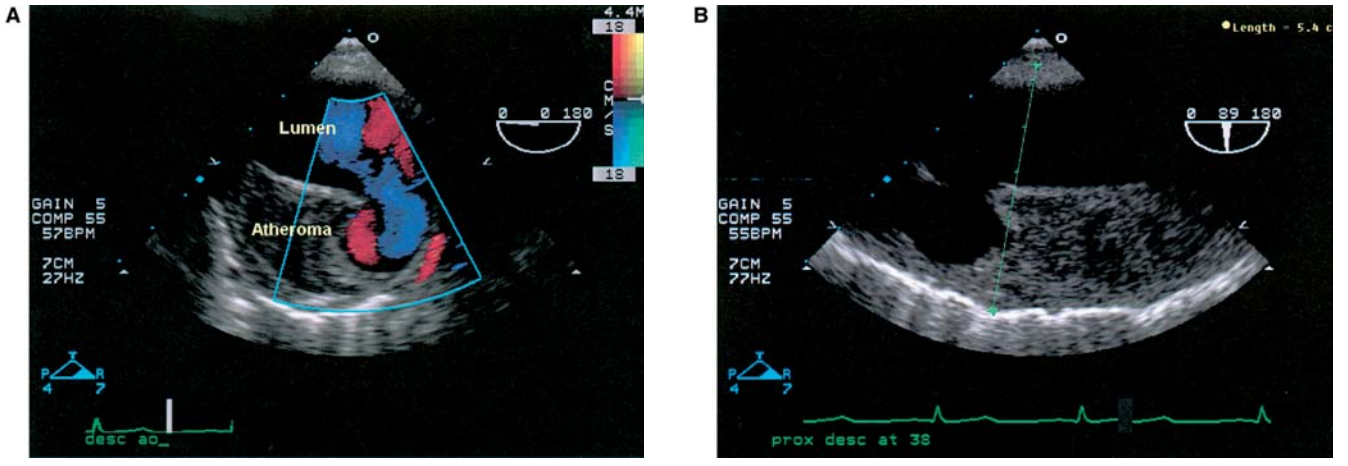

FIGURE 30–30. Short-axis (**A**) and long-axis (**B**) views of a descending thoracic aorta aneurysm with ulcerated atheroma.

tion can result from intramural hemorrhage and hematoma formation in the media, subsequently followed by perforation of the intima. The presence of an intimal flap is the most characteristic feature of aortic dissection. The pathogenesis of dissection is complex. Medial degeneration tends to be more extensive in older individuals and in patients with hypertension, Marfan syndrome, and bicuspid AVs.[21] The true lumen diameter typically is smaller than the false lumen diameter (Fig. 30–31A), and spontaneous contrast can often be seen in the false lumen. However, PWD should be used to confirm forward flow in the presumed true lumen during systole (Fig. 30–31B).

Aortic dissection is divided into acute and chronic types, depending on the duration of symptoms. Acute aortic dissection is present when the diagnosis is made within 2 weeks after the initial onset of symptoms. Approximately one third of patients with aortic dissection fall into the chronic category, in which symptom duration is >2 weeks. The most common site of initiation of aortic dissection is the ascending aorta (50%), followed by aortic regions in the vicinity of the ligamentum arteriosum.

Anatomically, aortic dissection has been classified by two schemes. The DeBakey classification consists of the three types: type I includes both the ascending and the descending aorta, type II includes only the ascending aorta, and type III includes only the descending aorta. The Stanford classification consists of two types: type A involves the ascending aorta regardless of the entry site location, and type B involves the aorta distal to the origin of the left subclavian artery. Any dissection involving the ascending aorta (DeBakey types I and II or Stanford type A) is an indication for repair, whereas dissections confined to the descending aorta can be medically managed, at least initially.

Endovascular repair of the aorta has gained popularity as a reliable alternative to conventional repair. TEE is used to supplement intraoperative angiography in guiding placement of thoracic endografts. During endovascular repair, TEE is the most sensitive imaging modality currently available for diagnosing endoleaks immediately after graft deployment. The ability to use intraoperative TEE for visualizing the thoracic and abdominal aorta and monitoring cardiac function makes it an invaluable tool during these procedures.[22]

Right Ventricle

The RV is crescent shaped, thin walled, and compliant. It is less contractile compared to the LV. Its oxygen requirements are lessened by its reduced muscle mass and lower afterload. The right coronary artery (RCA)

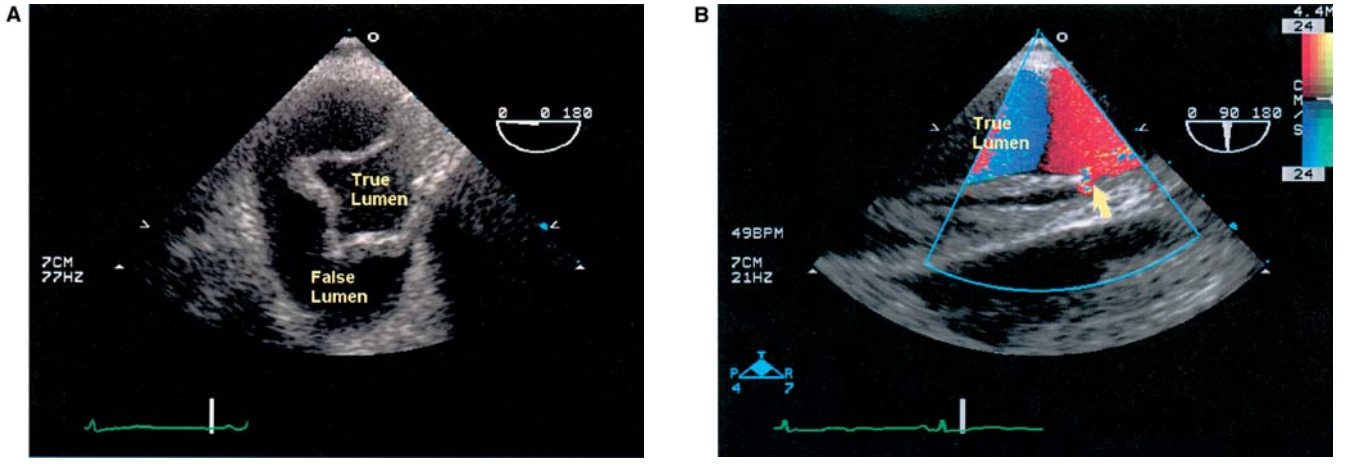

FIGURE 30–31. **A.** Descending aorta short-axis view of an aortic dissection. **B.** Descending aorta long-axis view of an aortic dissection at the level of an intimal tear (*arrow*).

supplies the RV free wall, the posterior descending artery supplies the inferior RV wall, and the anterior RV wall has a dual blood supply from the conus branch from the RCA and the moderator branch from the left anterior descending artery.[23] The RV is a low-pressure system, with an average pressure of 20/5 mm Hg. Therefore, coronary flow to the RV from the aorta follows this favorable pressure gradient, resulting in perfusion during both diastole and systole, unlike the high-pressure LV, which is perfused only during diastole.[24,25] RV contraction resembles peristaltic motion, which functions to prolong ejection time by ejecting blood even as proximal RV pressures decline, thus minimizing end-diastolic pressure and promoting venous return.[26] RV ejection results primarily from RV free wall inward motion, with a smaller contribution from descent of the base of the heart.

The RV is sensitive to changes in afterload and susceptible to coronary air embolism because of the anterior location of the RCA takeoff. Furthermore, the RV t is difficult to protect during cardiac surgery. Evaluation of the RV is a necessary part of a comprehensive TEE examination because RV dysfunction in cardiac surgery correlates with mortality.[27] However, because of its anterior position far from the TEE probe and its geometric complexity due to its crescent shape and twisting contraction, assessment of the RV with TEE is more challenging than that of the LV.

TEE examination of the RV is primarily performed qualitatively by assessing the RV in long axis with the ME four-chamber (Figs. 30–2B and 30–32B) and TG RV inflow views, as well as in short axis with TG mid-SAX (Fig. 30–34) and ME RV inflow–outflow views (Fig. 30–3B). The RV free wall is best viewed from the ME four-chamber and TG mid SAX views. When assessing RV function, RV dilation, presence of interatrial and/or interventricular septal shift to the left, RV wall-motion abnormalities, significant tricuspid insufficiency, and IVC engorgement indicate dysfunction.[28–30] *RV hypertrophy* is defined as end-diastolic free wall thickness >0.5 cm (or greater than half the thickness of the LV).

RV dilation is indicated by an RV diastolic diameter that exceeds the LV diastolic diameter in the TG mid-SAX view. RV dilation also can be graded from the ME four-chamber view. The normal-sized RV will not form part of the heart apex. If the apex of the heart includes the RV apex, then moderate RV dilation is present; if the apex is entirely formed by the RV, then severe dilation is present.[31]

Semiquantitative assessment of RV systolic function is described by the RV fractional area of contraction in the ME four-chamber view and the tricuspid annular plane systolic excursion (descent of the tricuspid annulus) in the ME four-chamber view. In a retrospective study, RV fractional area of contraction <35% was associated with poorer outcomes.[32] Tricuspid annular plane systolic excursion >25 mm correlates with normal RV EF.[33] However, because of the complexity of the RV anatomy, these measurements may be inaccurate, so a comprehensive qualitative assessment must be performed.

Tricuspid Valve

The tricuspid valve (TV) consists of anterior, posterior, and septal leaflets; the largest is the septal leaflet (Fig. 30–32A). In the presence of normal leaflets, TR is termed *functional* and is commonly due to RV dilation and/or dysfunction. In contrast, TR due to leaflet abnormalities is rare.

Like the RV, the TV lies in the far field, making 2D imaging difficult. In the ME four-chamber view, the anterior (or sometimes posterior) and septal leaflets are seen. In the ME RV inflow–outflow view, the posterior and anterior leaflets are seen on the left and right of the image screen, respectively (Fig. 30–3B). In the TG RV inflow view, the posterior leaflet is in the near field, and the anterior leaflet is in the far field.

Grading TR should consider many factors, including RA and RV size, hepatic flow patterns, vena contracta, and jet area. Severe TR correlates well with systolic flow reversal in the hepatic veins, a vena contracta measuring >6.5 mm in the apical four-chamber view , and TR jet area more than two thirds of RA area.[34,35] In addition, TV annulus >4 cm and tricuspid inflow velocity >1 m/s by CWD is associated with severe TR.[36]

In the absence of pulmonic stenosis, the pulmonary artery systolic pressure can be estimated if TR is present. To accomplish this, the peak pressure gradient is calculated and added to the measured central venous pressure. To

obtain the peak pressure gradient across the TV, the modified Bernoulli equation is applied to the peak TR jet velocity measured by CWD.

With regard to tricuspid stenosis, a mean inflow pressure gradient <2 mm Hg is considered mild, 2–6 mm Hg is moderate, and >6 mm Hg is severe. CWD is used to measure TV inflow velocities, which are used to determine pressure gradients. Multiple views should be interrogated to obtain the best alignment with diastolic inflow and, therefore, more accurate measurements.

Pulmonic Valve

The pulmonic valve is trileaflet, consisting of anterior, left, and right leaflets. Significant pulmonic disease in the adult without congenital heart disease is rare. As with the other right-sided structures, the pulmonic valve is anterior and difficult to image with TEE. The best views for visualizing the pulmonic valve are the ME RV inflow–outflow view (Fig. 30–3B) and upper esophageal aortic arch SAX view (Fig. 30–33A).

In the adult, pulmonic regurgitation usually is due to pulmonary hypertension and annular dilation. The examination should include the regurgitant jet vena contracta, jet length, RV size, and degree of CWD flow deceleration. Holodiastolic flow reversal in the main pulmonary artery (measured with PWD in the upper esophageal aortic arch SAX view) is indicative of significant pulmonic insufficiency.

Pulmonic stenosis is rare in the adult and is classified as valvular, subvalvular, or supravalvular. CWD is used in the upper esophageal aortic arch SAX view to obtain a peak pressure gradient (mild stenosis <30 mm Hg, moderate 30–64 mm Hg, severe >64 mm Hg).

Pulmonary Artery

Evaluation of the main and right pulmonary arteries is performed from the upper esophageal ascending aorta SAX view. The left pulmonary artery is difficult to image because it usually is obscured by air in the left mainstem bronchus. In the adult, the main pulmonary artery is approximately 5 cm in length. The normal main and right pulmonary artery dimensions are 0.9–2.9 cm and 1.2–2.2 cm, respectively. TEE has 80% sensitivity and 100% specificity for the diagnosis of pulmonary embolus, but its low negative predictive value of 53% makes this modality unsuitable for ruling out pulmonary embolus.[37]

Pericardium

The pericardial sac is a potential space between visceral and parietal pericardium. Pericardial effusion is a syndrome in which fluid accumulates in the pericardial sac. A wide variety of disease processes can lead to pericardial effusion. Depending on the size and speed of accumulation, a pericardial effusion can compromise venous return and lead to low cardiac output. Tamponade occurs when pericardial pressure exceeds the distending pressure of the cardiac chambers, resulting in impaired diastolic cardiac filling. Echocardiography is helpful for diag-

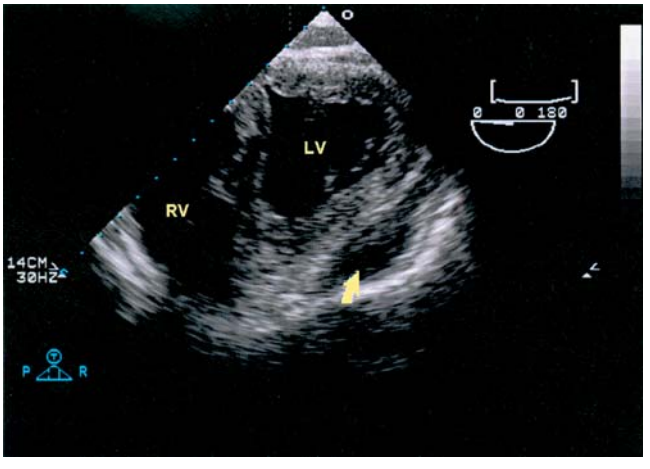

FIGURE 30–34. Transgastric short-axis view revealing a significant pericardial effusion (*arrow*). The right ventricle (RV) is enlarged, and the D-shaped left ventricle (LV) indicates elevated right ventricular pressures.

nosing pericardial effusion and cardiac tamponade, but cardiac tamponade ultimately is a clinical diagnosis.

Pericardial effusions can be visualized as an echolucent space surrounding the echogenic external border of the heart chambers (Fig. 30–34). A thorough TEE examination, including ME four-chamber, ME two-chamber, ME LAX, and TG basal SAX views, should be performed for evaluation of pericardial cavity and surrounding structures. Effusions that separate the visceral pericardium from the parietal pericardium by < 0.5 cm are small, and those with > 2-cm separation are large.

Characteristic echocardiographic findings of cardiac tamponade are RA systolic collapse, RV diastolic collapse, abnormal ventricular septal motion, and reciprocal respiratory variation in ventricular volumes. RA systolic collapse usually develops before RV diastolic collapse. Because of the tethering effect of the pulmonary veins, LA collapse is rare and implies the presence of a large effusion. PWD of mitral inflow velocity and pulmonary vein flow velocity also show a pronounced respiratory variation pattern in cardiac tamponade.

CONCLUSION

Intraoperative echocardiography has rapidly evolved over the last 3 decades since its introduction in the early 1970s and has become a standard of practice for cardiac anesthesia care. In addition, it now holds a place as an important and increasingly routine adjunct to noncardiac anesthesia practice. Whereas modalities such as 3D, tissue Doppler, and contrast have enabled expanded application of this diagnostic imaging technique for intraoperative anatomic, physiologic, and hemodynamic capabilities, new systems that are less expensive, portable, and user friendly have enabled the expansion of intraoperative echocardiography to a greater variety of settings. Today, hand-held as well as portable systems allow for use of ultrasound in the preoperative clinic, postanesthesia care unit, and ICU and have stimulated a new generation of ultrasound uses.

It is our hope that this chapter with its systematic approach to TEE examination will help grow and stimulate further use of this unique and important modality.

CHAPTER 31

Monitoring Respiratory Function

Dean R. Hess, PhD, RRT, and
Robert M. Kacmarek, PhD, RRT

Monitoring is the continuous, or nearly continuous, evaluation of the physiologic function of a patient in real time to guide diagnosis and management decisions, including when to make therapeutic interventions and assessment of those interventions.[1] Many physiologic parameters can be monitored during mechanical ventilation, including both invasive and noninvasive monitoring. Respiratory monitoring is an integral part of the care of mechanically ventilated patients in the operating room and in the intensive care unit. Arterial blood gases are also commonly used to assess respiratory function. This chapter reviews the use of blood gases and monitors for assessment of respiratory function.

ARTERIAL BLOOD GASES

Arterial blood gases refer to measurements of PCO_2 and PO_2. The measurement of pH is also included with blood gases. Measured hemoglobin saturation with oxygen (O_2Hgb), carboxyhemoglobin (COHgb), and methemoglobin (metHgb) may be included. Many laboratories also report calculated values of oxygen saturation, bicarbonate concentration, and base excess. These measurements assess oxygenation, ventilation, and acid–base status.

Oxygenation

Hypoxemia results from decreased delivery of oxygen from the atmosphere to the arterial blood, and *hypoxia* refers to decreased delivery of oxygen to the tissues (Table 31–1). Oxygen content is a combination of dissolved oxygen and that bound to hemoglobin. The amount dissolved in plasma is small and directly related to PO_2. The normal range of arterial PO_2 (Pa_{O_2}) is 80–100 mm Hg in healthy young adults breathing air at sea level. Pa_{O_2} normally decreases with increasing age and increasing altitude. Hypoxemia occurs when the lungs fail to adequately oxygenate arterial blood. Pa_{O_2} is often a reflection of lung function and not of hypoxia per se. Hypoxia can occur without hypoxemia and vice versa. Adequate Pa_{O_2} in acutely ill patients is unknown, but most clinicians agree that $Pa_{O_2} > 60$ mm Hg usually is acceptable.

Alveolar Gas Equation

The alveolar PO_2 ($P_{A}O_2$) is calculated from the alveolar gas equation:

$$P_{A}O_2 = (FIO_2 \times EBP) - (P_{A}CO_2 \times [FIO_2 + (1 - FIO_2)/R]), \quad (31\text{–}1)$$

where FIO_2 = fraction of inspired oxygen, EBP = effective barometric pressure (barometric pressure minus water vapor pressure), and R = respiratory quotient. For calculation of $P_{A}O_2$, R = 0.8 is commonly chosen. For $FIO_2 \geq 0.6$, the effect of R on the alveolar gas equation becomes the following:

$$P_{A}O_2 = (FIO_2 \times EBP) - (P_{A}CO_2). \quad (31\text{–}2)$$

For $FIO_2 < 0.6$, the alveolar gas equation becomes the following:

$$P_{A}O_2 = (FIO_2 \times EBP) - (1.2 \times P_{A}CO_2). \quad (31\text{–}3)$$

An increased difference between alveolar PO_2 ($P_{A}O_2$) and Pa_{O_2}, the $P(A\text{-}a)O_2$ gradient, can be due to shunt, $\dot{V}/\dot{Q}$ mismatch, or a diffusion defect. $P(A\text{-}a)O_2$ normally is ≤10 mm Hg breathing air and ≤50 mm Hg breathing 100% oxygen. The ratio of Pa_{O_2} to $P_{A}O_2$ ($Pa_{O_2}/P_{A}O_2$) also can be calculated as an index of lung function and normally is >0.75 at any FIO_2. Pa_{O_2}/FIO_2 is the easiest of the indices of oxygenation to calculate. The acute respiratory distress syndrome (ARDS) is associated with $Pa_{O_2}/FIO_2 < 200$, and acute lung injury (ALI) is associated with $Pa_{O_2}/FIO_2 < 300$. The oxygenation index (OI) is calculated from FIO_2, mean airway pressure ($\bar{P}aw$), and Pa_{O_2}:

$$OI = (FIO_2 \times \bar{P}aw \times 100)/Pa_{O_2}. \quad (31\text{–}4)$$

OI is commonly calculated for neonates but is seldom used in the care of adults. In neonates, OI >40 with maximal therapy is often used as a criterion for severe hypoxemia requiring extracorporeal life support.

Oxyhemoglobin Dissociation Curve

The oxygen saturation of hemoglobin is determined by the oxyhemoglobin dissociation curve (Fig. 31–1), where oxygen saturation is a function of PO_2. The affinity of hemoglobin for oxygen is high at high saturations and less at lower

KEY POINTS

1. Arterial blood gases are used to assess oxygenation, ventilation, and acid–base balance.
2. The right-to-left shunt fraction is the gold standard index of oxygenation efficiency in the lungs.
3. Dead space is that portion of the minute ventilation that does not participate in gas exchange.
4. Acid–base balance is explained by the Henderson-Hasselbalch equation or the strong ion difference.
5. Arterial blood gases primarily reflect lung function, whereas venous blood gases reflect the adequacy of tissue oxygenation and tissue carbon dioxide clearance.
6. Pulse oximeters pass two wavelengths of light through a pulsating vascular bed to measure arterial oxygen saturation.
7. Capnometry is the measurement of CO_2 at the airway opening during the ventilatory cycle.
8. Transcutaneous PO_2 is measured with a Clark electrode and transcutaneous PCO_2 is measured using a Severinghaus electrode.
9. Pulmonary mechanics is the expression of lung function through measurements of pressure and flow; from these measurements a variety of derived indices can be determined, such as volume, compliance, resistance, and work of breathing.
10. The decision to monitor, like any other clinical decision, should be based on achieving therapeutic objectives in a safe and cost-effective manner.

TABLE 31–1.

Causes of Hypoxemia and Hypoxia

Hypoxemia
- Decreased inspired oxygen: altitude
- Hypoventilation: respiratory center depression, neuromuscular disease, respiratory failure
- Shunt: pulmonary (e.g., atelectasis, pneumonia, pulmonary edema, acute respiratory distress syndrome) or cardiac (patent foramen ovale)
- $\dot{V}/\dot{Q}$ mismatch: airway secretions, bronchospasm

Hypoxia
- Hypoxemic hypoxia: lower than normal PaO2 (hypoxemia)
- Anemic hypoxia: decreased red blood cell count, carboxyhemoglobin, methemoglobin, hemoglobinopathy
- Circulatory hypoxia: decreased cardiac output, decreased local perfusion
- Affinity hypoxia: decreased release of oxygen from hemoglobin to the tissues
- Histotoxic hypoxia: cyanide poisoning

saturations. This effect facilitates oxygen loading in the lungs (where PO_2 is high) and oxygen unloading to the tissues (where PO_2 is low). The position of the oxyhemoglobin dissociation curve is not fixed. Factors that shift the curve to the left increase the affinity of hemoglobin for oxygen, and factors that shift the curve to the right decrease the affinity of hemoglobin for oxygen. The oxygen saturation of hemoglobin is also altered by conditions such as COHgb and metHgb. Carbon monoxide attaches to the oxygen binding sites of hemoglobin with a high affinity and decreases the ability of hemoglobin to carry oxygen. Thus, the hemoglobin oxygen saturation cannot be >70% if the COHgb level is 30%. Methemoglobin is produced when the iron in the hemoglobin molecule is converted from its common reduced state (Fe^{++}) to its oxidized state (Fe^{+++}). Hemoglobin can carry oxygen only if the iron is in the reduced state. Thus, metHgb decreases the ability of hemoglobin to transport oxygen.

Shunt

The right-to-left shunt fraction is the gold standard index of oxygenation efficiency in the lungs. It is calculated from the shunt equation:

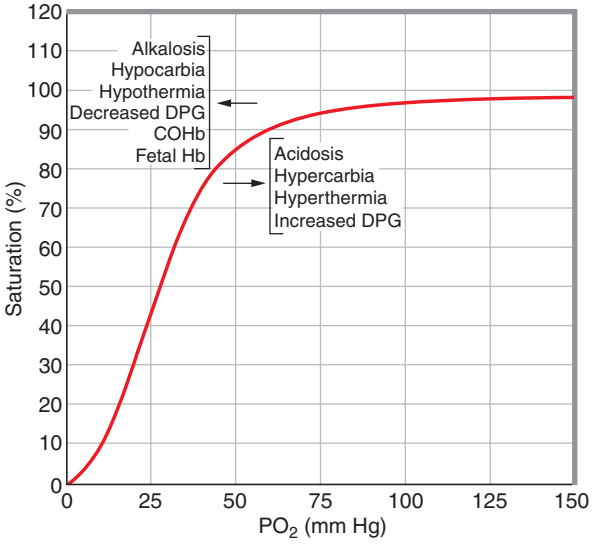

FIGURE 31–1. Oxyhemoglobin dissociation curve. Physiologic conditions that shift the curve to the left and to the right are indicated. Note that a shift to the left increases oxygen saturation for a given PO_2 (increased affinity) and a shift to the right decreases oxygen saturation for a given PO_2 (decreased affinity).

$$Q_S/Q_T = (C\bar{v}O_2 - CaO_2)/(C\bar{v}O_2 - C\bar{v}O_2), \quad (31–5)$$

where $C\bar{v}O_2$ = pulmonary capillary oxygen content (mL/dL), CaO_2 = arterial oxygen content, and $C\bar{v}O_2$ = mixed venous oxygen content. Oxygen content is calculated as follows:

$$CO_2 = (1.34 \times Hgb \times HgbO_2) + (0.003 \times PO_2). \quad (31–6)$$

To calculate $C\bar{v}O_2$, the pulmonary capillary PO_2 is assumed to equal the alveolar PO_2, and the pulmonary capillary hemoglobin oxygen saturation is assumed to be 100%. If measured when the patient is breathing 100% oxygen, Q_S/Q_T represents shunt (i.e., blood that flows from the right heart to the left heart without passing gas-exchanging alveoli). If measured at FIO_2 <1.0, then Q_S/Q_T represents both shunt fraction and $\dot{V}/\dot{Q}$ mismatch. A shunt >50% represents severe respiratory failure, whereas 5% approximates the normal value.

Ventilation

Arterial PCO_2 ($PaCO_2$) reflects the balance between carbon dioxide production ($\dot{V}CO_2$) and alveolar ventilation ($\dot{V}_A$):

$$PaCO_2 = \dot{V}CO_2/\dot{V}_A. \quad (31–7)$$

Thus, $PaCO_2$ varies directly with carbon dioxide production and inversely with alveolar ventilation. Note that $PaCO_2$ is determined by alveolar ventilation and not total minute ventilation per se. Minute ventilation affects $PaCO_2$ only to the extent that it affects alveolar ventilation. Clinical causes of hypoventilation (increased $PaCO_2$) and hyperventilation (decreased $PaCO_2$) are listed in Table 31–2. Because alveolar ventilation is determined by minute ventilation ($\dot{V}_E$) and the ratio of dead space to total ventilation (V_D/V_T), the relationship can be derived as follows:

$$PaCO_2 = \dot{V}CO_2/[\dot{V}_E \times (1 - V_D/V_T)]. \quad (31–8)$$

TABLE 31–2.

Clinical Causes of Hypoventilation and Hyperventilation

Hypoventilation
- Respiratory center depression: pathologic, iatrogenic
- Disruption of neural pathways affecting respiratory muscles: neuropathy, trauma
- Neuromuscular blockade: disease, paralyzing agents
- Respiratory muscle weakness: fatigue, disease

Hyperventilation
- Respiratory center stimulation: hypoxia, anxiety, central nervous system pathology
- Metabolic acidosis
- Iatrogenic: mechanical ventilation

P_{ACO_2} increases with an increase in V_D/V_T, an increase in $\dot{V}CO_2$, and a decrease in $\dot{V}_E$ (Fig. 31–2). Although a goal of mechanical ventilation traditionally has been to normalize P_{ACO_2}, at times an elevated P_{ACO_2} (permissive hypercapnia) may be more desirable than the high alveolar pressure required to normalize P_{ACO_2} in patients with acute respiratory failure.

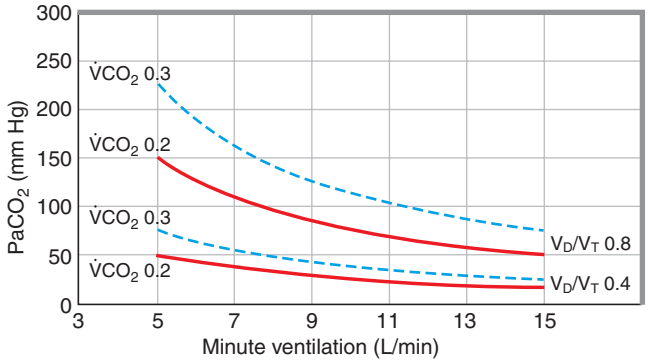

FIGURE 31–2. Relationship between P_{ACO_2}, minute ventilation, V_D/V_T, and $\dot{V}CO_2$.

Dead Space Ventilation

Dead space is that portion of the minute ventilation that does not participate in gas exchange.[2–4] It consists of anatomic dead space and alveolar dead space. Dead space is calculated using the Bohr equation:

$$V_D/V_T = (P_{ACO_2} - P\bar{E}CO_2)/P_{ACO_2}, \quad (31–9)$$

where V_D/V_T = fraction of total ventilation that is dead space, and $P\bar{E}CO_2$ is the partial pressure of CO_2 in mixed exhaled gas. The normal value of V_D/V_T ranges from 0.2 to 0.4. Causes of an increased V_D/V_T include pulmonary embolism, positive-pressure ventilation, pulmonary hypoperfusion, and high-rate, low-tidal-volume ventilation. Increased V_D/V_T has been associated with a high mortality rate in patients with ARDS.[5] Increased V_D/V_T also has been associated with a lower rate of weaning from mechanical ventilation.[6]

The traditional method for determining $P\bar{E}CO_2$ was to collect mixed exhaled gas in a large bag for 5 to 15 minutes. During the gas collection, the patient is undisturbed, with a stable $\dot{V}_E$, and an arterial blood sample is obtained to assess P_{ACO_2} during this time. Many current-generation mechanical ventilators have a constant bias gas flow through the circuit, which complicates the collection of mixed exhaled gas to calculate V_D/V_T. In this case, $P\bar{E}CO_2$ can be calculated from $\dot{V}CO_2$ and $\dot{V}_E$:

$$P\bar{E}CO_2 = (\dot{V}CO_2/\dot{V}_E) \times P_B. \quad (31–10)$$

Because dead space determinations require a leak-free system, they cannot be measured in patients with a bronchopleural fistula or with a leaking uncuffed tracheostomy tube. From the exhaled CO_2, $\dot{V}_E$, and barometric pressure (P_B), $\dot{V}_A$ can be calculated as follows:

$$\dot{V}_A = \dot{V}_E \times P\bar{E}CO_2/P_B. \quad (31–11)$$

$\dot{V}_A$ also can be calculated from V_D/V_T as follows:

$$\dot{V}_A = \dot{V}_E - (\dot{V}_E \times V_D/V_T). \quad (31–12)$$

Acid–Base Balance

Acid–base balance is explained by the Henderson-Hasselbalch equation:

$$pH = 6.1 + \log[HCO_3^-]/(0.03 \times PCO_2). \quad (31–13)$$

Metabolic acid–base disturbances are those that affect the numerator of the Henderson-Hasselbalch equation, and respiratory acid–base disturbances are those things that affect the denominator. The pH is normal (7.40) whenever the ratio $[HCO_3^-]/(0.03 \times P_{ACO_2})$ is 20:1. The metabolic component of acid–base interpretation usually is given as $[HCO_3^-]$. The metabolic component also can be expressed as base excess (BE). BE can be estimated as: BE = $[HCO_3^-]$ – 24. In other words, $[HCO_3^-]$ < 24 mmol/L corresponds with a negative BE, and $[HCO_3^-]$ > 24 mmol/L corresponds with a positive BE. Clinical causes of metabolic acid–base disturbances are listed in Table 31–3, and the degree of compensation for acid–base disturbances is given in Table 31–4.

The strong ion difference (SID) is a method of evaluating acid–base disturbances based on the Stewart physiochemical approach to acid–base chemistry.[7] Using this approach, the only variables that affect pH are PCO_2, SID, and the concentration of unmeasured strong ions. The normal value for SID is 40 mmol/L and is calculated as follows:

$$SID = [HCO_3^-] + 0.28 \times [\text{Albumin (g/L)}] + [\text{Inorganic phosphate (mmol/L)}]. \quad (31–14)$$

Metabolic acidosis is associated with a decreased SID, and metabolic alkalosis is associated with an increased SID (Table 31–5).

The anion gap is useful to differentiate causes of metabolic acidosis. Metabolic acidosis can be associated with a normal anion gap (hyperchloremic acidosis) or with an increased anion gap (normochloremic acidosis). The anion gap is calculated as follows:

$$\text{Anion gap} = [Na^+] - ([Cl^-] + [HCO_3^-]). \quad (31–15)$$

TABLE 31–3.

Clinical Causes of Metabolic Acidosis and Metabolic Alkalosis

Metabolic Acidosis
- Lactic acidosis (e.g., hypoxia)
- Ketoacidosis (e.g., uncontrolled diabetes)
- Uremic acidosis (e.g., renal failure)
- Loss of base from lower gastrointestinal tract (e.g., diarrhea)
- Loss of base from kidneys (e.g., acetazolamide, renal tubular acidosis)
- Poisons (e.g., methanol, ethylene glycol, aspirin)

Metabolic Alkalosis
- Hypokalemia
- Loss of acid from upper gastrointestinal tract (e.g., vomiting, gastric suction)
- Bicarbonate administration

TABLE 31–4.

Expected Compensation for Acid–Base Disturbances

Respiratory acidosis:	$\Delta HCO_3^- = 0.10 \times \Delta Paco_2$ (acute) $\Delta HCO_3^- = 0.35 \times \Delta Paco_2$ (chronic)
Respiratory alkalosis:	$\Delta HCO_3^- = 0.2 \times \Delta Paco_2$ (acute) $\Delta HCO_3^- = 0.5 \times \Delta Paco_2$ (chronic)
Metabolic acidosis:	$Paco_2 = 1.5 \times HCO_3^- + 8$
Metabolic alkalosis:	$Paco_2 = 0.9 \times HCO_3^- + 15$

If the acid–base status exceeds the expected level of compensation, a mixed acid–base disturbance is present.

TABLE 31–5.

Classification of Acid–Base Disturbances Using the Steward Approach

	Acidosis	Alkalosis
Respiratory	$\uparrow PCO_2$	$\downarrow PCO_2$
Metabolic		
Water excess or deficit	$\downarrow$SID, $\downarrow Na^+$	$\uparrow$SID, $\uparrow Na^+$
Chloride excess or deficit	$\downarrow$SID, $\uparrow Cl^-$	$\uparrow$SID, $\downarrow Cl^-$
Unmeasured strong ion excess	$\downarrow$SID, $\uparrow$unmeasured ions	

SID, strong ion difference.

A normal anion gap is 8–12 mmol/L. Causes of metabolic acidosis with an increased anion gap include lactic acidosis, diabetic ketoacidosis, and azotemic (renal) acidosis. Causes of metabolic acidosis with a normal anion gap include loss of bicarbonate from the gastrointestinal tract (e.g., diarrhea), acetazolamide (Diamox) therapy, and excessive chloride administration (e.g., HCl, NH_4Cl). The osmolality (osmol gap) is the difference between the measured osmolality of the plasma and that calculated as follows:

$$\text{Osmolality} = 2[Na^+] + [\text{Glucose}]/18 + [\text{BUN}]/2.8 + [\text{Ethanol}]/4.6, \quad (31\text{–}16)$$

where BUN = blood urea nitrogen. If the measured osmolality is >10 mOsm/L above the calculated value (osmol gap >10 mOsm/L), osmotically active particles whose metabolites may be organic acid may present. Metabolic acidosis with an osmol gap is consistent with the presence of the toxins methanol, ethanol, and ethylene glycol.

Temperature Correction of Blood Gases

Blood gases and pH are measured in the laboratory at 37°C. If the patient's temperature is abnormal, the in vivo blood gas and pH values will differ from those measured and reported by the blood gas laboratory. Using empiric equations, the blood gas analyzer can adjust the measured values to the patient's body temperature. Two ventilation strategies for hypothermic acid–base management have been suggested (usually during cardiopulmonary bypass)[8–13] During α-stat management, $Paco_2$ is maintained at 40 mm Hg when measured at 37°C. Thus, the dissociation fraction of the imidazole moiety of histidine is constant, whereas pH changes parallel to the neutral pH point of water. During pH-stat management, $Paco_2$ is corrected to the patient's actual body temperature. Because of increased gas solubility during hypothermia, the α-stat strategy results in relative hyperventilation. This issue is becoming increasingly important with the use of induced hypothermia after cardiac arrest and in the treatment of focal cerebral ischemia. Animal studies suggest that pH-stat management, as compared with α-stat management, results in improved cerebral blood flow and neurologic outcomes. The pH-stat approach allows differentiation of temperature-related changes from physiologic changes. Temperature-adjusted values should be used to compare blood gas levels with exhaled gas values (e.g., end-tidal PCO_2 [$PETCO_2$]) and to calculate oxygen content indices (e.g., right-to-left shunt) or tension indices [e.g., $P(A\text{-}a)O_2$].

Point-of-Care Measurement of Blood Gases

Point-of-care blood gas monitoring is performed near the site of patient care (e.g., operating room, intensive care unit). Point-of-care analyzers are available to measure blood gases and pH. These analyzers also can make other important useful measurements at the bedside, including levels of electrolytes, glucose, lactate, urea nitrogen, and hematocrit, and clotting studies [activated clotting time (ACT), prothrombin time (PT), and partial thromboplastin time (PTT)]. Point-of-care analyzers are small and portable (some are hand-held), they require minute blood volumes (several drops), and they provide rapid reporting of results (a few minutes). They are relatively easy to use (e.g., self-calibrating) and typically incorporate a disposable cartridge that contains the appropriate biosensors. The cost–benefit of these devices is unclear. Further, appropriate documentation for compliance with hospital standards is necessary. This requires appropriate quality control checks and instrument maintenance.

Venous Blood Gases

Arterial blood gases primarily reflect lung function, whereas venous blood gases reflect the adequacy of tissue oxygenation and tissue carbon dioxide clearance. A low mixed venous PO_2 level (<35 mm Hg) reflects tissue hypoxia and may be the result of decreased oxygen delivery or increased tissue oxygen uptake. Venous PO_2 typically is much lower than arterial PO_2, and there is often little relationship between the two. For example, the mixed venous PO_2 may be low and the arterial PO_2 may be high when cardiac output is reduced, lung function is normal, and FIO_2 is high. Normally, the mixed venous PCO_2 is only slightly greater than the arterial PCO_2. However, the venous PCO_2 depends on blood flow (cardiac output), and, in cases of low blood flow (e.g., cardiac arrest), the mixed venous PCO_2 may be high despite a normal or decreased arterial PCO_2. When venous blood gases are used to assess acid–base balance, mixed venous or central venous blood samples are preferable to peripheral venous samples. Interest in central venous oxygen saturation has increased with the use of goal-directed treatment of sepsis, in which $S\bar{v}O_2$ >70% was reported to be associated with a survival benefit.[14]

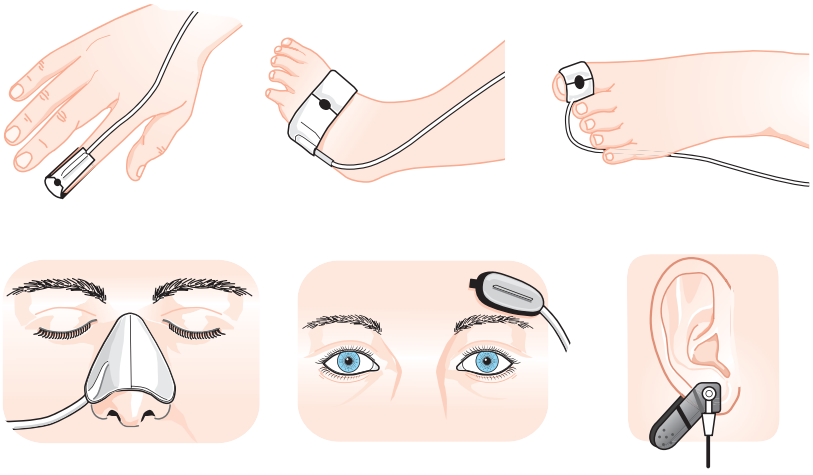

FIGURE 31–3. Examples of pulse oximetry probes. (Adapted from materials provided by Nellcor.)

PULSE OXIMETRY

Pulse oximetry, a technology unavailable until the mid-1980s, is now in widespread use. Continuous pulse oximetry is the standard of care in the operating room and for treatment of critically ill patients. A probe passes two wavelengths of light (660 and 940 nm) through a pulsating vascular bed. Although most pulse oximeters commonly use transmission oximetry (i.e., the light emitted from the light-emitting diodes [LEDs] is transmitted through the tissue and a photodetector is opposite the LEDs), other designs use reflectance oximetry (i.e., the light from the LEDs is reflected from the tissue, and the photodetector is on the same side of the tissue as the LEDs). The pulse oximeter probe can be placed on a number of sites, including the finger, toe, earlobe, nose, and forehead. In infants, the probe can be placed on the hand or foot (Fig. 31–3).

A number of limitations of pulse oximetry should be recognized, appreciated, and understood by everyone who uses pulse oximetry data.

- *Accuracy*: Most pulse oximeter errors can be explained by too little signal (e.g., low tissue perfusion levels, improper probe placement) or too much noise (e.g., motion, high levels of ambient light). Pulse oximeters use empirical calibration curves developed from studies of healthy volunteers. At saturations >80%, the accuracy of pulse oximetry is approximately ±4–5%. Below 80%, their accuracy is far worse, but the clinical importance of this is questionable. To appreciate the implications of the limits of accuracy of pulse oximetry, one must consider the oxyhemoglobin dissociation curve. If the pulse oximeter displays an Spo_2 of 95%, the true saturation could be as low as 90% or as high as 100%. If the true saturation is 90%, the Pao_2 will be approximately 60 mm Hg. If the true saturation is 100%, however, one does not know how high the Pao_2 might be. Also, a shift of the oxyhemoglobin dissociation curve can change the Spo_2, although no change in Pao_2 has occurred.
- *Misunderstanding by those who use pulse oximetry:* Although pulse oximetry is commonly used, it may be misunderstood by those using it. For example, it has been reported that a large percentage of junior physicians and staff nurses lacked knowledge and made serious errors in the interpretation of Spo_2.[15] However, this problem may have improved in recent years.[16]
- *Differences between devices and probes:* The pulse oximeter is unique in that it requires no user calibration. However, manufacturer-derived calibration curves programmed into the software vary from manufacturer to manufacturer and can vary among pulse oximeters from a given manufacturer. Moreover, the output of the LEDs can vary from probe to probe.
- *Penumbra effect:* If the finger pulse oximeter probe does not fit correctly, light can be shunted from the LEDs directly to the photodetector. This will cause a falsely low Spo_2 if Sao_2 >85% and a falsely elevated Spo_2 if Sao_2 <85%.
- *Dyshemoglobinemias:* Because traditionally available pulse oximeters use only two wavelengths of light, they are only able to evaluate oxyhemoglobin (O_2Hgb) and deoxyhemoglobin (HHgb). Abnormal elevations of carboxyhemoglobin (COHgb)[17] and metHgb[18] both result in significant inaccuracy in pulse oximetry, and pulse oximetry should not be used when elevated levels of these abnormal hemoglobins are present. It is noteworthy that a new pulse oximeter design that measures COHgb and metHgb in addition to O_2Hgb now is available. This design should be useful for patients with suspected elevations in COHgb and metHgb. Fetal hemoglobin[19] and sickle cell anemia[20] do not affect the accuracy of pulse oximetry.
- *Endogenous and exogenous dyes and pigments:* Intravascular dye administration can affect the accuracy of pulse oximetry, with methylene blue having the greatest effect.[21] Nail polish also can affect the accuracy of pulse oximetry and should be removed before pulse oximetry is begun.[22] Hyperbilirubinemia does not appear to affect the accuracy of pulse oximetry.[23]
- *Skin pigmentation:* Several studies have found that the accuracy and performance of pulse oximeters are affected by deeply pigmented skin.[24–26]
- *Perfusion:* Pulse oximeters require a pulsating vascular bed to function correctly. Under conditions of low flow (e.g., cardiac arrest or severe peripheral vasoconstriction), pulse oximetry becomes unreliable. Under these conditions, an ear probe may be more reliable than a finger probe.
- *Anemia:* Although pulse oximeters are generally reliable over a wide range of hemoglobin levels, they become less accurate and reliable with conditions of severe anemia (hematocrit <24 g/dL at low saturations, and hematocrit <10% at all saturations).[27]
- *Motion:* Motion of the probe can produce considerable artifact and unreliable and inaccurate pulse oximetry readings. This problem can sometimes be corrected by using a more stable probe site (e.g., the ear or toe rather than the finger).

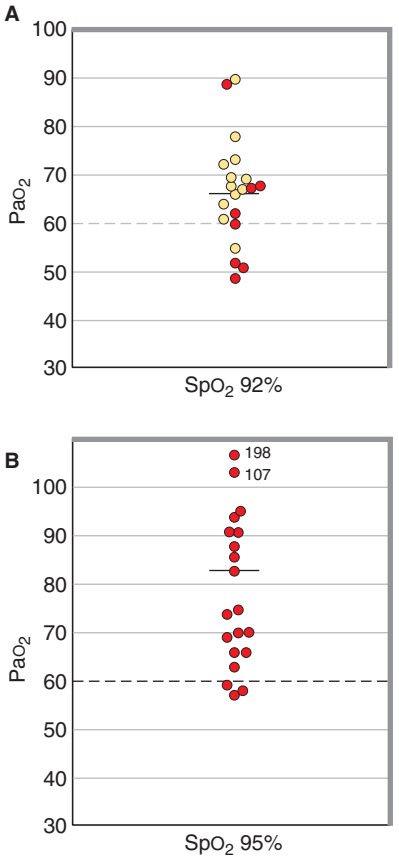

FIGURE 31–4. Top. In white patients (open circles), Spo_2 ≥92% is reliable in predicting Pao_2 ≥60 mm Hg. **Bottom.** In black patients, Spo_2 ≥95% was required to reliably predict Pao_2 ≥60 mm Hg.

- *High-intensity ambient light:* Because the photodetector of the pulse oximeter is nonspecific, high-intensity ambient light can produce interference. This problem can be corrected by wrapping the probe with a light barrier.
- *Abnormal pulses:* Venous pulses and a large dicrotic notch may affect the accuracy of pulse oximetry.
- *Safety:* Pulse oximetry is generally considered safe. However, burns as the result of defective probes and pressure necrosis can rarely occur.

Jubran and Tobin[26] evaluated the use of pulse oximetry in titrating supplemental oxygen in 54 critically ill ventilator-dependent patients (Fig. 31–4). In white patients, they found that an Spo_2 of 92% was reliable in predicting Pao_2 ≥60 mm Hg. In black patients, however, an Spo_2 of 95% was required. Although this method is useful for titrating a level of arterial oxygenation that does not produce hypoxemia, it does not eliminate the need for periodic arterial blood gas measurements. When pulse oximetry is used to titrate the FIO_2, the final FIO_2 setting should be confirmed by an arterial blood gas measurement.

If pulse oximetry is to be clinically useful, it must have a low failure rate. Intraoperative pulse oximeter failure was evaluated by Freund et al.[28] Overall, they found a failure rate <5%. Pulse oximetry failures tended to be greater in older patients, sicker patients, and during longer surgical procedures. Failure of pulse oximetry in other settings has not been reported. Perhaps the most frequent cause of pulse oximetry failure in the ICU is accidental disconnection or misplacement of the probe.

Motion artifact and low perfusion are common causes of pulse oximetry errors.[29–36] Manufacturers of pulse oximeters have developed improved software algorithms to calculate Spo_2 in an attempt to eliminate motion artifacts from the pulse signal. Three such devices on the market are the FAST (Fourier Artifact-Suppression Technology, Philips Medical Systems, Andover, MA), SET (Signal-Extraction Technology, Masimo, Irvine, CA), and Oxismart N-3000 (Nellcor, Pleasanton, CA). A comprehensive review concluded that the clinical performance of all of the new-generation pulse oximeters was better than that of earlier devices.[30] Although several studies have evaluated the performance of these new designs,[32–36] there was no strong and convincing evidence that the performance of any single new-generation device was superior to that of any other new-generation device.

Although it allows early detection of hypoxemia and related events, the impact of pulse oximetry on patient outcomes is unclear.[37] A large study (>20,000 patients) of pulse oximetry use during anesthesia and postanesthesia care found no difference in outcome.[38,39] Pulse oximetry is indicated in unstable patients likely to desaturate, in patients receiving a therapeutic intervention that is likely to produce hypoxemia (e.g., bronchoscopy), and in patients having interventions likely to produce changes in arterial oxygenation [i.e., changes in FIO_2 or positive end-expiratory pressure (PEEP)].

There may be important nonoxygenation monitoring applications for pulse oximetry. For example, Hartert et al.[40] reported the effect of pulsus paradoxus, and therefore the severity of air trapping in obstructive airway disease, on the pulse oximetry plethysmographic (POP) waveform (Fig. 31–5). They reported that, in patients with obstructive lung disease and elevated pulsus paradoxus, an altered pulse oximetry baseline tracing manifested as the respiratory waveform variation. Pulsus paradoxus was significantly correlated with the degree of respiratory waveform variation of the pulse oximetry tracing and the amount of auto-PEEP.

Respiratory variations in POP waveform amplitude has been shown to be useful in predicting fluid responsive-

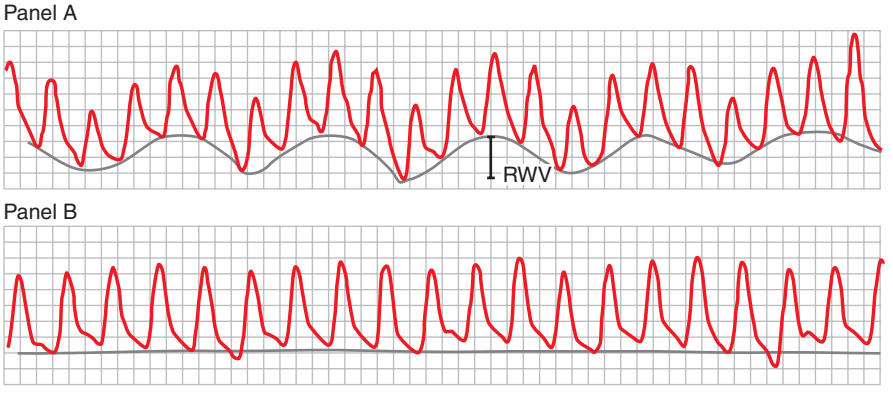

FIGURE 31–5. Pulse oximeter tracings from a 60-year-old woman with exacerbation of chronic obstructive pulmonary disease who was admitted to the ICU in ventilatory failure. **A.** Patient's pulse oximetry tracing at the time of admission reveals respiratory variability in the pulse oximeter plethysmography tracing. Measured pulsus paradoxus at this time was 16 mm Hg. **B.** Patient's pulse oximetry tracing after 12 hours of aggressive therapy. Pulsus paradoxus at this time was 8 mm Hg. Note the absence of respiratory waveform variation (RWV) in the baseline of the oximeter tracing after clinical improvement in airflow and resolution of elevated pulsus paradoxus. (From Hartert et al.[40] with permission.)

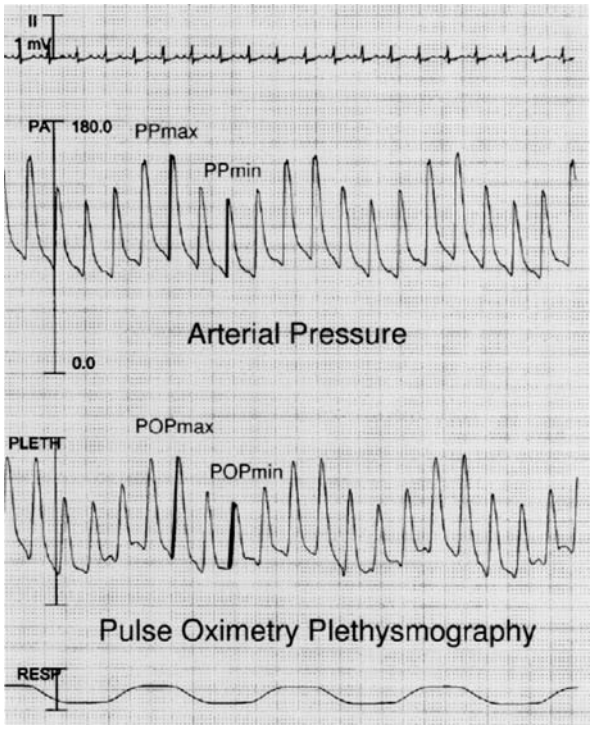

FIGURE 31–6. Comparison between invasive arterial pressure and pulse oximeter plethysmography recordings. Simultaneous recording of electrocardiographic lead (II), systemic arterial pressure (PA), pulse oximetry plethysmography (PLETH), and respiratory signal (RESP) in one illustrative patient. POP, pulse oximetry plethysmographic; PP, pulse pressure.

ness. POP waveform amplitude is measured on a beat-to-beat basis as the vertical distance between peak and preceding valley trough in the waveform (Fig. 31–6). Maximal POP (POP_{max}) and minimal POP (POP_{min}) are determined over the same respiratory cycle. ΔPOP is calculated using the following formula:

$$\Delta POP\,(\%) = 100 \times ([POP_{max} - POP_{min}]/[(POP_{max} + POP_{min})/2]). \quad (31\text{–}17)$$

The results of one study suggest that ΔPOP >15% is predictive of fluid responsiveness in mechanically ventilated patients with circulatory failure.[41]

CAPNOGRAPHY

Capnometry is the measurement of CO_2 at the airway opening during the ventilatory cycle.[42] Most capnometers measure CO_2 by infrared absorption, analyzing the absorption peak of CO_2 at 4.26 μm. Mass spectrometry and Raman spectrometry can also be used. A portable nonelectronic single-patient-use device is commonly used to produce a color change (colorimetric end-tidal CO_2 detection) in the presence of exhaled CO_2 (i.e., tracheal intubation). The color changes from purple with a low CO_2 concentration to yellow with CO_2 concentration of 2.0–5.0%.

Capnometers can be configured as mainstream or sidestream devices. With the mainstream capnometer, the measurement chamber is placed directly at the airway. With the sidestream capnometer, gas from the airway is aspirated through fine-bore tubing to the measurement chamber inside the device. Some devices (e.g., colorimetric capnometers) can only be used as mainstream devices, whereas other devices (e.g., Mass and Raman spectrometers) can only be used as sidestream devices. Infrared capnometers can be configured as either mainstream or sidestream devices. Each approach has advantages and disadvantages (Table 31–6). A new capnography technology, Microstream, has been introduced, which uses molecular correlation spectroscopy that operates at room temperature and emits only CO_2 specific radiation.[43] It features low flow rates, reduced dead space, and lack of moisture-associated occlusion problems.

Time-Based Capnography

For applications in the operating room and critical care unit, the time-based capnogram is often displayed (Fig. 31–7). Unlike the volume-based capnogram, the time-based capnogram has an inspiratory segment and an expiratory segment. PCO_2 usually is zero during the inspiratory phase. At the beginning of exhalation, PCO_2 remains zero as gas from the anatomic dead space leaves the airway (phase I). The capnogram then rises sharply as alveolar gas mixes with dead space gas (phase II). The curve then forms an alveolar plateau during most of exhalation (phase III). PCO_2 at the end of the alveolar plateau is the $PETCO_2$. The

TABLE 31–6.

Mainstream and Sidestream Capnometers

Advantages	Disadvantages
Mainstream Capnometer	
Sensor at patient's airway	Secretions and humidity block sensor
Fast response (crisp waveform)	Sensor heated to prevent condensation
Short lag time (real-time readings)	Bulky sensor at patient's airway
No sample flow to reduce tidal volume	Does not measure N_2O
	Difficult to use with nonintubated patients
	Cleaning and sterilization of reusable sensor
Sidestream Capnometer	
No bulky sensors or heaters at airway	Secretions block sample tubing
Ability to measure N_2O	Water trap required
Disposable sample line	Slow response to CO_2 changes
Can be used with nonintubated patients	Sample flow may decrease tidal volume

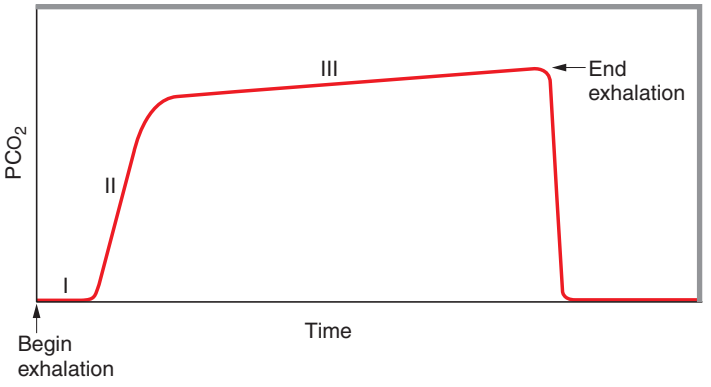

FIGURE 31–7. Time-based capnogram. I, anatomic dead space; II, transition from anatomic dead space to alveolar plateau; III, alveolar plateau.

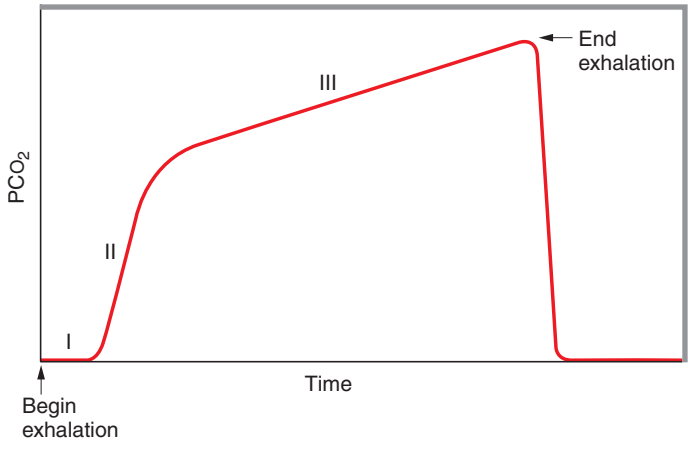

FIGURE 31–8. Capnogram produced with airflow obstruction.

capnogram with airflow obstruction is characterized by an increased slope of phase III (Fig. 31–8). This occurs because of the $\dot{V}/\dot{Q}$ heterogeneities that result from airflow obstruction.[44] In asthmatic patients with acute bronchospasm, the slope of phase III has been shown to correlate with peak expiratory flow rate, and this slope normalizes with β-agonist therapy.[45,46]

Carbon dioxide homeostasis is affected by $\dot{V}CO_2$, CO_2 transport from the tissues to the lungs, and $\dot{V}_A$. Conditions that increase $\dot{V}CO_2$ include fever, activity, sepsis, hyperthyroidism, trauma, burn injuries, and a high-carbohydrate diet. Conditions that decrease $\dot{V}CO_2$ include hypothyroidism, hypothermia (when shivering is blocked), sedation, and paralysis. Carbon dioxide from tissue metabolism diffuses into the circulation, producing a mixed venous PCO_2 ($P\bar{v}CO_2$) of approximately 45 mm Hg. The PCO_2 of an individual lung unit depends upon the $\dot{V}/\dot{Q}$ (Figure 31–9). Without perfusion (pure dead space; $\dot{V}/\dot{Q} = \infty$), P_ACO_2 is similar to inspired PCO_2 (i.e., zero). With a normal $\dot{V}/\dot{Q}$ unit, P_ACO_2 is the same as arterial PCO_2 (i.e., 40 mm Hg). With a low $\dot{V}/\dot{Q}$ unit, P_ACO_2 increases toward $P\bar{v}CO_2$ (i.e., 45 mm Hg). P_ACO_2, and thus P_ETCO_2, must always remain between zero and $P\bar{v}CO_2$. P_ETCO_2 normally is several millimeters of mercury less than P_aCO_2. However, the relationship between the P_aCO_2 and P_ETCO_2 will vary depending upon the relative contributions of various $\dot{V}/\dot{Q}$ units composing the lungs.[44]

Theoretically, P_ETCO_2 could be as low as inspired PCO2 (zero) or as high as $P\bar{v}CO_2$ (but not higher than this value). An increased or decreased P_ETCO_2 can result from changes in $\dot{V}CO_2$ and carbon dioxide delivery to the lungs, changes in alveolar ventilation, or equipment malfunction (Table 31–7). However, because of homeostasis, compensatory changes may occur so that P_ETCO_2 does not change despite some of these changes. For example, if $\dot{V}CO_2$ increases (such as with fever) and alveolar ventilation increases proportionately (the normal homeostatic response), then P_ETCO_2 may not change. Thus, P_ETCO_2 is a nonspecific indicator of cardiopulmonary homeostasis and often does not indicate the presence of any specific problem or abnormality.

If P_aCO_2 is measured, the gradient between P_aCO_2 and P_ETCO_2 [$P(a\text{-}ET)CO_2$] can be calculated. This gradient normally is small, usually < 5 mm Hg. With dead space–producing disease (high $\dot{V}/\dot{Q}$), P_ETCO_2 may be considerably less than P_aCO_2 (Table 31–8).[47–52] Although right-to-left blood shunting may result in a large gradient between P_AO_2 and P_aO_2, it will have only a small effect on $P(a\text{-}ET)CO_2$. On occasion, P_ETCO_2 may be greater than P_aCO_2. The reason for $P_ETCO_2 > P_aCO_2$ is not well understood and may be related to low (but finite) $\dot{V}/\dot{Q}$ regions within the lung that empty at end-exhalation. $P(a\text{-}ET)CO_2$ may decrease when measured at maximal exhalation in patients with airway obstruction.[53]

Perioperative measurement of P_ETCO_2 is a standard of care to determine proper endotracheal tube position.[54–60] Lack of exhaled CO_2 is consistent with an esophageal intubation. Capnography has also been reported useful for verifying feeding tube placement.[61,62] In the case of trache-

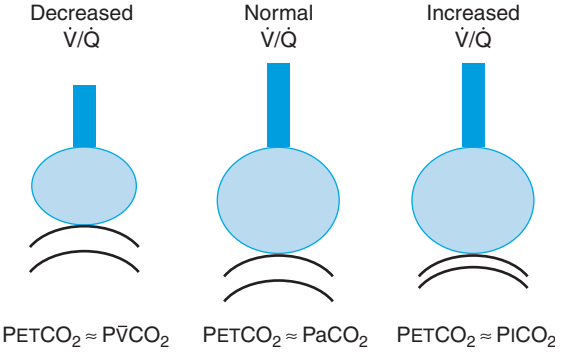

FIGURE 31–9. P_ETCO_2 with low $\dot{V}/\dot{Q}$, normal $\dot{V}/\dot{Q}$, and high $\dot{V}/\dot{Q}$.

TABLE 31–7.

Causes of Increased and Decreased $P_{ET}CO_2$

Increased $P_{ET}CO_2$	Decreased $P_{ET}CO_2$
Increased CO_2 production and delivery to the lungs: fever, sepsis, bicarbonate administration, increased metabolic rate, seizures **Decreased alveolar ventilation:** respiratory center depression, muscular paralysis, hypoventilation, chronic obstructive pulmonary disease **Equipment malfunction:** rebreathing, exhausted CO_2 absorber, leak in ventilator circuit	**Decreased CO_2 production and delivery to the lungs:** hypothermia, pulmonary hypoperfusion, cardiac arrest, pulmonary embolism, hemorrhage, hypotension **Increased alveolar ventilation:** hyperventilation **Equipment malfunction:** ventilator disconnect, esophageal intubation, complete airway obstruction, poor sampling, leak around endotracheal tube cuff

al placement of the feeding tube, CO_2 is detected in the gas aspirated from the feeding tube. $P_{ET}CO_2$ may also be useful for assessing the adequacy of cardiopulmonary resuscitation (CPR). The onset of cardiac arrest results in a decrease of $P_{ET}CO_2$ to zero. With the initiation of CPR, $P_{ET}CO_2$ increases and has been reported to increase immediately with return of spontaneous circulation.[63–66] In one study, patients successfully resuscitated following cardiac arrest had a $P_{ET}CO_2$ of 15 ± 4 mm Hg during CPR, whereas patients who could not be resuscitated had a $P_{ET}CO_2$ of only 7 ± 5 mm Hg.[67,68]

A common clinical cause of increased dead space is pulmonary embolism, and there has been interest in the use of capnography in this setting.[69–71] $P(a\text{-}ET)CO_2$ usually is increased when pulmonary embolism is present, but the gradient also is increased for a variety of other causes when pulmonary embolism is not present (e.g., any dead space–producing disease). Extrapolation of phase III of the volumetric capnogram to determine PCO_2 at 15% of the predicted total lung capacity has been reported to be useful in the diagnosis of pulmonary embolism (Fig. 31–10). With maximal exhalation, the gradient approaches zero in patients with obstructive lung disease but remains high in patients with pulmonary embolism.[71]

TABLE 31–8.

Causes of Increased $P(a\text{-}ET)CO_2$

High-rate, low-tidal volume ventilation

Volume-Based Capnography

The volume-based capnogram is displayed with PCO_2 on the ordinate and volume on the abscissa. Airway dead space volume (anatomic dead space), physiologic dead space fraction (V_D/V_T), and the volume of exhaled CO_2 ($\dot{V}CO_2$) can be determined from the volume-based capnogram (Fig. 31–11). If $\dot{V}CO_2$ is known, it is possible to calculate the metabolic rate:

$$REE = \dot{V}CO_2 \times 5.52 \times 1440, \quad (31\text{–}18)$$

where REE = resting energy expenditure (kcal/d), $\dot{V}CO_2$ is given in L/min, 5.52 = caloric equivalent for CO_2, and 1440 = number of minutes in a day.

Volumetric capnography can also be used to measure V_D/V_T [72–75] because $P\bar{E}CO_2$ can be calculated from $\dot{V}CO_2$ and $\dot{V}_E$:

$$\dot{V}CO_2 = \dot{V}_E \times P\bar{E}CO_2/P_B \text{ or } P\bar{E}CO_2 = (\dot{V}CO_2/\dot{V}_E) \times P_B. \quad (31\text{–}19)$$

V_D/V_T can then be calculated in the usual manner:

$$V_D/V_T = (PaCO_2 - P\bar{E}CO_2)/PaCO_2. \quad (31\text{–}20)$$

Cardiac Output Using Partial CO_2 Rebreathing

Using volume-based capnography, it is possible to noninvasively measure cardiac output with the partial CO_2 rebreathing technique (Fig. 31–12).[76–85] $\dot{V}CO_2$ is calculated on a breath-by-breath basis, and the Fick equation is applied to establish the relationship between $\dot{V}CO_2$ and cardiac output ($\dot{Q}$):

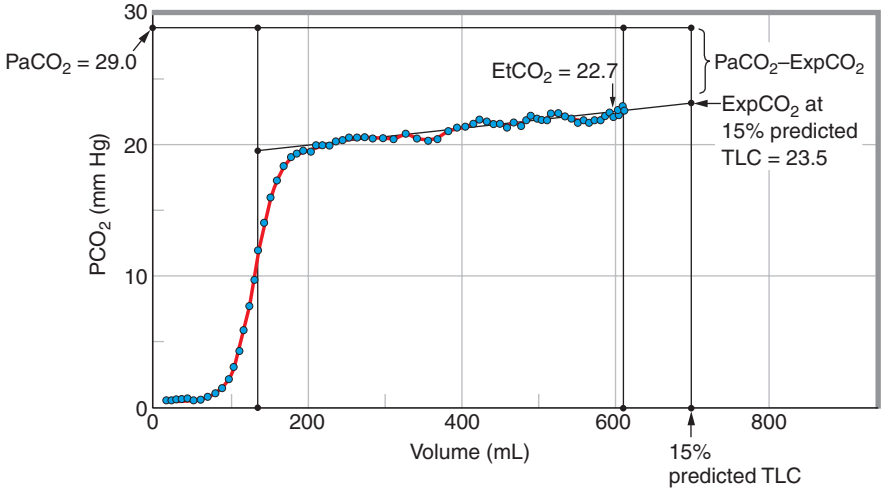

FIGURE 31–10. Capnogram in a patient diagnosed with pulmonary embolism. This patient had V_T of 612 mL. P_{ACO_2} was 29 mm Hg, $P_{ET}CO_2$ was 22.7 mm Hg, and 15% of the predicted total lung capacity was calculated to be 699 mL. $P_{ET}CO_2$ at this volume was 23.5 mm Hg after extrapolation of phase III. This relatively high percentage theoretically separates a patient with pulmonary embolism from a healthy patient or a patient with chronic obstructive pulmonary disease.

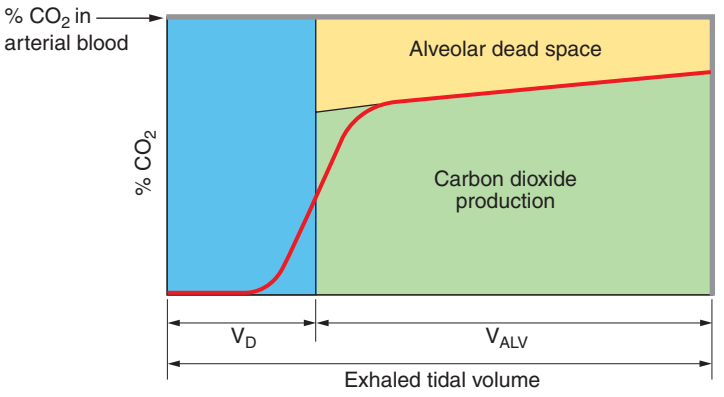

FIGURE 31–11. Components of volume-based capnogram. V_D, anatomic dead space; V_{ALV}, alveolar gas volume.

$$\dot{V}CO_2 = \dot{Q} \times (C\bar{v}CO_2 - CaCO_2), \quad (31–21)$$

where $C\bar{v}CO_2$ = CO_2 content of mixed venous blood, and $CaCO_2$ = CO_2 content of arterial blood. CO_2 rebreathing is performed for 35 seconds every 3 min. Assuming that $\dot{Q}$ remains constant during the rebreathing procedure yields the following:

$$\Delta\dot{V}CO_2 = \dot{Q} \times (\Delta C\bar{v}CO_2 - \Delta CaCO_2), \quad (31–22)$$

where $\Delta\dot{V}CO_2$ = change in $\dot{V}CO_2$ between normal breathing and rebreathing, $\Delta C\bar{v}CO_2$ = change in mixed venous carbon dioxide content, and $\Delta CaCO_2$ = change in arterial carbon dioxide content. If $C\bar{v}CO_2$ remains constant during rebreathing, the following equation is used:

$$\Delta\dot{V}CO_2 = \dot{Q} \times (-\Delta Cac_{O_2}). \quad (31–23)$$

When end-capillary content ($CcCO_2$) is used in place of $CaCO_2$, pulmonary capillary blood flow (PCBF), the blood flow that participates in alveolar gas exchange, is measured rather than $\dot{Q}$, and the following equation is used:

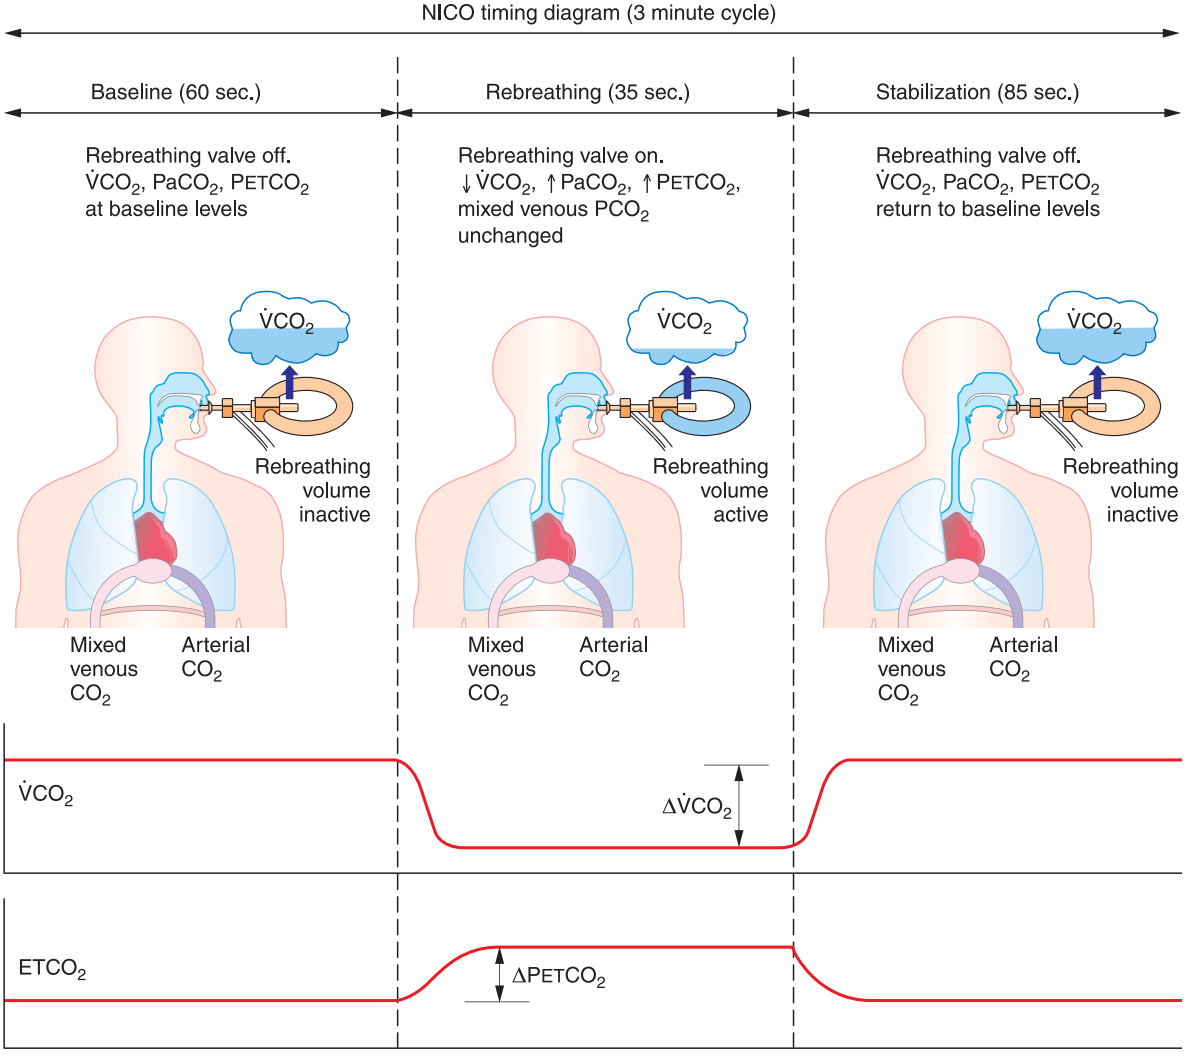

FIGURE 31–12. Rebreathing cycle used by Respironics Noninvasive Cardiac Output (NICO) monitor to measure cardiac output using the partial rebreathing technique.

$$\Delta\dot{V}CO_2 = PCBF \times (-CcCO_2 \; CcCO_2). \quad (31\text{–}24)$$

Assuming that $-CcCO_2$ is proportional to $\Delta PETCO_2$, the following equation can be used:

$$PCBF = \Delta\dot{V}CO_2/(S \times \Delta PETCO_2), \quad (31\text{–}25)$$

where $\Delta PETCO_2$ = change in $PETCO_2$ between normal breathing and rebreathing, and S = slope of the carbon dioxide dissociation curve from hemoglobin. Because cardiac output is the sum of PCBF and intrapulmonary shunt flow:

$$\dot{Q} = PCBF/(1 - \dot{Q}_S/\dot{Q}_T). \quad (31\text{–}26)$$

The noninvasive method for estimating Q_S/Q_T is adapted from Nunn's iso-shunt plots, which are a series of continuous curves indicating the relation between arterial oxygen pressure (PaO_2) and FIO_2 at different levels of right-to-left shunt. PaO_2 is noninvasively estimated using a pulse oximeter.

There are several potential limitations of partial rebreathing for the measurement of cardiac output. In nonparalyzed patients, rebreathing increases the respiratory rate, which reduces the magnitude of the signal and limits the ability to detect changes in $PETCO_2$ and $\dot{V}CO_2$. Noise is increased by respiratory pattern irregularities that produce an unstable $PETCO_2$ and $\dot{V}CO_2$, and these may impair accuracy. Additional cardiac output not calculated because of shunt fraction is estimated from SpO_2 and FIO_2, and these also may introduce errors.

Capnometry during Spontaneous Ventilation

Although capnometry is most often used with intubated and mechanically ventilated patients, techniques are available to measure $PETCO_2$ during spontaneous breathing. Nasal cannulae are commercially available for capnometry (Figure 31–13). When a capnometer is used with a nasal cannula, it is important that the sample is not contaminated with room air or oxygen flow, which will result in significant underestimation of $PETCO_2$. Although it can be technically difficult to accurately perform capnometry in nonintubated patients, $P(a\text{-}ET)CO_2$ values that are similar during both spontaneous breathing and intubation have been reported.[86–91]

TRANSCUTANEOUS PO_2 AND PCO_2

The transcutaneous PO_2 ($PtcO_2$) electrode uses the polarographic principle (Clark electrode). To produce a $PtcO_2$ approximating the PaO_2, the electrode must be heated to approximately 44°C. The relationship between PaO_2 and $PtcO_2$ is the result of a complex set of physiologic events. Simply stated, the increase in PO_2 caused by heating roughly balances the decrease in PO_2 caused by skin oxygen consumption and the diffusion of oxygen across the skin. It should be recognized that the close relationship between PaO_2 and $PtcO_2$ that occurs in neonates probably is more coincidental than physiologic. In adults, the $PtcO_2$ value frequently is less than the directly measured PaO_2. $PtcO_2$ is also affected by perfusion and may reflect the quantity of oxygen delivered to the skin under the electrode (the product of cardiac output and arterial oxygen content). $PtcO_2$ has been used in adults to monitor the results of vascular surgery, with the intent of evaluating perfusion rather than PaO_2 per se.

Transcutaneous PCO_2 ($PtcCO_2$) is measured using a Severinghaus electrode. Unlike the $PtcO_2$ electrode, a reasonably good correlation with $PaCO_2$ can be obtained at a temperature of 37°C. Because $PtcCO_2$ is consistently greater than $PaCO_2$, manufacturers incorporate a correction factor so that the $PtcCO_2$ that is displayed approxi-

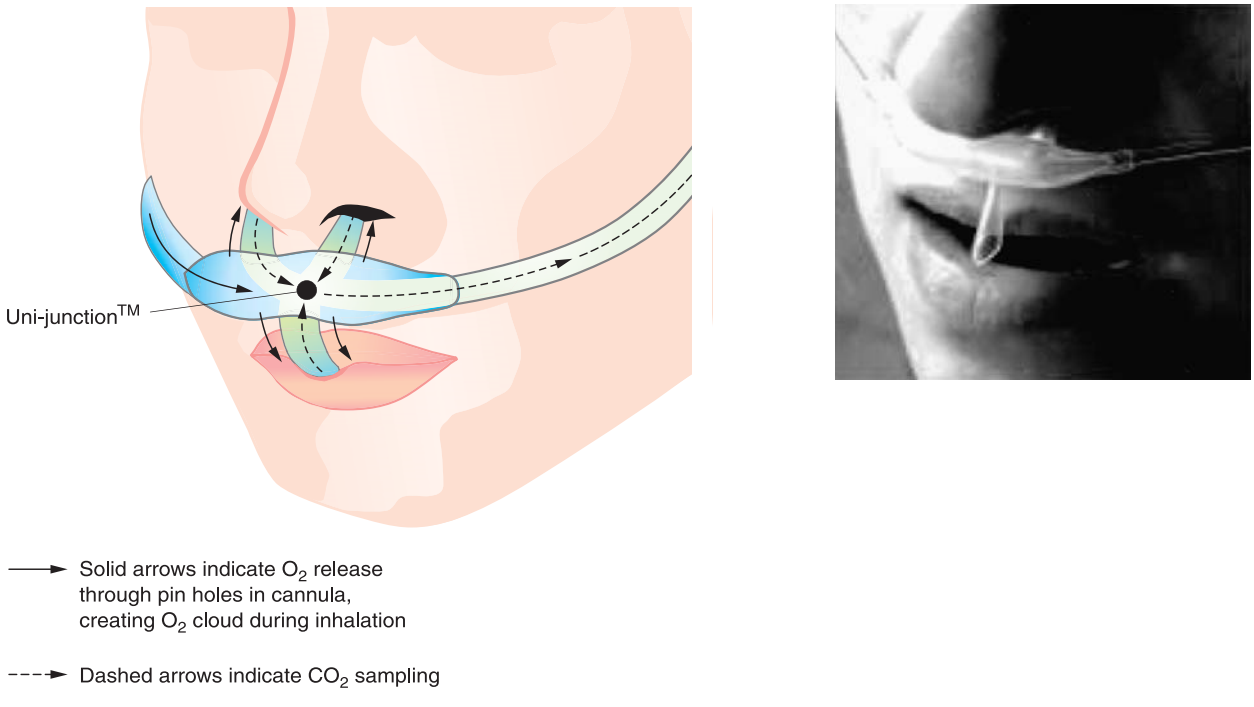

FIGURE 31–13. Nasal cannula designed for CO_2 sampling and oxygen administration (Smart CapnoLine, Oridion). The cannula samples CO_2 from both the nares and the mouth while oxygen is delivered through pinholes directed toward both the nose and mouth.

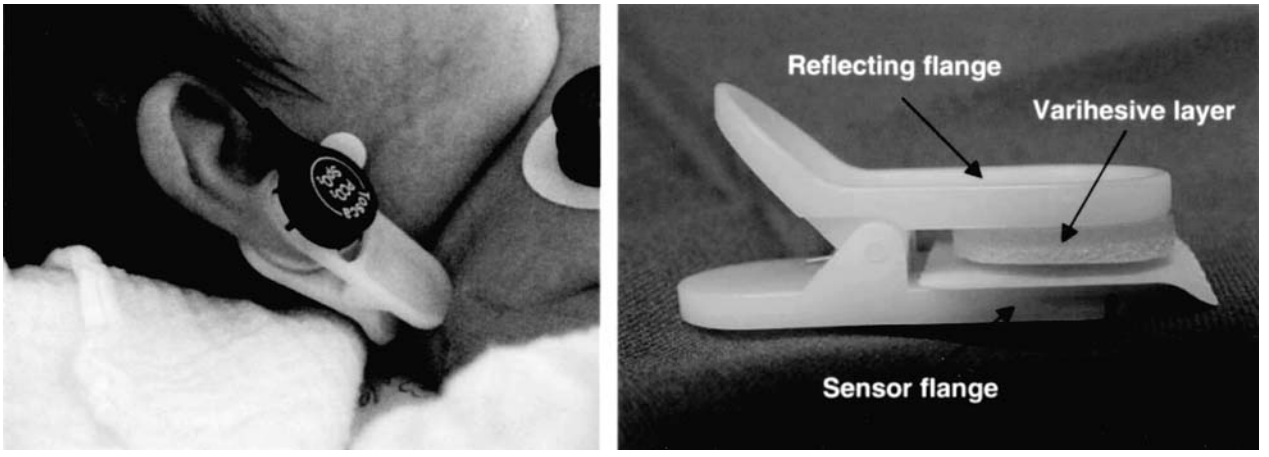

FIGURE 31–14. Disposable low-pressure adhesive attachment clip for transcutaneous sensor placement at the earlobe. The clip consists of two clip jaws connected by a coil spring. One of the jaws to be placed at the outside of the earlobe provides a retainer ring for inserting the sensor. This jaw also has a hole in the middle, in which a drop of contact gel has to be applied before inserting the sensor. The sensor can be rotated in the retainer ring for finding a position in which the sensor cable is not stretched or twisted. (From Bernet-Buettiker et al.[92] with permission.)

mates the $Paco_2$. Like $PtcO_2$, the proximity with which $PtcCO_2$ approximates $Paco_2$ is the result of a complex set of physiologic events; thus it is incorrect to believe that $PtcCO_2$ is the $Paco_2$. For example, decreased tissue perfusion causes $PtcCO_2$ to increase.

A miniaturized single sensor combining the measurement of pulse oximetry (Spo_2) and $PtcCO_2$ (TOSCA, Linde Medical Sensors) recently become available (Fig. 31–14). The TOSCA measurement system is based on a heated Severinghaus electrode combined with a pulse oximetry sensor and is attached to the earlobe with an attachment clip. The pressure exerted by the attachment clip to the skin is approximately 12 mm Hg. According to the manufacturerís data, the in vitro 90% response time for PCO_2 is <50 seconds. The sensor is calibrated in vitro using a one-point dry gas calibration with 7% CO_2 when the sensor is placed in its calibration chamber. The calibration takes 2 minutes, allowing rapid repositioning every 8 hours. The sensor is heated to 42°C to induce local vasodilatation and enhance skin permeability for CO_2 to improve gas diffusion at the site of measurement. The sensor is cleaned with alcohol and dried before each application. One drop of contact gel is applied on the skin in the center of the attachment clip before the sensor is applied. The sensor is removed after 8 hours, recalibrated, and fixed on the other earlobe. Several studies have reported the accuracy of this device compared to $Paco_2$.[92–96]

LUNG MECHANICS AND GRAPHICS

Pulmonary mechanics is the expression of lung function through measurements of pressure and flow.[97–99] From these measurements, a variety of derived indices can be determined, such as volume, compliance, resistance, and work of breathing. Pulmonary graphics are derived when one of the parameters of pulmonary mechanics is plotted as a function of time or as a function of one of the other parameters. This produces scalar pressure–time, flow–time, and volume–time graphics as well as flow–volume and pressure–volume loops. Current-generation critical care and anesthesia ventilators provide monitoring of pulmonary mechanics and graphics in real time.

Airway pressure is universally measured during mechanical ventilation. Peak airway pressure is predicted mathematically by the Equation of Motion, which describes the relationship between proximal airway pressure (Paw), the pressure generated by the respiratory muscles (Pmus), respiratory system compliance (C), tidal volume (V_T), airways resistance (R), flow ($\dot{V}$), and the level of PEEP:

$$Paw + Pmus = V_T/C + R \times \dot{V} + PEEP. \quad (31–27)$$

The Equation of Motion predicts that proximal airway pressure will increase with a higher tidal volume, lower respiratory system compliance, higher airway resistance, higher inspiratory flow, higher PEEP, and presence of auto-PEEP.

Because of airway resistance, proximal airway pressure will always be greater than alveolar pressure during inspiration when flow is present. During volume-controlled ventilation, plateau pressure (P_{plat}) is measured by applying an end-inspiratory breathhold for 0.5–2 seconds, during which pressure equilibrates throughout the respiratory system so that the pressure measured at the proximal airway approximates the peak alveolar pressure (Fig. 31–15). P_{plat} cannot be accurately measured during active breathing and thus cannot be measured with ventilator modes such as pressure support ventilation. During pressure-controlled

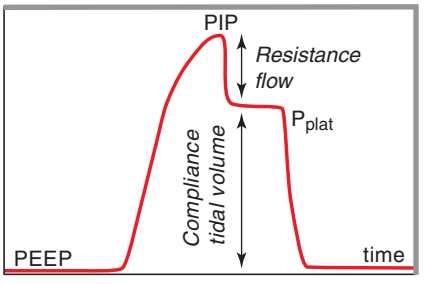

FIGURE 31–15. Schematic representation of a pressure waveform during volume-controlled ventilation. The difference between peak inspiratory pressure (PIP) and plateau pressure (P_{plat}) is determined primarily by airway resistance and flow. The difference between P_{plat} and the level of PEEP is determined by compliance and tidal volume.

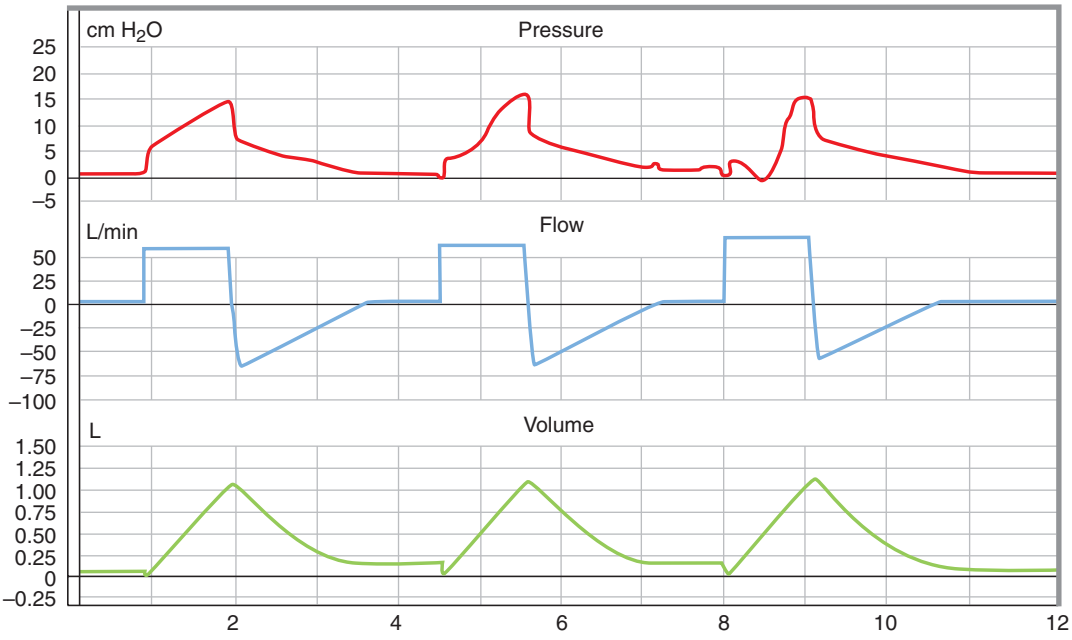

FIGURE 31–16. Example of patient–ventilator dyssynchrony in a patient on volume-controlled ventilation. Note the breath-to-breath changes in airway pressure waveform. (From Nilsestuen and Hargett[100] with permission.)

ventilation, the flow may decrease to zero before the end of the inspiratory phase, in which case peak inspiratory pressure (PIP) and P_{plat} are equal. Breath-to-breath variability of airway pressure occurs with patient–ventilator dyssynchrony (Fig. 31–16).[100,101]

P_{plat} is determined by tidal volume and respiratory system compliance:

$$P_{plat} = V_T/C. \quad (31–28)$$

P_{plat} indicates the risk of alveolar overdistension during mechanical ventilation and should be maintained at ≤30 cm H_2O.[102] The lower the P_{plat}, the lower is the risk of ventilator-induced lung injury.[103] However, a higher P_{plat} may be safe (and necessary) if intrapleural pressure is elevated (e.g., abdominal distension, decreased chest wall compliance).

Incomplete emptying of the lungs occurs if the expiratory phase is terminated prematurely. When this occurs, alveolar pressure does not equilibrate with proximal airway pressure at end-exhalation, and gas trapping results. The pressure produced by this trapped gas is called auto-PEEP or intrinsic PEEP. Auto-PEEP increases the end-expiratory lung volume (hyperinflation). It is measured by applying an end-expiratory pause for 0.5–2 seconds (Fig. 31–17). The pressure measured at the end of this maneuver that is in excess of the PEEP set on the ventilator is auto-PEEP.[104–108] For a valid measurement, the patient must be relaxed and breathing in synchrony with the ventilator. Many patients with chronic obstructive pulmonary disease (COPD) contract their abdominal muscles during exhalation. This is an important determinant of auto-PEEP for these patients but does not produce hyperinflation. It has also been shown that the end-expiratory pause method can underestimate auto-PEEP with complete airway closure during exhalation, as may occur during mechanical ventilation of patients with severe asthma.[108] The risk of auto-PEEP is greater with increased resistance and compliance (e.g., chronic obstructive lung disease), increased respiratory rate or increased inspiratory time (both decrease expiratory time), and at increased tidal volume. It follows that auto-PEEP can be reduced by decreasing minute ventilation (rate or tidal volume), increasing expiratory time, or decreasing the airways resistance (e.g., bronchodilator administration). During mechanical ventilation, set-PEEP may counterbalance auto-PEEP in patients with flow limitation, and thus auto-PEEP should be measured at PEEP = 0.

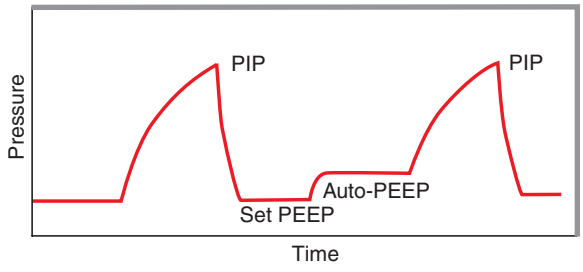

FIGURE 31–17. Measurement of auto-positive end-expiratory pressure (PEEP) with an end-expiratory pause maneuver. The difference between the pause pressure and the set PEEP level is the amount of auto-PEEP.

Esophageal pressure is measured with a balloon inflated with a small volume of air (<1 mL) that is placed into the lower esophagus.[109] Esophageal pressure changes reflect changes in pleural pressure. However, the absolute esophageal pressure does not reflect the absolute pleural pressure. Changes in esophageal pressure can be used to assess respiratory effort and

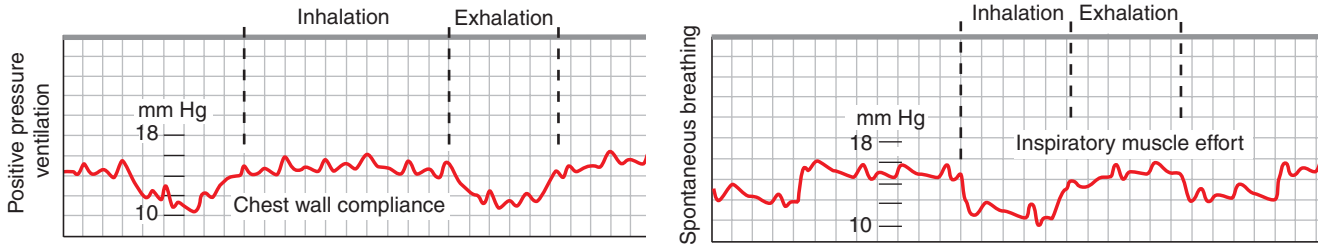

FIGURE 31–18. Left. During positive-pressure ventilation in a relaxed patient, the increase in central venous pressure (CVP) during the inspiratory phase is determined by chest wall compliance. **Right.** During spontaneous breathing, the decrease in CVP during the inspiratory phase is determined by inspiratory muscle effort.

work of breathing during spontaneous breathing, to assess chest wall compliance during full ventilatory support, and to assess auto-PEEP during spontaneous breathing. If an esophageal balloon is not present, changes in pleural pressure can be crudely estimated by observing the respiratory variability of the central venous pressure (Fig. 31–18).[110]

Gastric pressure can be measured with a balloon inserted into the stomach. Gastric pressure reflects intraabdominal pressure. Measures of phasic gastric pressure during spontaneous breathing usually reflect diaphragmatic function. Normally, gastric pressure (intraabdominal pressure) should increase during inhalation. If the gastric pressure decreases during a spontaneous inhalation, this is consistent with diaphragmatic paralysis (Fig. 31–19).[111] In the absence of a gastric balloon, respiratory variation of bladder pressure can be used.

If exhalation is passive, the change in esophageal pressure required to reverse flow at the proximal airway (i.e., trigger the ventilator) reflects the amount of auto-PEEP. Negative esophageal pressure changes that produce no flow at the airway indicate failed respiratory triggering efforts (Fig. 31–17). Clinically, this is recognized as a patient respiratory rate that is greater than the trigger rate on the ventilator (readily observed by inspecting chest wall movement).[112]

A useful application of the airway flow waveform is for detection of auto-PEEP. If the expiratory flow does not return to baseline, this indicates the presence of auto-PEEP. Although the flow waveform is useful for detecting auto-PEEP, it does not quantitatively indicate the amount of auto-PEEP. Dips in expiratory flow indicate trigger efforts in which the patient's inspiratory effort was insufficient to overcome auto-PEEP and trigger the ventilator (Fig. 31–20).

Respiratory system compliance (C_{rs}) is assessed in mechanically ventilated patients as the tidal volume divided by the pressure required to deliver that volume:

$$C_{rs} = \Delta V/\Delta P = V_T/(P_{plat} - PEEP). \quad (31–29)$$

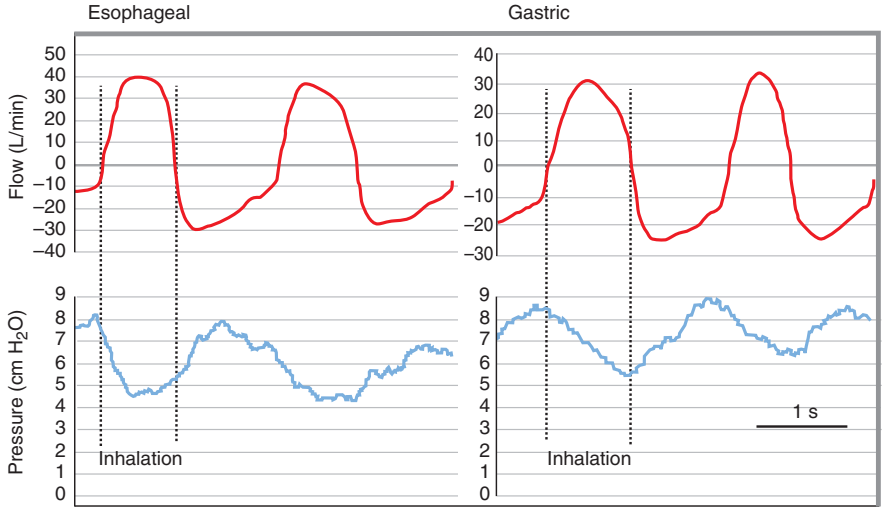

FIGURE 31–19. Esophageal and gastric pressure changes in a patient with diaphragmatic paralysis. Note that both esophageal and gastric pressures have negative deflections during the inspiratory phase. (From Lecamwasam et al.[111] with permission.)

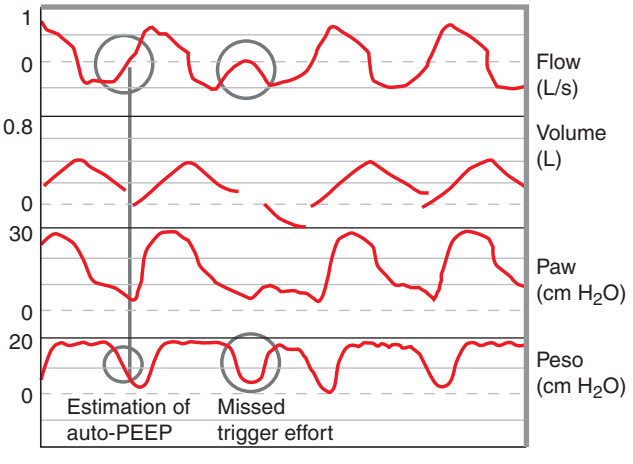

FIGURE 31–20. Esophageal pressure measurements in a patient with auto-positive end-expiratory pressure (auto-PEEP). Note that an esophageal pressure drop of approximately 10 cm H_2O is necessary to trigger the ventilator. This represents an auto-PEEP level of approximately 10 cm H_2O. Also note an inspiratory effort that is not great enough to overcome auto-PEEP and trigger the ventilator. Expiratory pressure does not return to zero before the subsequent breath is initiated.

Respiratory system compliance typically is 50–100 mL/cm H_2O in mechanically ventilated patients and is determined by the compliance of the lungs and chest wall. Chest wall compliance is calculated from the change in esophageal pressure (pleural pressure) during passive inflation. Chest wall compliance normally is 200 mL/cm H_2O and can be decreased by abdominal distension, chest wall edema, chest wall burns, thoracic deformities (e.g., kyphoscoliosis), and an increase in muscle tone (e.g., a patient who is "bucking" the ventilator). Chest wall compliance is increased with flail chest and paralysis. Lung compliance is calculated using the transpulmonary pressure; in other words, the difference between alveolar pressure (P_{plat}) and pleural pressure (esophageal). Normal lung compliance is 100 mL/cm H_2O and will be decreased by pulmonary edema (cardiogenic or noncardiogenic), pneumothorax, lung consolidation, atelectasis, pulmonary fibrosis, pneumonectomy or lung resection, mainstream intubation, and hyperinflation. Lung compliance is increased with emphysema.

During volume-controlled ventilation, inspiratory airways resistance can be estimated:

$$R_I = (PIP - P_{plat})/\dot{V}_I, \quad (31\text{–}30)$$

where $\dot{V}_I$ = end-inspiratory flow. A simple way to make this measurement is to set the ventilator for a constant inspiratory flow of 60 L/min (1 L/s). Using this approach, the inspiratory airways resistance is PIP – P_{plat}. Common causes of increased airway resistance are bronchospasm, secretions, and a small inner-diameter endotracheal tube. For intubated and mechanically ventilated patients, airways resistance should be < 10 cm H_2O/L/s at a flow of 1 L/s. Expiratory airway resistance typically is greater than inspiratory airway resistance.

The pressure–volume curve represents the static relationship between pressure and volume of the respiratory system (lungs, abdomen, rib cage, and respiratory muscles). It can be constructed using a number of techniques that measure pressure as the lungs are inflated or deflated.[113] This requires a completely relaxed chest wall; thus, the patient must be paralyzed for the best results. The respiratory system pressure–volume curve can be separated into the lung and chest wall curves by estimating pleural pressure with an esophageal balloon. In the normal respiratory system, the shape of the pressure–volume curve is nearly linear above the resting volume. The inflation and deflation curves demonstrate differences in their shape and pressure for a given volume (hysteresis). The inflation curve with ALI begins with a flat portion followed by a transition to a steeper more compliant region (Fig. 31–21). This transition has been called the lower inflection point (P_{Flex}). The curve continues with a linear progression and at its upper end undergoes another transition to a flat region. This transition has been called the upper inflection point. On deflation, a similar shape is achieved but at a lower pressure than the inflation curve. The lower P_{Flex} has been equated with the closing volume, and the upper P_{Flex} has been equated with overdistension. Determination of inflection points often is arbitrary and inaccurate. Methods have ranged from eyeball approximation to graphical curve-fitting methods. Interobserver variability in the determination of P_{Flex} has been reported.[114] Methods based on curve-fitting equations may provide more accurate estimates of the inflection points.

There has been enthusiasm for use of pressure–volume curves to optimize ventilator settings by setting PEEP above P_{Flex} and setting P_{plat} below the upper P_{Flex}. Recent observations and analysis of the pressure–volume curve in ARDS have changed its interpretation and implications for management. The chest wall affects P_{Flex} and determination of the upper inflection point.[115,116] These observations imply that the pressure–volume curve should be measured with an esophageal balloon to determine the inflection points for the lung alone. Because the pressure–volume curve represents the sum behavior of all ventilated lung units and given the heterogeneity of lung injury, it might not be possible to determine ideal points of recruitment or overdistension. Mathematical modeling suggests that PEEP settings based on P_{Flex} may not be adequate to ensure an "open lung."[117,118]

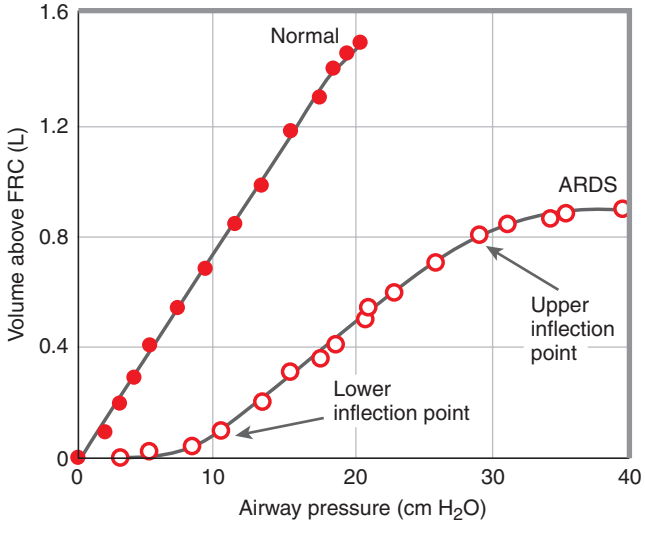

FIGURE 31–21. Pressure–volume curve during mechanical ventilation. Note that the curve is nearly linear in the normal condition. In acute respiratory distress syndrome, the curve demonstrates a lower inflection point and an upper inflection point.

MONITORING IN PERSPECTIVE

How much monitoring is needed? This is an important question for both clinicians and administrators. Clinicians often want to monitor everything possible, with a "more is better" attitude. On the other hand, administrators and managed care providers become concerned with the costs and complexity associated with monitoring.

The presence of many monitors at the bedside can be distracting to clinicians. Many monitoring systems tend to beep, buzz, and blink constantly, attracting attention excessively. Bentt et al.[119] found that a pulse oximeter alarm was present up to 47% of the time (28 min/h) in a 10-bed surgical

ICU, and that many of these were false alarms that required no intervention. During anesthesia monitoring, Kestin et al.[120] found that 75% of all alarms that sounded were spurious, and only 3% indicated a risk to the patient. In an adult ICU, monitor alarms were present 20% of the time, with an average peak sound level of nearly 80 dBA (decibels measured using the A weighting filter); the Environmental Protection Agency (EPA) recommends that noise levels in hospitals not exceed 45 dBA.[121] Monitoring is often useful in patient care. However, monitoring should not be done just because it is technically feasible. Technical capability must be balanced against clinical usefulness, cost effectiveness, and safety. The decision to monitor, like any other clinical decision, should be based on achieving therapeutic objectives in a safe and cost-effective manner.

CHAPTER 32

Intraoperative Neurologic Monitoring

John C. Keifer, MD, and
Cecil O. Borel, MD

Intraoperative neurologic monitoring is based on measuring changes in neurologic function that reflect injury to the nervous system. Neurologic function can be assessed intraoperatively either by repeated neurologic physical examinations or by inducing observable responses through electrical or magnetic stimulation of the nervous system. Because much of intraoperative neurophysiologic monitoring depends on some measurement of the electroencephalogram (EEG), this chapter starts with a brief overview of the cellular mechanisms responsible for the genesis of the EEG. Phenomena that modify electrical brain function and electrical activity are considered in order to appreciate the possibilities and limitations of electrical monitoring in guiding anesthesia administration and safeguarding the integrity of the nervous system. The use of anesthetic techniques that minimize interference with monitored neurophysiologic function are presented, as are techniques that allow for rapid emergence enabling intraoperative neurologic testing, immediate postoperative assessment, and continuous postoperative assessment in the ICU.

ELECTRICAL METHODS

EEG

The EEG was first measured in 1875 by Richard Caton, who noted the electrical oscillations on the exposed cortical surface of animals. The physiologic mechanisms and cortical morphology responsible for generating the EEG are presented by Martin,[1] and some essential features are summarized here.

Neural Basis of the EEG

The EEG is Derived from Postsynaptic Potentials on Pyramidal Cells The two major classes of cortical neurons are pyramidal and nonpyramidal. Pyramidal cells derive their name from their distinctive shape and are notable as the only neurons that project axons out of the cerebral cortex and locally as well. Their apical dendritic spines are oriented perpendicular to the cortical surface and extend through the lamina of the cortex, enabling connection with all of the nonpyramidal cortical cells. Nonpyramidal cells modulate pyramidal cell output through stimulation (glutamate alteration of postsynaptic potential) or inhibition [γ-aminobutyric acid (GABA) alteration of postsynaptic potentials; Fig. 32–1 and Table 32–1].

Collective Voltage of Cortical Neuron Ensembles are Measurable at the Scalp The parallel orientation of the pyramidal cells enables measurement of the constructive addition of polarity from each cell at the surface of the cerebral cortex (Fig. 32–2).

Because postsynaptic potentials last for a relatively long time and are geometrically aligned, it is possible for the potentials to summate to a sufficiently large magnitude that they can be measured by electrodes placed on the scalp. Action potentials, which are of a much larger magnitude than are postsynaptic potentials, are too brief to enable summation and therefore do not contribute to the EEG. Similar mechanisms for generation of the EEG are presented by Rampil,[2] Lukatch and Greenwald,[3] and McPherson.[4] The EEG is an electrical potential versus time measurement that measures cortical voltages at the scalp resulting from the collective postsynaptic potentials of ensembles of cortical pyramidal cells.

Synchronous versus Desynchronous EEG Patterns This cellular mechanism forms the conceptual basis of two basic patterns of EEG, synchronous and desynchronous EEG. A synchronous EEG is composed of large-amplitude peaks with slow-frequency oscillations. Referring to the basic mechanism presented previously, a synchronous EEG results when an ensemble of many cortical dendrites is polarized in synchrony. The voltage amplitude is large because the individual depolarizations are additive. The thalamus serves as the orchestrator of pyramidal cell depolarization during EEG synchrony, and the frequency of thalamic stimulation determines the slow rate of cortical polarization/depolarization.[5] A desynchronous EEG results when cortical dendrites are polarized by a less circumscribed group of afferent nerves. The consequence of

KEY POINTS

1. Anesthetic strategies to enhance intraoperative monitoring of the nervous system include techniques that minimize interference with neurophysiologic modalities as well as techniques that preserve neurocognitive function during structure and function mapping in the awake patient.
2. The cellular basis of a normal electroencephalogram (EEG) reveals a variety of pathways that produce alterations of electrical and neurocognitive function.
3. Synchronous EEG is seen with sleep, sedation and anesthesia, and cerebral ischemia.
4. Processed EEG algorithms can aid with objective assessment of EEG changes. Given an understanding of the EEG features analyzed by these algorithms, pitfalls leading to inaccurate assessment can be avoided.
5. Achieving reliability with evoked potential monitoring depends on minimizing anesthetic effect, maintaining a constant anesthetic level, and assuring adequate nervous tissue perfusion.
6. Intraoperative wakefulness for cortical mapping has been achieved by a variety of techniques. For a procedure to be successful, any techniques used must address the maintenance of effective ventilation during craniotomy and a balance of clear sensorium and sufficient analgesia to enable effective patient participation during cortical mapping.
7. Subarachnoid block for placement of epidural stimulating electrodes allows for maintained patient perception of electrode stimulation while providing effective anesthesia for laminotomy.

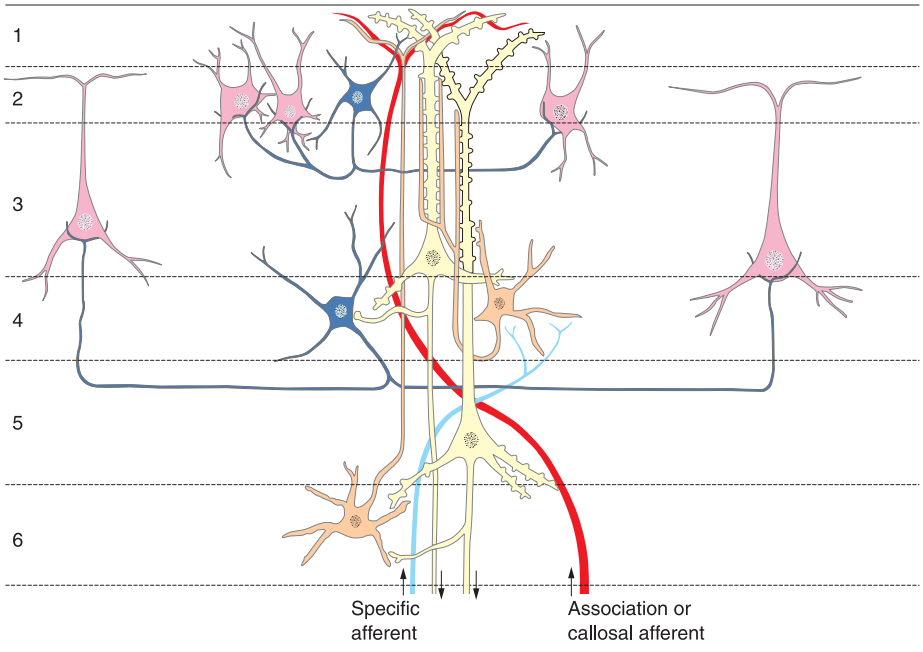

FIGURE 32–1. Schematic of cortical pyramidal, basket, and interneurons. (Data from Martin JH. The collective electrical behavior of cortical neurons: The electrocephalogram and the mechanisms of epilepsy. In: Kandel ER, Schwartz JH, Jessel TM, eds. Principles of Neural Science. 3rd ed. Appleton & Lange, 1991:777–91.)

diverse sources of polarizations is a faster frequency of oscillation. The polarizations are not additive and therefore are of lower amplitude. Drawing from this conceptual framework, certain patterns are evident in the normal waking and sleeping EEG (Fig. 32–3). A normal EEG from an awake alert person is characterized by irregular EEG oscillations with a variable frequency >12 (cycles/sec) and relatively small amplitude. Low-amplitude, high-frequency EEG activity, the hallmark of desynchronous EEG, is the typical EEG pattern of the awake and dreaming brain (the consciously perceiving brain). Departures from normal waking consciousness during sleep are characterized by a slowing of the oscillation frequency and an increase in amplitude of the voltage oscillation. Neuronal discharge is no longer subject to the ambient environmental stimulus–response characteristics of wakefulness. Orchestration of neuronal discharge now is directed by central pattern generators (presumably located in the thalamus).[5] The constructive interference of these waves is evidenced by large-amplitude, slow-frequency EEG traces, the hallmark of the synchronized EEG of the sleeping brain.

Desynchronous EEG: Wakefulness and Rapid Eye Movement Sleep One of the early findings in sleep research was that the EEG reverted from a synchronous pattern (low frequency, large amplitude) to a desynchronous pattern when a subject passed from non-rapid eye movement (non-REM) sleep to REM sleep. Because subjects were able to report dreams (cognitive activity) at the conclusion of these episodes and awake patients also demonstrated a desynchronous EEG, the notion developed that EEG desynchrony was the electrical correlate of a cognitively functioning brain. Conversely, EEG synchrony was the hallmark of the unconscious brain. The transition from desynchronous EEG to synchronous EEG during sleep onset is characterized by the gradual appearance of slow oscillations in the EEG. The tendency for an EEG to develop a synchronous pattern is also known as *slowing*.

TABLE 32–1.

Cortical Neurons Contributing to Generation of the Electroencephalogram

Neuron	Cytologic Features	Synapses with	Neurotransmitter	Stimulates or Inhibits Target Neuron
Pyramidal cell	Spiny dendrites	Only output neurons of the cortex	Glutamate	Stimulates
Interneuron	Stellate shape, no dendritic spines	Pyramidal cell dendrites	Glutamate	Stimulate
Basket cell	Envelop the soma of postsynaptic cell bodies, hence the name basket	Pyramidal cell bodies, hence the name basket	γ-Aminobutyric acid	Inhibits pericolumnar inhibition, enabling neurons in a given cortical column to function in relative isolation from neighboring columns

(Martin JH. The collective electrical behavior of cortical neurons: The electrocephalogram and the mechanisms of epilepsy. In: Kandel ER, Schwartz JH, Jessel TM, eds. Principles of Neural Science. 3rd ed. Appleton & Lange, 1991:777–91.)

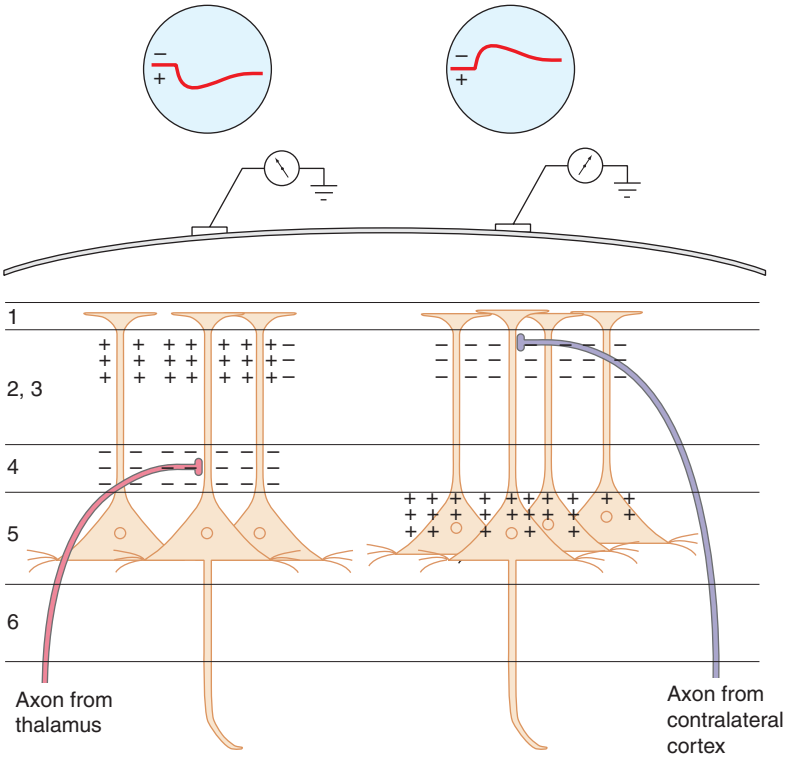

FIGURE 32–2. Scalp voltage potential depend on perpendicular orientation of pyramidal cells and the polarity of the apical dendrites. (Martin JH. The collective electrical behavior of cortical neurons: The electrocephalogram and the mechanisms of epilepsy. In: Kandel ER, Schwartz JH, Jessel TM, eds. Principles of Neural Science. 3rd ed. Appleton & Lange, 1991:777–91.)

Synchronous EEG: Natural Sleep, Drug-Induced Sedation, "Light" Anesthesia, and Cerebral Ischemia All of these states usually are marked by an alteration of consciousness. But all of these states are not equivalent in terms of the degree of altered wakefulness, nor are they equivalent in terms of the likelihood of return to normal consciousness. However, for all of these states, a return to normal waking consciousness is associated with a return of a desynchronized EEG pattern. In summary, the synchronous EEG does not specifically identify the cause of EEG synchrony (and its associated alteration of consciousness). Therefore, synchronous EEG will be less than specific in predicting the consequences.[6]

"The following four points, while highly simplified, represent key concepts in EEG generation. (1) EEG signals recorded at the skull surface represent the summated post synaptic potential of hundreds of thousands to millions of pyramidal neurons. (2) While EEG rhythms recorded at the skull surface are generated by neocortical neurons, these rhythms may originate either in the neocortex itself, or they may be 'imposed on' the neocortex by subcortical structures which 'pace' the activity of neocortical neurons. (3) Multiple neurotransmitter systems can be involved in generating different types of EEG activity. (4) EEG activity within individual frequency bands (i.e., delta, theta, alpha, beta or gamma) likely represents more than one phenomenon."[3]

Studies Suggesting the Cellular Mechanisms for EEG Synchrony: How Sleep, Anesthesia, and Cerebral Lesions Slow the EEG Amzica and Steriade[5] review the evidence for the cellular mechanisms of slow wave generation during natural sleep. Their summary describes three different oscillations that "coalesce into the polymorphic wave of slow wave EEG sleep" (Fig. 32–4). Salient points from their review include the following. (1) Cellular discharge data are obtained from cats anesthetized with ketamine and xylazine. Therefore, there is a leap of faith that the mechanism of slowing from sleep versus anesthesia is the same. (2) Human data during natural sleep are not obtained from single cells but from scalp EEG. Therefore, there is an assumption that cellular data from anesthetized cats can be extrapolated to unmeasured cellular phenomena of sleeping humans because of a similarity of the EEG from both groups. (3) Deafferented cortex (cortex disconnected from thalamic input by surgical prep or tumor) tends to reveal a slow wave pattern.

The *EPITIDE* (*E*nhanced *P*hasic *I*nhibition, *T*onic *I*nhibition and *D*epressed *E*xcitation) *theory* of anesthetic action on patterned brain activity proposes that anesthetic-induced prolongation of inhibitory currents may slow EEG activity by limiting neuronal discharge frequencies of EEG-generating neurons. Lukatch and Greenwald[3] propose that the EEG rhythms arise in neocortical neurons and may also be "imposed" on neocortical neurons by subcortical structures that "pace" the cortex. Multiple neurotransmitter systems are involved, and EEG activity within individual frequency bands likely represents more than one phenomenon. The anesthetic effect on EEG is not a simple transition from the desynchronized EEG to the synchronous EEG but involves an initial EEG activation at subanesthetic concentrations (perhaps an EEG correlate of the clinical excitement phase of subanesthetic levels during induction and emergence). At greater anesthetic exposure the EEG evolves into a synchronous pattern of slowing, followed at even greater exposure by isoelectric EEG with bursts of oscillation. It is hypothesized that at the network level, this cellular effect could produce a state in which low-frequency EEG oscillations (e.g., δ activity) are supported by the network, whereas higher-frequency oscillations are filtered out (much like the activity of a low-pass filter in an electronics circuit). Lukatch and Greenwald state that the theory relies on an anesthetic effect on the cortical networks to explain the EEG effect. The theory does not address the role of subcortical networks of cortical slowing proposed for the mechanism of natural sleep-related EEG slowing. Further observations are required for confirmation.

EEG changes induced by a variety of insults include EEG slowing, burst suppression, and isoelectric activity. Neuronal electrophysiologic changes responsible for these EEG changes were explored by Rabinovici et al.[7] This study used an in vitro rat brain slice model, which enabled the measurement of single-cell discharge and simultaneous cortical field potential (analogous to EEG) resulting from exposure to

the brain slice to hypoxia, ischemia, and hypoglycemia. The findings show that EEG slowing, burst suppression, and isoelectric EEG occur with varying patterns depending on the lesion, and that some patterns of damage occur with recovery from the insult. This study did not specifically address the role of subcortical structures (i.e., thalamus) in the generation of slowed EEG, suggesting that thalamic mechanisms may not be necessary for the genesis of a slowed EEG in response to cerebral insult.

The work of Amzica and Steriade, Lukatch and Greenwald, and Rabinovici et al. illustrate that ischemia, hypoxia, hypoglycemia, and anesthesia produce cortical EEG slowing by a variety of cellular electrophysiologic mechanisms that may not be distinguishable from the macroscopic EEG.

Intraoperative EEG Uses

The foregoing discussion indicates that a variety of "natural," pharmaco-

logic, and pathologic causes alter conscious brain function and the associated EEG. This overlap points to the necessity of obtaining confirmatory data to determine the cause and treatment of such EEG changes.

Ischemia Monitor The EEG is not homogeneous throughout the skull (Fig. 32–5). EEG activity varies considerably depending on the location of the electrode pair being monitored. Therefore, a standardized scheme of electrode application, the 10–20–20 system, has been developed to more reliably position EEG sensing electrodes using surface landmarks of the head for reference points. This reference system enables placement of electrodes at positions that are likely to detect EEG changes due to alteration of local perfusion or evoked EEG changes due to stimulation of a particular extremity (Fig. 32–6).

Doubt has been cast that the standard 10–20–20 system has sufficient spatial sensitivity to determine small areas of cerebral ischemia.[8] However, the EEG is symmetric about the midline, with EEG activity on one hemisphere generating a "mirror image" of the same area on the other side of the midline. This feature adds a benefit of internal control when assessing changes in an area of EEG activity. If the mirror image area of one hemisphere does not mimic the change on the other side, then the change is focal and likely due to a change in the activity of the area under monitoring. Symmetric changes of activity in both hemispheres noted in EEG suggest a global source of altered neural activity and therefore more likely due to global changes (i.e., blood pressure, oxygenation, anesthetic depth). The converse is also true. Focal changes in EEG activity over one portion of the brain may not be detected over another portion of the same brain. This fact

Data from Chiappa et al.[9]

has consequence when attempting to describe a global change in cerebral activity from one focal electrode pair.

The ischemic effect of carotid cross-clamping was reported by Chiappa et al.[9] in 1970 (Table 32–2). A variety of postclamping patterns were noted. The changes were not global but reflected local changes in activity, underscoring the importance of a symmetric array of electrodes in detecting changes over one hemisphere versus the other. EEG changes were sometimes observed over the cerebral hemisphere opposite to the clamped side, suggesting an interruption of collateral circulation.

A Cochrane meta-analysis reviewed two prospective randomized studies (composed of 590 patients) that compared routine selective shunting strategy versus no shunt strategy for carotid endarterectomy (CEA).[10] The analysis reviewed a third study that explored the potential benefit of intraoperative EEG monitoring for identifying CEA patients who would benefit from shunting. The authors concluded "There is still insufficient evidence from randomized controlled trials to support or refute the use of routine or selective shunting during carotid endarterectomy. Further, there is little evidence to support the use of one form of monitoring over another in selecting patients requiring a shunt."

"As regards the method of monitoring in selective shunting, until the efficacy of shunting has been demonstrated, further trials of the method of monitoring are probably not merited."[10] This Cochrane analysis does not address the use of other potential strategies for brain protection during endarterectomy, including hypothermia, burst suppression, induced hypertension, and techniques performed on an awake patient (either endovascular carotid angioplasty or transcutaneous endarterectomy performed under local anesthesia).

Once the decision is made to monitor the EEG for cerebral ischemic changes during any surgery, then comes the problem of determining whether a change in EEG is due to focal hypoperfusion, generalized hypoperfusion (from low systemic blood pressure), or an anesthetic effect. These possibilities guide the anesthesiologist toward a strategy of anesthetic management during procedures that may result in ischemia:

1. Rely on anesthetic agents that have the least effect on EEG activity (short-acting narcotics, benzodiazepine; Table 32–3).
2. Maintain a constant anesthetic level throughout the procedure, especially during critical periods.
3. Be prepared to raise and lower blood pressure with nonanesthetic agents (inotropes, chronotropes, vasoactive drugs, and volume).
4. Be prepared to use alternate ischemia monitors [i.e., somatosensory evoked potential (SSEP) if burst suppression will be used for "cerebral protection"].
5. Perform the carotid surgery with the patient awake.

USING EEG TO MONITOR BURST SUPPRESSION

The human data regarding burst suppression as a guide for administering anesthetics for cerebral protection is mixed. Patients in whom focal iatrogenic ischemia is induced during middle cerebral artery (MCA) aneurysm clip ligation have a significant advantage compared with those receiving isoflurane when they are given pentobarbital as the primary neuroprotective agent or when they receive propofol or etomidate titrated to achieve EEG burst suppression.[11] Melgar et al.[12] propose the use of EEG to identify CEA patients who develop ischemic changes following carotid cross-clamp that are refractory to induced hypertension. To these patients, they administer etomidate to achieve burst suppression and proceed with endarterectomy without shunting. Bush et al.[13] conclude that "Percutaneous carotid stenting with neuroprotection provides comparable clinical success to CEA performed under local anesthetic."

However, a multicenter study of the protective effects of propofol-induced burst suppression during cardiac valve replacement showed no effect.[14] Burst suppression achieved through various means (barbiturate or isoflurane) resulted in different effects on cerebral blood flow and calculated cerebral requirement for oxygen,[15] demonstrating that the balance of oxygen delivery to consumption is altered differently by these two agents at equivalent degrees of burst suppression. Therefore, the use of burst suppression as a guide to anesthetic administration during procedures that place the cortex at risk must take account of the anesthetic agent used for the burst suppression, the surgical procedure for which it is intended, as well as the other hemodynamic and ventilatory parameters effecting oxygen delivery to the cortex.

STATE OF ANESTHESIA MONITOR

Why Process an EEG?

The characteristics of the EEG associated with consciousness and unconsciousness are EEG synchrony and desynchrony. Synchronous EEG is obtained in natural sleep, sedation, anesthesia, and cerebral ischemia. Desynchronous EEG is observed during wakefulness and REM sleep (associated with dreaming). The degree of synchrony and desynchrony of the EEG varies. It is difficult for the human observer to reliably measure this feature by inspecting the unprocessed EEG. Therefore, methods for objec-

Intravenous and Inhalational Anesthetic Effect on Somatosensory Evoked Potential and Electroencephalogram

	Effect of Intravenous Anesthetics on Somatosensory Evoked Potentials		
	Early Cortical Waveform[d]		
Drug/Dosage	**Latency**	**Amplitude**	**Subcortical Waveform**
Thiopental			
2.5–5.0 mg/kg	‹10% ↑	5%–30% ↓	Negligible
75 mg/kg	15% ↑	60% ↓	Negligible
Pentobarbital			
Up to 20 mg/kg	≈10% ↑	45% ↓	None (latency), 20% ↓ in amplitude
Ketamine			
0.5 mg/kg	No effect	No effect	No effect
2–3 mg/kg + 2 mg × kg^{-1} × h^{-1}	No effect	0%–30% ↑	Negligible
Etomidate			
0.3–0.4 mg/kg + 2 mg × kg^{-1} × h^{-1}	‹10%↑	40%–180%↑	None (latency), 50% ↓ in amplitude
1 mg/kg	10% ↑	150% ↑	Negligible
Propofol			
2.5 mg/kg	‹10% ↑	No change	Negligible
Propofol			
2.5 mg/kg, then 10 mg × kg^{-1} × h^{-1}	10%–15% ↑	50%	NA
+			
Sufentanil			
0.5 μg/kg, then 0.25 μg × kg^{-1} × h^{-1}			
Midazolam			
0.1–0.3 mg/kg[a]	‹5% ↑	25%–40% ↓	Negligible
Diazepam			
0.1–0.25 mg/kg	Minimal	↓	NA
Morphine			
0.25 mg/kg	‹10% ↑	≈20% ↓	NA
Lidocaine			
1.5 mg/kg, then 3 mg × kg^{-1} × hg^{-1}	5% ↑	25%–30% ↓[b]	Negligible
Fentanyl			
2.5 μg/kg + N_2O	5%–10% ↑	Variable[c]	No change
25–100 μg/kg	‹10% ↑	10%–30% ↓	Negligible
Sufentanil			
Sufentanil + N_2O +0.5% isoflurane/1 μg/kg + infusion	5%–10% ↑	≈50% ↓	No change
5 μg/kg Sufentanil (alone)	≈5% ↑	≈40% ↓	No change (latency), 40% ↓ in amplitude
1 μg/kg + Sufentanil propofol	5%–10% ↑	No change	NA
Remifentanil (with 0.4 MAC isoflurane)			
1 μg/kg + 0.2 μg × kg^{-1} × min^{-1}	NA	15%–30% ↓	NA
2.5 μg/kg + 0.5 μg × kg^{-1} × min^{-1}		30%–40% ↓	
5.0 μg/kg + 1.0 μg × kg^{-1} × min^{-1}		≈40% ↓	
Clonidine			
2–10 μg/kg	No effect	No effect	No effect (latency), 10%↓ in amplitude
Alfentanil			
10 μg/kg alone	NA	50% ↓	NA
100 μg/kg + 2 with N_2O	No effect	40% ↓	NA
Dexmedetomidine			
Low sedative dose	NA	≈10% ↓	≈20% ↓ in amplitude
High sedative does	NA	≈30% ↓	≈10% ↓ in amplitude

tively quantifying the frequency and amplitude characteristics of the EEG have been developed.[2,16] Two methods currently in clinical use are the bispectral index (BIS) and entropy.[17,18]

The Processed EEG

EEG voltage oscillation is sufficiently irregular so that the voltage measured at one instant does not enable an exact prediction of voltage for the next instant. However, EEG voltage oscillation is not completely random. Knowing the voltage at a particular instant allows for prediction of the next voltage with some probability of certainty. The EEG signal is stochastic (from the Greek *stokhos,* meaning to aim), that is, it can be analyzed statistically but may not be predicted precisely. The stochastic nature of the EEG requires that the signal be described in terms of probability. The Fourier transformation of the EEG has been used to provide this summary and is the initial step used in both the bispectral and the entropy methods of EEG signal processing.

Bispectral Array

The three-pronged strategy underlying the analysis of "raw" EEG to derive the BIS is described by Sigl and Chamoun[16] and Rampil[2] (Fig. 32–7). This strategy includes the following: (1) determining the slow wave content of the signal (beta ratio); (2) determining the bico-

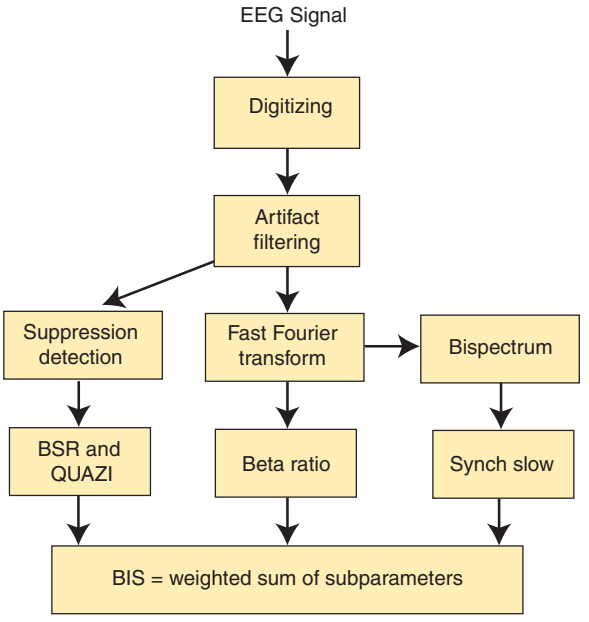

FIGURE 32–7. Three-pronged strategy for generating the bispectral index. (From Rampil[2] with permission.)

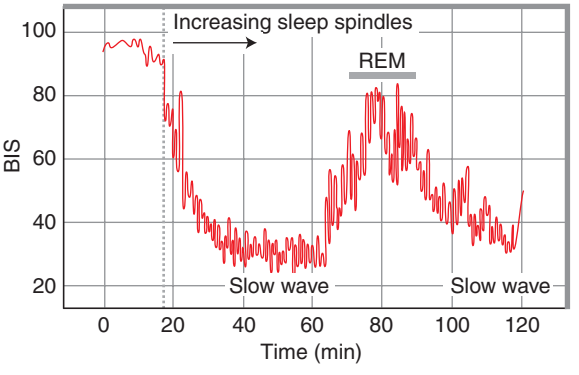
herence all frequency pairs derived from a Fourier transformation (synch slow); and (3) quantifying the amount of burst suppression present in the EEG (burst suppression ratio). These three features are combined in an unspecified, weighted fashion to derive the BIS.

Because the synchronous activity of EEG (slow frequency, large-amplitude oscillations) occurs during progression from wakefulness to natural sleep, does the BIS identify this as well? Sleigh answered this question in a study of human volunteers undergoing natural sleep. The results, summarized in the accompanying figure and table (Fig. 32–8), show that the BIS algorithm will assign low BIS numbers to EEGs from naturally sleeping volunteers. A return of desynchronous EEG (i.e., dreaming) is also identified by an increase in BIS number. The BIS shows a low number during physiologic sleep based on the prevalence of slow EEG activity during that time. The BIS assumption is that this slow EEG activity also corresponds to a deep state of anesthesia. The BIS algorithm does not uniquely identify an anesthetized EEG.

Phase coupling, which is measured by the bicoherence portion of the algorithm, may be the least useful component of the algorithm.[19] In a study of processed EEG obtained from human subjects undergoing induction of anesthesia, Miller et al.[19] conclude that although the power content of a slow-frequency EEG increases as subjects progress from wakefulness to anesthesia, the degree of phase coupling remains unchanged (Fig. 32–9).

These results show that bispectral analysis did not provide any more information than power spectral-based analysis, and that most of the changes in bispectral values result from a decrease in the relative high-frequency content of the EEG caused by anesthesia.[19]



Values of EEG indices at the start of each sleep stage

	BIS	SEF*	EMG	Delta	Alpha
Awake	92 ± 3	21 ± 3	85 ± 12	50 ± 5	52 ± 8
Light sleep	81 ± 9	17 ± 2	88 ± 6	50 ± 5	49 ± 6
Slow wave sleep	59 ± 10	12 ± 2	94 ± 5	50 ± 4	46 ± 7
REM	83 ± 6	14 ± 4	66 ± 14	59 ± 4	44 ± 3

Values are mean + SD.
Data are from 28 sleep stage transitions in five subjects.
BIS = bispectral index, SEF = spectral edge frequency, EMG = power in the low EMG waveband (70–110 Hz), EEG = electroencephalogram.
*The units of spectral power are decibels.

FIGURE 32–8. Bispectral index obtained from human volunteers during natural non-rapid eye movement and rapid eye movement sleep. (Modified from Sleigh JW, Andrzejowski J, Steyn-Ross A, et al. The bispectral index: a measure of depth of sleep? Anesth Analg 1999;88:659–661, with permission.)

Entropy Monitors

Entropy is a concept related to the amount of "disorder" within a system[18] and has been applied to thermodynamics and information theory by Shannon and Weaver and to power spectrums by Johnson and Shore in 1984. The entropy of a signal in the time domain or frequency domain can be computed in a variety of ways. The algorithm implemented by Datex-Ohmeda uses a combination of time and frequency domain approaches (Fig. 32–10). This approach allows for explicit separation of the contributions to entropy from any frequency. The computations are constructed such that the length of the time window for each individual frequency is individually chosen in order to optimize response times. To summarize the algorithm: the raw EEG (signal) is transformed to a power spectrum by fast Fourier transformation (Fig. 32–10, step 1). A Shannon function is performed on each integer frequency to determine the contribution of each frequency to the overall entropy (Fig. 32–10, step 2). The total amount of entropy is determined by summing all the entropy contributions from each integer frequency (Fig. 32–10,step 3). Entropy ranges from 0 (order) to 1 (complete randomness).

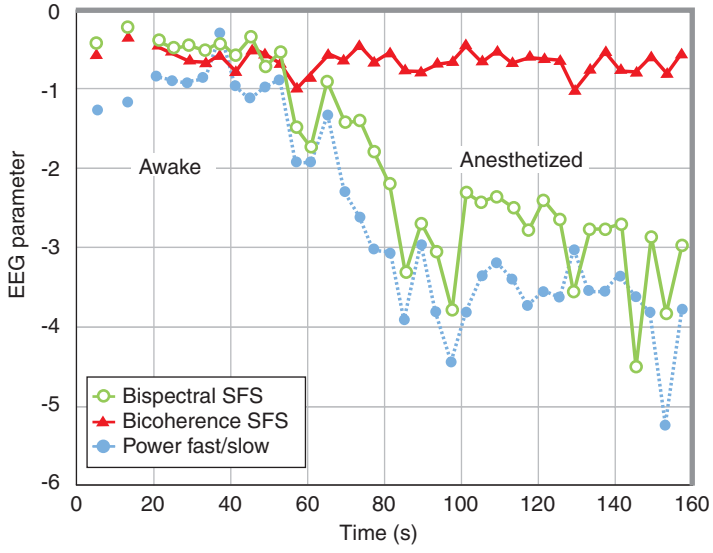


FIGURE 32–9. Wakefulness to anesthesia: comparative change in slow wave content and bicoherence of the electroencephalogram. Miller A, Sleigh JW, Barnard J, et al. Does bispectral analysis of the electroencephalogram add anything but complexity? Br J Anaesth 2004;92:8–13. © The Board of Management and Trustees of the British Journal of Anesthesia. State Entropy and Response Entropy State entropy (SE) is computed over the frequency range from 0.8–32 Hz. It includes the EEG-dominant part of the spectrum and therefore primarily reflects the cortical state of the patient. The time windows for SE are chosen optimally for each particular frequency component and range from 60–15 seconds. Response entropy (RE) is computed over a frequency range from 0.8–47 Hz. It includes both the EEG-dominant and electromyogram (EMG)-dominant parts of the spectrum. The time windows for RE are chosen optimally for each frequency.[18] A study by White et al.[20] comparing the entropy monitor and BIS of 30 laparoscopic patients showed that both the BIS and RE parameters increased after reversal of cisatracurium paralysis. However, the study was not designed to determine the ability of the RE monitor to function as an early predictor of emergence in a muscle-relaxed patient.

Wheeler et al.[21] studied RE in patients who were induced and paralyzed and found that RE increased in a portion of patients undergoing arterial catheter placement or head pin placement before recovery from paralysis. "We conclude that increased RE during painful stimulation was not dependent on recovery from paralysis but was seen more often in patients anesthetized with 0.8% compared with 1.4% isoflurane. This suggests that RE reflects frontal electromyography (FEMG) and may be useful to identify inadequate anesthesia and patient arousal during painful stimuli."

Entropy: Clinical Studies Anesthesia versus Sedation The study by White et al.[20] concluded that "the changes in SE and RE values followed a similar pattern to the BIS values during the perioperative period. Analogous to the BIS, the entropy indices display a high degree of sensitivity and specificity in assessing consciousness during the induction of and emergence from anesthesia and were able to detect changes associated with administration of IV (propofol) and volatile (desflurane) anesthetics during the maintenance period. Finally, the Entropy module experienced less interference with the displayed indices during use of the electrocautery unit than the BIS monitor."

How Does an Entropy Monitor Handle Burst Suppression? Periods of zero EEG voltage have zero entropy because the EEG value is constant. Burst suppression patterns contain variable amounts of entropy because a variable amount of the signal is composed of bursts of oscillations. Therefore the entropy algorithm has been successful in identifying and quantifying the degree of burst suppression.

Conclusion: Bispectral and Entropy Processing of the Raw EEG Whatever method is used—bispectral analysis or entropy—the strategy still seems to address the issue of identifying a synchronous versus a desynchronous EEG. The entropy method uses electrical frequencies in the EMG range in an attempt to use muscle activity as a gauge to anesthetic depth. Those strategies are useful if a number of dictums are kept in mind:

1. There are multiple ways to generate a synchronous EEG including ischemia, natural sleep, and anesthetic. Therefore, a synchronous EEG may not be predictive of the patient's response to stimulation or the time for change from a synchronous to a desynchronous EEG.
2. Although a synchronous EEG may imply a nonperceiving brain, it does not guarantee that state. Nor does it define absolute cutoffs for achieving a nonperceiving state.
3. The use of synchrony/desynchrony evaluation of EEG is effectively done when one looks for a change in the EEG pattern in response to stimulus. An absence of change during noxious stimulation may add confidence that cerebral arousal did not occur (retrospective), but it does not add confidence that noxious-induced activation will not occur (prospective). However, if noxious event-related changes in synchrony to desynchrony do occur, the patient might be at risk for a more overt response to noxious stimulus (in the form of gross movement or recollection of the event).

EVOKED EEG AND EVOKED MUSCLE RESPONSE

Intraoperative evoked potential monitors have received the greatest clinical usage in monitoring integrity of the spinal cord during surgery to correct spinal column deformities, to remove spinal cord tumors and vascular malformations, and to correct vascular lesions that jeopardize the spinal cord vascular supply. The decision to use monitoring is based on the risk and the magnitude of possible deficit versus the predictive value (positive and/or negative) of the monitor in a given operative setting. Except for a few exceptions (i.e., facial nerve monitoring during acoustic neuroma resection),[22] there are no mandatory uses of this monitoring even though a body of evidence supports its use in a variety of circumstances, including the follow-

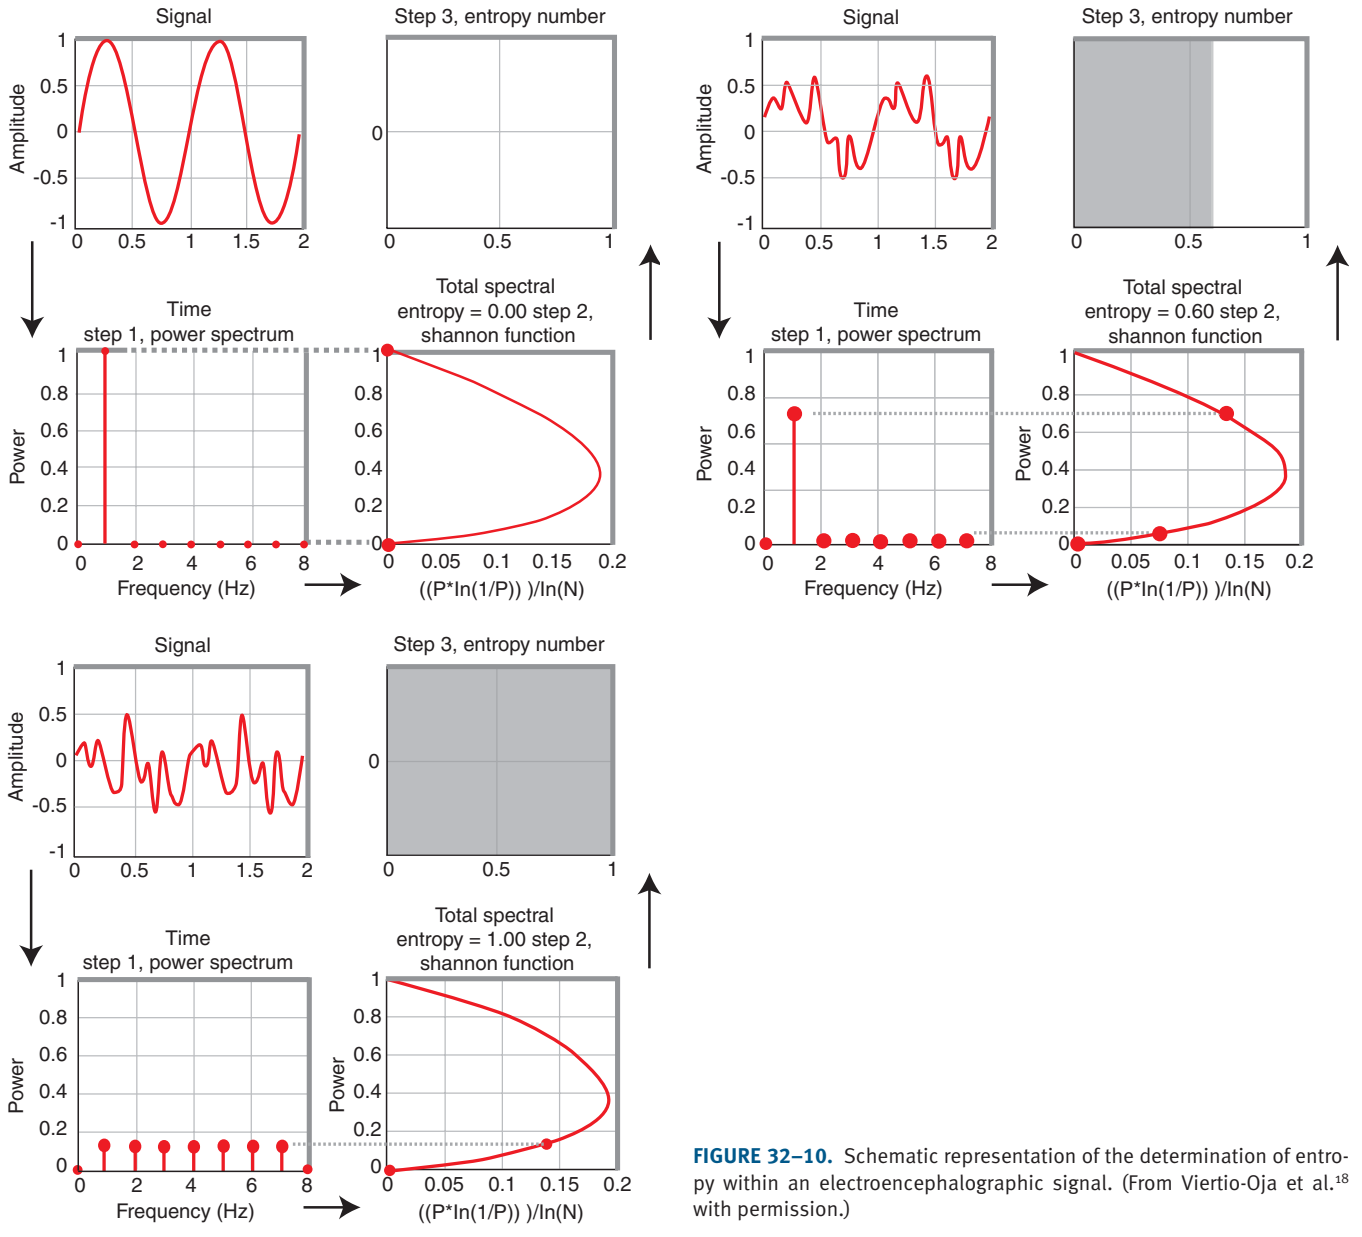

FIGURE 32–10. Schematic representation of the determination of entropy within an electroencephalographic signal. (From Viertio-Oja et al.[18] with permission.)

ing: (1) peripheral nerve or plexus surgery; (2) spinal cord surgery (deformity correction, traumatic spinal fracture repair, tumor removal); (3) brainstem surgery (posterior fossa tumor removal); (4) cerebrovascular surgery (CEA, aneurysm repair); or (5) identification of the sensory portion of the sensorimotor cortex (central sulcus identification or cortical mapping).[23]

How to Evoke a Cortical Response: Anatomy

Site of Stimulation

SSEPs are elicited by stimulation of a peripheral nerve at a distal site, typically the median or ulnar nerves at the wrist for acquiring SSEPs from the upper extremities and the posterior tibial nerves at the ankle or the peroneal nerves at the fibular head for acquiring SSEPs from the lower extremities. Stimulation typically is delivered by adhesive electrodes or fine needle electrodes.

Pathway of the Response Through the Spinal Cord

The SSEP signal enters the spinal cord through dorsal nerve roots and ascends the spinal cord via multiple pathways.[24,25] The posterior column spinal pathways, which decussate at the cervicomedullary junction, primarily mediate the SSEPs. Other pathways, such as the dorsal spinocerebellar tracts and the anterolateral columns, which decussate near the nerve root entry level, may contribute to the early SSEP responses that are used for monitoring purposes.[23]

Implications of Vascular Supply to Cord

The blood supply for nourishing the posterior column pathways that mediate SSEPs is generally thought to be the posterior spinal arteries (Fig. 32–11). The anterior spinal artery is generally believed to provide the primary blood supply to the anterior and anterolateral portions of the spinal cord, which constitute the remaining two thirds of the spinal cord. Motor pathway function is mediated by spinal cord pathways that receive their blood supply from the anterior spinal artery. Therefore, loss of motor function as a result of compromise of the blood supply to the anterior spinal artery may be associated with little or no loss of the sensory function, which is mediated

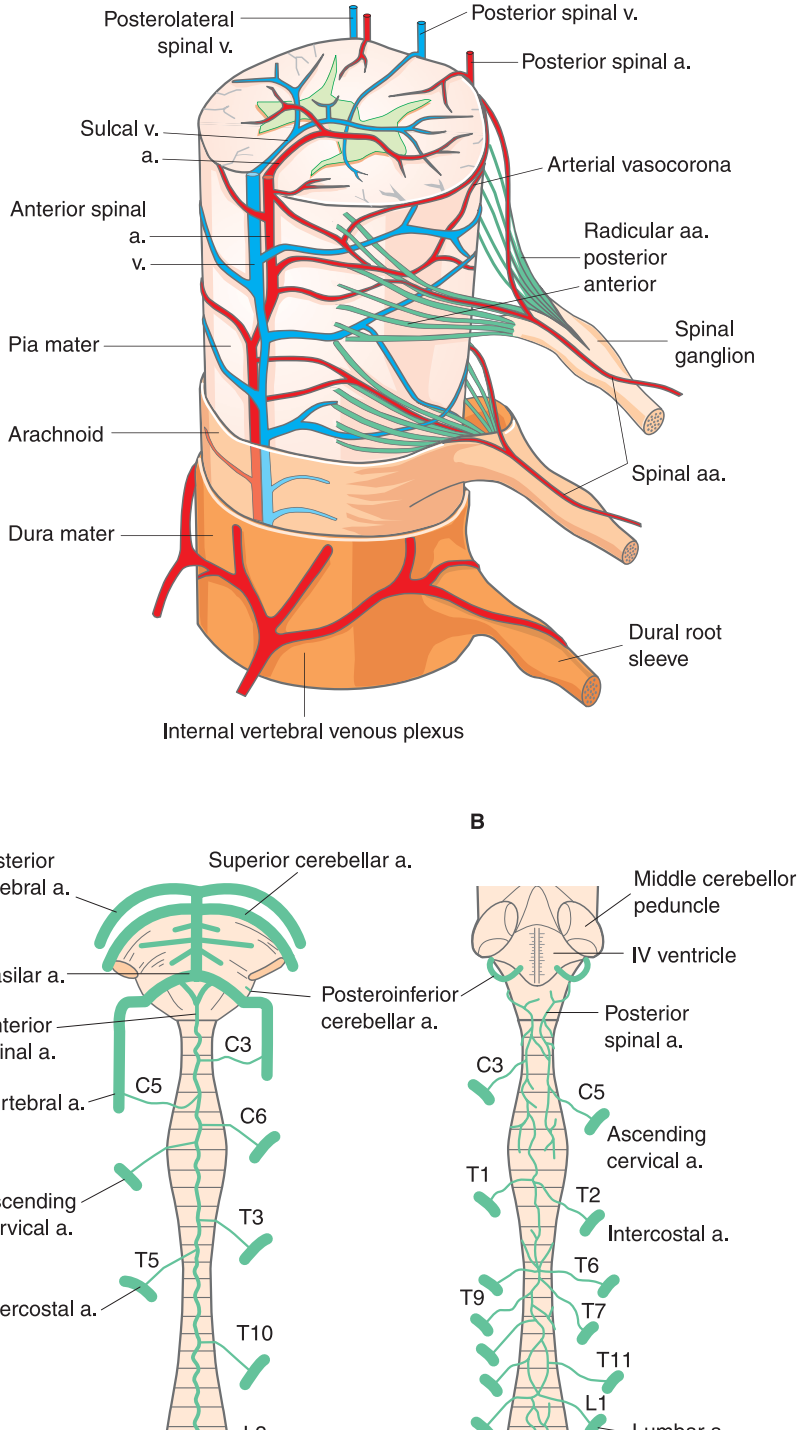

FIGURE 32–11. Vascular supply of the spinal cord. (Reprinted from Marshal WK, Mostrom JL. Neurosurgical diseases of the spine and spinal cord: anesthetic considerations. by the dorsal column pathways (anterior cord syndrome).

Global Cerebral Blood Flow

When cerebral perfusion drops to approximately 18 mL/min per 100 g of tissue, electrical activity of the brain decreases, and SSEPs begin to diminish in amplitude. When perfusion drops to 15 mL/min per 100 g of tissue, electrical activity of the brain drops still further, and SSEPs are generally not recordable. Further drops in blood flow to the brain, particularly if they are sustained, will result in cellular damage and irreversible changes in electrical activity.[23] These responses are dependent upon the blood supply to the brain and brainstem and the specific arterial branches that provide this supply. Perforating branches of the basilar artery and the vertebral artery supply the brainstem. The middle cerebral artery provides the blood supply to the area of the cortex, which mediates upper-extremity SSEPs, whereas the anterior cerebral artery provides the blood supply to the area of the brain that mediates lower-extremity SSEPs.

What Is the Response and How Is It Quantitated?

According to Banoub et al., "The single cortical sensory evoked response has a low amplitude (1–2 microV) compared with the much larger electroencephalogram waves (50–100 microV). Therefore, the EP wave has to be extracted from concurrent spontaneous electroencephalogram activity by repetitive stimulation and computer-signal averaging techniques" (Fig. 32–12).[26] "The EP waveform consists of a series of peaks and valleys presented as a graph of voltage over time and described in terms of amplitude, latency, and morphology. Amplitude is commonly measured as the waves' peak-to-peak voltage difference. Latency is the time from stimulus to the peak of the response. Interpeak latency is the interval between the peaks of interest" (Fig. 32–13).[26]

Anesthetic Effect on SSEP: Implication of Synapses Among Peripheral Nerve Sites, Brainstem, and Cortex

General anesthetics do not affect ascending SSEP responses up to the level of the medullary nuclei (nucleus cuneatus and nucleus gracilis). These early subcortical responses are predominantly a reflection of the integrity of spinal cord white matter and provide little

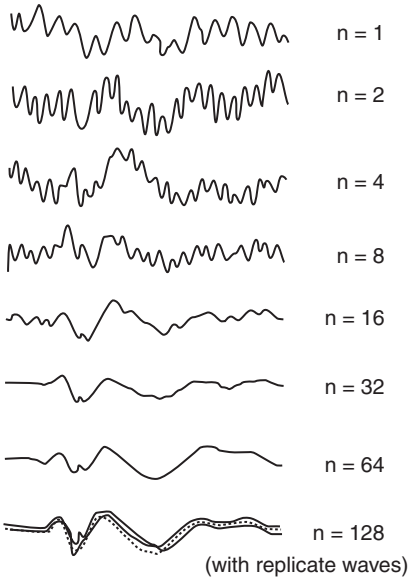

FIGURE 32–12. Evolution of somatosensory evoked potential from the electroencephalogram (EEG) following repetitive peripheral nerve stimulations and signal averaging of EEG epochs synchronized to each stimulus. This article was published in McPherson R. Intraoperative neurologic monitoring. In: Longnecker D, Tinker J, Morgan E, eds. Principles and Practice of Anesthesiology. St. Louis: Mosby, 1998: 883–906, with permission from Elsevier.

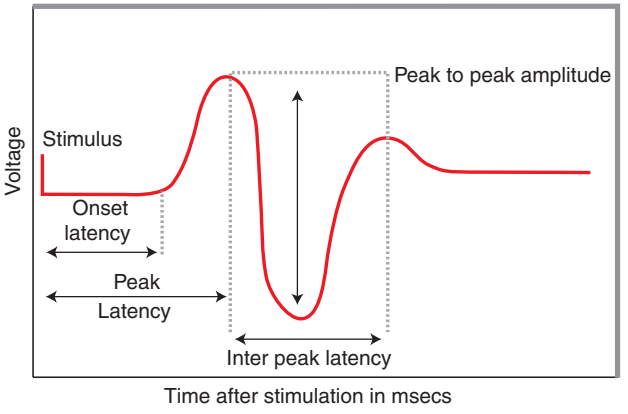

FIGURE 32–13. Amplitude and latency of somatosensory evoked potential. (From Banoub et al.[26] with permission.)

direct information about the condition of spinal cord gray matter. The short latency evoked responses from these "subcortical" structures are useful for determining the integrity of the monitoring system (i.e., is the stimulator working?, is electrode impedance sufficiently low to enable peripheral nerve stimulation?) and for distinguishing "real problems" in spinal cord integrity from "false positive problems" due to anesthetic-induced decrement of cortical SSEPs. Anesthetic effects on sensory responses are more pronounced in regions where synaptic transmission is prominent. Therefore, the effects are more pronounced in the EEG and cortically generated SSEP peaks. Responses of the brainstem, spinal cord, and peripheral nerve are markedly less affected because fewer synapses occur in these pathways. Anesthetic effects are clearly dose related. However, many agents have a disproportionate effect at low doses. Therefore, during periods of acute neural risk, a steady state of anesthesia is important.[27]

Choosing an Anesthetic Plan for SSEP Monitoring[26]

1. Criteria for significant changes are difficult to establish and therefore are empiric. A significant change in SSEP, reflecting loss of integrity of peripheral nerve or spinal cord, usually is taken as a 50% decrease in peak amplitude and a 10% increase in peak latency, provided these changes are not caused by anesthetic or temperature.
2. "General anesthesia has an inhibitory effect on neurotransmission and, therefore, on the EP. The effect of anesthetics is greater on synaptic transmission than on axonal conduction. For this reason, responses recorded from polysynaptic pathways (e.g., cortical recordings) are affected by anesthesia to a much greater extent than those recorded from oligosynaptic pathways (e.g., spinal cord and subcortical recordings)."[26]
3. "All volatile anesthetics produce a dose-dependent increase in SSEP latency and a decrease in amplitude. All volatile anesthetics, even at concentrations above 1.0 MAC, only minimally affect the sub-cortical waveform, resulting in high recordability and reliability."[26]
4. "The effect of volatile anesthetics on cortical SSEP amplitude is compounded by nitrous oxide."[26]
5. "Intravenous anesthetics generally affect SSEPs less than inhaled anesthetics do."[26]
6. Etomidate and ketamine increase SSEP amplitude.[26]
7. Propofol, midazolam, and barbiturates have a moderate depressant effect on SSEP amplitude. In a normothermic individual, SSEP monitoring can detect cerebral ischemia during barbiturate anesthesia at doses that induce burst suppression.[27–29]
8. "Most authors report minimal to no effect of opioids on SSEP amplitude."[26]
9. "Clonidine can be used as an anesthetic adjuvant without compromising SSEP monitoring. Dexmedetomidine affects SSEP amplitude minimally at sedative doses. During isoflurane anesthesia, dexmedetomidine blunts the effect of isoflurane on SSEP amplitude."[26]

Application of Evoked Potentials

SSEP monitoring is generally used to assess intraoperative spinal cord, brainstem, and regional cortical function. In the spinal cord, SSEP monitoring is used during spinal cord manipulation (e.g., spinal distraction and rod placement, intramedullary tumor and vascular malformation removal). In the brainstem, SSEPs are useful for monitoring lesions at the cervicomedullary junction, particularly below the entrance of the eighth cranial nerve to the brainstem, such as clivus chordoma resection. In the cortex, SSEPs are used for monitoring function in the anterior cerebral artery or middle cerebral artery distributions during procedures that place those areas at risk for ischemic damage (e.g., vascular surgery or tumor resection).

The brainstem auditory evoked response (BAER) is derived in similar fashion to the SSEP, but in this application the stimulus is an audible click delivered to the tympanic membrane through earphones. The evoked stimulus traverses the auditory nerve and brainstem tracts and arrives at the auditory cortex. The response of the EEG is summed in similar fashion to the SSEP, and a characteristic pattern of evoked peaks is generated (Fig. 32–14), corresponding to synapses that occur between the eighth nerve

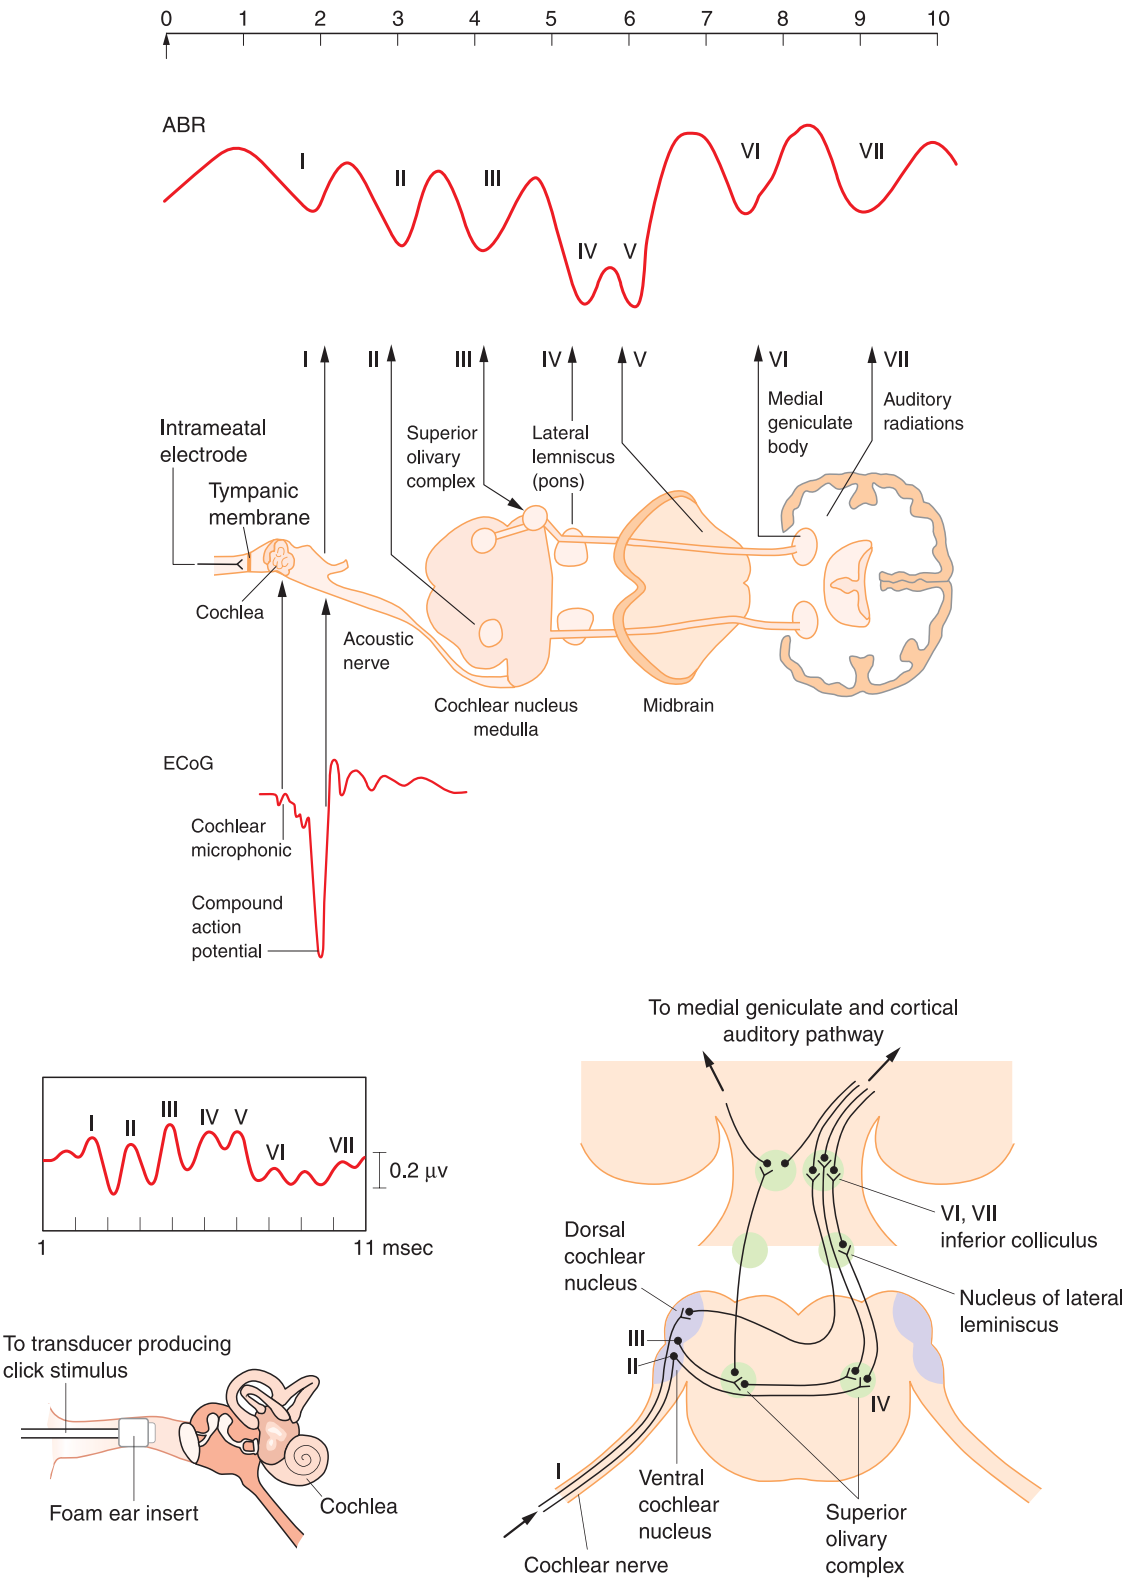

FIGURE 32–14. Schematics of auditory neural pathways.(From Mullatti et al.[30] with permission.)

and the cortex. BAERs typically are used during operations involving the eighth nerve (especially removal of acoustic neuromas) or procedures involving the brainstem or posterior cranial fossa to ensure integrity of neural structures in this area.

The use of mechanically evoked motor potentials has taken various forms: (1) identifying muscles that may be rendered paralyzed during dissection of a tethered spinal cord or meningomyelocele; (2) monitoring facial nerve function during head and neck operations that place the facial nerve at risk; and (3) determining that the application of a pedicle screw has not come in close contact to the nerve root contained in a neural foramen. Motor evoked potentials (MEPs), stimulated over the motor cortex and mea-

sured at the peripheral muscle, enable monitoring of motor tract integrity and are thought to provide more comprehensive scrutiny of the spinal cord when combined with SSEP monitoring.

Specific Cases and Use of Electrophysiologic Monitoring

A variety of surgical procedures and monitoring modalities that have been used productively is listed in Table 32–4.[23]

1. Before starting the case, get on the same page with both the surgeon and the neurophysiologist. What is the procedure? What is the tissue at risk? How is it at risk (tissue perfusion mechanical injury, etc.)? When is it at risk—beginning, middle, end, postoperatively? What modality will be used to monitor tissue at risk? Are baseline measurements required preoperatively? Can the anesthetic plan be adjusted such that the predictive value of the monitor is enhanced? Usually this is achieved by limiting the use of potent agents and nitrous oxide, but above all by keeping exposure levels as constant as is possible. Is the monitoring enhanced through use of muscle relaxants, or does the use of relaxants impede detection of an evoked motor response? Do monitoring techniques that require an unparalyzed but immobile patient rely on rapidly reversible deep narcotics and/or neuroleptic adjuncts such as dexmedetomidine? Are there alternatives in case of monitor failure (i.e., intraoperative wake-up)?
2. Constant communication among anesthesiologist, neurophysiologist, and surgeon regarding any significant changes in vital signs or administered anesthetic is essential. The neurophysiologist must relay assessment regarding the adequacy of monitoring and any change in monitoring parameters so that the cause and effect relationship can be identified.
3. Tailor the anesthetic plan to maximize a reliably timed and clear wake-up to enable rapid postoperative as-

sessment of tissue at risk, which enables timely corrective action.

What Is the Effect of Anesthetic Agents on Spontaneous and Evoked EEG?

Banoub et al.[26] present a succinct summary of anesthetic effect on SSEP.[26]

To summarize:

1. All potent inhaled agents prolong SSEP latency in a dose-dependent fashion.
2. All potent inhaled agents diminish SSEP amplitudes in a dose-dependent fashion.
3. Sole use of 60% nitrous oxide decreases SSEP amplitude but does not affect latency.
4. Additive use of nitrous oxide with a potent agent further decreases SSEP amplitude but does not increase latency more than that seen with the potent agent alone.

Troubleshooting a Change in SSEP

Because evoked potential monitoring is highly sensitive and relatively less specific, a fair frequency of "false-positive" changes in the amplitude and/or latency of evoked responses during surgical procedures can be expected. All three participants in the monitoring process (neurophysiologist, surgeon, and anesthesiologist) should have a consistent strategy for dealing with these events in order to determine whether the SSEP is a "false positive" (i.e., SSEP changes caused by monitor artifact or anesthetic effect impeding the ability to monitor the nervous system). Some preliminary points to consider are the use of preprocedural monitoring in an already damaged nerve tract. If preanesthetic testing is abnormal, then the likelihood of improvement with anesthesia and surgery is low, and monitoring of that tract should not be attempted. The neurophysiologist will be adept at determining false-positive signs to faulty electrode application by performing impedance checks and determining if the elicited responses are altered in redundant locations along the peripheral nerve/spinal cord/brainstem/cortex circuit. Global changes in SSEP will be explored to determine whether there is a problem with generalized electrical interference from electrocautery or other electrical monitors. While these causes are being eliminated, the anesthesiologist can ensure that the two main features of anesthesia-controllable effects—anesthetic depth and tissue perfusion—are optimal. If all these maneuvers do not improve the SSEP, then plan for rapid wake-up and testing. This part of the plan involves patient preparation for responding to commands to move appropriate extremities.[23]

Auditory Evoked Responses

The genesis of auditory evoked responses (auditory evoked potentials [AEPs]) has similarities with SSEPs. They are electrical cortical potentials, evoked through repetitive stimulation of a peripheral nerve, and are identified and measured by summating numerous brief (milliseconds) stimulus synchronized EEG epochs recorded from electrodes placed on the vertex and ear lobe. Cranial nerve VIII is stimulated by presenting audible clicks to the cochlea by earphones placed within the auditory canal. AEPs are grouped based on their respective latencies. Brainstem auditory evoked potentials (BAEP), also called auditory brainstem responses (ABRs), are composed of short-latency waves (approximately 2–10 msec) and are numbered I through VII. The purported neural structures that serve as the substrate for these short-latency waves are displayed in (Figure 32–14).[30] Procedures that have been monitored effectively include resection of acoustic neuroma, decompression of facial nerve for hemifacial spasm (which carries a large risk of hearing loss), posterior fossa work where the brainstem is at risk, clipping of basilar artery aneurysms, and sectioning of cranial nerve VIII for intractable tinnitus.

Midlatency AEPs (MLAEPs) have a poststimulus latency on the order of 20–100 msec and are generated from the medial geniculate and primary auditory cortex.[31] Although their amplitude is correlated with increasing indicators of anesthetic depth, MLAEPs are not a perfect monitoring modality because of poor agreement among experts as to what determines a good peak necessary for analysis.[32] Also, by determining the prediction probability (P_K)[33] of the midlatency BAER, Alpiger et al.[34] showed that end-expiratory sevoflurane concentration was a better predictor and may prove to be more useful in the clinical setting. Long-latency AEPs (also called auditory late responses [ALRs]) have a latency of 50–250 msec[35] and are generated from the frontal cortex and association areas.[31]

The early-latency BAEPs appear to be an exquisitely sensitive monitor for pathologic events during surgery. Because anesthetics and mild hypothermia have minimal effects, they are specific monitors as well. MLAEPs show promise as evoked responses for monitoring awareness and depth of anesthesia. When the concentration of anesthetics is increased, the amplitudes of MLAEP peaks are decreased and their latencies are elongated. Further testing will determine if these AEP-based monitors are superior to processed EEGs in detecting the transition from unconsciousness to consciousness.[31]

MEPs

An MEP is an electrical potential evoked from a muscle (myogenic response) or from a motor nerve (neurogenic response) by stimulating the motor cortex, spinal cord, or peripheral nerve. The source of stimulation can be either electrical or magnetic. MEP monitoring is primarily used to ensure the integrity of the motor tracts of the spinal cord during spinal cord or spinal column surgery. MEPs also are used to determine the positioning of epidural motor strip electrodes for chronic pain treatment.[36–39]

Why Obtain an MEP?

The review by Sala et al.[40] contains an extensive list of operations that can be monitored with MEPs:

1. Monitor anterior cord during spinal tumor removal, spinal vascular surgery (i.e., arterio-venous malformation [AVM], and spinal column distraction (scoliosis surgery)
2. Identify motor strip for analgesic electrode placement[36–39,41]
3. Monitor brainstem and thalamus for ischemia during basilar artery aneurysm surgery[42]
4. Facial nerve EMG during posterior fossa surgery[22,43]
5. Upper-arm EMG for surgery within the brachial plexus[44–46]
6. Lower-extremity EMG for myelomeningocele repair and release of tethered cord[40]
7. EMG during acetabular surgery in which epidural was used with passive EMG[47]

Why Spinal Cord Stimulation Differs from Transcranial Stimulation

Rose[48] and Toleikis et al.[49] show that neurogenic monitoring following direct spinal cord stimulation may not

specifically evaluate anterior spinal cord function. Measured impulses over the peripheral motor nerve may be due to antidromic stimulation of α_1 spindle afferents, which stimulate motor neurons. They believe that similar "contamination" may occur with transcranial stimulation. They offer a "collision" method of stimulation to circumvent this problem.[48,49]

MEP Monitoring during Anesthesia

Anesthetics decrease transcranial MEPs in a dose-dependent fashion, likely due to inhibition of the motor neuron because motor potentials evoked from direct stimulation of the spinal cord are maintained even at 1.5 MAC concentrations.[50,51] Intraoperative transcranial motor stimulation can be evoked through the use of total intravenous anesthesia (TIVA) with propofol and remifentanil. Multiple stimulation techniques may improve the quality of weak responses.[51–54]

Direct comparison of administration of an inhaled anesthetic with desflurane and nitrous oxide to a TIVA technique showed successful motor evoked monitoring with both techniques.[55] Tanaka et al.[56] propose a method for compensation of transcranial MEP that easily and accurately removes the effects of muscle relaxants.

The advent of MEP monitoring is a landmark in progress. MEP monitoring is the most appropriate technique for assessing the functional integrity of descending motor pathways in the brainstem and, foremost, in the spinal cord. Mapping of the corticospinal tract at the level of the cerebral peduncle as well as mapping of the VII, IX–X, and XII cranial nerve motor nuclei on the floor of the fourth ventricle is valuable for identifying "safe entry zones" into the brainstem (Figures 32–15 to 32–17).[57]

EMG

Elicited responses to motor nerve stimulation are measured as compound muscle action potentials (CMAPs) from intramuscular needle electrodes or surface electrodes adhered over the muscle of interest. Stimulation of these responses can be either passive or active. Passive stimulation is used to alert surgeons that a dissection has

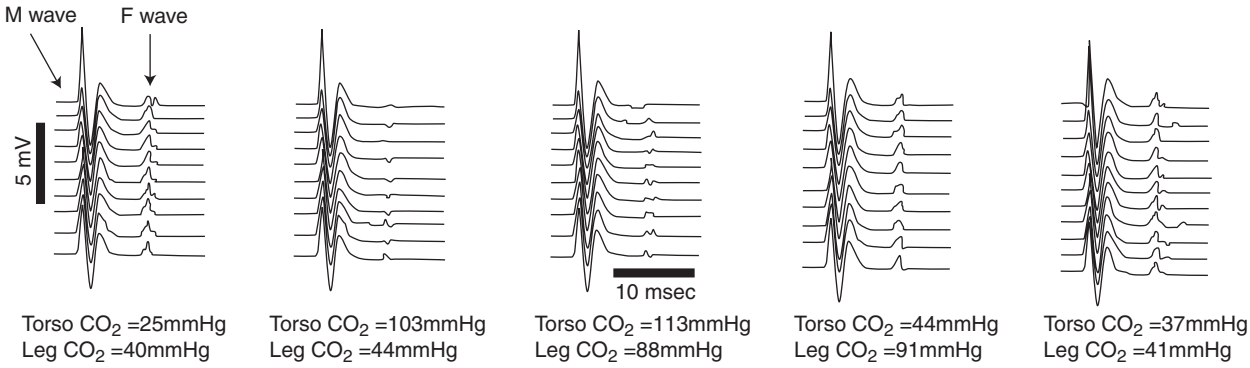

FIGURE 32–16. F wave and M wave. (From Dominguez C, Carstens E, Antognini JF. Carbon dioxide depresses the F wave by a central, not peripheral, mechanism during isoflurane anesthesia. Anesth Analg 2005;100:398–403.)

trespassed on a peripheral nerve by mechanically stimulating a motor fiber resulting in a muscle twitch. Active stimulation is used to electrically stimulate tissue of interest to determine which muscles are innervated by the nerve of interest. This strategy is used for brachial plexus exploration or for identifying nerve roots during meningomyelocele repair or release of tethered cord. The National Institutes of Health Consensus Conference on Acoustic Neuroma[22] recommended that facial nerve monitoring[43] be used in all patients undergoing surgical resection of an acoustic neuroma.

Intraoperative Wake-Up Test

Historically, before the use of electrophysiologic spinal cord monitoring, the functional integrity of the complete motor system (upper and lower motor neurons and peripheral musculature) was confirmed after spinal distraction for treatment of scoliosis by means of intraoperative emergence from anesthesia and demonstration of voluntary leg movement. This technique, the Stagnara wake-up test (named after one of its originators), was introduced in 1973 by Vazuelle et al.[58] and described by Owens.[59] Careful preoperative patient preparation is necessary to determine that the patient understands what is required and is able to comply. Muscle relaxation and anesthesia are reversed intraoperatively while the narcotic level is maintained. The patient emerges to a level of consciousness at which point the patient is asked to follow commands. The commands include hand grip and movement of feet. Use of the upper extremities assures that the patient is sufficiently awake to follow commands. If quadriplegia is a possibility, the patient can be asked to open the mouth or to grimace to determine that he or she is sufficiently awake.

The Stagnara wake-up test has a number of limitations. It is a test of gross motor function and cannot precisely assess specific muscle group or nerve root function. It is not a test of sensory function; therefore, a patient could have a significant sensory deficit in the presence of grossly normal motor tract function. The test is time consuming, requires reversal of anesthetic agents, and poses some risks to the patient, including aggressive patient movement resulting in trauma or extubation. Test administration can be difficult in patients with reduced capacities (e.g., mental retardation, deafness, inadequate language skills, insufficient emotional capacity). Repeated administration is difficult and not often undertaken. In most cases, the test is administered at the completion of all corrective maneuvers. This single administration can reduce its sensitivity to the onset of a neurologic injury and the subsequent efficacy of intervention. However, the wake-up test can be useful to further evaluate the veracity of a change in neurophysiologic monitoring parameters in a patient under general anesthesia.

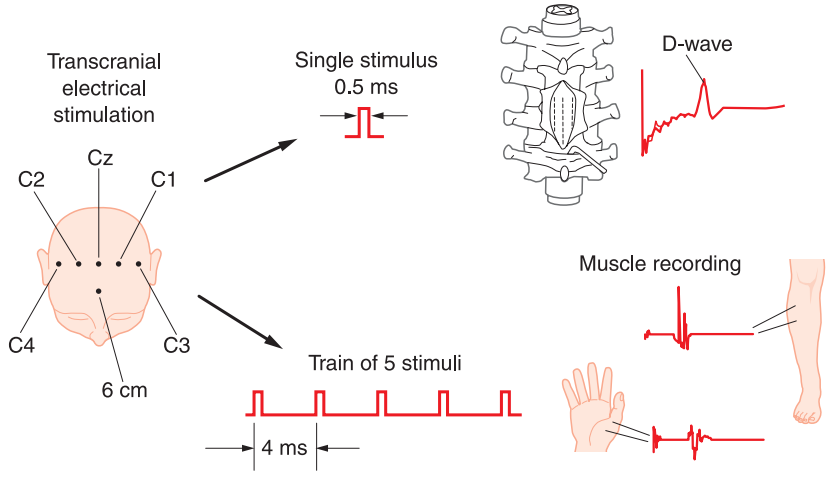

FIGURE 32–17. Obtaining a D wave. (From Sala et al.[40] with permission.)

CONSCIOUS INTRAOPERATIVE NEUROLOGIC TESTING

Awake Craniotomy

The "silent cortex" is so named because lesions of these cortical regions are not evident by simple neurologic testing. In distinction, lesions in the "eloquent cortex" are identified by alterations in normal neurologic function, including speech and motor and sensory function. Intraoperative monitoring of eloquent cortical function can be effectively performed through use of cortical mapping. Mapping is performed intraoperatively by transiently inducing functional ablation of small portions of the cortex with stimulating electrodes. Correlation of structure and function requires an awake patient who is capable of performing the neurologic function under surveillance

(i.e., speech or directed movement) so that a cortical stimulation of a particular portion of cortex can be linked with interruption of that function (i.e., aphasia or uncontrolled contraction of a muscle group). Anesthetic techniques that enable this testing vary. "Awake craniotomy" relies on local anesthetic blocks of scalp, periosteum, and dura supplemented by a "neurolept anesthetic."[60] More recently, general anesthetic for craniotomy followed by intraoperative emergence for cortical testing followed by reinduction of general anesthesia (the so called asleep–awake–asleep technique) have gained wide acceptance. Challenges of any method include issues of airway control (assuring sufficient airway patency and ventilatory drive to maintain acceptable oxygenation and carbon dioxide level) and minimizing coughing and Valsalva in a patient with an open cranium. These challenges are met through use of various airway adjuncts, including nasal trumpets and laryngeal mask airways. Significant reflux risk can be addressed by endotracheal intubation followed by extubation at the time of emergence for intraoperative testing. Another challenge is maintaining sufficient balanced analgesia and anxiolysis during the awake portion of the case in order to enable patient participation. A variety of intravenous anesthetic techniques have been used and tend to rely on quickly titratable and reversible narcotic (i.e., remifentanil) and anesthesia provided by infusion of propofol or infusion of dexmedetomidine.[61] A drawback to propofol is the respiratory depression associated with concomitant narcotic use. A relatively brief exposure to propofol infusion is associated with a brief predictable emergence time. However, because of context sensitivity, a more prolonged exposure is associated with a longer, less predictable emergence. Dexmedetomidine infusion in conjunction with a narcotic infusion provides dose-related deep sedation as well as maintenance of ventilatory drive during craniotomy. However, airway patency is not assured at higher doses, and emergence times are not as brisk. However, a low dose of α_2-agonist may be beneficial as a "rescue" medication for patients who, after emergence, demonstrate significant anxiety and hypertension that may preclude cortical testing.

Spinal Anesthesia for Epidural Placement of Spinal Cord Stimulating Electrodes

Accurate placement of spinal cord stimulating electrodes for treatment of chronic pain requires patient responsiveness in order to determine that the patient perceives the stimulating current in the same region as the perceived pain. Because electrodes placement may also require a laminotomy in order to introduce the electrode into the epidural space, the anesthetic challenge is to provide sufficient anesthesia for laminotomy and electrode placement while the patient is in a lateral or prone position. A combination of local anesthetic and conscious sedation is feasible. However, this technique runs the risk of airway loss. Additionally, prolonged deep sedation can impair patient response, which may hinder optimal electrode placement. A technique that involves the use of subarachnoid bupivacaine has been described. Spinal block is performed with the patient in the prone position, and hypobaric bupivacaine is introduced. Complete dermatomal anesthesia through blockade of the spinal nerve roots enables performance of a painless laminotomy. However, because spinal anesthetic does not completely block sensory tracts within the spinal cord, patient perception of stimulation from the epidural electrodes is maintained.[62]

SUMMARY

Surgery on and around the nervous system is safer when the functional integrity of the nervous system can be assured. Anesthetic agents, by definition and design, decrease neurologic function. Therefore, monitoring nervous system function during anesthesia can be challenging. The techniques discussed in this chapter offer a standardized approach to assessing intraoperative neurologic function. Much work is needed to improve the impact of anesthetics on intraoperative neurologic monitoring and surely will evolve.

CHAPTER 33

Monitoring and Managing Neuromuscular Blockade

Richard M. Pino, MD, PhD, and Hassan H. Ali, MD

Muscle relaxation can be achieved by direct central nervous system depression with volatile inhalation anesthetics or by neural blockade either at the peripheral nerve or with drugs that act at the neuromuscular junction. Neuromuscular blocking drugs (NMBDs) are essential in anesthetic practice to facilitate endotracheal intubation and provide optimum surgical conditions for a variety of procedures. Although volatile anesthetic agents can be used for muscle relaxation, the addition of NMBD significantly reduces the concentration of volatile anesthetics required to provide adequate analgesia and amnesia with rapid postoperative recovery. NMBDs have no inherent analgesic or amnestic properties, and their use is contraindicated if artificial ventilation is not possible.

HISTORICAL PERSPECTIVE

In 1850, Pelouze and Bernard demonstrated that curare, the arrow poison used by certain South American Indian tribes, abolished the effect of nerve stimulation on muscle but did not affect the excitability of either nerve or muscle. Curare and nicotine were thought to act directly on muscle through "receptive substances" rather than by action on axonal endings until stimulation of the vagus nerve was demonstrated to produce a substance, later identified as acetylcholine (ACh), that was the transmitter at the myoneural junction of voluntary muscle.

CELL BIOLOGY OF MUSCLE CONTRACTION

Basic Myoneural Structure

A motor unit is a series of muscle fibers that is innervated by the same motor nerve.[1] This nerve enters skeletal muscle and ramifies to an extent that depends upon the function of the specific muscle. Muscles involved in fine control are innervated by a high ratio of neurons to muscle fibers, such as the extraocular muscles with a 1:1 ratio of neuron to muscle fibers. In contrast, muscles that contract for more coarse activities (e.g., maintenance of posture) have multiple fascicles that are innervated by a single nerve fiber.

Stimulation of a single motor nerve leads to contraction of all the muscle fibers contained within the particular motor unit. As the axons terminate in troughs on the surface of the muscle fibers, their myelin sheaths are lost. The neuromuscular junction is the synapse that is formed at the endplate region of the muscle membrane and bare terminal of the motor nerve (Fig. 33–1). The synaptic cleft is a 50-nm-wide extracellular space that spans the short distance between the neuronal and muscle cell membranes.

Synthesis of ACh

Neuromuscular transmission begins with synthesis of the enzyme choline acetyltransferase in the organelle-rich cell body of the axon, followed by distal intracellular transport to the nerve terminal where it is concentrated. The choline acetyltransferase catalyzes the synthesis of ACh from acetyl-coenzyme A (acetyl-CoA) and choline. Hydrolysis of ACh in the junctional cleft is the primary source of choline. Most of the ACh (approximately 60%) is stored in the 5–10,000 synaptic vesicles of the nerve terminal. These vesicles are arranged in a triangular pattern, with the apex of each triangle close to a thickened area of the prejunctional membrane. This so-called active zone may be part of a system that orients and controls the site of release of ACh from the synaptic vesicles. The remainder of neural ACh is free in the cytoplasm. In the absence of nerve impulses, spontaneous release of small amounts of ACh depolarizes the postjunctional membrane to a

KEY POINTS

1. Muscle response can be measured by mechanomyography, electromyography, acceleromyography, and direct palpation.
2. Commonly used patterns of stimulation are single twitch, train of four, double burst, tetanic, and posttetanic count.
3. Clinical criteria, in addition to evoked responses, should be used to assess recovery of neuromuscular blockade.
4. Pharmacokinetics is the mathematical description of the relationship between time and the plasma concentration of a drug and its metabolites. Pharmacodynamics is the measurement of what the drug does in the body.
5. Reversal agents increase the concentration of acetylcholine in the junctional clefts to compete with the neuromuscular blocking drug (NMBD) to restore muscle activity.
6. Succinylcholine, the depolarizing NMBD, is metabolized by plasma cholinesterase. Atypical pseudocholinesterases cannot metabolize pseudocholinesterase at a normal rate, and prolonged neuromuscular blockade may result.
7. Immobility, prolonged use of NMBDs, and upper and lower motor neuron disease may cause the proliferation of extrajunctional receptors. These receptors affect severe hyperkalemia when stimulated with succinylcholine.
8. Nondepolarizing NMBDs are benzylisoquinoline (mivacurium, atracurium, cisatracurium, doxacurium) and steroidal molecules (vecuronium, rocuronium, pancuronium, pipecuronium).
9. The degradation of atracurium, cisatracurium, and mivacurium is independent on organ-specific elimination.
10. Pancuronium and vecuronium are metabolized in the liver to derivatives that are cleared by the kidney and that exhibit neuromuscular blocking activities. These derivatives accumulate with prolonged administration and renal insufficiency.

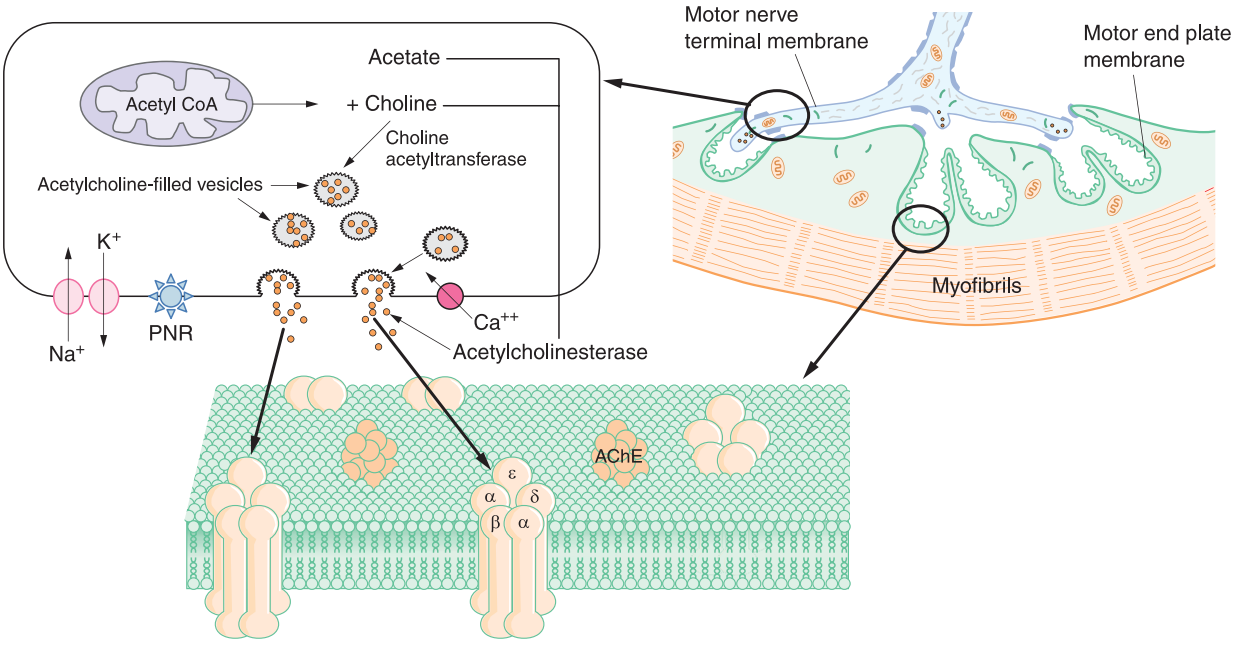

FIGURE 33–1. Schematic representation of the nerve terminal and myoneural junction. See text for details. PNR, prejunctional nicotinic receptor.

small extent. These 0.5- to 1.5-mV depolarizations, called *miniature endplate potentials* (MEPPs), are approximately 0.01 the magnitude of a standard endplate potential (EPP) and are not significant enough to trigger muscle contraction. According to the quantum theory,[2] calcium-mediated fusion of synaptic vesicles with the presynaptic membrane simultaneously releases approximately 200 to 400 quanta of ACh into the synaptic cleft. Each quantum contains 500–25,000 molecules of ACh. Motor neuron action potentials propagate via voltage-responsive ion channels that, in turn, open channels in the nerve terminal that serve as pathways for the influx of ionized calcium at the active zone.

ACh Receptors

The postsynaptic membrane is highly folded, increasing its surface area to allow a high concentration of nicotinic postjunctional receptors. Each receptor is composed of five integral linear protein subunits arranged as a rosette in the membrane: two alpha (α), and one each of beta (β), delta (δ), and epsilon (ε). Each subunit contains four helical domains. The sites of binding for ACh and NMBDs are on the extracellular α-subunits, although the receptors span the entire muscle cell membrane contacting both extracellular and intracellular spaces. The binding sites for ACh on the two α-subunits are not identical and can be characterized into high- and low-affinity sites based on their binding of competitive antagonists. Both sites must be occupied by ACh in order to propagate a muscle cell depolarization. After ACh binds to the active site of both α-subunits, the receptor undergoes a conformational change, opening a central channel within the five subunits. The structure of this channel permits the transit of sodium, potassium, and calcium ions while blocking anions and larger cations. When nondepolarizing NMBDs bind to either α-subunit, the channels cannot open, and a neuromuscular blockade occurs.

Depolarization and Muscle Contraction

Most of the released ACh molecules cross the synaptic clefts, bind to postjunctional receptors, and induce depolarization of the muscle cell. Depolarizations are created by the influx of sodium through specific channels, decreasing the membrane potential from –90 to +50 mV. During depolarization, as the membrane potential approximates 0 mV, potassium channels open and sodium channels close to limit the voltage flux to +10 mV. The action potential is self-propagating through a decrease in the adjacent membrane potential of approximately 15 mV, which open sodiums channels and depolarizes the membrane.

Depolarization is an all-or-none phenomenon. Once begun after the threshold is achieved, it continues until the entire membrane has depolarized. Therefore, the strength of individual contractions does not depend upon the amplitudes of the individual action potentials but is dependent on the sum of repetitive, additive, and fused contractions of different motor units. Calcium is released from the sarcoplasmic reticulum of the muscle upon depolarization to activate actin–myosin coupling within myofibrils resulting in contraction. Upon completion of depolarization, the ionic gradient is restored via an Na^+/K^+-dependent adenosine triphosphates (ATPase) to repolarize the membrane, and a refractory period follows during which time depolarization is not possible. Once depolarization is completed, the concentration of ACh markedly decreases in the synaptic cleft by diffusion through the postjunctional receptor. ACh is further reduced by degradation into acetate and choline by acetylcholinesterase, a key enzyme that is concentrated in the basal lamina of the muscle cell.

Prejunctional Receptors

The response of muscle contraction is also modulated by prejunctional receptors of the motor neuron. It is theorized that released ACh interacts with prejunctional nicotinic, and possibly muscarinic, receptors to further augment transmitter release. These receptors are believed to control a sodium-specific ion channel in contrast to the nonspecific cation channels of the postjunctional receptors. Sodium is essential for the synthesis

and mobilization of ACh, but it is not directly involved in the release process. Therefore, nondepolarizing NMBDs can bind to these ion channels, decrease the mobilization of ACh, and reduce its release from nerves that are stimulated with high-frequency stimuli. The clinical equivalent is seen in the fade to tetanic and train-of-four (TOF) stimulation.

Extrajunctional Receptors

Muscle cells can also exhibit a variable number of extrajunctional receptors that are embryologic remnants of the muscle cell membrane. In the fetus, these receptors are found throughout the muscle cell membrane. With maturation, extrajunctional receptors become markedly reduced while junctional receptors predominate. In addition to differences in their location, the extrajunctional receptor has a gamma (γ)-subunit substituted for the ε-subunit of the junctional receptor. Extrajunctional receptors also have short half-lives of <1 day compared with the >1-week half-lives of junctional receptors. Compared with junctional receptors, they are less sensitive to stimulation by ACh but have channels that remain open approximately four times longer than the postjunctional receptors. The clinical significance of extrajunctional receptors becomes evident when they proliferate in response to upper and lower neuron damage, muscular injury and disease (some muscular dystrophies, disuse atrophy, even cast immobilization), and trauma associated with major burns.[3]

TECHNIQUES USED TO MONITOR NEUROMUSCULAR BLOCKADE

We have described the basic mechanisms controlling the contraction of a single muscle fiber. This knowledge must be extrapolated to the bedside analysis of the contraction of anatomically distinct muscles to assess the patient's degree of neuromuscular blockade.

Objectives of clinical monitoring are as follows:

- Titration of NMBD doses to the desired level of paralysis
- Detection of unusual sensitivity, resistance, or altered clearance of a relaxant in the course of the anesthetic
- Evaluation of whether neuromuscular blockade can be pharmacologically reversed
- Assessment of the adequacy of reversal to assure that residual neuromuscular blockade is not present

The depth of neuromuscular blockade often is assessed by a measurement of the contraction of the adductor pollicis muscle as elicited by stimulation of the ulnar nerve at the wrist with surface electrodes.[4] When the ulnar nerve is not accessible, stimulation of several other peripheral nerves is useful (Fig. 33–2). The stimulus used to evoke muscle contraction usually is a rectangular waveform of 0.2-msec duration.[5] It is important to adequately clean and lightly abrade the skin for optimum adherence of surface electrodes and to minimize the impedance of the skin to prevent reduction of the applied current intensity.

Patterns of Stimulation

There are five patterns of stimulation.

1. *Single-twitch stimulus* (Fig. 33–3) usually is given at a frequency of 0.1 Hz, that is, one stimulus every 10 seconds.[6] The current is incrementally increased until a maximum twitch height is obtained. A current that is slightly greater than that used to achieve maximum twitch height is called the *supramaximal stimulus.* After an NMBD is administered, the decrements in twitch height are compared as percentages of the control twitch. This stimulus pattern is most often used to establish the basic pharmacodynamic properties of an NMBD. For example, the ED_{95} is the dose at which the twitch height is depressed by 95% of maximal height. The primary shortcoming of a single-twitch stimulus is the requirement for a control response prior to the administration of the NMBD.

2. *TOF stimulation* (TOF; Fig. 33–4) is the most commonly used stimulus.[7,8] Each train consists of four stimuli at 2 Hz (four stimuli in 2 seconds) that are again repeated every 10–12 seconds. In the absence of neuromuscular blockade, the TOF will evoke four twitches of equal strength when the abducted thumb is palpated after stimulation of the ulnar nerve. Because the strength of the first twitch (T_1) is compared with the second, third, and fourth twitches, control twitches are not required. With the onset of neuromuscular blockade, release of ACh by the first stimulus often evokes an adequate contraction. However, the ability of neurons to replenish and release ACh progressively diminishes with each stimulus of the TOF in the successive train. This can be manifested in two ways. First, with the onset of neuromuscular blockade, the amplitude of the fourth twitch (T_4) will decrease with successive stimuli. Second, within each TOF, there is a clear decrement between T_4 and T_1. The T_4/T_1 ratio can be easily compared if objectively measured. In clinical practice, when the strength of the first twitch is reduced to 75% of the maximal height, only three twitches will be demonstrable. With increased neuromuscular blockade to a T_1 of 20%, two twitches will be observed. At 90% suppression of T_1, only one twitch will be perceptible. These patterns are reversed as muscle activity returns and can be used with other clinical criteria to help determine the patient's suitability for extubation. Initial studies demonstrated that at $T_4/T_1 = 0.75$, awake patients can sustain a 5-second head lift, generate a vital capacity of 15–20 mL/kg with an inspiratory force of –25 cm H_2O, and cough effectively.[9]

3. *Tetanic stimulation* is used in conjunction with the TOF. When a profound depth of neuromuscular blockade has been established, the twitch response to TOF stimulation will be abolished.[6] With stimulation at a tetanic frequency of 50 Hz for 5 seconds, increased quanta of ACh are released into the synaptic cleft. The increased ACh causes a sustained muscle contraction during the duration of the stimulus and also augments its own subsequent release if a single TOF stimulus follows. This enhanced response after tetanic stimulation is called *posttetanic potentiation* (Fig. 33–3). Instead of a posttetanic TOF, a stimulation of 1 Hz can be applied 3 seconds after tetanus. The number of twitches then observed is termed the *posttetanic count.* A posttetanic count of 10 has been found to coincide with the appearance of the first twitch

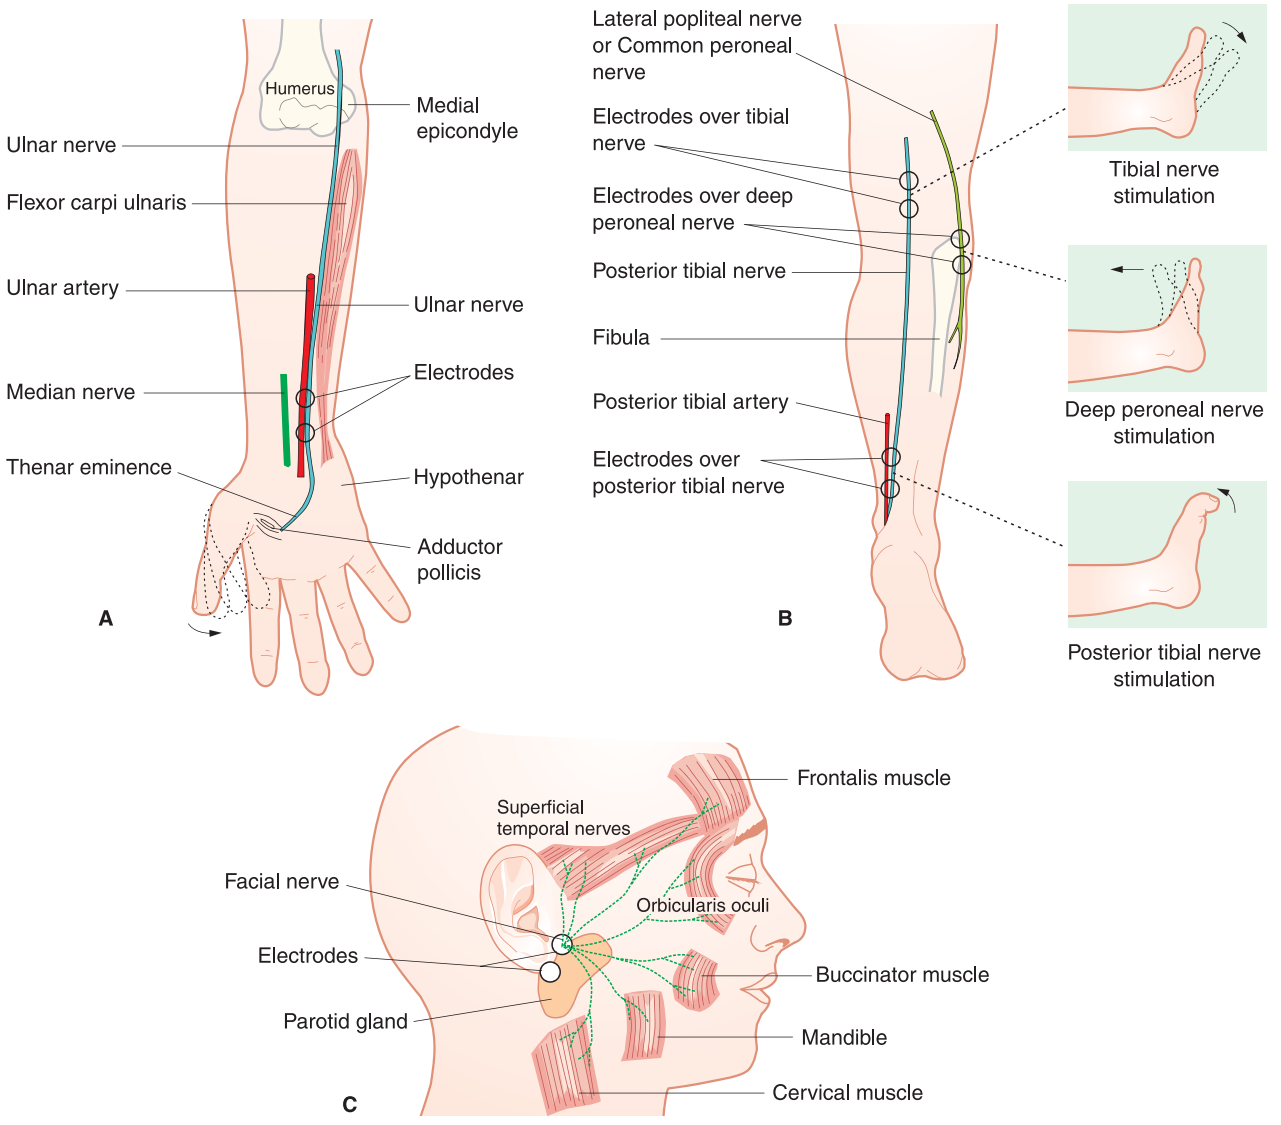

FIGURE 33–2. Diagram of sites suitable for nerve stimulation. **A.** Ulnar nerve. **B.** Tibial, deep peroneal, and posterior tibial nerves. **C.** Facial nerve. (Reprinted and modified from Ali HH. Monitoring neuromuscular function. Semin Anesth 1989;8:158, with permission from Elsevier.)

of the TOF. A postetanic count of 1 indicates that the first twitch of the TOF should appear in approximately 30 minutes when pancuronium is used or 8 minutes with vecuronium and atracurium.[10] In the absence of a posttetanic twitch, the blockade is sufficiently profound to suggest that immediate administration of reversal agents will not be effective.

4. *Double-burst stimulation* (DBS) was devised to increase the manual perception of fade.[11,12] DBS consists of two short bursts of three stimuli at 50 Hz separated by 750 msec. The responses to each burst are close enough to be palpated as a strong single muscle contraction. Any fade that is manifested with a partial blockade may be easier to detect between the sets of stimuli with DBS than with TOF. In the absence of fade to DBS, there is a 90% chance that TOF is ≥0.6 and a 75% chance that TOF is <0.6 when fade is present.

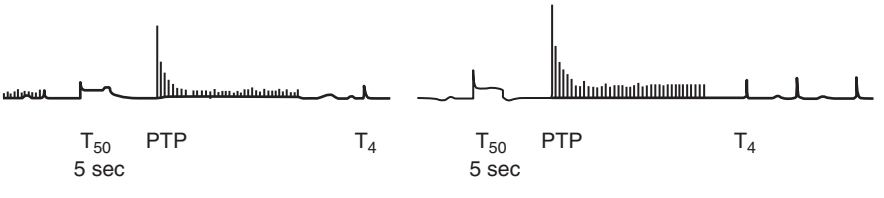

FIGURE 33–3. Evoked thumb adduction in response to single-twitch stimulation of 0.1 Hz before and after tetanic stimulation at 50 Hz for 5 seconds. Note the tetanic fade and posttetanic potentiation (PTP).

Methods Used to Quantify Muscle Responses[13] (Fig. 33–5)

Mechanomyography is an extremely accurate method that has been used for research on the basic pharmacodynamics properties of NMBDs. An isometric tension of a known preload is placed on the thumb. The thumb is attached to a transducer that measures

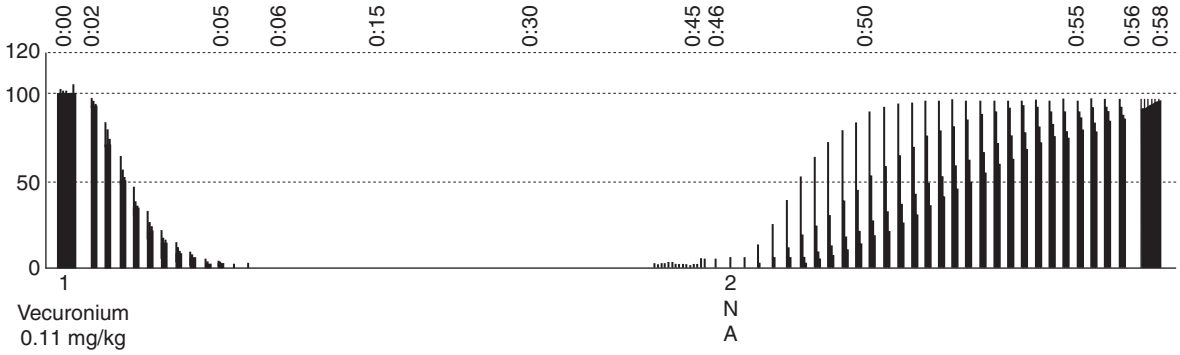

FIGURE 33–4. Integrated evoked electromyographic response to train-of-four (TOF) stimulation shows the response to vecuronium 0.11 mg/kg. At 47 minutes, the first response to TOF recovered spontaneously to 10% of control. Note during the onset there is minimal fade compared with that during recovery. Neostigmine (N) 4.0 mg and atropine (A) 1.5 mg were administered. Note the development of T_2, T_3, and T_4 and the progressive increase in TOF ratio, which reached 0.8 after 11 minutes of reversal.

the force of contraction of the adductor pollicis brevis muscle.

Electromyography (EMG) monitors compound motor unit action potentials that are generated a few milliseconds after the stimulus is delivered to a nerve. Two sensing electrodes are placed over a specific muscle and a ground electrode applied between the stimulating and sensing electrodes. The thenar, hypothenar, and first dorsal interosseous muscles of the hand are usually studied. Although each muscle cell responds in an all-or-none fashion, the amplitude of the EMG signal is proportional to the number of individual action potentials. In principle, the advantage of EMG is that it is closest to direct assessment of function of the neuromuscular junction.

Acceleromyography measures the isotonic acceleration across a joint with a small piezoelectric transducer.[14] This technique considers that the acceleration of a muscle is directly proportional to the force of contraction (assuming the muscle mass is constant). Acceleromyography is simple to perform and is clinically useful. One disadvantage is the inconsistency of the response.

Direct palpation of an abducted thumb during contractions evoked by ulnar nerve stimulation is the most common method used to assess neuromuscular blockade. With palpation, the clinician is measuring both the force of isometric contraction and the force of acceleration. Although it is a subjective assessment of neuromuscular blockade and has a considerable margin of error even in the hands of experienced clinicians,[15] direct palpation with TOF remains the gold standard in routine clinical practice.

PHARMACOLOGY OF NMBDS

Pharmacokinetics and pharmacodynamics are two important concepts pertinent to understanding the pharmacology of NMBDs.

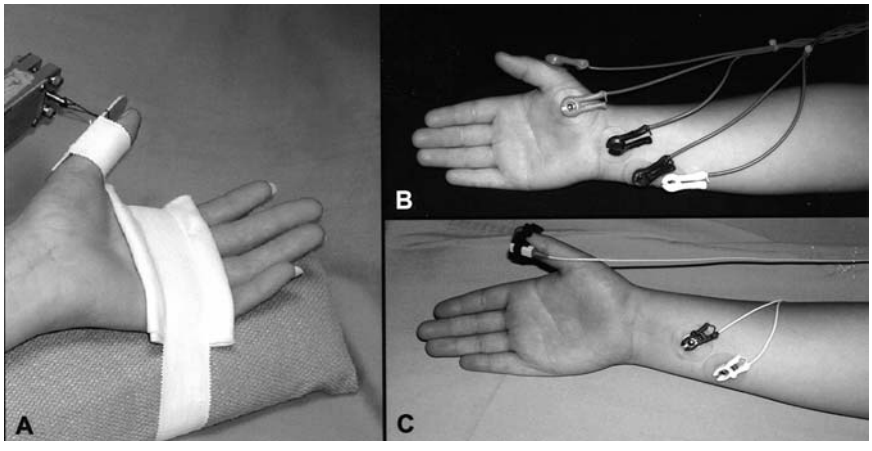

FIGURE 33–5. Methods used to quantify muscle responses to stimulation. **A.** Mechanomyography. **B.** Electromyography. **C.** Acceleromyography.

Pharmacokinetics

Pharmacokinetics is the mathematical description of the plasma concentration of the drug over time. The plasma concentration of a drug is initially high after an intravenous (IV) bolus and is followed by a rapid decline toward equilibrium during the distribution phase as a result of transfer between blood and tissue compartments. The initial volume of distribution (V_1) is the distribution space of the vessel-rich organs in contrast to the volume of distribution at steady state (Vd_{ss}), which is the apparent volume needed to explain the drug concentration after equilibrium between blood and the various tissues. The distribution half-life ($t_{1/2}\alpha$) defines the time needed for the blood concentration to decline by 50% and occurs before the elimination phase begins. This is quantified from the slope of the natural log of the blood concentration–time curve in the distribution phase. The $t_{1/2}\alpha$ is 2–10 minutes for the nondepolarizing NMBD. During the elimination phase, plasma levels of a relaxant decline at a slower rate than during the distribution phase because of excretion of the drug or its metabolite via the kidneys and/or the liver, spontaneous degradation, or a combination of both. The elimination half-life ($t_{1/2}\beta$) is computed from the slope of the natural log of the blood concentration–time curve for the elimination phase and is the time required for the plasma drug concentration to decrease by 50%. The $t_{1/2}\beta$ is sensitive to changes in either the volume of distribution at steady state or the clearance (C_L). The latter is defined as the volume of blood that is completely cleared of the drug per unit time. The $t_{1/2}\beta$ can range from 2.5 minutes (mivacurium) to approximately 2 hours (pancuronium),

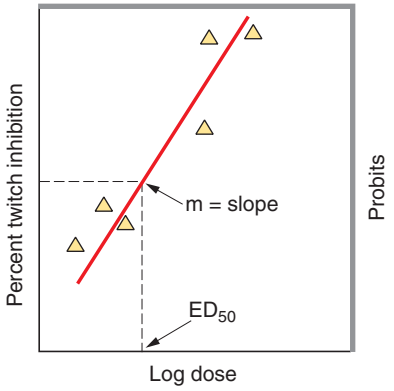

FIGURE 33–6. Log dose-probit transformation allows calculation of ED_{50}, estimation of ED_{95}, and comparison of potencies and mechanisms between different neuromuscular blocking drugs.

whereas C_L can vary from 2–100 mL/kg/min.

Pharmacodynamics

Pharmacodynamics is the principle of pharmacology that is most applicable to the clinical use of NMBDs. Pharmacodynamics includes the characterization of the therapeutic, pharmacologic, and toxic effects of the drug as well as the mechanism of drug action at the receptor. Dose–response studies of NMBD have established the relationship between increasing doses of a drug and the extent of neuromuscular blockade (Fig. 33–6). When a dose is simply plotted against response, comparisons of one NMBD with another become difficult. In order to estimate the 95% blocking dose (ED_{95}) of a relaxant and determine appropriate doses for intubation, a straight-line dose–response curve is needed. A log-dose probit analysis assigns an arbitrary number (probit) to each level of blockade (including 0% response and 100% response) to generate a straight line and facilitate the determination of the extent of block versus dose. The potency of different NMBDs then can be compared by examining the slope and parallelism of these straight lines. Different slopes and the absence of parallelism may indicate different mechanisms of blockade.

Although it is desirable to know the concentration–response relationships at the site of drug action, it usually is not possible to do so. An assumption is that a close relationship exists between the concentration of the drug in the plasma and the concentration at postjunctional receptors. This type of relationship for NMBDs is determined during continuous infusions at steady-state conditions, and comparisons between relaxants are noted by concentration in plasma at steady state and 50% paralysis ($Cpss_{50}$). Dose–response relationships (ED_{50}) and concentration–response relationships ($Cpss_{50}$) are altered by disease states, normal differences in physiology, and drug interactions and are reflected in differing dose requirements or plasma levels required to achieve the desired degree of blockade.

Onset of Neuromuscular Blockade

The onset time of neuromuscular blockade after administration of an NMBD is inversely related to potency.[16,17] Rapid plasma clearance contributes to a fast onset because the maximum drug effect occurs when the concentrations in the plasma and at the neuromuscular junction are equal. As the plasma concentration is decreasing, the effective concentration at the neuromuscular junction is increasing. Recovery from neuromuscular blockade begins immediately after both the plasma and junctional concentrations of the NMBD decrease. Therefore, when NMBDs have both equal potencies and equilibration rates, the drug with the faster clearance will cause a neuromuscular blockade more rapidly and of lesser magnitude than the NMBD with the slower clearance. A rapid onset and greater peak effect can be obtained by increasing the dose of the more rapidly cleared NMBD as long as there are no side effects with the increased dose. Thus, high-potency, low-clearance drugs have slow onset, whereas low-potency, rapid-clearance drugs have fast onset. Succinylcholine (SCh) has the fastest onset time to maximum effect. The onset times for the nondepolarizing NMBDs are rocuronium (shortest onset) < mivacurium < vecuronium < atracurium < cisatracurium.

Mivacurium is the only exception to these principles because it is a relaxant with both a high potency and a high clearance rate. Although mivacurium is assumed to have an intermediate potency, its high potency is demonstrable in patients with atypical plasma cholinesterase, and its rapid clearance is partly based on destruction of the compound as well as its distribution. Because these characteristics are antagonistic, mivacurium has a slower onset than expected.

Finally, nondepolarizing relaxants have a faster onset time, a less intense effect, and a more rapid recovery at the diaphragm and intrinsic muscles of the larynx than at the adductor pollicis.[18,19] This characteristic allows tracheal intubation at less intense degrees of neuromuscular blockade than evidenced at the adductor pollicis, provided adequate anesthesia is present. This is especially important for mivacurium. It is possible to have appropriate relaxation of laryngeal muscles while the adductor pollicis (and other muscles) still exhibit a marked twitch response. Furthermore, when the adductor pollicis twitch is abolished using small doses of mivacurium (≤0.15 mg/kg), the laryngeal muscles may already be recovering, and intubation may be difficult.

MUSCLE RELAXATION FOR TRACHEAL INTUBATION

The most common use for neuromuscular blocking agents is to facilitate endotracheal intubation during general anesthesia. This is especially important during a rapid sequence induction to swiftly intubate the trachea in order to protect the lungs from gastric contents. The standard drug for such rapid intubation remains SCh. When SCh is contraindicated, either an awake intubation can be performed or nondepolarizing relaxants can be administered. Conditions appropriate for intubation can be achieved within 2 minutes after administration of large doses of rocuronium, pancuronium, and cisatracurium, although the duration of neuromuscular blockade will be prolonged. In order to minimize unwanted cardiovascular side effects that may be produced with high doses of pancuronium, atracurium, or mivacurium, a divided dose technique may be used. The rationale for the divided dose technique is the initial binding of a large number of postjunctional receptors by a subparalytic dose of a nondepolarizing relaxant, called the "priming dose," which is insufficient to produce cardiovascular side effects. The balance of receptors subsequently are blocked to facilitate intubation within a short time after administration of the second dose of the NMBD.[20] For example, using the divided dose technique for mivacurium,[21] excellent intubation conditions were achieved

TABLE 33–1.

Pharmacodynamics of Succinylcholine

	Dose (mg/kg)	Onset (min)	Time to 25% Recovery (min)	Time to 95% Recovery
ED_{95}	0.2–0.25	1	8	12
Routine intubation	0.5–1.0	45 sec	10	12–15
Rapid intubation	1.0	4 sec	10	12–15
Pretreated intubation D-Tubocurarine (3 mg) Pancuronium (1 mg) Vecuronium (1 mg)	1.5	1.5	10	12–15
Infusion (mg/kg/min)	60–100	—	6[a]	15 – 30[a]

[a]After infusion stopped.

by 90 seconds and were identical to those obtained after rocuronium was administered at three (0.9 mg/kg) and four (1.2 mg/kg) times the ED_{95}.[22]

There are several caveats for the priming principle.[23] In some studies, the priming and intubating doses were determined after induction of anesthesia[24–26] and may not be appropriate for an urgent anesthetic when the patient has a full stomach. Individual patients differ in their sensitivity and response to relaxants. Some patients are not adequately relaxed after 90 seconds, and during light anesthesia they may cough, jerk, vomit, or have laryngospasm. Many patients have diplopia from the priming dose, and in some patients more troublesome effects of neuromuscular blockade develop, such as difficulty swallowing, airway obstruction, or inadequate ventilation. Without exception, after a priming dose is given, constant monitoring for these adverse effects is mandatory. Any comorbidity that impairs muscle blood flow (e.g., decreased blood volume or decreased cardiac output) will delay delivery of the NMBD to the neuromuscular junction and slow the onset of neuromuscular blockade.[27]

SUCCINYLCHOLINE

SCh is the only depolarizing NMBD in current use (Table 33–1).[3] Because it is structurally two molecules of acetylcholine linked together via the acetyl moieties (Fig. 33–7), SCh reacts with nicotinic receptors at the neuromuscular junction and also in autonomic ganglia. Additional SCh binding to muscarinic postganglionic receptors in the heart, secretory glands, and smooth muscle is responsible for many of this drug's side effects. The customary dose for intubation is 1.0 mg/kg (Table 33–1). It has been suggested that a dose of 0.6 mg/kg is efficacious while the time to a return to spontaneous ventilation is decreased.[28]

The rapid onset and brief duration of action of SCh are this drug's major advantages. They result from rapid metabolism of SCh in plasma to succinylmonocholine (a metabolite of minimal potency). The enzyme responsible for this activity is butyrylcholinesterase, usually referred to as *plasma cholinesterase.* The rapid metabolism of SCh by plasma cholinesterase is responsible for its brief duration of action, as relatively few of the injected molecules survive intact to reach the motor endplate. However, SCh molecules that reach the endplate are very resistant to metabolism by acetylcholinesterase, and neuromuscular blockade ends as SCh diffuses away from the neuromuscular junction (Table 33–2).

Two alleles control the quantity and quality of plasma cholinesterase. The normal gene is homozygous in 96% of patients. The activity of SCh is moderately prolonged in the 4% of patients who are heterozygous with ne normal and one atypical gene. It is greatly prolonged in the remainder of patients who are homozygous for the atypical gene. A clinical test for assessing these genetic differences uses the local anesthetic dibucaine, which inhibits the activity of normal, but not the atypical, plasma cholinesterase. A dibucaine number >80 (showing marked inhibition of the enzyme) indicates normal pseudocholinesterase, a dibucaine number <30 indicates a homozygote for the atypical enzyme, and dibucaine numbers between these values indicate heterozygotes. A more recent approach has been genotyping plasma cholinesterase variants and correlating the results with enzyme activity.[29]

Rare genes code for two additional atypical plasma cholinesterases.[30] The fluoride-resistant gene produces an atypical plasma cholinesterase that is not inhibited in vitro by the addition of a fluoride ion. The extremely poor degradation of SCh by this enzyme results in a greatly prolonged neuromuscular blockade. Another atypical enzyme produced by the "silent gene" is incapable of metabolizing SCh.

Decreased amounts of plasma cholinesterase that cause prolonged responses to SCh occasionally are problematic in patients with severe liver disease or in peripartum patients. Inhibition of plasma cholinesterase by echothiophate eyedrops, anticholinesterases, organophosphate insecticides, hexafluorenium, phenelzine, and some cytotoxic tumor agents also prolong the duration of SCh's neuromuscular blockade. In the absence or inhibition of SCh metabolism, the drug is eliminated from plasma by redistribution and slow renal elimination.

Phase I and Phase II Blockade (Table 33–3)

Because of its structural similarity to ACh, SCh's interaction with the postjunctional receptors creates an initial depolarization that spreads to adjacent membranes, causing disorganized contractions of motor units called *fasciculations.* Because SCh is not metabolized in the junctional cleft, the receptors and membranes remain depolarized and unresponsive to further stimuli, and paralysis ensues. After SCh diffuses away from the receptors, the membranes repolarize and once again become responsive to normal neuromuscular transmission. This sequence of events is known as *depolarization blockade* or *phase I blockade.* It is characterized by (1) fasciculations, (2) decreased response to single nerve stimuli, (3) absence of fade to tetanus, (4) minimal fade to TOF, (5) no posttetanic facilitations, (6) enhancement of block by anticholinesterase agents, and (7) rapid recovery. However, given prolonged exposure of the neuromuscular junction to SCh, there is a conformational change at the receptors. The block that results, termed *phase II block,* resembles that obtained with nondepolarizing NMBD. This level of paralysis is characterized by (1) marked fade of tetanus and TOF (>50% fade), (2) posttetanic potentiation, (3) tendency toward prolonged recovery in at least 50% of patients, and (4) the ability to reverse with anticholinesterases once plasma levels of SCh have been allowed to decrease (wait at least 10 minutes).

The establishment of a phase II blockade depends upon the dose of SCh and the duration of SCh exposure. When inhalation agents are used to maintain anesthesia, a phase II block usually is heralded by a tachyphylaxis to SCh over a cumulative dose range between 10 and 12 mg/kg. The identification of >50% fade on the TOF alerts the practitioner to the presence of phase II block, allows recovery to be followed over time, and permits the assessment of reversal after a plateau in recovery has been reached in patients in whom phase II blockade is prolonged.

TABLE 33–3.

Characteristics of Neuromuscular Blockade

- Depolarizing (Phase I) Block
  - Muscle fasciculation preceding the onset of neuromuscular blockade
  - Absence of posttetanic potentiation
  - Lack of fade to frequent stimulation (e.g., tetanus, train of four, or double burst)
  - Block antagonized by nondepolarizing drugs
  - Block potentiated by acetylcholinesterase inhibitors
- Nondepolarizing and Phase II Block
  - Absence of muscle fasciculation
  - Presence of posttetanic potentiation
  - Fade with frequent stimulation
  - Possible synergism between various groups of nondepolarizing relaxants
  - Phase II block and nondepolarizing block potentiate each other
  - Block may be reversed by acetylcholinesterase inhibitors

Side Effects

Hyperkalemia. In normal patients, the depolarization induced by SCh administration causes an increase in serum potassium level of 0.5–1.0 mEq/L. In some patients with elevated baseline serum potassium levels, this modest increase in potassium level after SCh administration will not cause a cardiac dysrhythmia.[31] However, the rapid rise of potassium from normal levels after SCh administration can be life-threatening in patients with burns, massive tissue trauma, disuse atrophy, hemiparesis, spinal cord trauma, and neuromuscular disorders, such as Guillain-Barré disease, amyotrophic lateral sclerosis, and Friedreich ataxia.[3] Possible mechanisms for SCh-induced hyperkalemia re (1) loss of motor nerve control over motor endplates that results in a proliferation of extrajunctional receptors, (2) damaged muscle membranes, and (3) defective muscle membranes in certain muscle diseases. In the acutely injured state, the critically dangerous period begins after a grace period of 48–72 hours. With burns and trauma, this period of SCh susceptibility can persist until recovery is well underway even for months. Patients with neuronal inju-

ries, such as spinal cord trauma, can have exaggerated responses for more than 6 months. The use of SCh in children is justified only for rapid sequence inductions. It is not warranted for routine pediatric use based on the increased risk of hyperkalemia in children with as yet undiagnosed congenital myopathies.

Increased intraocular pressure. SCh can increase the intraocular pressure (IOP). Increased IOP reaches a maximum approximately 2 minutes after SCh is administered and disappears in approximately 6 minutes. This increased IOP traditionally has been considered important for the patient with an open eye injury wherein an increased IOP may cause irreversible loss of vitreous or global contents. However, studies from institutions with great experience with acute eye injuries have not shown adverse effects from use of SCh.[32–34] Pretreatment with a nondepolarizing relaxant, followed by deep anesthetic induction and SCh for intubation, may prevent an increase in IOP. Alternatively, conditions for rapid endotracheal intubation can be obtained using large doses of nondepolarizing NMBD (two or three times ED_{95}), with the understanding that neuromuscular blockade will be greatly prolonged.

Increased intragastric pressure of approximately 40 cm H_2O occurs after SCh administration. This is blunted by pretreatment using a nondepolarizing drug followed by a larger dose of SCh (1.5 mg/kg) to achieve good intubating conditions. However, this increased gastric pressure is not believed to be clinically relevant because it is counterbalanced by an even greater increase in lower esophageal sphincter tone. Therefore, SCh is the most widely used drug for rapid sequence induction of patients with a suspected full stomach.

Increased intracranial pressure can occur via muscle fasciculations, creating a venous pressure elevation in epidural and jugular veins, and also through increased cerebral blood flow. Pretreatment with a nondepolarizing relaxant prevents this increase. However, an insufficient depth of anesthesia and hypercapnia are even more significant factors increasing intracranial pressure than the minor effects of SCh.

SCh will produce muscle contraction rather than relaxation in patients with myotonia congenita or myotonia dystrophica that can be severe enough to prevent intubation and ventilation. These contractures usually are self-limited and are not inhibited by nondepolarizing agents. Rhabdomyolysis and myoglobinuria can occur with SCh administration in some susceptible patients (e.g., myopathies, glycogen storage diseases). Finally, SCh is a triggering agent to be avoided in patients susceptible to malignant hyperthermia.

NONDEPOLARIZING NMBDS

Classification

Nondepolarizing NMBDs are classified by their duration of action and their chemical composition. The approximate duration of neuromuscular blockade provided by a single dose of these drugs may be short (< 20 minutes), intermediate (45–60 minutes), or long (> 1 hour). The currently available NMBDs are either steroidal molecules or benzylisoquinolines. The benzylisoquinolines are based on the structure of D-tubocurarine (curare [dTC]), a naturally occurring substance obtained from the vine *Chondodendron tomentosum* found in the Amazon Jungle. Curare is no longer commercially available. Pancuronium, the parent chemical of the steroidal NMBDs, was formulated from the compound malouetine, used by African tribesmen as arrowhead poison. Pancuronium is still used in clinical practice.

A brief discussion of the clinical pharmacology of commonly used nondepolarizing NMBDs is provided, beginning with the benzylisoquinolines in order of the duration of their neuromuscular blockade. Factors associated with either increased resistance or increased sensitivity to nondepolarizing relaxants are summarized in Tables 33–4 and 33–5.

TABLE 33–4.

Factors Associated with Resistance to Nondepolarizing Relaxants

Presence of extrajunctional receptors
Burns
Trauma (massive)
Upper motor neuron lesions
Lower motor neuron lesions
Demyelinating lesions (end-stage lesions may be very sensitive)
Prolonged immobilization
Aminophylline
Theophylline
Corticosteroids
Phenytoin

Benzylisoquinolines (Fig. 33–8)

Mivacurium (Short-Acting)

Mivacurium is a bisquaternary benzylisoquinoline diester with ED_{95} = 0.08 mg/kg, onset of 3.5 minutes, recovery time to 25% of baseline twitch of 15 minutes, and total duration of approximately 25 minutes (Tables 33–6 and 33–7).[35] At comparable doses, mivacurium has twice the duration of SCh and half the duration of intermediate drugs such as atracurium and vecuronium. The onset time can be shortened to 2 minutes by increasing the dose 3-fold. This will increase the duration of the block by 20%.[35] Mivacurium can cause histamine release when large doses are given by IV bolus.[36] In approximately 50% of patients, histamine is released when three times the ED_{95} of mivacurium (0.25 mg/kg) is given within < 30 seconds. However, when mivacurium was administered in a divided dose regimen of 0.15 mg/kg followed by 0.1 mg/kg 30 seconds later, histamine release did not occur, and good to excellent intubation conditions were achieved 90 seconds after the initial dose.[21,22] Mivacurium-induced blockade can be maintained by continuous infusion without alteration in its recovery characteristics.

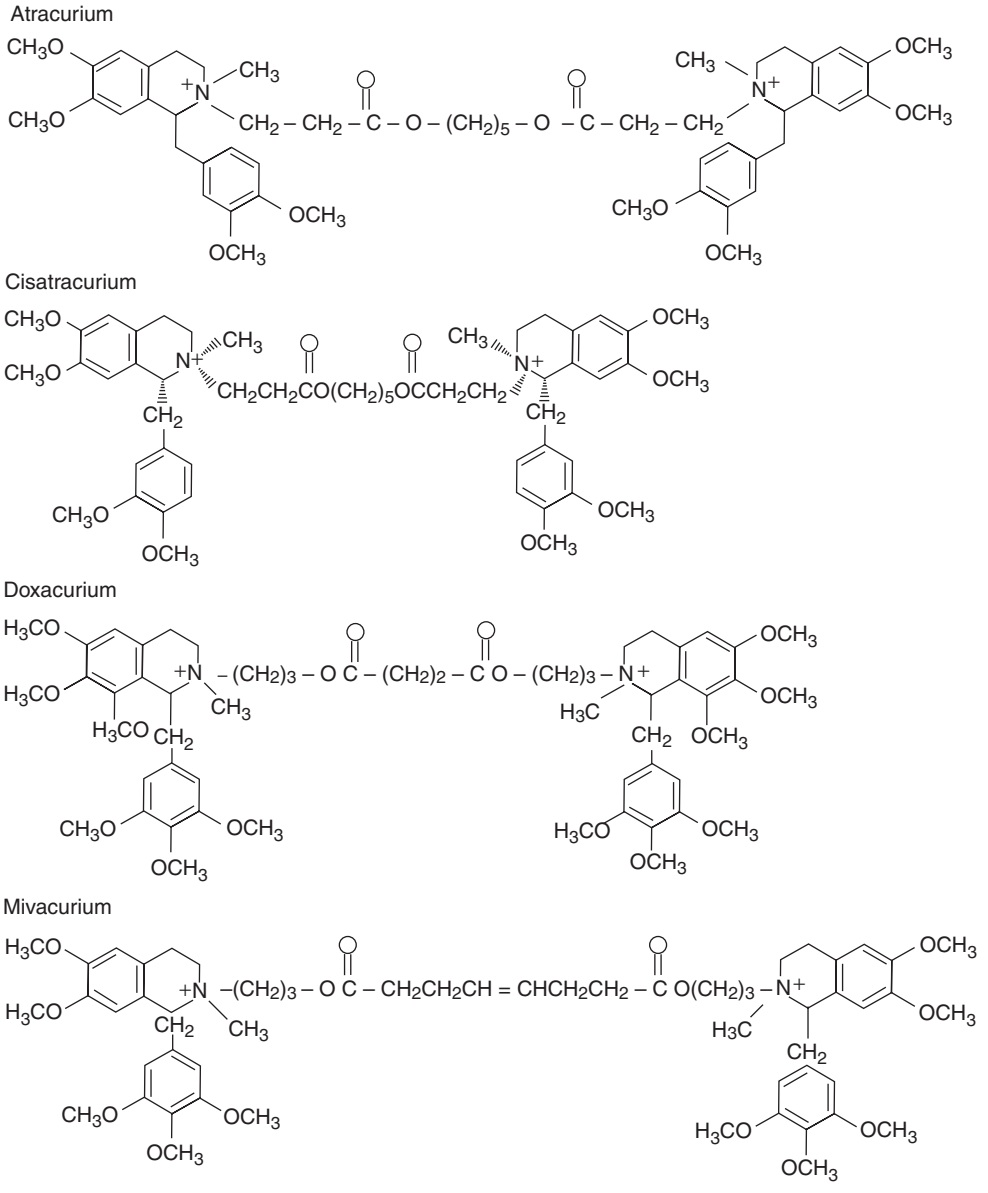

FIGURE 33–8. Chemical structures of the benzylisoquinoline neuromuscular blocking drugs.

The short duration of block produced by mivacurium is the result of rapid metabolism by plasma cholinesterase at approximately 70–80% the rate of SCh hydrolysis.[37] Biochemical genetic analysis has shown that the K variant of the plasma cholinesterase gene prolongs recovery from mivacurium.[38] Mivacurium consists of three stereoisomers—*cis–trans* (35–40%), *trans–trans* (50–60%), and *cis–cis* (4–8%)—that differ in their relaxant potency and pharmacokinetics.[39] The *cis–trans* and *trans–trans* isomers are 13 times more potent than the *cis–cis* isomer

TABLE 33–6.

Pharmacodynamics of Mivacurium

	Dose (mg/kg)	Onset (sec)	Time to 25% Recovery (min)	Time to 95% Recovery

	Vd_{ss} (mL/kg)	Clearance (mL/kg/min)	Elimination Half-Life (min)
Normal	112	55	2.32
Renal failure	150	76.6	
Hepatic failure	124	33.3	
Cirrhosis			11.1

and have elimination half-lives of approximately 2 minutes and clearances of 100 and 60 mL/kg/min, respectively. The *cis–cis* isomer has a half-life of 53 minutes and a clearance rate of 4.6 mL/kg/min. After long duration (hours) infusions of mivacurium, the recovery characteristics do not change, and, importantly, the plasma concentrations of the *cis–cis* isomer do not increase.

Mivacurium is metabolized by plasma cholinesterase.[35,37] As a nondepolarizing agent, it is competitively reversed by anticholinesterases by augmenting the concentration of ACh at the neuromuscular junction.[35] However, recovery may be slowed following reversal with neostigmine in the presence of a dense block (the absence of a twitch or one twitch on TOF stimulation). This delayed recovery is the result of a concomitant inhibition of plasma cholinesterase slowing the hydrolysis of mivacurium by 20–60 minutes and markedly prolonging neuromuscular block in patients with low baseline levels of plasma cholinesterase. Therefore, before attempting reversal of mivacurium with anticholinesterases, there should be an evidence of recovery manifested by the appearance of at least two twitches in response to TOF stimulation. Edrophonium may be a better choice of anticholinesterase to reverse the action of mivacurium because it inhibits plasma cholinesterase to a lesser degree than does neostigmine.

The recovery after a mivacurium infusion has been compared to recovery after infusions of atracurium, vecuronium, and SCh. Mivacurium blockade recovers from 5–95% approximately 15 minutes after stopping an infusion, regardless of the duration of infusion.[35] It has half the duration of recovery of atracurium and vecuronium[40] and equals the best of phase II-type recoveries of SCh[41] given by infusion. Because mivacurium does not depend on organ metabolism for elimination, there is no tendency toward accumulation. It behaves consistently across age groups and in patients with comorbid disease states having normal plasma cholinesterase activity and hepatic synthetic function.

Atracurium and Cisatracurium

Atracurium and cisatracurium are bisquaternary benzylisoquinoline diesters with similar intermediate durations of action that produce 95% blockade.[42,43] They are unique nondepolarizing blocking drugs that were specifically synthesized to degrade spontaneously and are independent of organ elimination. At physiologic temperature and pH, the Hofmann elimination reaction breaks down both drugs to produce a tertiary amine, laudanosine, and a monoacrylate compound.[43,44] Laudanosine at high plasma levels can cause cerebral excitation and seizure activity in animals, but this has not been a clinical problem in humans. Atracurium is additionally metabolized by nonspecific plasma esterases to a quaternary alcohol and acid.[45]

Atracurium has an elimination half-life of approximately 20 minutes, and its plasma clearance rate is 5–6 mL/kg/min.[46] This elimination half-life is approximately seven times shorter than that of long-acting relaxants, with a clearance rate approximately four times faster. The pharmacodynamics and pharmacokinetics of atracurium (Tables 33–8 and 33–9) are relatively unaltered in patients with renal failure[47] or hepatic failure,[46] in infants and children,[45,48] in the elderly,[49] and when given by continuous infusion.[50] Repeated administration or infusion shows no tendency for accumulation as evidenced by increased recovery times.[42] Atracurium causes release of histamine and hypotension when administered at doses >2.5 times its ED_{95}, especially when given as a rapid bolus (<15 seconds). When doses <0.5 mg/kg are given or when a large dose of atracurium (>0.6 mg/kg) is given slowly over 15–75 seconds, few patients elicit histamine release and hypotension (Fig. 33–9).[51]

TABLE 33–8.

Pharmacodynamics of Atracurium

	Dose (mg/kg)	Onset (min)	Time to 25% Recovery (min)	Time to 95% Recovery

Cisatracurium is one of the 1R-*cis*,1'R-*cis* configurations of one of the 10 isomers of atracurium and is approximately four times as potent as atracurium. The ED_{95} is 0.05 mg/kg, with an onset time of 7.5 minutes to complete blockade (2 minutes longer than atracurium), a clinical duration of 45 minutes, and a time to >70% TOF ratio of 67 minutes (Tables 33–10 and 33–11).[44] Cisatracurium recovery indices are unaffected by total dose of relaxant or method of administration. In contrast to atracurium, doses of cisatracurium as great as eight times the ED_{95} have been administered rapidly without any evidence of histamine release.

Doxacurium

Doxacurium is a long-acting bisquaternary benzylisoquinoline diester that is poorly metabolized by plasma cholinesterase. Its ED_{95} is 25–30 μg/kg.[52] Unlike the other benzylisoquinolines, organ elimination is required for its metabolism. This drug is excreted by the kidney as the major pathway of elimination, and its action is prolonged in renal failure.[53] It also is excreted unchanged in the bile.[53] Doxacurium exhibits no dose-related cardiovascular side effects. It is useful in long cases wherein extubation is not needed immediately postoperatively, in patients who would benefit from its lack of cardiovascular effects, and perhaps as an adjunct to permit ventilation for short periods in sedated patients in the ICU.

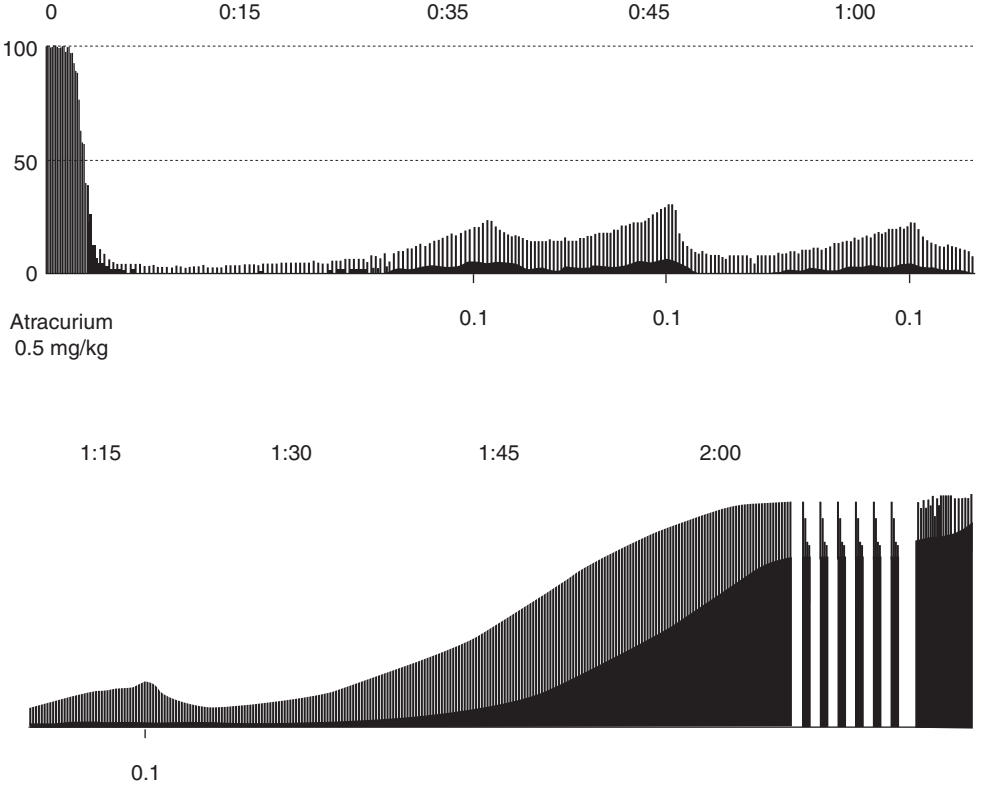

FIGURE 33–9. Initial dose of atracurium was 0.5 mg/kg, followed by four increments of 0.1 mg/kg every 15 minutes. Note when T_1 spontaneously recovered to control height and train-of-four ratio was 0.74 and increased to 0.85 in the next 4 minutes. (From Ali HH, Miller RD. Monitoring of neuromuscular function. FIGURE 33–10. Chemical structure of steroidal class neuromuscular blocking drugs.

Steroidal Muscle Relaxants (Fig. 33–10)

Vecuronium

Vecuronium (Tables 33–12 and 33–13, Fig. 33–4) is the monoquaternary analogue of the steroidal relaxant pancuronium.[54] Vecuronium is a more potent NMBD than pancuronium,[55] with half to one third of its duration of action by demethylation at the 2-position of the D ring, the position of the steroid nucleus that is responsible for its potency. It is a lipophilic compound that is easily absorbed by the liver and excreted into the bile mostly as the unchanged drug, the predominant method of elimination.[55] The action of this drug can be prolonged in patients with liver disease.[56] Vecuronium is metabolized in the liver to 3-desacetylvecuronium, 17-desacetylvecuronium, and 3,17-desacetylvecuronium.[57] The 3-desacetylvecuronium has neuromuscular blocking properties at approximately half the potency of vecuronium. This metabolite is eliminated by the kidneys, which may account for the prolonged block when vecuronium is given as a continuous infusion to facilitate mechanical ventilation of patients in the ICU who have compromised renal function.[58,59] Recovery times are increased in infants younger than 1 year, based on their increased sensitivity to vecuronium and larger volume of distribution and decreased clearance rate.[60]

Vecuronium does not have effects on heart rate and blood pressure through modification of the A ring of the steroidal nucleus.[61] At doses >0.1 mg/kg, it may inhibit the enzyme histamine-*N*-methyltransferase,[62] which may contribute to occasional reports of histamine-like reactions to vecuronium.[63,64] This may be a concern especially when other drugs that release histamine (e.g., the antibiotic vancomycin) are administered or when histamine-rich organs are manipulated during a surgical procedure.[62]

Rocuronium

Rocuronium (Tables 33–14 and 33–15) is the 2-morpholino, 3-desacetyl 16-*N*-allylpyrrolidino derivative of vecuronium.[65] It was developed specifically to have a rapid onset of action. It achieves this effect partly by being approximately six times less potent than vecuronium and by having a similar molecular weight.[16] This results in a larger number of molecules reaching the neuromuscular junction per circulation time and may contribute to the more rapid development of its neuromuscular blockade. Rocuronium undergoes rapid uptake by the liver because of its relative lipophilicity. Unchanged rocuronium has been found in the urine (8.7%) and in the bile (>50%), indicating dual pathways for its elimination.[66] The rapid redistribution of rocuronium from the

TABLE 33–12.

Pharmacodynamics of Vecuronium

neuromuscular junction contributes to its intermediate duration of action at lower doses. The pharmacokinetics of this drug have been reported to be altered in patients with major renal[67] and hepatic[68] disease. In both infants and elderly patients, the changes in the pharmacokinetics of rocuronium increases the duration of action.[69] Rocuronium does not produce alterations in heart rate and blood pressure.[70]

The ED_{95} of rocuronium is 0.3 mg/kg, with a recovery index of 8 minutes and a clinical duration of < 20 minutes. Mean onset times at 2× ED_{95} (0.6 mg/kg), 3× ED_{95} (0.9 mg/kg), and 4× ED_{95} (1.2 mg/kg) are approximately 90, 75, and 55 seconds, respectively, with ranges of 48–156, 48–144, and 36–84 seconds.[71] These are the most rapid onset times at equipotent doses of any nondepolarizing relaxant currently available. It has been suggested that this drug in appropriate doses may be useful as an alternative to SCh for rapid intubation of the trachea.[71] Because rocuronium depends on organs of elimination for its termination of action,[72] it has a dose-related escalation of clinical duration. At 2×, 3×, and 4× the ED_{95} dose, expected durations to 25% recovery are 37 (range 23–75), 53 (range 25–88), and 73 (range 38–150) minutes, respectively.[71] In addition, recovery from lengthy rocuronium infusions is markedly slower than from single doses of moderate quantity (e.g., 0.6 mg/kg).

Pancuronium

Pancuronium (Tables 33–16 and 33–17) is predominantly eliminated by the kidney and has a prolonged duration of neuromuscular blockade in patients with renal insufficiency. Clearance of pancuronium is minimally altered in patients with obstructive hepatic disease, whereas the volume of distribution at steady state is increased.[73] This implies that in patients with hepatic disease, greater doses may be needed to establish neuromuscular blockade that might be prolonged. In elderly patients, the duration of action is prolonged secondary to compromised clearance of the drug. Approximately 10–20% of the injected dose of pancuronium is metabolized in the liver to three metabolites: 3-hydroxypancuronium, 17-hydroxypancuronium, and 3,17-dihydroxypancuronium. The 3-hydroxy metabolite is about half as

potent as the parent compound and is cleared by the kidney.

Pancuronium has a tendency to increase heart rate, blood pressure, and cardiac output through a vagolytic action at muscarinic receptors in the autonomic nervous system and via inhibition of catecholamine reuptake at sympathetic nerve terminals.

Pipecuronium

Pipecuronium is a potent steroidal class relaxant that is slightly more potent than pancuronium, with an ED_{95} of 40 μg/kg.[74] There is essentially no organ metabolism of pipecuronium, and it is entirely eliminated in the urine by renal excretion. In patients with renal failure, excretion is delayed, clearance is decreased, elimination half-life is lengthened, and the duration of the neuromuscular blockade may be prolonged.[41] Because the quaternary nitrogen groups are distant from the 3,17-acetoxy substitutions in the steroid nucleus, pipecuronium is not vagolytic and does not block autonomic ganglia in the clinically used dose range.[75]

MAINTENANCE OF NEUROMUSCULAR BLOCKADE BY INFUSION

Intermittent intravenous bolus doses of nondepolarizing NMBDs to maintain adequate levels of surgical paralysis are readily accomplished by giving one fifth to one third the original dose titrated against some objective criteria (e.g., number of twitches in the TOF, clinical evaluation of abdominal relaxation). This process usually is necessary every 40–60 minutes, although more frequent supplemental doses are needed with the short-and intermediate-acting agents. An appropriate option for maintaining more constant and prolonged neuromuscular blockade is a continuous infusion to achieve steady-state plasma levels of drug within a therapeutic window. The infusion of NMBD can be titrated to achieve a stable depth of neuromuscular blockade (usually one or two responses to TOF) permitting a rapid reversal when needed, for example, for daily assessment of a patient's neurologic status.

SCh has been given in the past by IV infusion for maintenance of neuromuscular blockade but is no longer routinely used for this purpose. During infusion of SCh, neuromuscular blockade can change from phase I to phase II block in approximately two thirds of patients receiving a nitrous-narcotic anesthetic, with an extremely variable time of onset. Approximately half of these patients recover rapidly (5–95% recovery in 15 minutes). The remaining half recover to approximately 75% in roughly 30 minutes and require reversal with an anticholinesterase drug.[76] Inhalational anesthetics hasten the onset of phase II block, which usually is heralded by tachy-

phylaxis. The key to successful use of SCh as a continuous infusion is to recognize the presence of phase II block (TOF fade >50%) and to not attempt to reverse until a plateau of recovery has been reached.

Vecuronium and rocuronium by infusion have been used with considerable success. After maintaining steady-state paralysis of approximately 95% and then discontinuing the infusion, mean recovery time to 25% is approximately 13 minutes, and mean 5–95% recovery times are approximately 32 minutes.[77] However, there is an age-dependent decrease in the steady-state drug infusion requirement and an increased recovery time required for patients older than 60 years.[58] These and other findings suggest that disease states or age that alter organ elimination generally decrease maintenance drug infusion requirements and slow the speed of recovery to some extent with vecuronium. This is especially true for long-term infusions in patients with renal failure, because the 3-desacetyl metabolite of vecuronium, which is a potent neuromuscular blocking compound, is eliminated by the kidney.[59,78]

Atracurium and cisatracurium have similar recovery characteristics after infusions in healthy patients. The 25% recovery time after infusion is approximately 12.5 minutes, and the 5–95% mean recovery time is 26.6 minutes during oxygen/nitrous oxide/narcotic anesthesia. Unlike vecuronium, atracurium and cisatracurium show no tendency toward prolonged recovery in disease states, such as renal failure, cirrhosis, and hepatic failure, or at the extremes of age because of its spontaneous degradation by the Hofmann elimination reaction and metabolism by nonspecific plasma cholinesterases.

Mivacurium, because of its metabolism by human plasma cholinesterase at 70% the rate of SCh, has significant clinical potential for maintenance of blockade by continuous infusion. During balanced anesthesia, the time from discontinuing the infusion of mivacurium to 25% recovery was 5.7 minutes, with a 5–95% recovery time of 13.6 minutes.[40] Its recovery characteristics are much shorter than those of atracurium, cisatracurium, vecuronium, and rocuronium and compare favorably with the short recovery times achieved with SCh.

RELAXANTS IN THE INTENSIVE CARE UNIT

NMBDs in the intensive care unit can be valuable adjuncts for managing intubated and mechanically ventilated patients.[79] Neuromuscular blockade may be helpful for diminishing the risk of barotrauma by reducing peak airway pressures, minimizing oxygen consumption in hypothermic patients by preventing shivering, decreasing intra-abdominal pressure, and stopping respiratory activity that is asynchronous with the ventilatory cycle when all other treatments have failed. NMBD also can be given to help mechanically ventilated patients with unusual problems (status epilepticus, tetanus, botulism) that are resistant to conventional methods of treatment. The use of NMBD in critically ill patients must be balanced with the most serious side effect of severe myopathy.[59,79–81] This critical illness myopathy is characterized by marked atrophy of type I and type II muscle fibers, little evidence of inflammation, and sparing of the motor and sensory nerves.[82] Although the steroidal muscle relaxants have been implicated because the myopathy associated with their use is similar to the myopathy caused by exogenous corticosteroid administration,[59,83] all classes of NMBD contribute to myopathy. In the ICU, the underlying complex systemic disease processes (including sepsis and burns), prolonged immobility, ventilator dependence, use of various drugs that may affect the neuromuscular system, and the initial more frequent use of the steroidal muscle relaxants as compared with the benzylisoquinolines in ICU patients have confounded studies of myopathy caused by prolonged neuromuscular blockade.[79]

Atracurium and *cisatracurium* can be given to critically ill patients with renal failure.[84] The epileptogenic effects of laudanosine, a metabolite of the Hofmann degradation, have not been reported in patients receiving atracurium infusions. The highest plasma concentrations of laudanosine measured in human plasma during continuous infusions in the ICU are <6 μg/mL, far lower than the 17 μg/mL needed to produce seizures in animals.[85]

Pancuronium, because it is the NMBD in longest use, frequently was given to ICU patients prior to the availability of the benzylisoquinoline NMBD and sedatives, such as propofol, to facilitate mechanical ventilation. Because of its cardiovascular effects, pancuronium may be a poor choice for patients in whom dysrhythmias and tachycardia would be detrimental. Furthermore, because pancuronium is primarily excreted by the kidneys, patients with compromised renal function may experience a prolonged duration of effect, causing confusion over the patient's neurologic status.

Vecuronium is eliminated primarily by biliary clearance and only minimally by renal clearance. When vecuronium was administered as an infusion to maintain approximately 80% blockade in patients with renal and respiratory failure, recovery to control twitch height after stopping the infusion took from 6–37 hours compared with an approximately 1-hour recovery for cisatracurium.[59] A prolonged recovery may occur secondary to accumulation of the 3-desacetyl metabolite of vecuronium that has approximately 50% of the parent compound's neuromuscular blocking activity and is cleared by the kidney.

RESIDUAL NEUROMUSCULAR BLOCKADE

Residual neuromuscular blockade is observed occasionally in patients admitted to the postanesthesia care unit (PACU).[86–89] "Recurarization" is the term that initially was coined for patients who were reparalyzed after seemingly adequate reversal of neuromuscular blockade in the operating room. Recurarization is clearly a misnomer: what we observe in the PACU is failure to adequately reverse the action of neuromuscular blockade. One long-standing guide for the clinician has been a return to TOF ratio = 0.7 as a reliable indicator for the return of sufficient muscular function to permit endotracheal extubation.[6,90] If we base recovery on the level of pharyngeal function at rest and during swallowing in partially paralyzed subjects, recovery to TOF ratios >0.9 has been advocated.[91] The return of TOF toward baseline should be considered only one criterion in concert with the sum total of multiple clinical observations such as respiratory function and the ability to follow com-

TABLE 33–18.

Criteria of Adequate Recovery

Criteria used depend on whether the patient is awake or somnolent.

Patient Is Awake
- Opens eyes widely to command and denies diplopia
- Sustains tongue protrusion
- Swallows effectively
- Sustains a head lift for 5 seconds
- Sustains a firm hand grip
- Has an effective cough
- Has a vital capacity of at least 15 mL/kg
- Can generate an inspiratory force of at least 30 cm H_2O

Patient Is Somnolent
- Can generate an inspiratory force of at least 30 cm H_2O
- Responds to nerve stimulator appropriately, including sustained tetanic response to 50 Hz for 5 seconds
- TOF or DBS stimulus yields ratio >0.7 or no discernible fade of fully abducted thumb

DBS, double-burst stimulation; TOF, train of four.

mands (Table 33–18) as an indication of adequate recovery from neuromuscular blockade.

Reversal of neuromuscular blockade by the administration of an anticholinesterase (e.g., neostigmine or edrophonium) is routinely needed in the operating room or PACU (Fig. 33–11). Through inhibition of acetylcholinesterase activity, the concentration of ACh will increase and be available to compete with the nondepolarizing NMBD. A muscarinic antagonist is simultaneously administered to limit any untoward effects of ACh (bradycardia, bronchospasm, or gastrointestinal hyperactivity). Because the anticholinesterase and muscarinic antagonist should have similar durations, the usual drug pairs that are commonly given are neostigmine/glycopyrrolate or edrophonium/atropine. The timing of the administration of anticholinesterases is important. Profound neuromuscular blockade with NMBD that is dependent on organ elimination may require up to 80 minutes for full recovery.[92–94] In routine clinical practice, upon return of the TOF to a single twitch, adequate recovery from neuromuscular blockade to allow successful extubation usually is present within 20 minutes. In lieu of acetylcholinesterase inhibitors, drug-specific cyclodextrins may provide reversal of neuromuscular blockade in the future. A γ-cyclodextrin, sugammadex, has been synthesized to reverse a profound neuromuscular blockade after rocuronium administration.[95,96] This is accomplished by encapsulating rocuronium, decreasing its free concentration in the plasma, and thereby removing this NMBD from the neuromuscular junction. The sugammadex–rocuronium complex is cleared by the kidney. Although sugammadex is specific for rocuronium, it is tempting to speculate that similar encapsulating agents for the other steroidal and benzylisoquinoline NMBD will be synthesized.

CHAPTER 34

Monitoring and Managing Perioperative Electrolyte Abnormalities, Acid–Base Disorders, and Fluid Replacement

Patrick J. Neligan, MD, and
Jiri Horak, MD

The human body is an aqueous soup containing carbohydrates, protein, fat, ions, and trace elements bundled into and around cellular structures built on an exoskeleton. Fundamental to the structure and function of the body are the chemical properties of water. Patients who are undergoing surgery or suffering with critical illness undergo dramatic changes in the volume, distribution, and composition of body water. Patients undergoing the most minor of procedures will undertake a period of fasting, rehydration with intravenous fluids and neurohormonal changes in fluid distribution. To understand strategies and implications of perioperative fluid administration, it is important that one understands the homeostatic mechanisms by which the body maintains its internal milieu.

Homeostasis refers to the capacity of the human body to maintain a stable constant condition by means of constant dynamic equilibrium adjustments controlled by a medley of interconnected regulatory mechanisms. The concept dates from the foundations of scientific medicine, specifically the work of Claude Bernard (1813–1878). Multiple systems exist in the body to test and control deviations from the normal range in vital functions, including the autonomic nervous system, the renin–angiotensin–aldosterone–vasopressin axis, and the hypothalamic–pituitary–adrenal axis. The body thus self-regulates to maintain a variety of physiologic and metabolic variables in the state of equilibrium, despite a staggering range

KEY POINTS

1. Water is the single most abundant compound in the body, constituting approximately 50–70% of body weight.
2. One third of body water is extracellular, representing approximately 20% of body weight. Of this one third is located within the intravascular compartment, and two thirds is extravascular or interstitial.
3. Electrolytes are characterized by their degree of dissociation (strong or weak ions), the number of particles present (millimoles), the number of electrical charges per unit (milliequivalents), and the number of active molecules per unit volume (milliosmoles).
4. Although osmolality is equal through each of the body's compartments, electrolyte composition varies. Sodium and chloride are principally extracellular. Potassium, phosphate, magnesium, and calcium are principally intracellular.
5. Perioperative patients undergo a predictable "stress" response during which there is significant fluid and electrolyte flux. The magnitude and timing of these changes are key to management strategies.
6. Changes in extracellular sodium concentrations often, but not always, reflect body water composition. Hyponatremia is indicative of free water overload, whereas hypernatremia is indicative of dehydration.
7. Depletion of serum concentration of principally intracellular ions (potassium, phosphate, magnesium, and calcium) reflects significant total body electrolyte depletion.
8. All acid–base abnormalities can be explained in terms of strong ion difference, weak acid concentration, $PaCO_2$ and extracellular free water.
9. The six primary acid–base abnormalities are acidosis because of increased $PaCO_2$, acidosis because of reduced strong ion difference (SID), acidosis because of increased A_{TOT}, alkalosis associated with reduced $PaCO_2$, alkalosis because of increased SID, and alkalosis because of reduced A_{TOT}.
10. A variety of tools are available for interpreting acid–base abnormalities. These include the base deficit excess, the corrected anion gap, the strong ion gap, and the base deficit-excess gap.
11. Treatment of acid–base abnormalities should be directed at correcting the underlying cause.
12. Initial perioperative or emergency fluid resuscitation strategies involve crystalloid resuscitation to replace insensible loss and restore interstitial volume, lost as a consequence of transcapillary refill.
13. Upper GI losses should be replaced with isotonic saline. Lower GI and extracellular fluid losses should be replaced with balanced salt solutions. Blood loss can be initially be replaced with crystalloid in a 1:3–5 ratio, but as blood loss increases, the volume of crystalloid required increases geometrically.
14. Overresuscitation with crystalloid may lead to poor perioperative outcomes. "Normal saline" solution, given in significant volume, causes metabolic acidosis and hyperchloremia may reduce splanchnic blood flow.
15. Colloid solutions restore circulating volume more rapidly than crystalloid, with less tissue edema. Their use remains controversial.
16. Volume replacement strategies for major surgery should not be formula based, but dynamic and goal directed, using volume- and flow-monitoring devices.
17. Patient outcomes appear to be optimal when the patient is resuscitated fully on the day of surgery or injury and resuscitation efforts rapidly decelerate.
18. Consideration should be given to postoperative fluid restriction, in particular in patients undergoing lower intestinal resection.

of variations in the level of human activities and externalities. A key part of homeostasis is maintenance of body water in terms of circulating volume, volume distribution, and composition. The systems involved in homeostasis are dedicated to maintaining the delicate balance of homeostatic function despite externalities such as tissue trauma or surgery. The anesthesiologist is in a unique position to manipulate these systems for the good of the patient.

Key to the understanding of homeostasis is the role of water and ions in body fluids. Changes in water and electrolyte distribution lead to significant physiologic upset, often manifest as acid–base abnormalities. Acid–base abnormalities all result from changes in carbon dioxide tension, water and electrolyte distribution, and extracellular protein concentration. Intravenous fluids, administered to the majority of perioperative patients have significant effects on water and electrolyte distribution and also impact acid–base balance. Initial perioperative or emergency fluid resuscitation strategies involve crystalloid resuscitation to replace insensible loss and restore interstitial volume. Overresuscitation with crystalloid may lead to poor perioperative outcomes. "Normal saline" solution causes metabolic acidosis and the associated hyperchloremia may reduce splanchnic blood flow.

A careful dynamic or goal-directed approach to fluid administration is supplanting traditional formulaic approaches. Furthermore, widely established practices such as fluid administration to replace third space losses and postoperative maintenance fluid administration are undergoing rigorous evaluation. This chapter sequentially reviews these concepts.

WATER AND IONS

Physical Chemistry of Water

The human body is composed principally of water. Water is a simple triatomic molecule composed of 2 molecules of oxygen and 1 molecule of hydrogen, bound covalently. There is an unequal charge distribution; oxygen nuclei have a particularly strong attraction for electrons. This results in a H-O-H bond angle of 105°. Thus water behaves like a charged molecule, a dipole, with a negative oxygen and positive hydrogen end. This polarity—molecules clumping together—is responsible for important chemical properties of water. Water has a high surface tension, low vapor pressure, high specific-heat capacity, high heat of vaporization, and a high boiling point. These factors have enabled life on this planet. Water is a powerful ionizing solvent—substances dissolved in water separate into component parts. Water is slightly ionized: when molecules collide, enough energy is produced to transfer a proton from one water molecule to another. Thus water slightly dissociates into a negatively charged hydroxylated (OH) ion and positively charged protonated (H_nO^+) ion.[1] All metabolic activity in the body occurs in this aqueous medium. Thus compounds ingested or administered to the body are impacted by the chemical properties of water.

Water Distribution in Body Compartments

Water is the single most abundant compound in the body, constituting approximately 50–70% of body weight. Males contain relatively more water (on average 60%) than do females (on average 50%). There is an inverse relationship between total body fat and total body water (TBW). Females have less skeletal muscle and have more subcutaneous fat, thus lower TBW. TBW varies dramatically, depending on the age of the individual. Neonates have very high TBW (70–80%). Conversely, elderly patients have relatively lower TBW (52% for males, 45% for females). Body water is neither liquid nor easily accessible. It is divided into two separate compartments: the intracellular and the extracellular compartments (or spaces). Two-thirds of body water is intracellular, principally in skeletal muscle. One-third of body water is extracellular, representing approximately 20% of body weight. Of this one third is located within the intravascular compartment, and two thirds is extravascular or interstitial. To place this in context, a 75-kg male has a TBW of 45 L, of which 15 L is extracellular and 5 L is intravascular (Fig. 34–1). The interstitial fluid contains ultrafiltrated plasma (intravascular water), transudated plasma, and fluid and electrolytes actively pumped out of cells (transcellular fluids). Water freely moves from the intracellular to the extracellular space, but dissolved ions cannot do so. Consequently, the clinician should be aware that administration of electrolyte-rich solutions may have a dramatic impact on extracellular ionic composition and, indeed, on acid–base chemistry.[2,3]

Most of the fluid in the interstitium is derived from filtration and diffusion from the capillaries. The extracellular space is a matrix made up of collagen fiber bundles and proteoglycan filaments. Fluid is entrapped in the minute spaces between the filaments, taking the form of a gel ("tissue gel"). Fluid does not flow easily through this gel. Indeed, fluid diffuses through the gel, molecule by molecule. There is little "free fluid" in the interstitium. Free fluid exists only as small rivulets that course along the collagen fibers or cells. When there is significant extravascular fluid expansion, such as in volume overload or congestive heart failure, these rivulets turn into pockets, then rivers, of free flowing water. As a consequence, tissues feel boggy or edematous.

Ionic Constituents of Body Compartments

Charge

Compounds introduced into aqueous solutions dissociate into their component parts, depending on the ion dissociation constant (pK_a).[4] This describes the tendency of the molecule or ion to

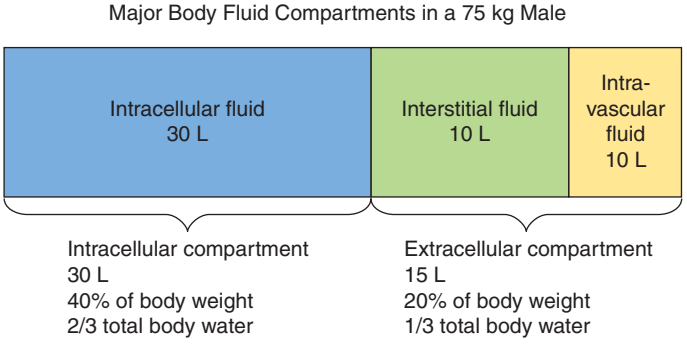

FIGURE 34–1. Body fluid compartments.

keep a proton at its ionization center. Strong ions, characterized by low pK_a, rapidly split into their component parts. Examples of strong ions include sodium (Na^+), chloride (Cl), potassium (K^+), magnesium (Mg^{2+}) and lactate.

The physiologic and chemical activity, and thus the importance, of electrolytes depend on several variables. These include the number of particles present per unit volume (in terms of moles or millimoles), the number of electrical charges per unit volume (in equivalents or milliequivalents), and the number of osmotically active molecules per unit volume (in osmoles or milliosmoles). It is important that the clinician be aware of these properties and distinguishes each from the others when managing and monitoring fluids and electrolytes in perioperative care. It is also important to be aware of the physiologic functions of the most important ions.

The chemical composition of the body's various fluids is described in terms of chemical combining activity or chemical "equivalents." When the concentrations of different ions within each fluid compartment are expressed in this way, the sum of all positive ions (cations) exactly equals the sum of all negative ions (anions). This is the law of electrical neutrality.

The atomic weight of an element is approximately the sum of protons and electrons in the nucleus: the weight of 1 atom of oxygen is 16. The weight of 1 atom of hydrogen is 1. The molecular weight of a compound can be determined by the chemical formula of the compound, and then adding together the atomic weights of all the elements constituting that compound.

One mole (1 mol) of any substance is its molecular weight expressed in grams (i.e., gram-molecular weight) and contains 6.023 × 1023 molecules (the Avogadro number). A millimole (mmol) of a substance is 1/1000 of a mole, or the substance's weight expressed in milligrams. In addition, 1 mol of any *gas* (e.g., oxygen, carbon dioxide) under standard conditions occupies a constant volume of 22.4 L and 1 mmol/L of gas occupies 22.4 mL. Regardless of whether a substance is ionized or nonionized, organic or inorganic, the terms *mole* and *millimole* are applicable.

Electrolytes combine with each other strictly in proportion to their ionic valencies. Originally, oxygen was chosen as the standard of reference; 8 g of oxygen will combine with 1 g atomic weight of hydrogen. By convention, the chemical standard of reference for combining power is the electric charge (+) of 1 atomic weight (1 g) of hydrogen. Thus 1 equivalent (1 Eq) of an ion is that amount that can combine with 1 g of hydrogen and thus is chemically equivalent to 1 g of hydrogen.

One equivalent of hydrogen consists of 6.023 × 1023 particles, weighs 1 g, and carries a positive charge. This quantity of hydrogen ions neutralizes or balances 1 Eq of hydroxyl ions, which consists of 6.023 × 1023 particles, weighs 17 g, and carries a negative electric charge. The result of this neutralization is the formation of 1 mol of water weighing 18 g. Such ions are termed univalent and balance each other in a 1:1 ratio. For all univalent ions, 1 Eq equals 1 mol.

Certain ions (e.g., calcium Ca^{2+}, magnesium Mg^{2+}, sulfate SO_4^{2}) are divalent and carry either 2 positive charges (divalent cations) or 2 negative charges (divalent anions). These multivalent ions have greater chemical-combining power than do univalent ions. As electrochemical neutrality must be maintained in all reactions, 1 divalent cation (e.g., Ca^{2+}) will react with 2 univalent anions (e.g., 2 × Cl). In other words, 1 mol of divalent cation (6.023 × 1023 particles) supplies 2 Eq and will offset 2 mol (1 Eq each) of univalent anion.

The ionic concentrations present in body fluids are relatively small and are expressed in terms of milliequivalents (mEq) rather than equivalents. In the case of univalent ions, 1 mEq is equal to 1/1000 of the gram-atomic weight (i.e., atomic weight expressed in mg); is the same as 1 mmol of the ion in question; and consists of 6.023 × 1020 particles. For divalent ions, 1 mEq consists of 3.012 × 1020 particles and weighs 1/2000 of the gram-atomic weight. One mmol of divalent ions equals 2 mEq. An equivalent (or milliequivalent) of any ion is its atomic weight expressed in grams (or milligrams) divided by the valence. Electrolytes do not combine gram for gram or milligram for milligram; they combine equivalent for equivalent or milliequivalent for milliequivalent of opposite polarity. Therefore, in any given fluid compartment or intravenous solution, the number of milliequivalents of cations is balanced by precisely the same number of milliequivalents of anions.

Distribution

There are different electrolyte concentrations in each body fluid compartment; Table 34–1 lists the average values. In the extracellular compartment, the major cation is sodium and the principal anions are chloride and bicarbonate. Sodium and chloride are free in solution, but appreciable fractions of calcium and magnesium are

TABLE 34–1.

Ion Distribution in Different Compartments

Electrolyte	Plasma (mEq/L)	Plasma Water (mEq/L)	Interstitial Fluid (mEq/L)	Intracellular Fluid (mEq/kgL)
Cations				
Sodium	142	152	145	10
Potassium	4	4	4	156
Calcium	5	5	3	3
Magnesium	3	3	1	26
Total	154	164	153	195
Anions				
Chloride	103	109	114	2
Bicarbonate	27	29	30	10
Phosphate	2	2	2	108
Sulfate	1	1	1	20
Organic acids	5	6	5	
Protein	16	17	1	55
Total	154	164	153	195

bound to protein. Interstitial fluid represents a partial ultrafiltrate of plasma devoid of platelets and erythrocytes and with a lower concentration of protein. The principal plasma protein, albumin, carries a significant a negative charge at pH 7.4, and its diffusion across capillary endothelium is restricted. Consequently, because of the greater protein content (i.e., organic anions) in plasma, the total plasma concentration of cations is greater and the concentration of inorganic anions is less than in the interstitial fluid. Electroneutrality is maintained within each fluid compartment, but because of protein distribution, there is an asymmetry of ion distribution between plasma and the interstitium. Within each fluid compartment, the total cations must equal the total anions, but a greater number of diffusible ions reside in the compartment containing the most organic anions. As a result, a slight osmotic pressure gradient is established, which, under normal conditions, is counterbalanced by capillary hydrostatic forces. This is an example of the Gibbs-Donnan principle, which describes the unequal distribution of diffusible ions on either side of the cell membranes bordering these fluid compartments.

The ionic concentrations for plasma water differ from those of plasma because of the exclusion of solids, notably lipids and large proteins, which total approximately 7%. Plasma proteins occupy a volume far out of proportion to the few milliequivalents of anion they represent. One liter of plasma contains about 940 mL of water. The remaining volume is occupied, for the most part, by protein. Ions are generally dissolved in the aqueous phase of plasma, so that concentrations in plasma water exceed those in whole plasma by a factor of 1000/940. Clinical laboratories usually report electrolyte values as the ionic concentration in a given volume of whole plasma or serum, and, although slightly inaccurate, this is generally accepted. However, if the lipid or protein content of plasma is significantly increased, there will be a corresponding decrease in the reported concentration of ions per liter of plasma (e.g., pseudohyponatremia). The volume of water in the sample may be significantly less than the total volume; therefore the ionic concentrations will be underestimated.

Within the intracellular compartment, potassium and magnesium are the predominant cations, whereas phosphate, sulfate, and protein are the most abundant anions. There is a marked difference between intracellular and extracellular water in terms of ionic concentrations. The ratio of intracellular to extracellular potassium is almost 30:1. Likewise, sodium and chloride are portioned along a steep concentration gradient in the opposite direction. There are more ions in the intracellular compartment than the extracellular compartment. Significant proportions of intracellular ions are bound to protein or cellular constituents and are osmotically inactive.

Many biologic processes are dependent on the presence of transcellular impediments to ion transport. Large polyvalent protein and organic phosphate anions are confined intracellularly because of their absolute membrane impermeability. For smaller ions, maintaining different ionic concentrations across cell membranes is in part, dependent on the active accumulation and extrusion of certain ions from within cells. Active, energy-dependent "ion pumps" (contained within cell membranes) generate the ionic concentration gradients observed among the various fluid compartments. For example, the tendency for sodium ions to diffuse from extracellular fluid (high concentration) into cells (low concentration) is opposed by the active transport of sodium ions out of cells. Similarly, the tendency for potassium ions to diffuse along a concentration gradient from the intracellular fluid (high concentration) to the extracellular fluid (low concentration) is opposed by an active accumulation process. For the anesthesiologist this means that when fluids are administered perioperatively, sodium and chloride remain in the extracellular space.

Ionic distribution results in electrical polarization across cells. Sodium is predominantly extracellular and cells are far more permeable to potassium than to sodium. Thus, potassium ions tend to diffuse down a concentration gradient and out of a cell. The result is an increasing negative charge within the cell that tends to counteract this diffusion, restraining further potassium movement. Membrane polarization is largely a function of the difference in potassium concentration on either side of the membrane. For most cells under normal conditions, the resting transmembrane potential difference is 60 to 90 mV. Alterations in the distribution of ions, particularly in the extracellular space, can result in a change in this resting potential and cellular dysfunction. Hypoxia, in particular, destroys this delicate charge balance and leads to unopposed diffusion of ions along concentration gradients. This results in cellular swelling, a result of sodium and water entering cells, and hyperkalemia, as a result of outward leakage of potassium.

Concentration of Ions

By convention, the concentrations of most intravenous solutions are expressed as percentages (usually weight in grams or milligrams per 100 mL of solution). For example, 0.9% saline solution (normal saline) represents 0.9 g sodium chloride/100 mL water. In the United States, laboratory measurements of, for example, glucose, albumin, and creatinine, continue to be expressed as milligrams percent (i.e., mg/100 mL of blood, serum, or plasma). The major limitation of this measurement technique is the impact of temperature on substance volume.

Internationally, molality and molarity are widely used to describe concentration. Molality is the number of moles of solute per 1000 g of solvent. It is independent of temperature. A mol*al* solution of saline will contain 58.5 g of sodium chloride dissolved in 1000 g of water. The mol*ar* concentration is the number of moles of solute per 1000 mL of solution (usually water) at a specified temperature. In clinical practice, millimoles are used. Thus, we use millimoles per kilogram of solution (millimolal [mmol]) and millimoles per liter of solution (millimolar [mM]).

Water Distribution and Movement

Cell membranes are permeable to water. Water molecules continuously move between fluid compartments in the body. Water movement is governed by hydrostatic and osmotic pressures. Hydrostatic pressure is dynamic and results from pulsatile blood flow. This pressure gradually reduces from a mean in the aorta of 90–95 mm Hg, to a mean of 30–40 mm Hg in the capillaries. Hydrostatic pressure is higher in the lower limbs in the erect patient. The capillary network is fe-

nestrated, and the hydrostatic pressure within the capillary is sufficient to push fluid through these fenestrations into the interstitium. Once in the capillary system, however, osmotic forces are more important than hydrostatic forces. Osmosis is the movement of water thru a semipermeable membrane from a location in which solute is in low concentration to a location in which solute is in high concentration. The membrane is permeable to solvent, not solute, resulting in a pressure gradient. Osmotic pressure is the hydrostatic pressure that must be applied to the solution of greater concentration to prevent water movement across the membrane.

Osmotic pressure is dependent on the number of osmotically active molecules in solution and not their molecular weight, electric charge, or valence number. Small numbers of large molecules are less osmotically active than large numbers of small molecules. One gram molecular weight (i.e., 1 mol) of a nondissociating compound (e.g., glucose, urea) consists of 6.023×10^{23} molecules and is termed 1 osmole (Osm). For nondissociating compounds, 1 mmol is equivalent to 1 mOsm; 1 mOsm of any solute dissolved in 1 kg of water will decrease the activity of water by 17 mm Hg. Ionized substances tend to dissociate in solution and thereby generate more osmotically active particles. For example, 1 gram-molecular weight of sodium chloride (NaCl)—consisting of 6.023×10^{23} molecules—dissociates into twice this number of ions in solution and exerts an osmotic effect of approximately 2 Osm. One mole of sodium sulfate (Na_2SO_4) results in 4 Eq (2 Na^+, SO_4) but dissociates so as to exert an osmotic effect approaching 3 Osm (Na, Na, SO_4).

Osmolarity is the number of osmoles of solute per liter of solvent plus solute. Osmolality, on the other hand, is the solute concentration per kilogram of solvent (water). Osmolality is more widely used in clinical practice, as its value is unaffected by the presence of fat and protein in plasma. Osmolality is generally measured with a freezing point osmometer.

Extracellular osmolality is approximately 290 ± 10 mOsm/kg H_2O, and, presumably, the intracellular osmolality level is identical. As 1 mOsm/kg H_2O exerts an osmotic effect equivalent to 17 mm Hg, the osmotic pressure of most body fluids is approximately 300×17, or 5100 mm Hg.

Quantitatively, osmotic pressures greatly exceed any hydrostatic pressure in the body. The magnitude of these osmotic forces can be appreciated when one realizes that an osmotic pressure difference of only 6 mOsm/L, across a semipermeable membrane, can move as much water as the entire hydrostatic pressure generated by the heart.

Osmotic forces throughout the body (with the exception of the renal medulla) are equal, as water can readily cross cell membranes. Thus the osmolality of the intracellular and extracellular spaces equalize, despite differing compositions. This has significant impact in health and disease. Loss of extracellular fluid (ECF) volume leads to increased ECF osmolality and subsequent cellular dehydration.

Sodium, chloride, and bicarbonate account for 90–95% of the osmotic activity present in plasma and interstitial fluid. Other ions and organic compounds (e.g., glucose, urea, amino acids) account for most of the remainder. Plasma proteins provide negligible osmotic effect. The major intracellular osmotic solutes are potassium, magnesium phosphate, and protein. Total body osmotic solute is portioned such that two thirds is contained within the intracellular fluid (ICF) compartment and one third resides in the ECF compartment. This localization of total body solute in turn explains the overall distribution of body water.

In most situations, the concentrations of certain osmotically active substances can be combined to provide a remarkably accurate (within 10%) estimate of serum osmolality (S_{osm}):

$$S_{osm}\ (\text{mOsm/kg } H_2O) = (2 \times [Na] + [K]) + ([\text{glucose}]/18) + ([\text{BUN}]/2.8)$$

where glucose and blood urea nitrogen (BUN) concentrations are expressed in mg/dL and sodium concentration [Na^+] is in mEq/L. The calculations for BUN and glucose resolve the results into mmol/L.

Occasionally, osmotically active compounds are present in the extracellular fluids that are not accounted for by the above calculation. When osmolality is measured, and then calculated, a gap between the two figures becomes evident (osmolal gap). This gap is normally less than 10 mOsm/kg H_2O. Pharmacologically, the gap is increased by the administration of mannitol or alcohol. Pathologically, the gap may be widened by poisoning with ethylene glycol, propylene glycol, or isopropyl alcohol.

Tonicity describes the relative osmolality of solutions. A solution is said to be isotonic when it is isoosmotic (i.e., the same osmotic pressure) with the body fluids. Intravenous fluids that are formulated as balanced salt solutions (Normosol-R or Plasma-Lyte) are isotonic with respect to plasma. Normal saline (0.9% NaCl) is slightly hypertonic to plasma. Lactated Ringer solution is slightly hypotonic. However, functionally, these fluids act as isoosmotic solutions and do not impact the size of erythrocytes. Administration of hypertonic fluids (e.g., 3% or 7.5% NaCl, 7.5% sodium bicarbonate, 10% mannitol) leads to a dramatic increase in ECF osmolality and cellular dehydration. Often this is intentional, such as the administration of mannitol or hypertonic saline to head-injured patients. Occasionally, hyperosmolality occurs pathologically, as in diabetes insipidus, diabetic ketoacidosis (caused by ketones and glucose) or nonketotic hyperosmolar syndrome (caused by glucose), and acute renal failure (caused by urea and other nitrogenous waste products).

Hypotonic solutions (e.g., 0.45% NaCl) have fewer osmotically active particles per volume compared with the reference solution and tend to produce cellular swelling.

Finally, although the terms *tonicity* and *osmolality* are frequently used interchangeably, an alteration in one does not necessarily lead to an alteration in the other. The classic example of this is urea. Urea is freely permeable throughout the body water. It does not affect tonicity, but will cause an increase in extracellular osmolality.

ALTERATIONS IN FLUID AND ELECTROLYTE DISTRIBUTION

Impact of Surgical Stress Response on Perioperative Fluid Distribution

Insensible Losses

Perioperative care is characterized by dramatic changes in fluid and electrolyte content and distribution in the various fluid spaces in the body. These

changes are predictable and follow a characteristic pattern described by Cuthbertson[5] and Moore,[6,7] widely known as the "stress response." An understanding of this process is central to understanding the dynamics of fluid and electrolyte flux in the perioperative period and is helpful in guiding therapy.

The stress response has traditionally been considered a biphasic "ebb and flow" phenomenon. After an injury or surgical incision, initially there is significant peripheral vasoconstriction, shunting of blood from the periphery to the midline (to preserve vital organs), and a drop in body temperature. Simultaneously, there is a fall in capillary hydrostatic pressure, promoting a rapid shift of protein-free fluid from the interstitium into the capillaries.[8] This is known as "transcapillary refill" and it includes mobilization of fluid from the splanchnic circulation, in particular the splanchnic veins.[9] This induces a state of absolute hypovolemia in the extracellular space. There is a dramatic increase in the release of vasopressin (antidiuretic hormone) and activation of the renin–angiotensin–aldosterone axis to conserve salt and water.

The second phase, the hypermetabolic or "flow" phase, occurs within hours, characterized by a dramatic increase in cardiac output, driven by catecholamines, vasodilatation, increased capillary permeability and an increase in temperature. A generalized catabolic state ensues, characterized by insulin resistance, hypercortisolism, and protein breakdown. Thus the patient develops tachycardia, leucocytosis, hyperthermia, hyperglycemia, and tissue edema. The magnitude of this response is proportionate to the degree of injury or extent of surgery. Significant intracellular fluid deficit may be incurred to maintain circulating volume. A period of fluid sequestration occurs, as a result of extravasation of fluid consequent of widespread capillary leak, urinary output falls, and tissue edema may become evident. Vasodilatation and relative intravascular hypovolemia occurs. During this period, patients typically require administration of resuscitation fluids to maintain blood pressure and circulating volume. Weight gain ensues.

Eventually a state of equilibrium arrives, usually day 2 after a procedure, when active sequestration stops. This is followed by a phase of diuresis during which the patient mobilizes fluid and recovers. Initially there is a precipitous drop in serum albumin. Restoration of albumin levels is associated with recovery. Moreover, intracellular fluid volume returns to normal. Inward shift of fluid from the extracellular to the intracellular space is associated with intracellular movement of ions such as potassium, magnesium, and phosphate. Hence hypophosphatemia, hypomagnesemia, and, in particular, hypokalemia are usually evident on a serum chemistry panel at this time.

The practicing clinician must be aware of the stages of the stress response when deciding whether or not to administer fluid and electrolytes. For example, early in the flow phase, significant intracellular and interstitial fluid depletion may exist, despite the appearance of "normal" cardiovascular measurements (blood pressure, cardiac output, stroke volume). This requires repletion with free water and isotonic crystalloid. During the vasodilatory, hypermetabolic phase, the circulating volume requires support, taking into account the large volume of distribution of administered crystalloid. During the equilibrium phase, the administration of intravenous fluid is dependent on the objective of the clinician. The clinician may choose to continue fluid administration, to keep organs well hydrated, or to stop administering fluid, preventing the formation of further tissue edema. During the diuretic phase, the major objective of the clinician is to allow the patient to return to baseline body weight, and to aggressively replete electrolytes.

It can be argued that the administration of anesthesia significantly reduces the ebb or shock phase. Nevertheless, patients undergoing surgery are usually dehydrated secondary to fasting, bowel lavage, or their primary disease (e.g., esophageal cancer). Consequently, the perioperative period should be viewed as follows: (a) dehydration phase, (b) shock phase, (c) relative and absolute hypovolemic phase (as a consequence of vasodilatation, fluid sequestration, and blood loss), (d) equilibrium phase, and (e) diuresis phase. Certain operations are associated with greater blood loss because of overt or microvascular bleeding (vascular surgery); other operations are associated with greater tissue injury because of, for example, bowel handling. Thus, within this paradigm, a "one-formula-fits-all" approach is neither scientific nor effective. Where extensive fluid shifts are to be expected in the perioperative period, it is worthwhile to obtain a preoperative weight so as to have a baseline goal for the patient's postoperative diuresis.

Hypovolemia

There is little excess water-storage capacity in the human body. With the exception of congestive heart failure, perioperative patients are more than likely to present in a state of relative or absolute hypovolemia. This may be mild dehydration, as a consequence of fasting, or severe dehydration, because of the administration of purgatives (for bowel lavage), persistent diarrhea, nasogastric suctioning, fistula drainage, or the inability to consume water and electrolytes. Clinical findings that may alert the clinician to dehydration include confusion, loss of skin turgor, longitudinal furrowing of the tongue, dry mucus membranes, sunken eyes, collapsed veins, cold extremities, and highly concentrated urine. A 15–30% loss of intravascular volume will lead to resting tachycardia. Blood pressure is usually maintained despite a volume loss of up to 40%, caused by intense vasoconstriction and transcapillary refill. In addition cardiac output and cardiac index remain within normal limits and the only hemodynamic indication of hypovolemia is a reduction in stroke volume.[10]

On evaluation of the patients' chemistry panel, a high urea to creatinine ratio ($>$10:1), hypernatremia, and metabolic (contraction) alkalosis (caused by increased strong ion difference, a consequence of free water deficit) should alert the clinician to an ECF volume deficit. An ECF volume deficit can be confirmed by a urine specimen (assuming normal renal function) that is significantly concentrated (e.g., 500–1400 mOsm/kg H_2O) and that has a high specific gravity and low sodium content ($<$20 mEq/L).

Of particular importance is the problem of relative hypovolemia. Typically, this occurs in patients who are being treated with vasodilator drugs such as angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, α_1-receptor antagonists (e.g., phenoxybenzamine) and α_2-adrenergic agonists (e.g., clonidine). Administration of anesthetic agents typically causes widespread vasodilatation and rela-

tive hypovolemia; in patients who are treated with these drugs, severe hypotension may ensue. Likewise, in patients who present with acute shock as a result of volume loss or vasoplegia, such as occurs with sepsis, the administration of an anesthesia induction agent (propofol or thiopental), followed by the application of positive-pressure ventilation, may result in life-threatening hypotension (Fig. 34–2).

The decision to rehydrate patients prior to and during induction of anesthesia must be guided by the clinical assessment, quantification of preoperative fluid deficits and the nature of the surgery. Preoperative fasting of 12 hours or more may result in a fluid deficit of more than 1 L, consisting principally of free water. Ambulatory patients who are administered 30 mL/kg of fluid have significantly less dizziness and postoperative nausea and vomiting than those who are given less fluid or none at all.[11–13] It is unclear whether prehydration should involve hypotonic crystalloid or balanced salt solution. The administration of dextrose-containing fluids is associated with increased pain, thirst, and blood glucose compared with patients given dextrose-free balanced salt solutions.[14] For patients who have preexisting gastrointestinal fluid losses, significant electrolyte depletion is to be anticipated. For upper gastrointestinal losses, for example, secondary to nasogastric suctioning, vomiting, or gastroparesis, hypochloremia is to be anticipated; "normal" saline is the replacement fluid of choice. For patients with lower gastrointestinal system losses, significant losses of sodium and potassium are to be anticipated, and balanced salt solution should be administered. Subsequent to surgical incision, administered fluids should be isotonic because of the 50–100-fold increase in antidiuretic hormone (ADH) activity that persists for the duration of the stress response. Large-volume resuscitation with hypotonic fluid may result in acute severe hyponatremia, cerebral edema, and seizures.

Hypervolemia

Signs of preoperative hypervolemia include a cardiac gallop rhythm, jugular venous distension, ankle and/or sacral edema, an enlarged liver, and pulmonary edema. Although there are no pathognomonic laboratory signs of hypervolemia, hyponatremia, below-normal values of urea and creatinine, and low serum osmolality, may be indicative of free water overload.

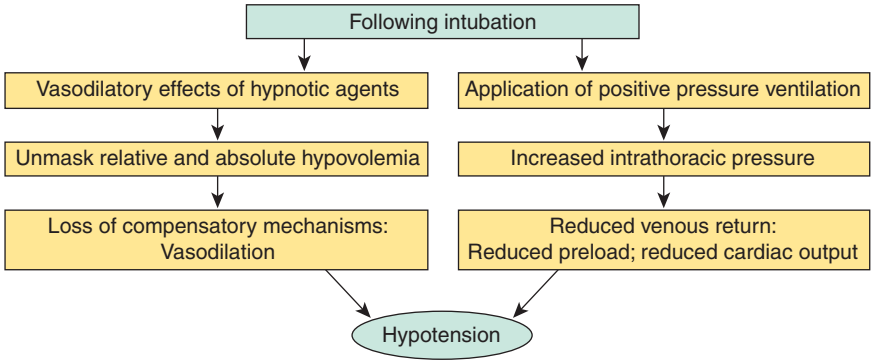

FIGURE 34–2. Hemodynamic consequences of induction, intubation, and positive-pressure ventilation.

Postoperative hypervolemia is an inevitable consequence of current fluid administration strategies that has generally been considered benign. Traditionally, generous volumes of intravenous fluid are administered in the operating room to replete fasting deficits, maintenance requirements, and third space fluid losses. The consequence is an inevitable weight gain of 4–6 kg for major surgery.[15] This approach has been challenged because of emerging evidence of adverse outcomes associated with perioperative fluid overload.[16]

The concept of "third space" fluid loss or functional extracellular fluid deficit derived originally from work by Shires et al.[17] The hypothesis behind third spacing is that as a consequence of trauma, hemorrhage, tissue injury, or tissue handling, extracellular fluid becomes sequestered in nonfunctional tissue spaces, presumably the injured tissue, the bowel lumen, and other potential spaces, such as the pleura and peritoneum. This fluid serves no physiologic purpose and may lead to organ hypoperfusion and, in particular, acute renal failure. Proponents point to the dramatic difference in the incidence of acute renal failure during the Vietnam War, in which liberal fluid management strategies were used, versus the Korean War, where fluid restriction was the norm. A small body of subsequent work investigated extracellular fluid volume in the perioperative period with a series of radiolabeled tracers. Brandstrup et al. systematically evaluated this literature and found significant flaws in the methodology.[18] Indeed, there is little or no published evidence that significant third space fluid loss occurs in clinical practice. Fluid resuscitation strategies based on this premise are associated with an elevated incidence of acute lung injury, abdominal compartment syndrome, prolonged ileus, myocardial ischemia, extensive tissue edema, impaired wound healing, and delayed discharge from hospital.[16,19,20]

Large-volume fluid resuscitation leads to significant sequestration of fluid in lax tissues, the splanchnic veins, and the peritoneum. Following resolution of the stress response, this fluid is mobilized into the intravascular space and the patient usually undergoes rapid diuresis. However, in cases of diastolic dysfunction or congestive heart failure (CHF), the patient may develop acute pulmonary edema ("flash pulmonary edema") or acute myocardial ischemia. This process has been termed "deresuscitation." Gentle preemptive administration of furosemide may increase venous capacitance and induce earlier diuresis.

Sodium Physiology

Sodium is the most abundant extracellular ion, and is responsible for maintenance of the extracellular volume.

There is a dynamic relationship between total body water and extracellular sodium concentration. This water balance is influenced by intakes and outputs, antidiuretic hormone, renin–angiotensin–aldosterone, and serum osmolality. As sodium ion is excluded from the intracellular space and is the predominant osmotically active substance in the ECF, isolated changes in water volume are generally reflected by inverse changes in the serum sodium concentration and serum osmolality. Hyponatremia generally indicates an expansion in free water volume as

compared with normal. Hypernatremia generally indicates a reduction in free water concentration.

Total body sodium concentration averages 60 mEq/kg of body weight in a healthy adult male (i.e., 4200 mEq in a 70-kg man). Approximately 2000–2200 mEq is dissolved in the ECF. Another 1800 mEq resides within the skeletal system, which constitutes 15–16% of body weight. Thus, total body sodium is proportioned as follows: approximately 50% is extracellular, 40% is in bone, and 10% or less is intracellular.

Body sodium is often considered in terms of exchangeable and nonexchangeable moieties. Nonexchangeable sodium is that fraction adsorbed on hydroxyapatite crystals contained deep within the long bones of the skeleton. It amounts to approximately 18 mEq/kg of the total body sodium concentration. More important clinically is the exchangeable sodium, which represents 42 mEq/kg of total body sodium. This exchangeable fraction includes all sodium within the ECF and ICF, and about half of the bone sodium. Exchangeable sodium is in diffusion equilibrium with plasma (serum) sodium and is reflected in the normal ECF concentration of sodium (i.e., 136–145 mEq/L). This exchangeable reservoir serves to mitigate concentration changes when sodium is either lost (e.g., sweat, diarrhea) or retained (e.g., cirrhosis, CHF). As a result, the concentration of sodium may provide little useful information about the total body sodium content.

The daily adult requirement for sodium averages 1–2 mEq/kg/d. Normal dietary intake ranges between 100 and 200 mEq/d. The kidney is the principal site of sodium regulation, through changes in the rates of glomerular filtration and tubular resorption. Approximately 180 L of water and 24,000 mEq of sodium are filtered and resorbed by the kidneys each day. This is modulated by the interaction of a variety of neurohormonal modulators, including the sympathetic nervous system, the renin–angiotensin–aldosterone system, atrial natriuretic peptide, and antidiuretic hormone. Diseases or drugs that impact the normal renal or neuroendocrine function impact the normal sodium–water homeostasis. For example, congestive heart failure is characterized by adrenergic activation, release of renin–angiotensin–aldosterone, retention of both salt and water in the renal tubules, and hypervolemia. The administration of angiotensin-converting enzyme inhibitors results in vasodilatation, lowering the blood pressure, diuresis, and natriuresis.

Hyponatremia

Hyponatremia exists when the serum (or plasma) sodium concentration is below 135 mEq/L. It may occur in an isotonic, hypertonic, or hypotonic state (Fig. 34–3). If the blood is hypoosmolar in relation to the brain, water enters the brain and can cause acute cerebral edema, particularly in patients who are euvolemic. This may occur with large-volume administration of hypotonic fluids and in patients who develop "TURP" syndrome, which is caused by intravasation of hypotonic fluid during transurethral resection of the prostate gland (TURP). This may lead to a spectrum of neurologic upsets ranging from confusion, to seizures, to coma, to brainstem herniation. Rapid correction of low sodium can lead to osmotic demyelination of the brain/brainstem because of rapid shrinkage of the brain.

Serum osmolality is governed by contributions from all molecules in the body that cannot easily move between the intracellular and extracellular space. Sodium is the most abundant electrolyte, but glucose, urea, plasma proteins, and lipids are also important. A patient with diabetic ketoacidosis may have hyponatremia, but normal osmolality, because of hyperglycemia, hypertriglyceridemia, and increased plasma ketones. Each of these compounds is osmotically active. Patients with acute renal failure may have hyponatremia as a result of uremia, which is characterized by the accumulation of urea and other nitrogenous waste products.

Hypotonic hyponatremia is when a patient has hyponatremia with low measured and calculated serum osmolality. If serum osmolality is normal or high, this is *isotonic* or *hypertonic hyponatremia* or *pseudohyponatremia*.

Serum osmolality is calculated as follows:

$$2(Na + K) + BUN/2.8 + glucose/16 \text{ (in mEq/L)}$$

or in SI units (mmol/L)

$$2(Na + K) + urea + glucose$$

Classically, we divide pseudohyponatremia into conditions in which the measured and calculated serum osmolalities are the same—hyperglycemia or uremia—and those in which there is an osmolar gap; some osmoles are clearly present as measured by serum osmolality but not identified by standard blood tests. The source of unmeasured osmoles may be endogenous (lipids or proteins), or exogenous (alcohols: ethanol, ethylene glycol, methanol, or isopropyl alcohol). The recognition of pseudohyponatremia is important because therapy for the de-

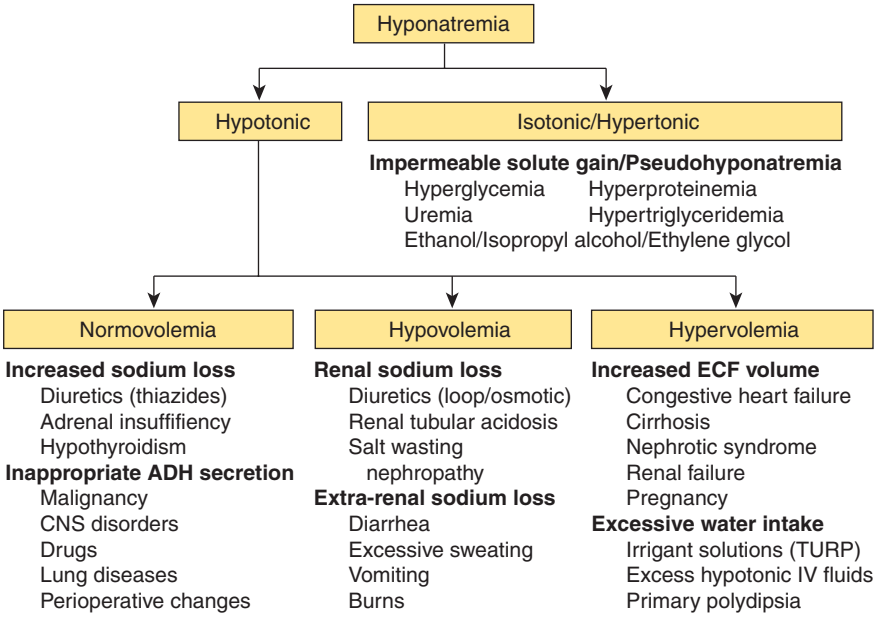

FIGURE 34–3. Hyponatremia.

creased serum sodium concentration is not indicated.

Hypertonic hyponatremia occurs when a decreased serum sodium concentration coexists with an increased serum osmolality. An increase in concentration of any osmotically active substance, which is confined predominately to the ECF (e.g., glucose, glycerol, mannitol), will result in water movement out of cells along the osmolar gradient. The osmolar load usually evokes an osmotic diuresis, leading to urinary loss of both sodium and water. These losses may, in turn, potentiate both the hypertonicity and the hyponatremia. Clinically, the most frequent cause of this water and electrolyte disturbance is the occurrence of significant hyperglycemia in uncontrolled or poorly controlled diabetes mellitus. The measured serum sodium concentration decreases approximately 1.6 mEq/L for each 100 mg/dL increment of blood glucose.

True hyponatremia may result from increased total body water, associated with edema (liver failure, congestive heart failure, renal failure, or nephrotic syndrome), hypotonic fluid overload, or sodium loss in excess of free water. Total body sodium concentration is increased and there is a concomitant defect in the excretion of solute-free water. Water retention is proportionately greater than sodium retention, resulting in hypervolemic hyponatremia. This may be associated with extensive tissue edema. Despite the dramatic increase in extracellular fluid volume, there is a tendency toward venous pooling and accumulation of fluid in lax tissues and the peritoneum. Consequently, the plasma volume and, indeed, stroke volume, may be reduced, leading to renal hypoperfusion and activation of volume defence mechanisms by way of the juxtaglomerular apparatus and renin–angiotensin–aldosterone axis. This leads to a vicious cycle of hypervolemia, characteristically associated with congestive heart failure.

Dehydration associated with hyponatremia (hypovolemic hyponatremia) may be of renal or extrarenal origin. Renal losses are identified by a urinary sodium of >40 mEq/L, and are characterized by the inability of the body to retain sodium. This may be caused by loop, thiazide, or osmotic diuretics, carbonic anhydrase inhibitors, primary aldosterone deficiency (Addison disease or adrenal insufficiency), or cerebral salt wasting (associated with subarachnoid hemorrhage). If the urinary sodium is less than 20 mEq/L, then the site of sodium loss is outside the kidney, usually the lower gastrointestinal tract, and associated with diarrhea. The mechanism of hyponatremia is the inbuilt priority of preservation of volume over osmolality. Hence, in this situation there is a dramatic increase in plasma ADH levels.

A number of diseases and drugs cause abnormal release of antidiuretic hormone, either as a consequence of ectopic production of ADH (ADH-secreting tumors) or increased release of this compound from the posterior pituitary gland (Table 34–2). The result is a paradoxically concentrated urine with dilute blood (the urinary osmolality is higher [>300 mOsm] than the serum osmolality [<300 mOsm]). The result is a state of hypervolemic or euvolemic hyponatremia. The syndrome of inappropriate antidiuretic hormone secretion (SIADH) is easily confused with the cerebral salt wasting syndrome: the SIADH improves with fluid restriction, whereas the cerebral salt wasting syndrome does not.

TABLE 34–2.

Syndrome of Inappropriate Antidiuretic Hormone (ADH) Secretion

Increased hypothalamic production of ADH

1. Neuropsychiatric disorders
   - Infections: meningitis, encephalitis, brain abscess
   - Vascular: thrombosis, subarachnoid or subdural hemorrhage, temporal arteritis, cavernous sinus thrombosis, stroke
   - Neoplasm: primary or metastatic
   - Skull fracture, traumatic brain injury
   - Psychosis, delirium tremens
   - Other: Guillain-Barré syndrome, acute intermittent porphyria, autonomic neuropathy, postpituitary surgery, multiple sclerosis, epilepsy, hydrocephalus, lupus erythematosus
2. Drugs
   - Intravenous cyclophosphamide
   - Carbamazepine
   - Vincristine or vinblastine
   - Thiothixene
   - Thioridazine, other phenothiazines
   - Haloperidol
   - Amitriptyline, other tricyclic antidepressants or serotonin-reuptake inhibitors
   - Monoamine oxidase inhibitors
   - Bromocriptine
   - Lorcainide
   - Clofibrate
   - General anesthesia
   - Narcotics, opiate derivatives
   - Nicotine
3. Lung diseases and interventions
   - Pneumonia
   - Tuberculosis
   - Lung abscess, empyema
   - Acute respiratory failure
   - Positive pressure ventilation
4. Perioperative period—associated with the stress response to injury and pain

Ectopic (nonhypothalamic) production of ADH

- Cancer
  - Small cell carcinoma of lung (67% patients with small cell have impaired water excretion), bronchogenic, duodenum, pancreas, thymus, olfactory neuroblastoma, bladder, prostate, uterus
  - Lymphosarcoma, reticulum cell sarcoma, mesothelioma, Ewing sarcoma
  - Hodgkin disease, leukemia
  - Pulmonary tuberculosis

Several factors in perioperative medicine can contribute to functional SIADH, including emotional stress, anxiety, nausea, pain, the administration of opiates, and mechanical ventilation. Obstetric patients frequently receive oxytocin in order to increase uterine contractility. Indeed, the acute stress response should be seen as a state of free water retention, and for that reason large-volume resuscitation hypotonic fluids should be avoided. Conversely, SIADH as a result of other causes (Table 32–1) is treated, initially, with water restriction (Table 34–3). Chronic SIADH may be treated by inducing a state of nephrogenic diabetes insipidus, for example, by administering drugs such as lithium and demeclocycline.

A potentially fatal cause of hyponatremia, particular to perioperative medicine is TURP syndrome. This procedure requires continuous irrigation of the operative field to improve visibility and distend the bladder or prostatic urethra. The systemic absorption of these irrigating solutions can produce acute and sometimes dramatic hyponatremia. To prevent current dispersion from the resectoscope, the irrigating fluids cannot contain electrolytes; consequently, distilled water solutions containing isotonic glycine, mannitol, and/or sorbitol are usually used. During TURP, systemic absorption of the irrigating solutions is influenced by the duration of exposure, the number and size of venous sinuses opened, extravasation of the fluid into tissues outside the bladder or prostatic capsule, and the hydrostatic pressure of the fluid. The majority of patients undergoing TURP probably intravasate some hypotonic fluid, and there are few sequelae. However, when large volumes are absorbed, severe hyponatremia leading to cerebral edema may ensue. Consequently, urologists routinely administer furosemide when resection is complete. On occasion, it is necessary to administer hypertonic fluids to replete a sodium deficit.

If hypertonic saline is to be used, the sodium deficit must be calculated (the normal serum sodium is 140 mEq/L) as follows:

Step 1: Determine the patient's weight in kilograms prior to illness.

Step 2: Calculate the sodium deficit.

It is usual to correct only half the sodium deficit (NaD) (hence the deficit/2):

$$\text{NaD} = (\text{desired sodium} - \text{patient's sodium})/2$$

If the patient's weight is 70 kg, and the serum sodium is 120 mEq/L, then the desired change is 10 mEq/L.

Total body deficit (TD) of sodium is the sodium deficit × TBW:

$$\text{NaD} \times (\text{weight in kg} \times 0.6) = \text{TD}$$

The formula is applied as follows:

$$10 \times (70 \times 0.6) = 420 \text{ mEq}$$

Step 3: Calculate the rate of replacement.

Most physicians replace the deficit at a rate of replacement (RoR) of no more than 0.5 mEq/h. The patient has a deficit of 10 mEq, so at this rate (0.5 mEq/h), the deficit will be replaced over 20 hours (10/0.5).

$$\text{RoR in hours} = \text{NaD}/0.5$$

Step 4: Replace the sodium deficit with the fluid of your choice.

Because the amount of fluid required depends on the sodium content of that fluid (Table 34–4):

$$\text{TD}/[\text{Na fluid/mL}]/\text{RoR} = \text{per hour fluid replacement}$$

For example, if one is using 3% saline in this 70-kg male patient who has a serum sodium of 120 mEq/L, the calculation is as follows:

$$(420/0.513)/20 = 41 \text{ mL/h}$$

That is, after 20 hours, assuming no other fluids are given, the patient's serum sodium will rise to 130 mEq/L. If 0.9% saline is given, the calculation is as follows:

$$(420/0.13)/20 = 160 \text{ mL/h}$$

Care must be taken when repleting sodium deficits to avoid the problem of osmotic demyelination (central pontine myelinolysis). Rapid correction of hyponatremia may trigger demyelination of pontine or extrapontine neurons, leading to neurologic dysfunction that may include quadriplegia, pseudobulbar palsy, seizures, coma, and even death.[21] For that reason serum sodium is raised slowly and only 50% of the deficit is corrected.

TABLE 34–3.

Management of Hyponatremia

If Na concentration is >125, the treatment is water restriction, 500–1000 mL/d
If Na concentration is <125, or water restriction is not possible, furosemide 40–80 mg IV, repeated as necessary, with replacement of electrolyte losses
If this strategy is unsuccessful at raising serum sodium, treatment with hypertonic saline may be necessary: NaCl 0.9% contains 1 mEq of Na in 6.5 mL (i.e., 0.154 mmol/mL), NaCl 1.8%, contains approximately 1 mEq Na per 3.25 mL, 3% NaCl contains approximately 1 mEq Na per 2 mL
If the cause is syndrome of inappropriate diuretic hormone secretion, and the patient does not respond to fluid restriction, then loop diuretics may be helpful; an alternative treatment is to cause a nephrogenic diabetes insipidus, by administering demeclocycline 300–600 mg BID

TABLE 34–4.

Sodium Content of Various Intravenous Fluids

Fluid (Infusate)	Na Content (mEq/L)	Sodium Concentration per mL
Lactated Ringer solution	130	0.13 mEq/mL
0.9% NaCl	154	0.154 mEq/mL
1.8% NaCl	308	0.38 mEq/mL
3% NaCl	513	0.513 mEq/mL
5% NaCl	855	0.855 mEq/mL

Hypernatremia

A serum sodium of >145 mEq/L represents a hypertonic and hyperosmolar state. There is a net deficit of water in relation to sodium. This implies neither an increase in total body sodium nor a deficit in total body water. Hypernatremia is rarely encountered in routine perioperative patients; however, it is not an uncommon finding in the intensive care unit and, consequently, in patients traveling to the operating room from the ICU for subsequent procedures. When the serum osmolality exceeds 305–310 mOsm/kg H_2O, ADH secretion is stimulated and the urine becomes severely concentrated (i.e., osmolality greater than 800–1000 mOsm/kg H_2OH_2O). The thirst response is activated in an attempt to stem cellular dehydration. Hypertonicity and hypernatremia rarely develop in the presence of an intact thirst mechanism and access to water. However, critically ill patients are often too sedated to express thirst and/or unable to drink water.

The imbalance between TBW and sodium that occurs in the hypernatremia may develop from either water loss or sodium gain (Fig. 34–4 and Table 34–5).[22] This may result from pure dehydration, the presence of a free water deficit (hypovolemic hypernatremia) such as occurs with administration of loop or osmotic diuretics, excessive evaporative losses (nonhumidified breathing systems), or diabetes insipidus (either cranial or nephrogenic). Patients with diabetes insipidus may present to the operating room in three circumstances. First, patients with traumatic brain injury complicated by diabetes insipidus may present for neurosurgery, for example, for decompressive craniectomy. Second, a patient who has undergone devastating brain injury, either traumatic or hemorrhagic, complicated by diabetes insipidus, may present for organ harvest, following brain death. Finally, a patient who has been chronically treated with lithium, for bipolar disorder, complicated by diabetes insipidus, may present for routine surgery. In each of these situations, the major risk to the patient (or to the patient's organs) is not hypernatremia but hypovolemia, and the anesthesiologist must be careful to replenish perioperative urinary losses.

Hypernatremic hypernatremia is associated with sodium gain, in the presence of either euvolemia or hypervolemia. This may result from administration of hypertonic saline, sodium bicarbonate, blood transfusion (sodium citrate), or parenteral nutrition (sodium acetate). Hypernatremia may be accompanied by metabolic alkalosis associated with an increase in the strong ion difference, from either dehydration of sodium gain.

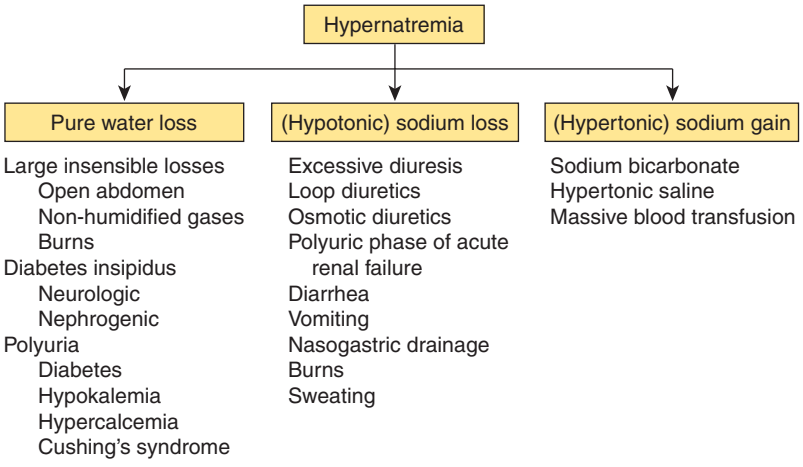

FIGURE 34–4. Hypernatremia.

Hypernatremia can be associated with significant neurologic sequelae; initially, the brain shrinks as a consequence of volume depletion, which makes the blood vessels vulnerable to rupture. The brain adapts to dehydration by expressing more solute, which may lead to cerebral edema, neurologic deficit, or convulsions.

The clinical approach to the management of the hypernatremic patient is to identify and treat the source, and replace the free water deficit. To correct hypernatremia, fluid and electrolyte losses must be restored. The rate of correction depends on the duration of hypernatremia. In general, for critically ill patients, correction at a rate of 1 mEq Na/L/h is appropriate; if hypernatremia is prolonged, the 0.5 mEq Na/L/h is more advisable (to reduce the risk of rebound cerebral edema).

For young males, the free water deficit is calculated as follows:

$$\text{free water deficit} = 0.6 \times \text{patient's weight in kg} \times ([\text{patient's sodium}/140] - 1)$$

where 0.6 × weight = estimated body water and 140 = desired sodium. (To calculate the free water deficit for females and elderly males multiply the weight in kg by 0.5.) Thus for a 70-kg young male with a serum sodium of 150 mEq/L, the free water deficit equals 3 L.

Either isotonic or hypotonic fluid can be used to replace the free water loss. However, the more hypotonic the fluid administered, the more rapidly the deficit will be replaced.

In the example above, if one wished to reduce the patient's serum sodium by 10 mEq/L, how much of what fluid does one use? This depends on the amount of sodium in the chosen fluid,

TABLE 34–5.

Causes of Hypernatremia

Pure water loss
Large insensible losses: no humidifier on mechanical ventilator
Diabetes insipidus
Neurologic—associated with head injury, brain hemorrhage, or meningitis
Nephrogenic—caused by lithium, demeclocycline, amphotericin B, heavy metal poisoning, hypokalemia, and hypercalcemia
Hypotonic fluid loss
Excessive diuresis with loop of osmotic diuretics
Polyuric phase of acute renal failure
Diarrhea
Vomiting
Nasogastric drainage
Burns
Sweating
Hypertonic sodium gain
Sodium bicarbonate infusion
Hypertonic saline administration

TABLE 34–6.

Sodium Content of Fluids Used to Treat Hypernatremia

Fluid (Infusate)	Na Content (mEq/L)	Change per Liter in 70 kg Male with Na 150 mEq/L
Dextrose 5% in water	0	−3.5 mEq Na/L
0.2% NaCl in D_5W	34	−2.7 mEq Na/L
0.45% NaCl	77	−1.7 mEq Na/L
Lactated Ringer solution	130	−0.5 mEq Na/L

and then applying this figure to the formula below (Table 34–6):

$$\text{change in serum Na per liter} = \frac{\text{infusate Na} \ (\text{serum Na})}{[(\text{weight in kg} \times 0.6) - 1]}$$

If one chose D_5W (dextrose 5% in water) and planned to correct this patient's sodium at a rate of 1 mEq/L/h, because each 1 L will correct 3.5 mEq, the rate of fluid infusion would be 1000 mL/3.5 = 285 mL/h.

Clearly, for simple hypernatremia, the choice of fluid determines the volume required to correct the sodium abnormality (a much larger volume of lactated Ringer solution than of D_5W is required). The administration of free water, for example, via the enteral route, is probably the most effective method for replenishing extracellular water deficit.

Potassium Physiology

Potassium is the major intracellular cation in the body and has several roles, the most important being the generation of the resting cell membrane potential and the action potential, as well as protein synthesis, acid–base balance and maintenance of intracellular osmolality.

The total body potassium content ranges from 50–55 mEq/kg body weight. Potassium is an intracellular cation, and approximately 98% of the body stores are located within the ICF compartment (i.e., only a total of 60–70 mEq exists in the ECF). A huge concentration gradient exists between the ICF and ECF compartments (150 mEq/L and 3.5–5.5 mEq/L, respectively). The primary mechanism for establishing and maintaining this concentration gradient is the sodium-potassium–activated adenosine triphosphatase (ATPase) "pump," which is located in the plasma membrane of all body cells. These membrane-bound ionic transport pumps and the selective permeability characteristics of cell membranes are responsible for the transmembrane electrical potential difference found in all living cells. Potassium is the ion responsible for generating cellular electrical activity. Hence, hypo- and hyperkalemia result in significant neuromuscular dysfunction.

The total amount of potassium present in the body is approximately 3200 mEq, 90% of which is intracellular, which is regulated by a variety of homeostatic mechanisms. Of total body potassium, approximately 135–150 mEq/L is intracellular, compared to plasma levels of 3.5–5.5 mEq/L. The daily requirement is about 1 mEq/kg/d absorbed from the small intestine. Potassium excretion exactly matches intake and body stores are quantitatively stable. Potassium balance is predominately governed by urinary loss. The kidney can adjust urinary potassium excretion from less than 1 mEq/L to greater than 100 mEq/L. In addition, there is some secretion of potassium in the colon.

Two factors impact renal handling of potassium: renal tubular fluid flow and aldosterone. The majority of filtered potassium is reabsorbed in the proximal tubule. The distal tubules then secrete potassium. This is influenced by the intracellular potassium concentration, the rate of urinary flow, and the anionic charge of the urine. As the rate of flow increases, there is a significant increase in potassium excretion. This explains hypokalemia associated with diuresis. Conditions that increase distal tubular sodium delivery promote potassium excretion and sodium reabsorption, particularly in the presence of aldosterone.

One of the most important roles of potassium is the resting membrane potential and in the repolarization phase of action potentials. The normal cell membrane is relatively permeable to potassium ions, and impermeable to sodium and anions. The anions generate a negative intracellular potential. Potassium is held intracellularly against the electrochemical gradient by the action of the Na^+-K^+ ATPase pump that maintains the resting membrane potential. The relative ratio for intracellular to extracellular potassium is responsible for electrochemical activity. Hence abnormalities of potassium concentration directly impact neuromuscular activity.

Hyperkalemia

Hyperkalemia is generally defined as a serum potassium concentration of greater than 5.5 mEq/L. There are numerous conditions, diseases, and drugs that produce hyperkalemia by disrupting the normal external and/or internal potassium balance (Table 34–7). Factitious hyperkalemia is associated with hemolysis of the blood sample.

Several factors may produce a transient increase in serum potassium concentration as a result of transcellular shift. This includes administration of succinylcholine (0.3–0.5 mEq/L in normal subjects), burns, diabetes, metabolic acidosis, and nonselective β-blockers.

Succinylcholine may be associated with significant hyperkalemia in certain

TABLE 34–7.

circumstances, such as conditions where there is muscle membrane degeneration (e.g., trauma, burns, or primary muscle disorders) or neural denervation (e.g., stroke, multiple sclerosis, Guillain-Barré syndrome or spinal cord injuries). Impaired potassium excretion is associated with acute and chronic renal failure, adrenal insufficiency, hypoaldosteronism (for any reason), and the use of angiotensin-converting enzyme (ACE) inhibitors.

In hyperkalemia the resting membrane potential is decreased toward the threshold potential (Fig. 34–5). With mild hyperkalemia (i.e., a serum potassium concentration of less than 6–7 mEq/L) there is increased automaticity as reflected by atrial and/or ventricular ectopy. Progressive hyperkalemia enhances rapid repolarization (phase 3), which causes shortening of the T-wave interval and symmetrical peaking of the T wave. If the serum potassium concentration continues to increase, the inward movement of sodium (phase 0) and calcium (phase 2) will diminish; the PR interval becomes prolonged and, eventually, the P waves (atrial phase 0) will disappear. Within the ventricular muscle mass, both conduction velocity and the height of the action potential are reduced. The net result is a widened QRS complex and reduced contractility. If the hyperkalemia progresses, the QRS complex will become smooth, wide, and sinusoidal as it merges with the T wave (serum potassium concentration of >10 mEq/L). Without treatment, ventricular fibrillation will ensue.

Emergency treatment is aimed at quickly stabilizing the myocardium and restoring normal transmembrane electrical potentials; 10–30 mL of 10% calcium gluconate can be administered over 3–5 minutes (or 5–10 mL calcium chloride may be substituted). Calcium reduces both the threshold potential and the excitability of cell membranes. The duration of action is roughly 30–60 minutes; a second dose may be necessary. Alternative temporizing measures include administration of sodium bicarbonate, nebulized albuterol, or insulin and dextrose in combination. Each has the impact of sending potassium into cells. One unit of regular insulin is recommended for each 2 g of dextrose. For example, 1 ampule of D50 (i.e., 50 mL of 50% dextrose) would be immediately followed by 12 units of regular insulin.

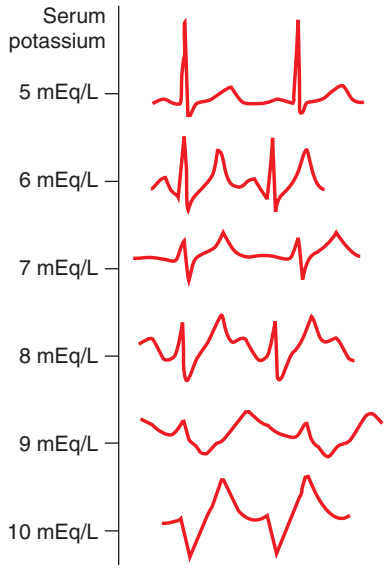

FIGURE 34–5. Electrocardiogram (ECG) changes associated with progressive hyperkalemia.

More definitive treatment of hyperkalemia can be achieved by administering exchange resins administered orally or rectally. These include calcium or sodium polystyrene sulfonate in combination with sorbitol, that facilitates potassium excretion through colonic exchange of calcium or sodium for potassium. If this approach fails, hemodialysis may be required.

Hypokalemia

Hypokalemia is typically considered a potassium level of less than 3.5 mmol/L, although patients may be asymptomatic until the level is less than 2.5 mmol/L. Although the relative fall in extracellular potassium may appear small (1–2 mEq/L) this represents a significant total body deficit of potassium, up to 500 mEq. On average, plasma potassium decreases by 0.3 mmol/L for each 100-mmol reduction in total body stores.

Acute hypokalemia is associated with either inadequate intake or absolute loss of potassium from the body, governed by the law of mass conservation, or transcellular movement (Fig. 34–6 and Table 34–8). Causes of absolute loss include vomiting, diarrhea, bowel fistulae, loop and osmotic diuretics, and the diuretic phase of acute renal failure. Causes of intracellular potassium shifting include metabolic alkalosis, use of β_2-adrenergic agonists, hyperadrenergic states (including the acute stress response), administration of insulin, and hypothermia. Chronic causes of hypokalemia include malnutrition, malabsorption, diuretic usage, corticosteroid administration, and Conn syndrome (primary hyperaldosteronism).

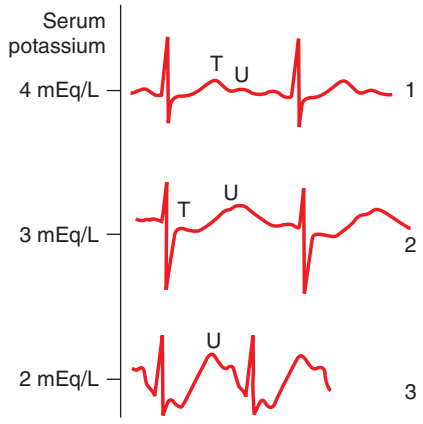

FIGURE 34–6. Electrocardiogram (ECG) changes associated with progressive hypokalemia. Strip 1: normal ECG; strip 2: flattened T wave, prominent U wave; strip 3: prolonged PR interval, prolonged QRS, ST-segment depression, heightened U waves, and prolonged QT interval.

Potassium depletion causes muscle weakness. The ratio of intracellular to extracellular potassium increases, thereby reducing the resting potential (phase 4) and creating a state of hyper-

polarization. When the action potential is initiated (phase 0), it is of supernormal magnitude. The time allotted for calcium entry (phase 2) is shortened, and repolarization (phase 3) is prolonged, leading to a greater relative refractory period. The diminished calcium entry affects skeletal muscle and may lead to myalgia, cramps, and weakness. The smooth muscle components of the bladder, gastrointestinal tract and the peripheral vasculature are also affected leading to urinary retention, ileus, and postural hypotension. The ensuing vasoplegia may be catecholamine insensitive.

Hypokalemia impacts cardiac conduction and contractility. Progressive electrocardiographic changes are typical (see Fig. 34–6): T-wave amplitude decreases, QT interval lengthens, the U wave appears or becomes broader and taller, the ST segment sags, and P-wave amplitude and QRS duration increase. Cardiac arrhythmias are relatively common. The most common dysrhythmias are atrial fibrillation and premature ventricular systoles, but supraventricular tachycardia, junctional tachycardia, and Mobitz type I second-degree atrioventricular block may also occur. Hypokalemia may induce digitalis toxicity (Fig. 34–6).

It is probably unnecessary to administer potassium supplements to a patient with mild hypokalemia. If moderate to severe hypokalemia (< 3.0 mEq/L) is present, intravenous potassium chloride or potassium phosphate is usually administered. The maximal recommended rate of infusion is 0.5–0.7 mEq/kg/h. The repletion of total body potassium stores requires approximately 200 mEq for each 1 mEq/L reduction in the serum potassium concentration. Magnesium is an essential cofactor for transcellular sodium–potassium ion pumps. If hypomagnesemia coexists, magnesium supplements should be administered to ensure intracellular potassium repletion.

Calcium Physiology

Calcium is an essential inorganic element that plays a crucial role in many biologic functions. It is the single most abundant electrolyte in the human body. A normal adult contains between 1000 and 1400 g of calcium, of which 99% is located in bone, where it is the primary structural component. Approximately 1% of the total calcium pool resides in the soft tissues and the ECF compartment. Circulating calcium exists in three forms: a free ionized fraction (50%), a fraction bound to protein (mostly albumin) (40%), and a diffusible, nonionized fraction (10%) in which calcium is chelated with circulating anions (e.g., bicarbonate, phosphate, citrate). The ionized fraction is the calcium that is physiologically active, and it is the concentration of this fraction that is closely regulated by parathyroid hormone, vitamin E, and calcitonin. These substances alter the resorption of calcium from various target organs, including the skeletal system, the gastrointestinal tract, and the kidneys.

A measurement of total serum calcium (the analysis most often performed when a calcium level is requested) reflects the quantitative contribution of all three forms of circulating calcium. The normal value will vary depending on the particular laboratory but is generally in the range of 8.5–10.5 mg/dL (4.5–5.5 mEq/L or 0.96–1.27 mmol/L). The reported quantity may be misleading because of albumin binding, and calcium concentration measured in this way must be corrected for albumin concentration. Modern laboratories have the capability of directly measuring ionized calcium. The normal values for this measurement usually range from 4–5 mg/dL (2.1–2.6 mEq/L or 1.17–1.29 mmol/L).

Calcium has a number of important physiologic functions. As an essential component in neuromuscular transmission, calcium is involved in myocardial contractility by way of voltage-sensitive calcium channels in the myocardium. Calcium is involved in both depolarization and the magnitude of muscle contraction. Calcium is stored in the sarcoplasmic reticulum. Neurochemical activation leads to an increase in cytoplasmic calcium concentration. Calcium binds to troponin C and this complex binds to tropomyosin, which facilitates the interaction between actin and myosin, resulting in cardiac muscular contraction. Increased intracellular calcium is associated with increased contractility, inotropy, and cardiac output. Calcium is removed by reuptake into the sarcoplasmic reticulum and by extrusion via the Ca^{2+}-Na^{+} pump located in the plasma membrane. This results in relaxation. Calcium is also an essential component in both skeletal muscle and smooth muscle contractility.

Calcium is an important cofactor for blood coagulation. The cytoplasm of platelets contains contractile filaments of actin and myosin that enable activated platelets to change their shape and release the contents of their granules. This process is driven by intracellular calcium. Calcium is important in the activation of thrombin, acting as a cofactor with factors VII, IX, and X.

Calcium is absorbed by the small intestine under the influence of calcitriol, a derivative of vitamin D. Calcitriol also facilitates absorption of phosphate from the intestine and the nephron, and influences bone formation and osteoclastic activity. The major control hormone for calcium metabolism is parathyroid hormone (PTH). This hormone causes release of calcium and phosphate from bone. It also enables renal calcium reabsorption and renal phosphate excretion, and activates calcitriol. Calcitonin has the opposite impact on serum calcium to PTH. It inhibits renal reabsorption of calcium and inhibits osteoclastic bone formation.

Hypercalcemia

Hypercalcemia is associated with numerous conditions and disorders, including hyperparathyroidism, immobilization, chronic renal failure, adrenal insufficiency, thyrotoxicosis, sarcoidosis, and various drugs (Table 34–9, Fig. 34–7).

The most common cause of hypercalcemia is hyperparathyroidism. Anesthesiologists encounter these patients because they are frequently scheduled for parathyroidectomy. The second most common cause of acute hypercalcemia is malignancy, either secondary to bone destruction by metastases or as a consequence of secretion of calcemic factors by the tumor. This problem is most frequently encountered in breast cancer, myeloma, bronchogenic, and renal cell carcinoma.

A wide variety of clinical symptoms are characteristic of hypercalcemia, often described as "bones, stones, groans, and moans." Patients develop bony pain, renal calculi, abdominal symptoms, and neuropsychiatric problems. Abdominal problems include nausea and vomiting, constipation, and acute and chronic pancreatitis. Hypercalcemia may impact cardiac electrical conduction by progressive shortening of the QT interval, leading to arrhythmias and possible cardiac

  - β-Adrenergic agonists

arrest. Hypertension as a consequence of contraction of vascular smooth muscle is commonplace. Hypercalcemia has varying effects on the kidney. It may cause polyuria and polydipsia (mimicking diabetes mellitus) by interfering with ADH activity on the collecting ducts. It may reduce renal blood flow and glomerular filtration. It may cause nephrocalcinosis, interstitial nephritis and urolithiasis. In the central nervous system, hypercalcemia may cause anxiety, depression, irritability, lethargy, confusion, and psychosis.

The mainstay of therapy is hydration, either with or without the use of loop diuretics such as furosemide. Renal clearance of sodium and chloride are closely linked, so the coadministration of salt solutions and diuretics allows rehydration and natriuresis. Other alternative therapies include chelators (e.g., phosphates and ethylenediaminetetraacetic acid [EDTA]), osteoclast inhibitors (e.g., mithramycin, glucocorticoids, calcitonin, diphosphonates), and calcium channel blockers (verapamil).

Hypocalcemia

Ionized hypocalcemia develops when there is significant calcium loss from the body. In perioperative medicine, this may be associated with massive blood transfusion, massive crystalloid resuscitation, or following parathyroidectomy (Table 34–10). Other causes include acute and chronic renal failure, vitamin D deficiency, hypomagnesemia, rhabdomyolysis, malnutrition, burns, sepsis, and acute pancreatitis. Critically ill patients are frequently hypocalcemic. During massive transfusion, the presence of citrate in the blood may result in significant hypocalcemia. The hallmark of hypocalcemia is neuromuscular irritability, with symptoms ranging from paresthesia to tetany and seizures. In addition, hypocalcemia may augment the neuromuscular blockade caused by nondepolarizing muscle relaxants. Mild hypocalcemia (ionized calcium levels of 3.2–3.9 mg/dL), even in critically ill patients, usually does not evoke symptoms. Patients who are undergoing parathyroidectomy may develop acute postoperative hypocalcemia, requiring supplementation.

muscle spasms, particularly of the fingers and thumb (carpal spasm). The term *tetany* has been used to describe this process, in which there is repetitive neuromuscular discharge after a single stimulus. Tetany can be elicited by tapping over the facial nerve, proximal to the auricle; this leads to twitching of the ipsilateral facial muscles particularly around the eyes and mouth (the Chvostek sign). Carpal spasm can be elicited by inflating a blood pressure cuff around the arm for several minutes, presumably causing mild ischemia and provoking muscle contraction (the Trousseaus sign). Pain, anxiety, and hyperventilation may precipitate muscular spasms in postoperative patients. This has the potential to cause stridor or laryngospasm.

Acute symptomatic hypocalcemia is a medical emergency that warrants the intravenous administration of calcium. Therapy should not be withheld, even if the cause of the hypocalcemia is unclear. In adults, the recommended treatment is a 100-mg bolus of elemental calcium (over 5–10 minutes), followed by a continuous infusion administered at a rate of 0.5–2 mg/kg/h. Note that a bolus dose of calcium will only increase the ionized calcium concentration for 1–2 hours. Consequently, repeated boluses or an infusion is required.

Two different calcium salt preparations are readily available for intravenous administration: calcium chloride and calcium gluconate. Calcium chloride 10% contains 27.2 mg of elemental calcium in 10 mL. Calcium gluconate contains 9.3 mg of elemental calcium per 10 mL. Calcium chloride is very irritating to the peripheral vasculature and should be administered directly into the central venous circulation, if at all possible. In addition, the chloride salt is acidifying and theoretically should not be used when acidemia coincides with hypocalcemia. Thus, in the presence of significant metabolic acidosis, calcium gluconate should be used.

Magnesium Physiology

Magnesium is the fourth most abundant cation within the body and is the second most prevalent intracellular cation next to potassium. Within the body, magnesium is distributed such that 50–60% resides in the skeletal system and another 20% is located within muscle tissue. The ICF to ECF concentration ratio is about 15:1. At any one time, less than 1% of total body magnesium circulates within the intravascular fluid compartment, and thus serum levels do not reflect total body stores.

Depending on the particular laboratory, the normal total serum magnesium concentration ranges from 1.5–2.0 mEq/L. Similar to calcium, the circulating magnesium consists of three components: a chelated fraction (5%), a protein-bound fraction (33%), and an ionized, diffusible fraction (62%). Ionized magnesium is physiologically active and carefully regulated to maintain homeostasis. Because laboratories cannot report ionized magnesium, total magnesium is used.

Magnesium is a cofactor for more than 300 enzymatic reactions involving energy metabolism and nucleic acid synthesis. It is also involved with hormone receptor binding, calcium channel gating, transmembrane ion flux, regulation of adenylate cyclase, muscle contraction, neuronal activity, vasomotor tone, cardiac excitability, and neurotransmitter release.[23] From many perspectives, magnesium can be viewed as a physiologic calcium antagonist.

Both parathyroid hormone and vitamin D have regulatory influences on renal and gastrointestinal magnesium absorption. In turn, the ionized magnesium concentration influences parathyroid hormone secretion. The circulating ionized magnesium is primarily regulated by the kidney; the majority of filtered magnesium is conserved through proximal tubular resorption. Renal magnesium wasting occurs with hypermagnesemia, hypercalcemia, hypophosphatemia, hypercalciuria, loop diuretics, ACE inhibitors, aminoglycosides, amphotericin, cyclosporine, and cisplatin. Hypomagnesemia is almost universal in patients undergoing major surgery. Hypomagnesemia may also result from malnutrition, malabsorption, inadequate administration (including ECF dilution), diarrhea, laxatives, vomiting, and diabetes (Table 34–12).

Hypomagnesemia is associated with a variety of clinical manifestations, that involve the neuromuscular and cardiovascular systems (Table 34–13). One interesting manifestation of hypomagnesemia is a cardiac arrhythmia known as *torsade de pointes*. This is derived from a French ballet expression for "twisting of the points." It refers to a specific polymorphous ventricular tachyarrhythmia in which the morphology of the QRS complexes varies from beat to beat. The ventricular rate varies from 150–250 beats/min. The arrhythmia is effectively treated with potassium and magnesium boluses.

In cases of hypomagnesemia, the total deficit is often greater than anticipated, as this is primarily an intracellular cation. The deficit of magnesium is often 1–2 mEq/kg and effective repletion may require a total dose of elemental magnesium in the range of 2–4 mEq/kg (given over several days). For mild acute hypomagnesemia, 4–6 g of magnesium can be added into intravenous fluids and infused over 30 minutes. Rapid infusion is associated with an unpleasant hot flash, and may induce acute hypotension. A continuous maintenance infusion of magnesium sulfate should then be administered for

4 to 7 days. This maintenance fluid should contain a total daily dose of 600 to 900 mg of elemental magnesium. In emergency situations the loading dose can be infused more rapidly, so long as continuous electrocardiogram (ECG) monitoring is performed and the rate of administration does not exceed 15 mg/min of elemental magnesium. For the duration of intravenous magnesium therapy, patients should be carefully monitored for evidence of magnesium toxicity and frequent assessment of the total serum magnesium concentration is mandatory.

Hypermagnesemia results from magnesium-containing antacids, enemas, total parenteral nutrition, acute renal failure, adrenal insufficiency, hypothyroidism, and nephrogenic diabetes insipidus.

Hypermagnesemia impairs neuromuscular function and produces progressive neuromuscular blockade. There is a heightened sensitivity to both depolarizing and nondepolarizing muscle relaxants. Magnesium has significant cardiac and hemodynamic effects. As a functional calcium channel blocker, magnesium may cause vasodilatation and hypotension.

Magnesium has been used in a variety of clinical situations, including perioperative care, to control blood pressure, and to prevent seizures in preeclampsia (Table 34–14). Magnesium may be used to control heart rate in ventricular and supraventricular arrhythmias, particularly when hypokalemia coexists. It has been used to treat torsade de pointes and digitalis toxicity. Magnesium has been used to reduce the adrenergic response to induction of anesthesia and intubation.[24] It has been used therapeutically as a smooth muscle relaxant in acute severe asthma.[25] Other therapeutic roles for magnesium in perioperative medicine and critical illness include perioperative analgesia, treatment of myocardial infarction, and treatment of tetanus.[26] The analgesic properties of magnesium appear to be associated with its antagonistic properties on *N*-methyl-D-aspartate (NMDA) receptors and calcium channel blockade. Calcium channel blockers are antinociceptive and potentiate the effects of morphine.[26]

The clinical manifestations of hypermagnesemia correlate well with the total serum magnesium concentration. These include somnolence, hypoventilation, postural hypotension, and at higher doses, respiratory and cardiac arrest. In patients who are treated with high-dose magnesium, and in obstetric patients with preeclampsia and eclampsia, for example, careful monitoring of neuromuscular function must be performed to avoid devastating neuromuscular blockade, which leads to respiratory arrest.

Treatment for hypermagnesemia is to enhance urinary excretion, principally by combining saline infusion and furosemide. Direct antagonism of toxic effects can be provided by intravenous calcium, although the duration of action is relatively short. In circumstances in which reversal of effect is not possible because of acute renal failure, hemodialysis is required.

TABLE 34–14.

Therapeutic Uses of Magnesium

- Cardiovascular
  - Supraventricular arrhythmias (associated with hypokalemia)
  - Torsade de pointes
  - Digitalis toxicity
  - Acute myocardial infarction (reperfusion, antiarrhythmia, coronary vasodilatation)
- Pulmonary
  - Acute severe asthma
- Obstetrics

  - Anticonvulsant in preeclampsia
- Anesthesia
  - Antiadrenergic therapy for intubation
  - Prevention of succinylcholine induced muscular pain
  - Reduction in postoperative pain (NMDA antagonism)
  - Neuromuscular blockade (including treatment of tetanus)

NMDA, *N*-methyl-D-aspartate.

Phosphate Physiology

Phosphorous is the most abundant intracellular anion, its concentration is approximately 100 mmol/L. One-hundredth of the body's mass is made up of phosphate, most of which is stored as hydroxyapatite crystals in the bone matrix; only 15% is metabolically active and 1% is present in the blood. The average diet provides 800–1400 mg of phosphorous daily. Of this, 70% is absorbed through the gut, mainly by passive transport, but there is also some active transport, stimulated by vitamin D metabolites. Normal plasma range is between 2.8 and 4.5 mg/dL. The main organ of regulation of phosphate is the kidney. Phosphorous is filtered by the nephron, and mostly reabsorbed in the proximal tubule in cotransport with sodium. This cotransport is regulated by phosphorous intake (i.e., serum phosphorous levels) and PTH. PTH inhibits the cotransport mechanism, and increases urinary excretion of phosphorous. In the blood, phosphate is present in multiple forms—as phospholipids, as $PO4^3$, as H_2PO_4, and HOP_4^2.

Every metabolic action in the body requires chemical energy, principally in the form of adenosine triphosphate (ATP). The high energy bonds in ATP are derived from phosphate. This is essential for muscle contractility, neuronal transmission, and electrolyte transport. Phosphate is a key building block for many essential intracellular compounds, including nucleic acids, phospholipids, enzymes, and nucleoproteins. Many of the intracellular messenger chemicals employ phosphate, these include cyclic adenosine monophosphate and cyclic guanosine

monophosphate. Phosphate has an essential role in both aerobic and anaerobic metabolism, and in 2,3-DPG (diphosphoglycerate), which is involved with hemoglobin–oxygen interactions at the tissue level. Phosphate is involved in cascades within the coagulation and immune systems. Finally, phosphate is the main intracellular buffer in the body, and is a component of the extracellular weak acid buffering system (A_{TOT}).

Hypophosphatemia is caused by inadequate intake, excessive loss or redistribution within the body (Table 34–15). Inadequate intake may result from malnutrition or malabsorption (short-bowel syndrome, tropical sprue, celiac and Crohn disease, radiation enteritis). Agents that bind with phosphate may reduce its absorption. These include magnesium and aluminium antacids and sucralfate (which contains aluminium).

Excessive loss of phosphate is associated with diuresis and dialysis. Osmotic diuretics and hyperglycemia cause increase urinary loss, as do theophylline and acetaminophen in overdose. The most phosphaturic diuretics are carbonic anhydrase inhibitors. Hypophosphatemia can rapidly occur during intermittent and continuous renal replacement therapies.

Hypophosphatemia may result from intracellular redistribution, during administration of catecholamines or β-adrenergic agonists, insulin surges (hyperglycemia), and alkalosis for any reason.

In general, muscles do not function well in hypophosphatemic states (Table 34–16). This relates to the importance of phosphate as the body's source of chemical energy. Hypophosphatemic causes weakness of respiratory muscles, particularly the diaphragm, and causes a leftward shift of the oxyhemoglobin dissociation curve (increasing the tendency for hemoglobin to cling to oxygen). Patients who are hypophosphatemic may be slow to wean from mechanical ventilation.[27,28] As one would expect, hypophosphatemia causes skeletal muscle weakness, which may mimic myopathy. In addition, low serum phosphate may interfere with blood cell function and cause increased red cell fragility.

Hypophosphatemia may cause myocardial dysfunction,[29] and may make the myocytes less sensitive to the stimulatory effects of catecholamines. This effect is reversible. Table 34–16 lists other complications of hypophosphatemia.

A particularly important cause of hypophosphatemia is the "refeeding syndrome." Severely malnourished individuals develop a total body depletion of phosphorous; serum phosphorous levels are maintained by redistribution from the intzracellular space. The body uses endogenous fuel stores as its main source of energy. Fat and protein (from muscle) are metabolized. Glucose delivery, either enterally or parenterally, as part of a feeding strategy, leads to a dramatic increase in circulating insulin levels. This results in rapid uptake of glucose, potassium, phosphate and magnesium into cells. The serum concentration of these species falls dramatically. Simultaneously, there is a dramatic increase in extracellular fluid volume. There is an increase in cardiac workload, with increased stroke work, heart rate, and oxygen consumption. This sudden increase in demand for nutrients and oxygen may outstrip supply. Moreover, in patients with cardiovascular disease, the sudden increase in cardiac work and circulating fluid can precipitate acute heart failure. The sudden administration of carbohydrates exerts a considerable strain on the respiratory system, whose musculature may well be atrophied because of starvation. There is an increase in CO_2 production and O_2 consumption, and a resultant increase in the respiratory quotient. The consequence of this is an increase in minute ventilation, leading to dyspnea and tachypnea, and possibly to acute respiratory failure.

The serum phosphorous level falls precipitously with refeeding, as a consequence of a shift of phosphate from the extracellular to the intracellular compartment. This results from increased intracellular demand for the synthesis of phosphorylated com-

TABLE 34–15.

Causes of Hypophosphatemia

- Decreased absorption
  - Malnutrition
  - Phosphate binding antacids
  - Malabsorption syndromes
    - Crohn disease
    - Celiac disease
    - Gastrointestinal fistulae
  - Phosphate-binding agents
  - Magnesium and aluminum antacids
  - Sucralfate
  - Vitamin E deficiency
- Increased loss
  - Volumn expansion
  - Diuretics
  - Dialysis
  - Steroids
  - Alcoholism
  - Renal transplantation
  - Hyperparathyroidism
  - Metabolic acidosis
  - Pancreatitis
  - Burns
- Redistribution
  - Shifts from serum into cells
    - Recovery from the stress response
    - Carbohydrate infusions
    - Hyperglycemia
    - Hormonal effects
      - Catecholamines (epinephrine, dopamine, terbutaline, albuterol)
      - Insulin
      - Glucagon
      - Calcitonin
    - Respiratory alkalosis
    - Refeeding syndrome
    - Leukemic blast cell crises
    - Hungry bone syndrome

Preparations Available for Phosphate Repletion

Intravenous Preparations	Phosphate Concentration	Sodium Concentration	Potassium Concentration
Neutral sodium potassium PO_4	1.1 mmol/mL	0.2 mEq/mL	0.02 mEq/mL
Neutral sodium PO_4	0.09 mmol/mL	0.2 mEq/mL	0
Sodium PO_4	3.0 mmol/mL	4.0 mEq/mL	0
Potassium PO_4	3.0 mmol/mL	0	4.4 mEq/mL

pounds. This may result in respiratory failure, cardiac failure, cardiac arrhythmias, rhabdomyolysis, seizures, coma, and red cell and leucocyte dysfunction.

Perioperative patients are vulnerable to hypophosphatemia because of the catecholamine surge associated with the stress response. If severe malnutrition is suspected, the anesthesiologist should avoid the administration of glucose-containing intravenous fluids and aggressively supplement intracellular ions, potassium, magnesium, calcium, and phosphate (Table 34–17).

Hyperphosphatemia is caused by increased administration or absorption, decreased loss, or increased production (Table 34–18). Increased intake can occur as a result of excessive intravenous administration or oral supplementation or vitamin D intoxication. Occasionally, hyperphosphatemia results from recurrent administration of phosphate-containing enemas. There is reduced excretion in renal failure, hypoparathyroidism, and hypomagnesemia. Increased serum phosphate levels may result from diseases that cause widespread cell destruction: tumor lysis syndrome, rhabdomyolysis, bowel ischemia, hemolysis, and malignant hyperthermia. Pseudohyperphosphatemia may occur as a result of hypertriglyceridemia.

Acute hyperphosphatemia is associated with hypocalcemia, muscle weakness, and tetany. In chronic hyperphosphatemia, as occurs in chronic renal failure, calcium may be deposited in the tissues (ectopic/metastatic calcification). The treatment for acute hyperphosphatemia is administration of phosphate binding salts—calcium, magnesium, and aluminum.

Chloride Physiology

Chloride is the second most abundant extracellular ion, and the most important extracellular anion. Chloride is absorbed in roughly equimolar concentrations with sodium in the small bowel. In addition, chloride is actively secreted into the gastric lumen with potassium that is subsequently pumped back into the parietal cell. The consequence is a significant fall in pH (gastric acidity). Chloride has a wide variety of other functions in the body. It represents one third of extracellular osmoles; it is involved in volume homeostasis, regulation of pH in the kidney, organic solute transport, and cell migration, proliferation, and differentiation.

Chloride channels are abundant in the body.[30] These are involved in a variety of functional roles in diverse processes, such as blood pressure regulation, cell cycle and apoptosis, muscle tone, volume regulation, synaptic transmission, and cellular excitability.[31] The benzodiazepine receptor gates a chloride channel, a key element in anesthesia pharmacology. A significant number of diseases appear to result from chloride channel abnormalities (Table 34–19). Mutations that result in a loss of function of the voltage-gated chloride channel, CLC-5, are associated with Dent disease, which is characterized by low-molecular-weight proteinuria, hypercalciuria, nephrolithiasis, and renal failure.[32] Mutations of another voltage-gated chloride channel, CLC-Kb, are associated with a form of Bartter syndrome, whereas other forms of Bartter syndrome are caused by mutations in the bumetanide-sensitive sodium-potassium-chloride cotransporter (NKCC2) and the potassium channel, ROMK. Mutations of the thiazide-sensitive sodium-chloride cotransporter (NCCT) are associated with Gitelman syndrome.[32] Mutations of chloride transport proteins are responsible for cystic fibrosis, renal tubular acidosis, neuromuscular disorders, and some forms of epilepsy.

The role of chloride in acid–base chemistry is discussed in Acid–Base Chemistry below. Essentially hyperchloremia is associated with metabolic acidosis; hypochloremia is associated with metabolic alkalosis. Chloride has an important role in renal function.[32] Thiazide diuretics may modulate blood pressure by controlling serum chloride concentration by way of a sodium-chloride cotransporter. Hyperchloremia produces progressive renal vasoconstriction and a fall in glomerular filtration.[33] In addition, hy-

- Cystic fibrosis
- Epilepsy
- Osteopetrosis

perchloremia results in splanchnic hypoperfusion.[34] Administration of chloride rich solutions such as 0.9% saline may result in hyperchloremia, renal dysfunction, nausea and vomiting and hyperventilation.

Physiology of Albumin

Albumin is the most abundant extracellular protein. It is a single polypeptide with 585 amino acids and a molecular weight range of 65,000 daltons (Da) to 69,000 Da. Thus a medium-size compound (IgG, e.g., is 150,000 Da), in addition to being highly soluble, is small enough to pass through fenestrated endothelium, such as in the nephron. Proteinuria does not occur in normal individuals because of the strong negative charge (17 mEq) carried by albumin that rebuts the protein in the glomerulus. Albumin is a weak acid whose concentration significantly impacts extracellular buffering capacity.

Albumin is manufactured in the liver at a rate of 9–12 g/d. The normal serum albumin is 30–50 g/L (3–5 g/dL). There is no storage, no reserve. Being the major source of oncotic pressure in health, the rate of production of albumin is controlled by changes in osmotic pressure and osmolality of extravascular perihepatic space. There is limited capacity to increase production. Increased synthesis is driven by the neuroendocrine system, chiefly by insulin, thyroid hormones, and cortisol.

Albumin is catabolized at a rate of 9–12 g/d (the same rate as it is produced) by pinocytosis in cells adjacent to the vascular endothelium. Albumin is not catabolized in starvation—under these circumstances, protein is derived from muscle, following exhaustion of fat stores.

Although albumin is perceived as intravascular protein, the total extravascular albumin actually exceeds the total intravascular amount by 30%.[35] The ratio of albumin to water is, however, higher in the intravascular space (the extracellular fluid is two-thirds interstitial and one-third intravascular), hence the colloidal effect. Albumin cyclically leaves the circulation, through the endothelial barrier at the level of the capillaries, passes into the interstitium, and returns to the bloodstream through the lymph system via thoracic duct. The circulation half-time for this process is 16–18 hours. Of the total intravascular albumin, 4–5% extravasates in this way per hour. This rate of movement is known as the transcapillary escape rate (TER), which is determined by capillary and interstitial free albumin concentration, capillary permeability to albumin, movements of solvent/solute, and the electrical charges across the capillary wall. The concentration of albumin in lymph protein content is approximately 80% that of plasma.

Albumin has a variety of physiologic and pharmacologic roles (Table 34–20). Albumin binds drugs and ligands, and reduces the serum concentration of these compounds (Table 34–20). An example is the serum calcium, the free (ionized) concentration of which needs to be corrected for albumin There are four binding sites on albumin with varying specificity for different substances. Competitive binding of drugs may occur at the same site or at different sites (conformational changes). The drugs that have important albumin binding are warfarin, digoxin, nonsteroidal antiinflammatory drugs, midazolam, and thiopental. The relevance of a low albumin and drug binding is unknown.

Albumin is a major source of sulfhydryl groups; these "thiols" scavenge free radicals (nitrogen and oxygen species). The anticoagulant and antithrombotic effects of albumin are poorly understood.

Low serum albumin is a nonspecific marker of disease. A fall in the albumin concentration indicates deterioration, whereas a rise appears to reflect recovery. Very low levels of albumin appear to reflect a poor outcome. The relevance of low albumin on ligand binding is unknown.

In critical illness there is a reduction in the production of albumin, because of favored hepatic production of acute-phase proteins such as globulins, fibrinogen, and haptoglobin. Other proteins whose levels fall in this situation include prealbumin, retinal-binding protein, transferrin, and somatomedin C. This process is known as "hepatic reprioritization." During conditions of stress or tissue injury, such as major surgery, trauma, or critical illness, there develops a generalized increase in vascular permeability, associated with release of cytokines and cytotoxic material. This leads to leakage of protein rich fluid into the interstitium (capillary leak). Aggressive volume resuscitation with crystalloid, gelatins, or hydroxyethyl starch significantly reduces albumin concentration by a dilutional effect. Hence hypoalbuminemia during the stress and systemic inflammatory response is a result of hemodilution, redistribution, and hepatic reprioritization. Low serum albumin (and prealbumin) represents a negative acute-phase response.

In critical illness, there is a stronger correlation with colloid oncotic pressure and total protein than with serum albumin concentration. In these patients, the decreased albumin is compensated for by an increase in acute-phase proteins.[36] Nonetheless, there is increased leakage of albumin that drags fluid into the extravascular space. The overall fluid flux is less than would be predicted if albumin was the only protein responsible for oncotic pressure in the Starling equation. Thus low serum albumin does not necessarily mean low plasma oncotic pressure, and does not always cause edema.

Hypoalbuminemia is associated with various disease states (Table 34–21), including liver dysfunction, nephropathies (in particular nephrotic

syndrome), preeclampsia and eclampsia, and burns. Hypoalbuminemia in preoperative patients is indicative of severe malnutrition and is a known indicator of poor surgical outcomes. Preoperative nutrition targeting an increase in albumin improves outcomes.[37] In critically ill patients, there is a strong relationship between the dynamic fall in serum albumin concentration and patient outcomes.[38] The lower the serum albumin plunges, the greater the mortality, morbidity, length of stay, and complication rate. Blunt et al. showed that nonsurvivors in intensive care had lower mean albumin concentrations than did survivors, and there was, significantly, no difference between the colloid oncotic pressures of the two groups.[39] Finally, changes in albumin concentration have significant impact on acid–base balance, which is discussed in detail in the following section.

ACID–BASE CHEMISTRY

Primary Principles

Acid–base chemistry refers to the study of the relative ratio of hydrogen to hydroxyl ions in extracellular fluid, particularly in arterial blood. Intracellular hydrogen ion concentration, or pH (its negative logarithm), is equivalent to the pH of water at body temperature, and varies little despite significant changes in extracellular pH. The body carefully controls the relative concentrations of hydrogen and hydroxyl ions in the extracellular and intracellular spaces. Alterations in this "balance" lead to significant cardiovascular problems because of dysfunction of transcellular ion pumps. The anesthesiologist is expected to identify changes in acid–base chemistry, determine their origins, and treat them. However, the tools available, based on traditional methods derived from epidemiologic studies of respiratory cripples and extrapolation of the Henderson-Hasselbalch equation, are often unhelpful in perioperative medicine. These approaches, the "Boston" approach of Schwartz and Brackett, and the "Copenhagen" approach of Siggaard-Anderson, frequently fail to identify perioperative acid–base abnormalities, particularly when multiple abnormalities are present simultaneously. Moreover, these approaches do not provide guidance with regard to the source of the anomaly.[40] In general, the cause of acid–base disturbances is more clinically relevant than the acid–base anomaly itself. The majority of causes of such perturbations are easily explained, but some, such as dilutional and hyperchloremic acidosis, previously eluded description.

The "modern" physical–chemical approach, originally introduced by Peter Stewart[41] and subsequently refined by several investigators,[42–44] has significantly enhanced our understanding of these problems and simplified the clinical application.[4,45] This approach has gained widespread acceptance in perioperative medicine and critical care, and is the basis of this segment of the chapter.[46]

Acids, Bases, and Water

Water is a highly ionizing solvent that autodissociates into a negatively charged hydroxylated (OH) ion and positively charged protonated (H_nO^+) ion.[47] Conventionally, this self-ionization of water is written as follows:

$$H_2O \rightarrow H^+ + OH$$

The symbol H^+ is convenient because, even though protons dissociating from water have many aliases (such as H_3O^+, $H_5O_2^+$ and $H_9O_4^+$), most physicians and chemists refer to them as hydrogen ions. Indeed, the concept of "free hydrogen ions" referred to in texts is metaphorical. Water dissociation is constant (K_w), and is governed by changes in temperature, dissolved electrolytes, and cellular components:

$$K_w = [H^+][OH]$$

In other words, if $[H^+]$ increases, then [OH] decreases by the same magnitude. The self-ionization of water is miniscule. In pure water at 77°F (25°C), the $[H^+]$ and [OH] are 1.0×10^7 mEq/L.[48] Using the Sorenson negative logarithmic pH scale, this is a pH of 7.0. Water becomes alkaline with falling temperature (at 32°F [0°C] pH is 7.5) and acidic with increasing temperature (at 212°F [100°C] pH is 6.1). Physiologic pH, that at which the body resides, differs between the intracellular (pH 6.9) and compartment (pH 7.4) and between venous (pH 7.5) and arterial (pH 7.4) blood. Conventionally, acid–base balance refers to changes in hydrogen ion concentration in ECF from 7.4. This is reasonable as cells are relatively impervious to ionic materials, and the ECF is rapidly influenced by changes in fluids, electrolytes, and carbon dioxide tension. Thus acidosis (an increase in hydrogen ion concentration) occurs when the pH is less than 7.3, and alkalosis (a decrease in hydrogen ion concentration) occurs when pH is greater than 7.5.

One reason for the confusion regarding the concept of acids and bases is the variety of apparently conflicting theories that define acidity versus alkalinity. This results, in a particular fixation with the concept of an acid being a "proton donor" (Brønsted-Lowry definition) and a base being a "proton acceptor." However, as all acid–base changes in physiology are derived from alterations in water dissociation,[49] it is simpler to define an acid as a substance that increases hydrogen ion concentration when added to a solution. A base is a substance that decreases hydrogen ion (and increases hydroxyl ion) concentration, when added to a solution. This definition, although closer to Arrhenius' theory, is entirely consistent with Brønsted-Lowry,[4,50] and more easily understood.

The extracellular fluid is an ionic soup containing uncharged cells and particles, dissolved gases (oxygen and carbon dioxide), and fully and partially dissociated ions. Many of these factors influence water dissociation, dependent on chemical charge, quantity, and degree of dissociation.[51] In addition, ionized particles, particularly sodium and chloride, as we have seen, exert a significant osmotic effect. Thus physical chemistry and extracellular fluid volume are interconnected. These particles obey three distinct laws[45]: (a) electrical neutrality—the net positive charge must equal the net nega-

tive charge; (b) mass conservation—the total quantity of a substance in the extracellular space is constant unless added, removed, generated, or destroyed; (c) dissociation equilibria for all incompletely dissociated substances (albumin, phosphate, and carbonate) must be obeyed at all times. Thus, to determine the acid–base status of a fluid, all substances to which these rules might be applied must be accounted for. These include fully dissociated ("strong") ions, partially dissociated ("weak") acids, and volatile acid species.

Stewart determined that the relative concentration of hydrogen and hydroxyl ions in health and disease is determined by three independent variables: the strong ion difference (SID), the total concentration of weak acids (A_{TOT}), and the partial pressure of carbon dioxide (PCO_2; Table 34–22).[4,41] Hydrogen, hydroxyl ions, and bicarbonate are dependent variables. Because their concentration is entirely dependent on independent variables, isolated loss of hydrogen ions or bicarbonate from the gut or kidney cannot induce a change in acid–base balance.

TABLE 34–22.

What Determines pH?

Using a physiochemical approach, it is possible to determine the effect of carbon dioxide, completely dissociated ions, and partially dissociated ions on water dissociation, and, hence, hydrogen ion concentration. Six simultaneous equations can be constructed and solved for $[H^+]$[4,40]:

1. Water dissociation equilibrium	$[H^+] \times [OH^-] = K_w$
2. Weak acid dissociation equilibrium	$[H^+] \times [A^-] = K_A \times [HA]$
3. Conservation of mass for weak acids	$[HA] + [A^-] = [A_{TOT}]$
4. Bicarbonate ion formation equilibrium	$[H^+] \times [HCO_3^-] = K_C \times PCO_2$
5. Carbonate ion formation equilibrium	$[H^+] \times [CO_3^{2-}] = K_3 \times [HCO_3^-]$
6. Electrical neutrality	$[SID] + [H^+] - [HCO_3^-] - [A^-] - [CO_3^{2-}] - [OH^-] = o$

Interestingly, there are 6 independent simultaneous equations, and just 6 unknown, dependent variables determined by them: [HA], $[A^-]$, $[HCO_3^-]$, $[CO_3^{2-}]$, $[OH^-]$ & $[H^+]$.

There are 3 known independent variables: [SID], $[A_{TOT}]$, and PCO_2

Although the above equations look relatively simple, fourth-order polynomials are required for the resolution.

Solving equations for $[H^+]$:

$[SID] + [H^+] - K_C \times P_C / [H^+] - K_A \times [A_{TOT}] / (K_A + [H^+]) - K_3 \times K_C P_C / [H^+]^2 - K_W / [H^+]$

In order words, $[H^+]$ is a function of SID, A_{TOT}, PCO_2, and a number of constants. All other variables, most notably $[H^+]$, $[OH^-]$, and $[HCO_3^-]$ are dependent, and thus cannot independently influence acid–base balance. Hence, it is possible to resolve all acid–base abnormalities into a problem of one or more of these three variables.

Strong Ions

Strong ions are completely dissociated at physiologic pH. The most abundant strong ions in the extracellular space are sodium (Na^+) and chloride (Cl). Other important strong ions include K^+, SO_4^{2}, Mg^{2+}, and Ca^{2+}. Each applies a direct electrochemical and osmotic effect.

In the extracellular space—the difference between the charge carried on strong cations and strong anions—is calculated as follows:

$$SID = ([Na^+] + [K^+] + [Ca^{2+}] + [Mg^{2+}]) - ([Cl] + [\text{other strong anions: A}]) = 40–44 \text{ mEq}$$

This excess of positive charge, called the *strong ion difference* by Peter Stewart,[41] is always positive, and is balanced by an equal amount of "buffer base," principally in the form of phosphate, albumin, and bicarbonate.[52] SID independently influences water dissociation, determined by electrical neutrality and mass conservation. If all other factors (PCO_2, albumin, and phosphate) are kept constant, an increase in SID will decrease hydrogen ion liberation from water (and increase hydroxyl ion liberation), causing alkalosis (Fig. 34–8). A decrease in SID increases hydrogen ion liberation, to maintain electrical neutrality, causing acidosis.

The chief determinant of SID is the relationship between the relative concentration of sodium, chloride and free water in ECF. The normal ratio of sodium to chloride is approximately 1.4:1. Any process that reduces that ratio reduces SID and leads to acidosis (sodium loss, chloride gain, or free water gain). Any process that increases that ratio increases SID and leads to alkalosis (sodium gain, chloride loss, or free water gain).

Weak Acids

Albumin and phosphate are weak acids, whose degree of dissociation is related to temperature and pH. Weak acids, represented by the symbol A_{TOT}, independently influence acid–base balance, depending on absolute quantity and dissociation equilibria.[41,53]

The principal limitation of traditional approaches to acid–base balance has been the limited attention paid to changes in A_{TOT}.[54] Although this may be valid in otherwise healthy patients, perioperative care and critical illness cause hypoalbuminemia as a result of crystalloid administration, hepatic prioritization, and capillary leak.[55] A reduction in serum albumin or phosphate leads to metabolic alkalosis.[43] Hypophosphatemia is associated with malnutrition, refeeding, diuresis, and hemodilution. Hyperphosphatemia occurs in renal failure. Hyperphosphatemia leads to metabolic acidosis.

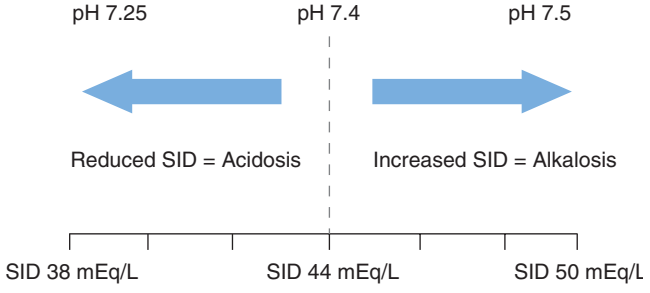

FIGURE 34–8. Impact of changes in strong ion difference on pH. Increased SID causes metabolic alkalosis. Decreased SID causes metabolic acidosis.

Carbon Dioxide

Aerobic metabolism results in the production of large quantities of carbon dioxide. Carbon dioxide is hydrated by carbonic anhydrase in red cell erythrocytes to carbonic acid. This liberates the equivalent of 12,500 mEq of H^+ per day. Hydrogen ions bind to histidine residues on deoxyhemoglobin, and bicarbonate is actively pumped out of the cell. Carbon dioxide exists in four forms: carbon dioxide [denoted $CO_2(d)$], carbonic acid (H_2CO_3), bicarbonate ions (HCO_3), and carbonate ions CO_3^2. The principal mechanism of excretion is through alveolar ventilation, although some CO_2 is excreted from the kidney as bicarbonate as part of a sodium–chloride cotransporter.

Chronic respiratory acidosis is associated with increase in total body CO_2 content, reflected principally by an increase in serum bicarbonate. Mathematically $\Delta HCO_3 = 0.5\ \Delta PaCO_2$.[40] It is important that this not be confused with metabolic compensation for hypercarbia, a relatively slow process that reduces SID by increasing urinary chloride excretion.[56]

Acid–Base Disturbances

Overview

Acid–base disturbances are an important part of clinical and laboratory investigation of perioperative and critically ill patients.

There are 6 primary acid–base abnormalities (Table 34–23):

1. Acidosis as a result of increased $PaCO_2$
2. Acidosis as a result of decreased SID: increased chloride (hyperchloremic), reduced sodium (dilutional)/increased free water
3. Acidosis as a result of increased A_{TOT}: hyperphosphatemia, hyperproteinemia
4. Alkalosis as a result of decreased $PaCO_2$
5. Alkalosis as a result of increased SID: decreased chloride (hypochloremic), increased sodium/decreased free water (contractional)
6. Alkalosis as a result of decreased A_{TOT}: hypophosphatemia, hypoalbuminemia

Acute Respiratory Acidosis and Alkalosis

Acute respiratory acidosis results from hypoventilation, which is caused by loss of respiratory drive, neuromuscular or chest wall disorders, or rapid shallow breathing, and which increases the fraction of dead space ventilation. Acute respiratory acidosis is often associated with a precipitous reduction in pH as a result of the absence of a rapid buffering system for large quantities of carbon dioxide. Acute respiratory alkalosis (pH >7.5) is caused by hyperventilation, as a result of either anxiety, central respiratory stimulation (as occurs early in salicylate poisoning), or excessive artificial ventilation. Acute respiratory alkalosis usually accompanies acute metabolic acidosis (pH <7.35), in which case the reduction in PCO_2 from baseline (usually 40 mm Hg) is equal to the magnitude of the base deficit. For example, in a patient with lactic acidosis, with a lactate of 10 mEq/L, the base deficit should be 10, and the PCO_2 should be 30 mm Hg. If the PCO_2 is higher than expected, there is a problem with the respiratory apparatus. This is seen, for example, in a multitrauma patient, in whom there is massive blood loss, causing lactic acidosis, plus a flail chest, causing respiratory acidosis.

TABLE 34–23.

Classification of Acid–Base Abnormalities

	Acidosis	Alkalosis
Respiratory	Increased PCO_2	Decreased PCO_2 ↑ SID ↓ [Cl^-]
Metabolic		
1. Abnormal SID^+		
a. Because of water	Water excess = dilution ↓ SID^+ ↓ [NA+]	Water deficit = contraction ↑ SID^+ ↑ [NA+]
b. Because of electrolytes	Chloride excess	Chloride deficit
Chloride (measured)	↓ SID^+ ↑ [Cl^-]	↑ SID^+ + ↓ [Cl^-]
Others (unmeasured anions), e.g., lactate, ketoacids	↓ SID ↑ [A^-]	—
2. Abnormal A_{TOT}		
a. Albumin [Alb]	↑ [Alb^-] (intravenous albumin)	↓ [Alb^-]
b. Phosphate [Pi]	↑ [Pi^-]	↓[Pi^-]

Acute Metabolic Acidosis

Acute metabolic acidosis is caused by an alteration in SID or A_{TOT}. SID is changed by an alteration in the relative quantity of strong anions to strong cations. This can be caused by anion gain, as occurs with lactic-, renal-, keto-, and hyperchloremic acidosis, or cation loss, as occurs with severe diarrhea. Acidosis also results from increased free water relative to strong ions—dilutional acidosis—which results from excessive hypotonic fluid intake, certain poisonings (methanol, ethylene glycol, and isopropyl alcohol), or hyperglycemia (Fig. 34–9).

In acute metabolic acidosis, three diagnoses should be immediately investigated: lactic acidosis (send a serum lactate as it should mirror the magnitude of base deficit), ketoacidosis as a consequence of diabetes (the patient should be hyperglycemic and have positive urinary ketones), and acute renal failure demonstrated by high serum urea and creatinine and low total CO_2. The latter is a diagnosis of exclusion. The presence of a low serum sodium (>135 mEq/L) should alert the clinician to the possibility of a dilutional acidosis caused by alcohol poisoning. Alcohols such as ethanol, methanol, isopropyl alcohol, and ethylene glycol are osmotically active molecules that expand extracellular water (glucose and mannitol have the same effect but also promote diuresis, as the molecules are small enough to be filtered by the kidney). Suspicion of alcohol poisoning is raised by the presence of an osmolar gap—a difference between the measured and calculated serum osmolality greater than 12 mOsm demonstrates the presence of unmeasured osmoles. Toxicology laboratories can investigate for the presence of various toxic alcohols.

Renal acidosis is caused by accumulation of strong ion products, such as

sulphate and formate, of metabolism excreted exclusively by the kidney. In addition, there is accumulation of a weak acid, phosphate.

The administration of intravenous fluids to patients has significant impact on acid–base balance. There are changes in free water volume, SID, and A_{TOT} (principally albumin). "Dilutional acidosis" results from administration of pure water to extracellular fluid (which is alkaline). This can occur with large-volume administration of any fluid whose SID is 0, for example, 5% dextrose, 0.9% saline (contains 154 mEq of both Na^+ and Cl^+), and other hypotonic saline infusions. Dilutional acidosis results from a reduction in serum sodium or an increase in chloride relative to sodium. This "hyperchloremic acidosis" is frequently seen in the operating suite following large-volume administration of 0.9% saline solution or 6% hetastarch (both formulated in normal saline) (Fig. 34–10).[57,58] In an experimental model of sepsis, Kellum[59] showed that dogs treated with 5% hydroxyethyl starch diluted in lactated Ringer solution (Hextend) and lactated Ringer solution (both with a SID of 20) had less acidosis and longer survival than those treated with normal saline.

What is the relevance of hyperchloremic acidosis? Brill et al. found that acidosis caused by hyperchloremia was associated with better outcomes than either lactic acidosis or ketoacidosis.[60] This supports the contention that it is the underlying problem that increases patient risk. Nonetheless, metabolic acidosis, regardless of origin, can depress myocardial contractility and reduce cardiac output and tissue perfusion. Acidosis inactivates membrane calcium channels and inhibits the release of norepinephrine from sympathetic nerve fibers, leading to vasodilatation and maldistribution of blood flow. Additionally, metabolic acidosis is associated with an increased incidence of postoperative nausea and emesis.[61] Plasma chloride levels affect afferent arteriolar tone through calcium-activated chloride channels and modulate the release of rennin.[62] Hyperchloremia can reduce renal blood flow and glomerular filtration rate.[63] Hyperchloremia reduces splanchnic blood flow.[34] In a study of healthy volunteers, normal saline was associated with reduced urinary output compared with lactated Ringer solution.[64] Finally, in a study of fluid prehydration to prevent contrast nephropa-

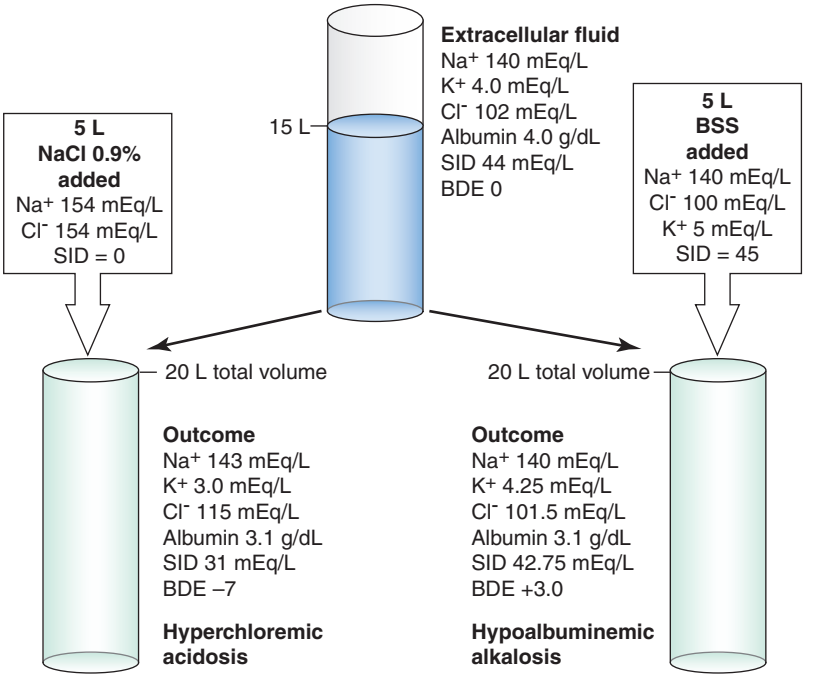

FIGURE 34–9. Impact of extracellular fluid (ECF) expansion with NaCl 0.9% versus an idealized balanced salt solution (balanced salt solutions) on acid–base chemistry. Note the impact of the fluid on both SID and on albumin concentration (A_{TOT}). In both of these examples the contribution of albumin dilution to base deficit excess is approximately 3 mEq/L. ECF expansion with NaCl, with a SID of 0, leads to hyperchloremic acidosis; the magnitude of acidosis is less than would be predicted by the change in SID. ECF expansion with the idealized balanced salt solutions is alkalizing because of albumin dilution.

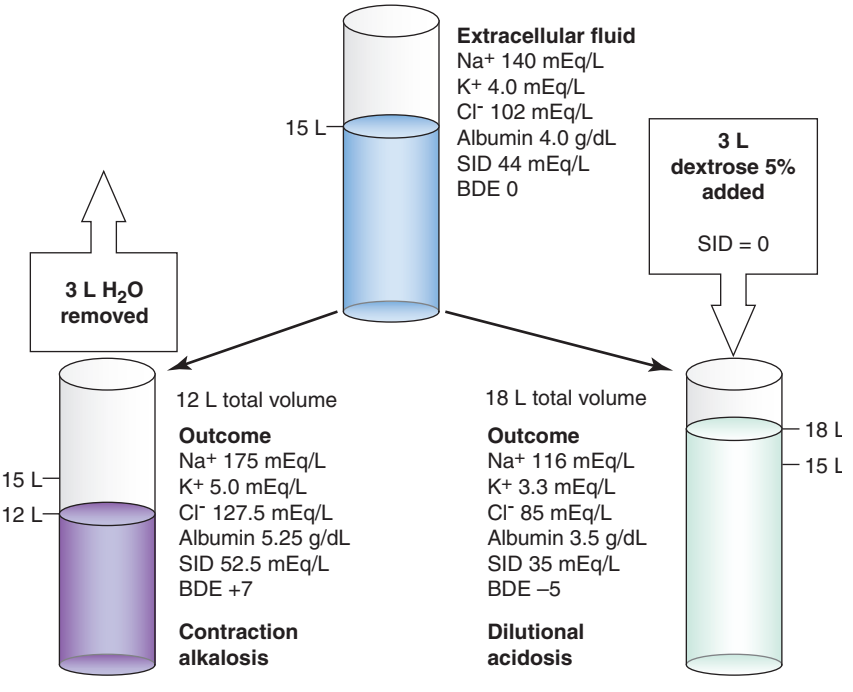

FIGURE 34–10. Impact of loss and gain of free water on acid–base chemistry. In the left-side example, removal of 3 L of water leads to increased SID and increased albumin. The former is alkalinizing, the latter acidifying and the result is a contraction alkalosis. In the left panel the ECF is diluted with 3 L dextrose 5% (SID 0, a physiologic method of delivering free water). Note the impact of the fluid on both SID and on albumin concentration (A_{TOT}). The main impact of hemodilution with free water is reduced SID; this is dilutional acidosis.

thy, the use of sodium bicarbonate was associated with a 11.9% absolute reduction in the risk of renal injury (defined as a 25% increase in creatinine).[65]

Acute Metabolic Alkalosis

Perioperative metabolic alkalosis is usually of iatrogenic origin. Hyperventilation of patients with chronic respiratory failure results in acute metabolic alkalosis because of chronic compensatory alkalosis associated with chloride loss in urine. More frequently, metabolic alkalosis is associated with increased SID caused by sodium gain. This occurs as a result of administration of fluids in which sodium is "buffered" by weak ions, citrate (in blood products), acetate (in parenteral nutrition), and, of course, bicarbonate.

The most frequent single disturbance in acid–base chemistry in perioperative and critically ill patients is hypoalbuminemia.[66] This is ubiquitous, causes an unpredictable metabolic alkalosis, and may mask significant alterations in SID, such as lactic acidemia. All intravenous fluids that do not contain albumin are alkalizing (see Fig. 34–10). Thus, all patients who receive significant volumes of intravenous fluid in the operating room develop a hypoalbuminemic alkalosis. It is unknown whether this anomaly has any clinical significance.

Critically ill patients are vulnerable to significant changes in SID and free water. Nasogastric suctioning causes chloride loss; diarrhea leads to sodium and potassium loss. Surgical drains placed in tissue beds may remove fluids with varying electrolyte concentrations (the pancreatic bed, e.g., secretes fluid rich in sodium). Fever, sweating, oozing tissues, and inadequately humidified ventilator circuits lead to large-volume insensible loss and contraction alkalosis. Loop diuretics and polyuric renal failure may be associated with significant contraction alkalosis as a consequence of loss of chloride and free water.

Parenteral infusions may be responsible for stealth alterations in serum chemistry. Many antibiotics, such as piperacillin-azobactam, are diluted in sodium-rich solutions. Others, such as vancomycin, are administered in large volumes of free water (5% dextrose). Lorazepam is diluted in propylene glycol, large volumes of which will cause metabolic acidosis similar to that seen with ethylene glycol.[67]

Continuous renal replacement therapy is used in critical illness to hemofiltrate and hemodialyze patients who are hemodynamically unstable. Rocktaschel et al.[68] demonstrated that continuous renal replacement therapy resolves the acidosis of acute renal failure by removing strong ions and phosphate. However, metabolic alkalosis ensued as a consequence of the unmasking of metabolic alkalosis caused by hypoalbuminemia.

Regulation of Acid–Base Balance

Carbon dioxide tension is controlled principally by chemoreceptors in the medulla and peripherally in the carotid body and aortic arch. An increase in the PCO_2 or in the acidity of cerebrospinal fluid stimulates the breathing center to increase alveolar ventilation. When respiratory failure occurs, the principal CO_2 buffering system, hemoglobin, becomes overwhelmed, leading to the rapid development of acidosis. In response, the kidney excretes an increased chloride load, using NH_4^+, a weak cation, for electrochemical balance. Thus ECF osmolality is maintained.

"Metabolic" acid is buffered principally by increased alveolar ventilation, producing respiratory alkalosis and extracellular weak acids, which include plasma proteins, phosphate and bicarbonate. The bicarbonate buffering system (92% of plasma buffering and 13% overall) is, probably, the most important extracellular buffer. The pK_a of bicarbonate is relatively low (6.1), but the system derives its importance because of the enormous quantity of carbon dioxide in the body. The coupling of bicarbonate and H_2O produces carbon dioxide, which is excreted through the lungs. There is an increase in alveolar ventilation.

In metabolic acidosis, chloride is preferentially excreted by the kidney. Indeed, this is the resting state of renal physiology, as sodium and chloride are absorbed in the diet in relatively equal quantities.[69] In metabolic alkalosis, chloride is retained, and sodium and potassium are excreted.

Abnormalities in the renal handling of chloride may be responsible for several inherited acid–base disturbances. In renal tubular acidosis, there is inability to excrete Cl in proportion to Na^+.[70] Similarly, pseudohypoaldosteronism appears to be caused by high reabsorption of chloride.[71] Bartter syndrome is caused by a mutation in the gene encoding the chloride channel—CLCNKB—which regulates the Na-K-2Cl cotransporter (NKCC2).[72]

Analytic Tools Used in Acid–Base Chemistry

Abnormalities of acid–base balance provide valuable information regarding changes in respiratory function, electrolyte chemistry and underlying disease processes. Although blood gas analysis is ubiquitous, it provides only partial information regarding acid–base chemistry. Abnormalities of pH, base deficit excess (BDE) or bicarbonate concentration reflect effect (and not always accurately), but not always cause. Measurement of each of the strong and weak ions that influence water dissociation, although cumbersome, is essential.[42]

This section considers some of the tools that have evolved over the past 50 years to assist our interpretation of acid–base conundrums. None are entirely accurate, and each has a dedicated group of followers.[73] Clinicians often confuse mechanisms of interpretation with the underlying causes of acid–base abnormalities. For example, a fall in serum bicarbonate during metabolic acidosis reflects hyperventilation and the activity of the carbonate system as an extracellular buffer. The acidosis is not caused by depletion or dilution of bicarbonate; instead, it is caused by decreased SID (usually by unmeasured anions [UMAs]) or increased A_{TOT}. We deal with each of these approaches chronologically and discuss the merits and demerits of each.

CO_2-Bicarbonate (Boston) Approach

Schwartz et al., at Tufts University in Boston, developed an approach to acid–base chemistry using acid–base maps and the mathematical relationship between carbon dioxide tension and serum bicarbonate (or total CO_2), derived from the Henderson-Hasselbalch equation, to predict the nature of acid–base disturbances.[74] A number of patients with known acid–base disturbances, at steady states of compensation, were evaluated. The degree of compensation from what was considered normal was measured for each disease state. The investigators were able to describe 6 primary states of acid–base imbalance, using linear equa-

tions or maps, relating hydrogen ion concentration to PCO_2 for respiratory disturbances, and PCO_2 to HCO_3 concentration for metabolic disturbances (Table 34–24). For any given acid–base disturbance, an expected HCO_3 concentration was determined. The major drawback of this approach is that it treats HCO_3 and CO_2 as independent rather than interdependent variables.

Base Deficit/Excess (Copenhagen) Approach

Singer and Hastings pioneered an alternative approach to acid–base chemistry in 1948, by moving away from the Henderson-Hasselbalch equation toward quantifying the metabolic component.[52] They proposed that the whole-blood buffer base could be used for this purpose. The buffer base represented sum of the bicarbonate and the nonvolatile buffer ions (essentially the serum albumin, phosphate, and hemoglobin). Applying the law of electrical neutrality, the buffer base was forced to equal the electrical charge difference between strong (fully dissociated) ions. Thus, normally

$$\text{buffer base} = [Na^+] + [K^+] - [Cl]$$

Alterations in buffer base represented, essentially, changes in strong ion concentrations (which could not be easily measured in 1948). Buffer base increases metabolic alkalosis and decreases metabolic acidosis. The major drawback of the use of buffer base measurements is the potential for changes in buffering capacity associated with alterations in hemoglobin concentration.

Siggard-Anderson and colleague, in 1958, developed a simpler measure of metabolic acid–base activity, the base deficit excess.[75] They defined BDE as the amount of strong acid or base required to return the pH of 1 L of blood to 7.4, assuming a PCO_2 of 40 mm Hg, and temperature of 100.4°F (38°C). The initial use of whole-blood base excess was criticized because of the dynamic activity of red cells within the acid–base paradigm, that is, the gas and electrolyte exchange. This approach was modified in the 1960s to use only serum base excess, and the calculation became the *standardized* base excess. Current algorithms for computing the standardized base excess are derived from the Van Slyke equation (1977).[76] The BDE approach to acid–base chemistry was validated by Schlitig[77] and Morgan.[78]

Simple mathematical rules can be applied using the BDE in each of the common acid–base disturbances (Table 34–25). For example, in acute respiratory acidosis or alkalosis, BDE does not change. Conversely, in acute metabolic acidosis, the magnitude of change of the PCO_2 (in mm Hg), is the same as that of the BDE (in mEq/L), and the change in BDE represents the overall sum total of all acidifying and alkalinizing effects. This makes interpretation of acid–base abnormalities simple, but misleading.

The base deficit approach has two significant limitations: First, it does not account for changes in acid–base chemistry associated with hypoproteinemia; indeed, the Van Slyke equation assumes normal serum proteins, which is not the case in critical illness. The second limitation is that this approach does not distinguish between metabolic acidosis associated with hyperchloremia and that associated with unmeasured anions.

Anion Gap Approach

To address the primary limitation of the Boston and Copenhagen approaches, the anion gap was developed by Emmit and Narins in 1975.[79] The anion gap approach is based on the law of electrical neutrality and is entirely consistent with the work of Stewart and Fencl. The sum of the difference in charge of the common extracellular ions reveals an unaccounted for "gap" of 12 to 16 mEq/L (Fig. 34–11):

$$\text{anion gap} = (Na^+) - (Cl + HCO_3)$$

If the patient develops a metabolic acidosis, and the gap "widens" to, for example, 20 mEq/L, then the acidosis is caused by unmeasured anions, either lactate or ketone. If the gap does not widen, then the anions *are* being measured, and the acidosis has been caused by hyperchloremia (bicarbon-

TABLE 34–24.

Changes in PCO_2 and $[HCO_3^-]$ in Response to Acute and Chronic Acid–Base Disturbances

Disturbance	HCO_3^- vs $PaCO_2$
Acute respiratory acidosis	$\Delta HCO_3^- = 0.2\ \Delta PaCO_2$
Acute respiratory alkalosis	$\Delta HCO_3^- = 0.2\ \Delta PaCO_2$
Chronic respiratory acidosis	$\Delta HCO_3^- = 0.5\ \Delta PaCO_2$
Metabolic acidosis	$\Delta PaCO_2 = 1.3\ \Delta HCO_3^-$
Metabolic acidosis	$\Delta PaCO_2 = 0.75\ \Delta HCO_3^-$

Modified from Narins RB, Emmet M. Simple and mixed acid–base disorders: a practical approach. Medicine 1980; 59:161–187.

TABLE 34–25.

Changes in Standardized Base Deficit or Excess (BDE) in Response to Acute and Chronic Acid–Base Disturbances

Disturbance	BDE vs PaCO2
Acute respiratory acidosis	ΔBDE = 0
Acute respiratory alkalosis	ΔBDE = 0
Chronic respiratory acidosis	ΔBDE = 0.4 ΔPaCO2
Metabolic acidosis	ΔPaCO2 = ΔBDE
Metabolic alkalosis	ΔPaCO2 = 0.6 ΔBDE

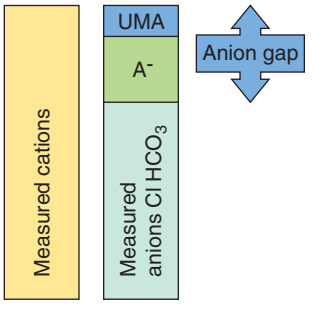

FIGURE 34–11. The anion gap. A^-, phosphate and albumin; UMA, unmeasured anions.

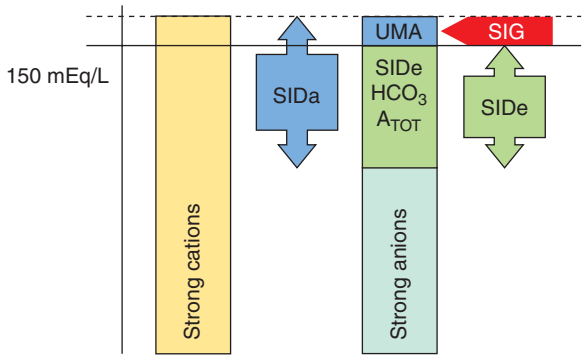

FIGURE 34–12. The strong ion gap (SIG). SIDa, apparent SID; SIDe, effective SID; UMA, unmeasured anions.

ate cannot independently influence acid–base status). Although this is a useful tool, it is weakened by the assumption of what is or is not a "normal gap."[80] The majority of critically ill patients are hypoalbuminemic, and many are also hypophosphatemic.[44] Consequently, the gap may be normal in the presence of unmeasured anions. Fencl and Figge developed a variant known as the *corrected anion gap*[81]:

anion gap corrected (for albumin) = calculated anion gap + 2.5 (normal albumin g/dL – observed albumin g/dL)

A second weakness with this approach is the use of bicarbonate in the equation. An alteration is $[HCO_3]$ concentration, which can occur for reasons independent of metabolic disturbance, for example, hyperventilation. The base deficit and anion gap frequently underestimate the extent of the metabolic disturbance.[42]

Stewart-Fencl Approach

A more accurate reflection of true acid–base status can be derived using the Stewart-Fencl approach.[4,45] Like the anion gap, the Stewart-Fencl approach is based on the concept of electrical neutrality. There exists in plasma a SID $[(Na^+ + Mg^{2+} + Ca^{2+} = K^+) - (Cl + A)]$ of 40–44 mEq/L, balanced by the negative charge on bicarbonate and A_{TOT} (the buffer base). There is a small difference between SIDa (apparent SID) and weak acid buffers (SIDe [effective SID]). This represents a strong ion gap (SIG), which quantifies the amount of unmeasured anion present (Fig. 34–12).

$$SIDa = ([Na^+] + [K^+] + [Mg^{2+}] + [Ca^{2+}]) - [Cl]$$

$$SIDe = [HCO_3] + [\text{charge on albumin}] + [\text{charge on Pi}] \text{ (in mmol/L)}$$

Pi is inorganic phosphate. The degree of weak acid ionization is pH dependent, so one must calculate for this:

$$[alb] = [\text{alb g/L}] \times (0.123 \times pH - 0.631)$$

$$[Pi] \text{ (in mg/dL)} = [Pi]/10 \times pH - 0.47$$

$$SIG = SIDa - SIDe$$

The BDE and SIG approaches are consistent with one another, and can be derived from a master equation.[82] The Stewart approach,[45] refined by Figge,[43,83] Fencl,[4,42] and others, more accurately measures the contribution of charge from weak acids, which change with temperature and pH.

The weakness of this system is that the SIG does not necessarily represent unmeasured strong anions, merely all anions that are unmeasured. Furthermore, SID changes quantitatively in absolute and relative terms when there are changes in plasma water concentration. Fencl[42] addressed this by correcting the chloride concentration for free water (Cl *corr*) using the following equation:

$$[Cl]corr = [Cl]\text{observed} \times ([Na+]\text{normal}/[Na+]\text{observed})$$

This corrected chloride concentration can then be inserted into the SIDa equation above. Likewise, the derived value for UMAs should also be corrected for free water using UMA instead of Cl in the above equation.[42] In a series of 9 normal subjects, Fencl estimated the "normal" SIG as 8 ± 2 mEq/L.[42]

Although accurate, the SIG approach is cumbersome and expensive, requiring measurement of multiple ions and albumin. An alternative approach, used by Gilfix et al.,[84] and subsequently by Balasubramanyan et al.[85] and Story and Bellomo[86] is to calculate the BDE gap. This allows recalculation of BDE using strong ions, free water, and albumin. The resulting BDE gap should mirror the SIG and the anion gap.

We find the simplified calculation of Story et al. to be most useful.[87] They use two equations to calculate the BDE for sodium/chloride/free water (BDE_{NaCl}) and for albumin (Table 34–26). Figure 34–13 presents a unified approach to solving acid–base problems.

TABLE 34–26.

Calculation of Base Deficit-Excess of Sodium Chloride-Free Water and Albumin[a]

$BDE_{NaCl} = ([Na+]–[Cl^-])–38$
$BDE_{Alb} = 0.25\ (42 - \text{albumin g/L})$
$BDE_{NaCl} - BDE_{Alb} = BDE_{calc}$
$BDE - BDE_{calc}$ = BDE gap = the effect of unmeasured anions or cations
These calculations simplify the framework for "eyeballing" a chemistry series:
- Normal Na = 140
  - –For every 1 mEq/L increase in Na from 140, base excess increases by +1
  - (Na 150 = BDE + 10 = contraction alkalosis)
  - –For every 1 mEq/L decrease in Na from 140, base deficit increases by –1
  - (Na 130 = BDE – 10 = dilutional acidosis
- Normal Cl = 102
  - –For every 1 mEq/L increase in Cl from 102, base deficit increases by +1
  - (Cl 110 = BDE – 8 = hyperchloremic acidosis
  - –For every 1 mEq/L decrease in Cl from 102, base excess increases by +1
  - (Cl 90 = BDE + 12 = hypochloremic, chloride sensitive, alkalosis)
- Normal albumin = 42 g/L or 4.2 g/dL
  - –For every 0.4 g/dL decrement in albumin from 4.0, there is a 1.0 mEq/L increase in base excess.

[a]This approach involves calculating the base deficit excess (BDE) for sodium, chloride, and free water (BDE_{NaCl}), and that for albumin (BDE_{Alb}). The result is the calculated BDE (BDE_{calc}). This is subtracted from the measured BDE to find the BDE gap.

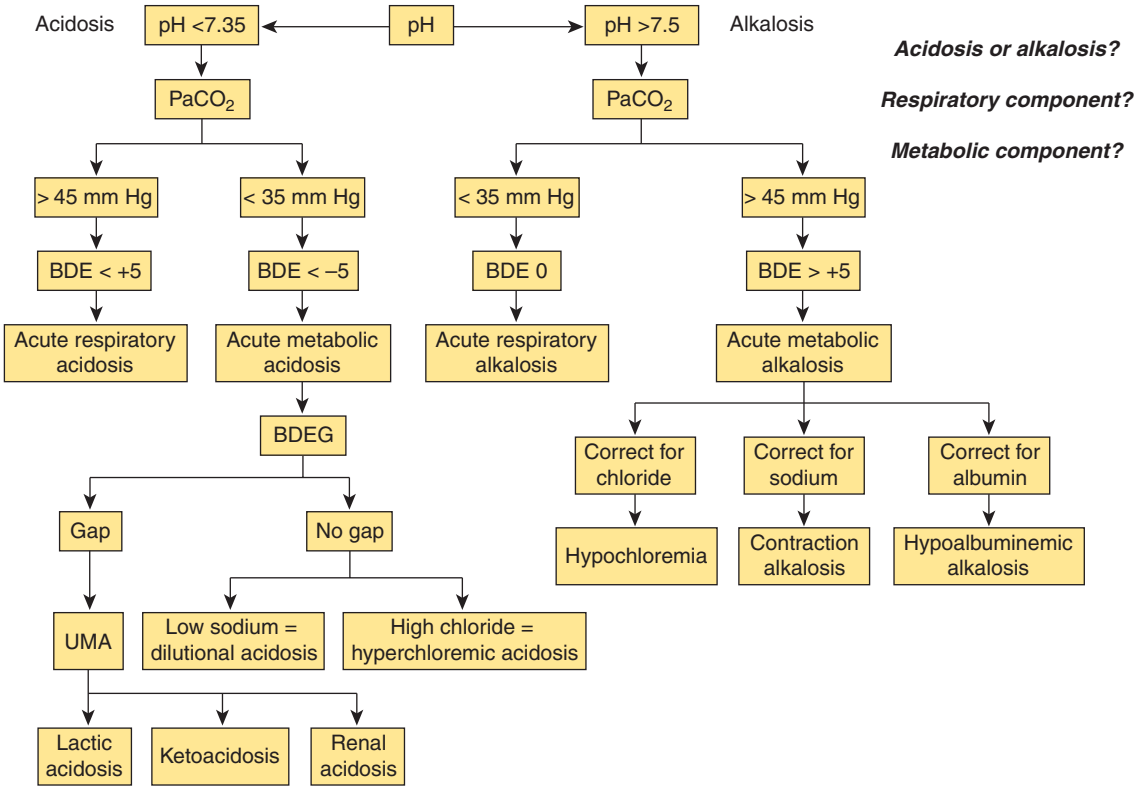

FIGURE 34–13. Mechanism for solving an acid–base problem. BDE, base deficit or excess; BDEG, base deficit excess gap.

Treating Acid–Base Disturbances

Therapeutic treatment of acid–base disturbances is controversial; many regard it as "window dressing" rather than addressing the cause. This refers particularly to the use of sodium bicarbonate in the treatment of lactic acidosis.[88] Therapeutic use of sodium bicarbonate has three effects: (a) volume expansion, as the 7.5% solution is hypertonic (hence the often remarked improvement in cardiovascular performance); (b) increased SID as a consequence of the administration of sodium without accompanying strong anion;[89] and (c) increased CO_2 generation. There is no evidence that sodium bicarbonate administration improves outcomes in circulatory shock.[88] Much discussion has focused on bicarbonate inducing intracellular acidosis,[90] but this is probably clinically insignificant.[88,91] Lactic acidosis is treated with volume resuscitation and source control; diabetic ketoacidosis is treated with volume resuscitation and insulin.

Hyperchloremic or dilutional acidosis is treated by increasing the SID of infused fluids, for example, by infusing sodium without chloride. Although no such fluid is available commercially, such a fluid can be constructed by using sodium bicarbonate or sodium acetate.

Sodium gain is "chloride sensitive" alkalosis, treated by administration of net loads of chloride—0.9% NaCl, potassium chloride, calcium chloride, and, occasionally, hydrogen chloride. It is important to correct chloride-sensitive alkalosis, as the normal compensatory measure is hypoventilation, increasing $PaCO_2$, which may lead to CO_2 narcosis or failure to liberate from mechanical ventilation. There is no specific treatment for hypoalbuminemic alkalosis.

Renal acidosis is treated with dialysis, which removes fixed acids. However, alteration in SID using sodium bicarbonate or sodium acetate can be used, for patient comfort, as a bridge to dialysis.

There has been significant interest in hypercapnic acidosis over the past decade following the introduction of "permissive hypercapnia" in acute respiratory distress syndrome, to prevent ventilator-associated lung injury.[92] There is accumulating evidence that hypercapnia has a lung-protective effect, and that reversing the acidosis may have adverse effects.[93] Nevertheless, in patients with hypercapnic acidosis and associated cardiovascular instability we recommend the use of *Tris*(hydroxymethyl)-aminomethane (THAM).[94] THAM titrates hydrogen ions (e.g., lactic acid or CO_2) according to the following reaction:

$$R\text{-}NH_2 + HA \rightarrow R\text{-}NH_3^+ + A^-$$

THAM is a proton acceptor that generates NH_3^+/HCO_3 without generating CO_2, and the protonated $R\text{-}NH_3^+$, along with chloride, is eliminated by the kidneys. THAM has the significant advantage of buffering acidosis without increasing serum sodium or generating more carbon dioxide.

Monitoring Blood Gases: Alpha Stat versus pH Stat

Water dissociation is temperature dependent. Thus extracellular pH varies with body temperature, becoming more alkalotic with progressive hypothermia and more acidotic with hyperthermia. Hence patients presenting in a state of hypothermia, or induced hypothermia (for cardiac surgery), would be expected to exhibit significant metabolic alkalosis on a blood gas. Blood gas machines heat the blood sample to an idealized 98.6°F (37°C), enabling the clinician to make inferences regarding the presence or absence of respiratory or metabolic abnormalities from a con-

stant perspective. This "alpha-stat" approach is widely used in perioperative medicine. An unfortunate drawback of this approach is that many clinicians are unaware of the impact of temperature on pH. Incumbent in this hypothesis is that, despite temperature changes, the body is capable of maintaining homeostatic function, and intracellular enzymes and transcellular ion pumps will continue to function.

Intracellular pH is 6.8 at 98.6°F (37°C), which is neutral pH at that temperature. Extensive animal investigation has established that intracellular pH remains neutral across a wide array of body temperatures. The reason that this occurs appears to relate to the constant buffering capacity, across pH, of intracellular histidine moieties.[95] This neutrality has the effect of maintaining intracellular enzymatic activity. Carbon dioxide becomes more soluble in blood as temperature drops. Moreover, hypothermia is associated with reduced metabolic activity. Consequently, hypothermia results in respiratory alkalosis and reduced cerebral blood flow.

Some clinicians believe that pH should be kept constant, despite changes in temperature (the pH-stat hypothesis). Thus, when measuring a blood gas, the patient's current body temperature is entered into the machine and a series of calculations corrects the blood gas to that temperature. Thus if a patient has a temperature of 82.4°F (28°C), the pH will be reported, for example, at 7.65 and the PCO_2 at 22 mm Hg.

Poikilothermic animals (reptiles) use an alpha-stat system of pH control, and can function over a broad range of temperatures.[96] Hibernating animals, however, use a pH-stat strategy, induced by hypoventilation. The consequent increase in intracellular CO_2 content reduces cellular metabolism and may have a protective effect.[97]

Clinicians that adopt a pH-stat approach will correct the blood pH by adding carbon dioxide during cardiopulmonary bypass. The resulting respiratory acidosis is thought to improve neurologic outcomes in cardiac surgery. For example, cerebral; blood flow decreases 40% during cardiopulmonary bypass at 78.8°F (26°C) using alpha-stat management but remains similar to baseline with pH-stat management.[98]

The higher PCO_2 in pH stat approaches is thought to improve neurologic outcomes by (a) inducing a rightward shift of the oxyhemoglobin dissociation curve promoting O_2 unloading to tissues, (b) reducing the cerebral metabolic rate of oxygen and increasing neuronal tolerance to ischemia, and (c) modulating the *N*-methyl-D-aspartate receptor that limits the neurotoxic effects of excitatory amino acids.[99] There is little data to support the use of the pH-stat approach in adults, and benefit, if it exists at all, is probably confined to infants who are undergoing cardiac surgery.[99] We do not recommend the adoption of the pH-stat approach for the majority of perioperative patients.

ESTIMATING PERIOPERATIVE FLUID REQUIREMENTS

Traditional approaches to perioperative fluid management have focused on rigorous calculation of fluid deficits; the administration of "maintenance" fluids, calculated on body weight and metabolic activity; repletion of insensible losses and third space losses (dependent on the anatomical region of surgery); and replacement of blood loss with crystalloid (in a 1:3 ratio) or colloid (in a 1:1 ratio). There are many limitations to this approach; chief among them is the potential for significant weight gain and fluid overload. Additionally, the actual presence of third space fluid loss has been questioned. Nevertheless, these approaches continue to be widely advocated in practice and a short description follows.

Preoperative Deficits

In adults who are undergoing elective surgery, despite guidelines that water is permissible up to 2 hours preoperatively,[100] oral intake is usually restricted for up to 12 hours before the procedure. This period of restricted oral intake may be considerably longer when surgery is scheduled late in the day. The resulting fluid deficit is primarily because of water loss.

The traditional approach involves calculating the hourly maintenance fluid rate and multiplying that by the time of restricted fluid intake. The maintenance fluid is calculated using a 4–2–1 system (4 mL/kg/h for the first 10 kg body weight, 2 mL/kg/h for the next 10 kg body weight, and 1 mL/kg/h beyond that body weight). An alternative system is to administer 1.5 mL/kg. Of this total, 50% of this deficit volume is replaced over the first hour of intravenous fluid therapy and 25% is replaced during each of the ensuing 2 hours. The entire deficit is replaced in 3 hours, which is accomplished by adding the fluid deficit to the basal infusion rate of the maintenance fluids. Simultaneously, account must be taken for insensible losses during and after surgery. This is associated with, for example, evaporation at the site of surgery, hyperventilation, fever, sweating, denuded skin, burns, and the use of nonhumidified oxygen therapy administered at high flow rates. Again, much of this loss is in water not extracellular fluid.

Additional preoperative deficits may also occur. The most common is volume loss through the bowel as a consequence of preoperative administration of purgatives ("bowel preparations"). This leads to an absolute deficit of water and electrolytes, principally sodium and potassium, but also chloride as a result of renal compensatory loss. This requires replacement with a balanced salt solution. There is no clear published guideline for the absolute volume that must be replaced to overcome bowel preparation losses, but the majority of anesthesiologists estimate this at 1000–2000 mL. Other preoperation causes of absolute hypovolemia with associated electrolyte loss include vomiting, gastric suction, diarrhea, and ostomy output. Upper gastrointestinal losses should be repleted with chloride-rich solutions, preferably 0.9% saline. Lower gastrointestinal losses should be repleted with balanced salt solutions.

Internal losses are volume deficits that cannot be easily quantified as they represent redistribution of fluid within the body. Traditionally these are considered "relocation" losses into cavities and third spaces, but also represent expansion of the extracellular fluid space secondary to capillary leak. The cavitary losses (e.g., pleural, ascitic, and pericardial fluid) are simple transudates of plasma that often require a relatively prolonged period to accumulate in significant quantities. Consequently, the impact on the ECF volume is generally minor, as there is usually some degree of compensation for this redistribution of vascular fluid. Although significant cavitary fluid ac-

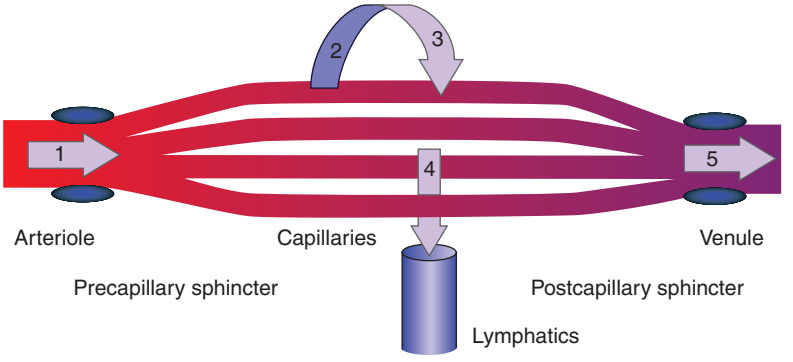
cumulation does occur in hypervolemic states, the most important variant of this genre is ascites. Ascitic fluid, secondary to cirrhosis, ovarian cancer, or carcinomatosis, once drained, inevitably reaccumulates, leading to massive fluid shifts and the potential for significant intravascular dehydration.

There are many other causes of fluid redistribution losses in perioperative medicine. These usually involve significant edema in conjunction with injured tissue (as may occur with obstructed, ischemic, or dead bowel), in particular when compartment syndromes occur, and when secretory fluid becomes trapped in obstructed bowel. These "third space" and cavitary losses create a new ECF pool that is sequestered and essentially nonfunctional.

Internal blood loss also diminishes the ECF volume. Such losses may be significant when associated with retroperitoneal hematoma, leaking aneurysm, pseudoaneurysm or vascular anastomosis, pelvic or femoral fracture, or splenic rupture. Depending on the acuteness of the hemorrhage, some degree of compensation may have occurred. Typically, this involves transcapillary refill (Figs. 34–14 and 34–15), the movement of extracellular fluid into the vascular space to maintain perfusion of fight-or-flight organs (midline structures and skeletal muscle). Although this may lead to a small drop in the hemoglobin concentration, it is essential to understand that in situations of acute isovolemic blood loss, hemoglobin remains essentially unchanged despite massive blood loss. This may lead to false reassurance, particularly in young patients who have tremendous compensatory capacity through tachycardia and intense vasoconstriction.

Clearly, estimation of fluid deficits and ongoing fluid losses differs depending on the nature of the patients and the type of surgery. Emergency procedures are often associated with significant fluid shifts that must be accounted for.

Fluid used to replace pure volume losses should be nearly isotonic with respect to plasma and should also contain sodium and chloride. In general, a polyvalent, balanced salt solution (e.g., mildly hypotonic, lactated Ringer solution) is used. Ideally, both internal and external preoperative fluid deficits should undergo total correction before the administration of an anesthetic.



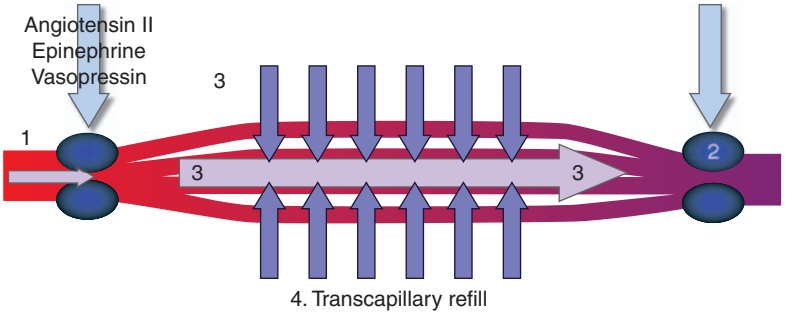
1. Precapillary sphincters are relaxed, and blood flows into the capillary bed
2. Fluid is filtered on the arterial side and returns
3. On the venous side or
4. Through lymphatics
5. Blood returns through the postcapillary sphincters to the venous system

FIGURE 34–14. The normal microcirculation.

However, an urgent need for surgery may preclude replacement of the entire deficit. Relatively small volume deficits (i.e., less than 20% of the blood volume) can often be replaced with an isotonic or balanced salt solution administered over a period of 15 minutes or less. Although most patients will tolerate this amount of acute intravascular volume expansion, care must be taken in patients with a history of hypertension or diastolic dysfunction. In this case, rapid volume administration may precipitate acute pulmonary edema. Importantly, 40–60% of the infused solution will redistribute to the extracellular compartment within 15–30 minutes, and 80% will redistribute by 1 hour (Fig. 34–16). If the patient has significant extracellular fluid deficit, this is an effective method of resuscitating that space. However, if blood loss is the problem, significant tissue edema will result from large-volume crystalloid resuscitation to maintain hemodynamic goals.

Intraoperative Fluid Losses

Intraoperative fluid losses (similar to preoperative losses) can be categorized as either internal or external. Traditional approaches to intraoperative fluid management involve estimation of distribution volume deficits and repletion of this apparent ECF volume loss with isotonic fluids. Significant volume is lost or sequestered into "third" spaces. It is assumed that the volume of fluid sequestered is proportional to the amount of surgical trauma. Thus major orthopedic procedures, surgery within the chest cavity, bowel resections, and hysterectomies are examples in which a significant quantity of third spacing occurs (i.e., perhaps 4–5% of body weight). The



1. The blood pressure falls, reflex vasoconstriction follows
2. The pre-capillary and post-capillary sphincters contract
3. This reduces the volume and increases the velocity of blood passing through
4. Fluid is sucked back into the circulation by the flow of blood, this process is called "transcapillary refill," and allows remobilization of fluid

FIGURE 34–15. Compensation for hypovolemia.

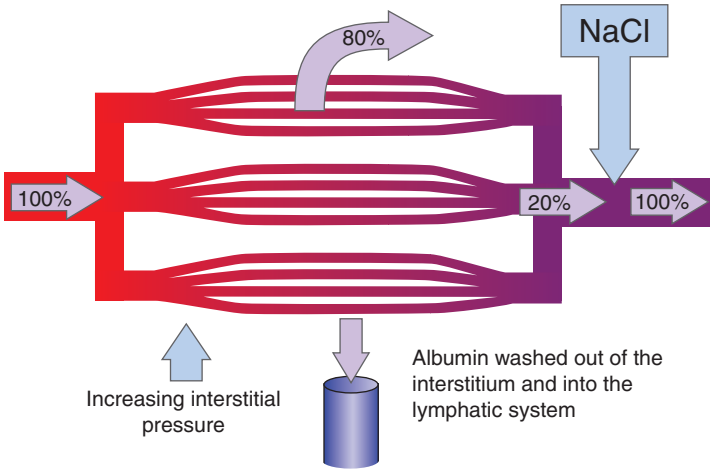


FIGURE 34–16. Crystalloid extravasation. When isotonic crystalloid fluids are administered to the perioperative patient, up to 80% of the infused volume extravasates into the interstitium.

exact quantity of sequestered fluid is impossible to ascertain, and replacement of these third-space losses is an approximation.

Conservative approaches to third space fluid replacement, based on the amount of tissue exposure and degree of tissue trauma, are as follows: minimal trauma, 2–4 mL/kg/h; moderate trauma, 4–6 mL/kg/h; extensive trauma, 6–12 mL/kg/h. This volume replacement is in addition to maintenance fluids and repletion of preoperative losses.

External fluid losses during surgery are predominantly a result of insensible or evaporative losses and blood loss. Significant evaporative losses may occur when either the peritoneal or pleural surfaces are exposed to ambient conditions, depending on the relative humidity of the air in the operating room and the rate of exchange of air within the room. This is free water loss that is almost impossible to quantify. Traditional approaches involve the administration of 1–4 mL/kg/h of fluid to replete these losses, with higher volumes administered depending on the cavity or tissue surface exposed. Patients with extensive burns have massive insensible volume losses, and volume repletion is formula driven, based on the surface area burned.

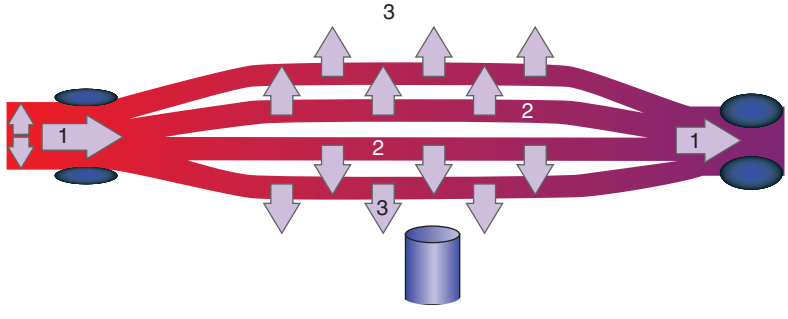
Intraoperative blood loss may lead to significant tissue hypoperfusion and organ injury. It is, however, difficult to quantify as a result of, for example, accumulation in drains, drapes, suction canisters, and administration of lavage fluid. The estimated blood loss almost always underestimated true blood loss. Administration of crystalloid or colloid to fixed hemodynamic goals will progressively deplete the hemoglobin concentration, providing a useful index of blood loss. However, underresuscitation of the patient is often associated with a falsely reassuring hemoglobin concentration.

Traditional approaches to blood replacement have identified a 3:1 ratio of crystalloid to blood loss. This is incorrect.[101] With increasing volumes of crystalloid administration the extracellular space becomes progressively more compliant, resulting in a geometric increase in transcapillary leakage that volume replacement for blood loss parallels.[102] This process is known as cytopempsis and principally reflects the progressive hypoalbuminemia associated with volume replacement.[10] In his original animal study, Moss described a 5:1 ratio of crystalloid replacement to blood loss when losses reached 35% of blood volume, reaching an inflection point at this level, with subsequent ratios increasing geometrically. At 75% blood loss the ratio reaches 16:1.[10] Consequently, consideration should be given to replete blood losses with colloid solutions or blood component therapy.

Postoperative Fluid Losses

Both internal and external fluid losses continue into the postoperative period. Depending on the patient's preoperative status, intraoperative management, and surgical procedure, combinations of volume, concentration, and composition disturbances are not infrequent. Over the first 24–36 hours after a procedure, fluid continues to be sequestered into the extracellular space, principally as a result of capillary leakage (Fig. 34–17).[103] Evidence of end-organ hypoperfusion may become apparent, in particular oliguria. Recurrent boluses of fluid may be required to restore organ function. On postoperative day 2, a steady state appears to be reached, followed by fluid mobilization and diuresis. Patients lose up to 1000 mL of water per day in insensible losses, but also gain water from metabolic activity. Although traditional teaching emphasizes the administration of hypotonic glucose-containing intravenous fluids to prevent dehydration and ketosis, there is very little support for this position in the literature. Indeed the controversy of "dry" versus "wet" has existed for as long as intravenous fluid therapy has been available.[104] Furthermore, postoperative clear fluid administration may be associated with worse outcomes, and dextrose administration is associated with undesirable hyperglycemia.

External losses may persist into the postoperative period as a result of, for example, continued bleeding, nasogas-



1. There is widespread vaso- and venodilatation
2. The endothelium becomes porous
3. Protein-rich fluid leaks out into the extracellular space causing edema

tric suctioning, surgical drains, diarrhea, and evaporative losses. It is imperative that the clinician quantify these losses and replenish them with fluids appropriate for the site of loss (e.g., balanced salt solutions for ECF loss, normal saline for upper GI losses).

FLUID REPLACEMENT CRYSTALLOIDS

Nature and Makeup of Crystalloid Solutions

Crystalloid solutions are intravenous fluids that involve electrolytes or dextrose dissolved in sterile water (Table 34–27). Crystalloid solutions may be hypotonic, isotonic, or hypertonic. They may have a SID of 0 (dextrose solutions or NaCl 0.9%) or a SID that approximates plasma (balanced salt solutions, e.g., lactated Ringer solution, Normosol, Plasmalyte). Dextrose-based fluids distribute evenly across total body water. Hypotonic fluids distribute across body water in proportion to electrolyte content. Isotonic fluids, being electrolyte based, distribute evenly through the extracellular fluid, but remain extracellular (Fig. 34–18). Hypertonic fluids remain in the compartment into which they are injected (bloodstream) and expand that compartment by dragging fluid from the intracellular and extracellular space along the osmotic gradient. The choice of intravenous fluids, used therapeutically, is determined by the clinical indication and prevailing conditions. For example, hypotonic fluids are typically used to replace free water deficits. Isotonic fluids are used to replace extracellular fluid losses. Slightly hypotonic balanced salt solutions, such as lactated Ringer solution, replace free water and extracellular fluid losses. Hypertonic fluids are typically used as plasma expanders, used in acute resuscitation, but may reduce edema volume. Hypertonic saline is typically used in traumatic brain injury. Table 34–26 is a comprehensive list of crystalloid solutions. The following section addresses the most commonly administered formulations.

Dextrose 5%

Water cannot be administered into the intravascular space because red cell lysis results. Dextrose as a 5% solution is isosmotic with plasma, but rapidly becomes free water as the glucose content is metabolized. Consequently, free water therapy has traditionally taken the form of dextrose solutions. Alternative "hypotonic fluids" include 0.45% NaCl + dextrose 5% and 0.25% NaCl. Water, administered as dextrose, distributes to the total body water. Thus when 1000 mL of dextrose is delivered, two-thirds of it enters the intracellular space and a tiny fraction remains intravascular. Consequently, dextrose, and all hypotonic fluids, should be avoided when intravascular volume expansion is desired. Dextrose has been used traditionally to treat dehydration losses before and after surgery. However, the caloric content of dextrose is problematic (200 kcal/L). Glucose cannot be used as fuel in perioperative patients. Administration of glucose results in hyperglycemia as a result of stress catecholamine release and insulin resistance, during the stress response. Perioperative hyperglycemia is associated with increased risk of death, myocardial ischemia, and stroke.[105–107] Thus the traditional postoperative fluid regimens, which emphasize the use of glucose to prevent ketosis and replenish free water deficits, require reevaluation.

"Normal" Saline

"Normal" saline consists of an equimolar solution of sodium (154 mEq/L) and chloride (154 mEq/L). The solution has an osmolality of 308 mOsm, slightly hypertonic to plasma, and a

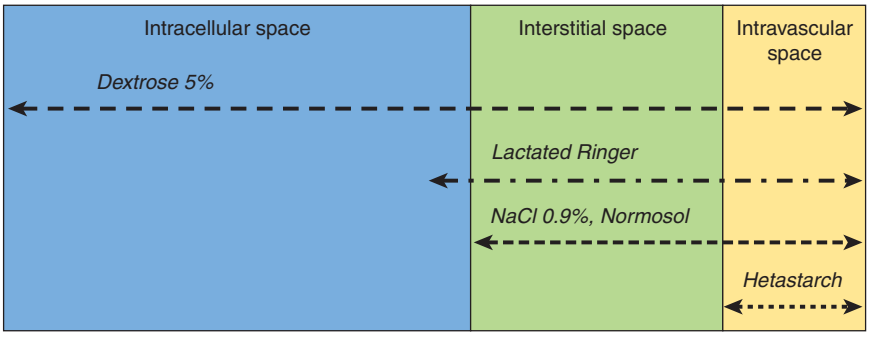

FIGURE 34–18. Volume of distribution of crystalloid solutions.

SID of 0. Consequently, administration of moderate to large quantities of this fluid is associated with mild hypernatremia, progressive hyperchloremia, and metabolic acidosis (see Fig. 34–10).

Saline continues to be widely used in hospital practice, particularly in neurosurgery, where it is used as a component of osmotic therapy. The widely accepted use of this solution in patients with renal failure has been questioned. Traditionally balanced salt solutions were avoided in this patient population because of concerns regarding accumulation of potassium in renal failure. However, a study by O'Malley et al. demonstrated a 20% absolute risk increase (number needed to treat: 5) for hyperkalemia in patients undergoing renal transplantation who were administered saline rather than lactated Ringer solution.[108] Moreover, there was a 30% incidence of metabolic acidosis, requiring treatment, in the saline group, versus 0% in the lactated Ringer group.

Although not widely recognized, chloride ion excretion is a primary role of the kidney, as sodium and chloride are absorbed in roughly equimolar concentrations in the diet; a net excretion of chloride over sodium is necessary. Chloride is involved with regulation of renal vascular tone.[109] Hansen demonstrated that K^+-induced contraction of smooth muscle cells in the afferent arteriole is highly sensitive to chloride.[110] Thus chloride is a functional renal vasoconstrictor. Hyperchloremia has been shown to produce dose dependent renal vasoconstriction and a reduction in glomerular filtration rate.[111,112] In addition hyperchloremia may be associated with an increased risk of acute renal failure in vulnerable patients, such as those receiving radiographic contrast dye.[113]

Wilkes et al. demonstrated that, compared with balanced salt solutions, patients who received intraoperative saline-based solutions had significantly reduced splanchnic blood flow,[34] as estimated using gastric tonometry. Williams et al. randomized healthy volunteers to 0.9% saline versus an equal volume of lactated Ringer solution. Saline administration was associated with lower pH and longer time to first urination.[64] This tendency toward fluid retention may result from the higher chloride content or the higher osmolality of the solution that induces inappropriate ADH secretion by "fooling" the midbrain that the patient is dehydrated.[64]

Crystalloid solutions of any type enhance coagulation as measured by thrombelastograph analysis and routine coagulation studies.[114,115] When patients were hemodiluted up to 30% with saline, coagulation parameters increased.[116] The most likely mechanism is an imbalance between the naturally occurring anticoagulants and activated procoagulants, with a reduction in antithrombin III probably being the most important.[117] This effect lowers the threshold above which positive feedback into the intrinsic coagulation pathway occurs, leading to the enhanced coagulation. Although it has been suggested that resuscitation with 0.9% normal saline is associated with increased risk of bleeding versus balanced salt solutions,[118] there is minimal human data to support this claim. One study of 0.9% saline versus lactated Ringer solution in aortic aneurysm surgery showed no difference in outcome variables, but a higher perioperative blood loss in the saline group.[119]

Lactated Ringer Solution

Lactated Ringer solution is the most widely used balanced salt solution, and is recommended as part of advanced trauma life support. Although balanced, it does not fully reflect the electrolyte distribution of the extracellular fluid. The sodium component is relatively low (130 mEq/L) and the chloride level high (109 mEq/L), making the SID significantly lower than plasma. Nevertheless, perioperative patients tend to lose more water than sodium as a result of insensible losses, and as all intravenous fluids dilute albumin, a slightly hyperchloremic solution is favored (Fig. 34–19). Hence studies that looked at the acid–base changes associated with lactated Ringer solution have reported few abnormalities.[34,64] The slight hypotonicity may worsen cerebral edema in patients with traumatic brain injury, although this has never been proven. In that circumstance, lactated Ringer solution is generally avoided. Because bicarbonate is unstable in electrolyte solutions, lactated Ringer solution is buffered in lactate. Lactate is metabolized by the liver to carbon dioxide and water. Care must be taken with this fluid in end-stage liver disease because the patient cannot metabolize lactate, which then functions as a strong ion, leading to metabolic acidosis. In addition, lactate may be converted to glucose, leading to hyperglycemia; consequently, this solution is

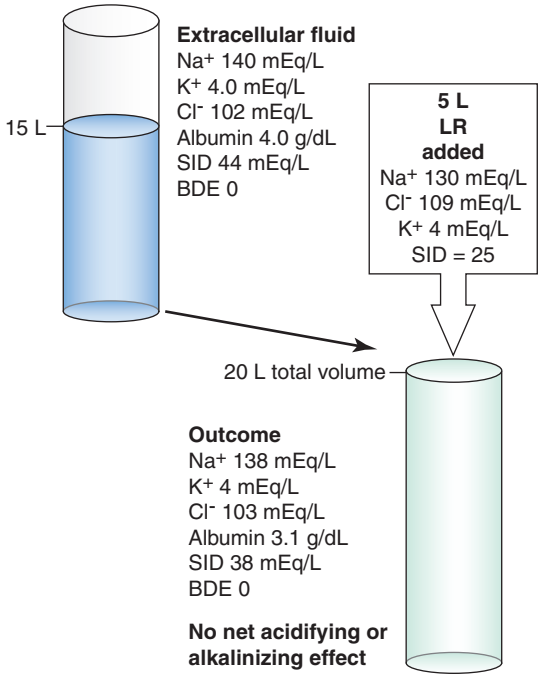

FIGURE 34–19. Extracellular fluid dilution with lactated Ringer solution. Although moderate volumes of this fluid have both acidifying effects (low strong ion difference) and alkalinizing effects (dilution of albumin), these effects offset each other and the net acid–base change is negligible.

rarely administered during diabetic crises.

An important issue with the use of lactated Ringer solution concerns its interaction with packed red cells for transfusion. First, lactated Ringer solution contains calcium, which may lead to clotting of the blood before it enters the bloodstream. Second, there is the theoretical concern that mixing this hypotonic fluid with blood will lead to hemolysis.

Balanced Salt Solutions

A variety of balanced salt solutions are available that attempt to mimic extracellular fluid content. The solutions available in North America are Normosol-R and Plasma-Lyte 148, which are essentially identical. Although attractive in conception, there is little published data to suggest that any of these fluids is superior to lactated Ringer solution. Plasma-Lyte comes in a number of different formulations and different buffering solutions. Normosol is buffered in acetate and gluconate, both weak anion buffers; this suggests a better acid–base profile in liver failure. Both Normosol and Plasma-Lyte 148 contain 140 mEq/L Na, 98 mEq/L Cl, and 5 mEq/L K, with a SID of 47. Administration of either of these solutions leads to progressive metabolic alkalosis (see Fig. 34–10). As calcium is not a component of either of these solutions, Normosol and Plasma-Lyte can be safely administered alongside blood.

In choosing a crystalloid solution to administer to a patient, the clinician must take into account the patient's hydration status, anticipated volume of crystalloid to be administered, and the potential side effects. For the majority of patients, a balanced salt solution such as lactated Ringer (Hartmann) solution should be administered. This has the advantages of relative isotonicity, an electrolyte composition similar to extracellular fluid, minimal impact on acid–base chemistry, universal familiarity, low cost, and a strong safety profile. Concerns about hyperkalemia and renal failure are probably overstated. Lactated Ringer solution is an excellent choice for both resuscitation and rehydration, resulting in neither hypernatremia nor hyperchloremia. Isotonic saline solutions should not be administered in large volume. If blood is to be administered through the same intravenous line as the crystalloid, Normosol-R or Plasma-Lyte 148 should be substituted for lactated Ringer solution.

Hypertonic Saline

Normal plasma osmolality is 280–295 mOsm/L. Any solution whose osmolality exceeds 310 mOsm/L is a hypertonic fluid. In practical terms, this refers to hypertonic saline and sodium bicarbonate solutions (Table 34–28). A variety of different hypertonic saline (HS) solutions are commercially available, the most commonly used are 1.8% HS, 3% HS, 7.5% HS, and 23.4% HS. The latter is not generally used as an intravenous fluid, but is, for example, injected into hydatid cysts.

There are two well-defined uses of hypertonic fluids. The first is intravascular volume expansion in patients in hypovolemic shock, as a means of low-volume high-impact resuscitation. The second is a corollary—intracellular volume depletion. This approach is widely used in neurosurgery and neurocritical care to reduce cerebral volume and intracranial pressure.

Hypertonic saline dramatically increases the osmotic pressure in the compartment into which it is injected. Water flows along the osmotic gradient into the compartment, expanding its volume for several hours. In the intravascular space, HS causes endothelial cell shrinkage, arteriolar dilation and reduced viscosity, thereby increasing flow.[120] It may also increase myocardial contractility, although there are conflicting data on this issue. The metabolic consequences of HS are hypernatremia, hyperosmolality, and hyperchloremic acidosis.[121] The degree of hypernatremia and hyperosmolality is lower than one would expect because of the relatively low volume administered.[122]

The logic behind the use of HS in shocked states is based on two observations: (a) isotonic crystalloids are very inefficient plasma volume expanders and result in significant tissue edema; and (b) hypertonic solutions expand the plasma volume by a significantly greater amount than the volume administered. Consequently, significant hemodynamic benefit accrues from relatively low volumes of fluid administered. This may be of particular use in combat situations, where the weight and size of medical supplies of great importance.

Numerous small studies and case reports suggest that patients have better hemodynamic profiles when given HS than if administered isotonic crystalloid.[123] No study of prehospital administration of HS has shown an overall statistically significant benefit. Indeed, published benefits accrue in statistically weaker subgroup analysis. For example Mattox et al. studied 422 patients in a randomized, double-blind, multicenter trial of prehospital HS with dextran versus an equal volume of isotonic crystalloid.[124] Patients who had been administered HS with dextran and who required surgery had improved survival. Wade et al. reported improved survival in patients with penetrating trauma who were administered HS.[125] A meta-analysis by the same group failed to demonstrate a benefit to using HS in trauma patients.[126] A more recent large clinical trial failed to demonstrate improved clinical outcomes at 6 months.[127] Currently, HS is not used in this setting. The major controversy in trauma is

TABLE 34–28.

Characteristics of Hypertonic Solutions

Fluid	Sodium Concentration (mEq/L)	Chlorine Concentration (mEq/L)	Bicarbonate Concentration (mEq/L)	Osmolality (mOsm/L)
0.9% NaCl	154	154	—	308
1.7% NaCl	291	291	—	582
3% NaCl	513	513	—	1026
7.5% NaCl	1283	1283	—	2566
10% NaCl	1712	1713	—	3424
23.4% NaCl	4004	4004	—	8008
Mannitol	—	—	—	1098
7.5% $NaHCO_3$	900	—	900	1600
8.4% $NaHCO_3$	1000	—	1000	2000

not the usefulness of HS, but the timing of use.

Hypertonic saline has been used in the perioperative care of cardiac surgical patients. To date, data has revealed only that HS reduces perioperative weight gain and has a diuretic effect.[128] HS may be an effective component of a goal-directed approach to fluid resuscitation, but this has yet to be studied.

The most frequent indication for HS use has been in traumatic brain injury.[129] Death from brain injury is primary, as a direct result of the event, or secondary, because of ischemic brain injury, cerebral edema, and brain herniation. Intracranial hypertension is the clinical manifestation of secondary brain injury. Under normal conditions, the blood–brain barrier limits bulk flow of fluid from cerebral capillaries into brain parenchyma by forming a semipermeable membrane, which is moderately permeable to water and relatively impermeable to small solutes and proteins. The balance of Starling forces (the transcapillary hydrostatic pressure gradient that is counterbalanced by an osmotic pressure gradient) determines the magnitude of flow into the brain substance.[128] In areas where the blood–brain barrier is disrupted, this balance disappears, facilitating the flow of proteins and electrolytes across the membrane.[129] Hydrostatic pressure becomes the dominant driving force for fluid movement from the intravascular space to brain tissue. This leads to brain swelling with an increase in intracranial pressure, a decrease in cerebral perfusion pressure, cerebral hypoxia, and secondary brain injury. Interruption of this continuing cycle of injury is the basis of treatment in traumatic brain injury.[130] Osmotherapy using mannitol has been the therapy of choice in traumatic brain injury for a generation. However, mannitol has several limitations, including hyperosmolality, osmotic diuresis leading to hypotension, and accumulation in brain tissue leading to reverse osmotic effects.

Hypertonic saline has reemerged over the past decade as an alternative to mannitol. Permeability of the blood–brain barrier to sodium is low. HS produces a significant osmotic gradient, leading to shrinkage of brain tissue (assuming that the blood–brain barrier is intact) and reduces intracranial pressure. HS improves overall systemic perfusion and, presumably, oxygen delivery, and may modulate the inflammatory response.[131]

FLUID REPLACEMENT COLLOIDS

Colloids and Colloid Oncotic Pressure

For the majority of patients undergoing surgery and anesthesia, gentle hydration with crystalloid repletes dehydration losses and mild blood losses. However, significant tissue injury (including major surgery) leads to a slightly different paradigm that involves classic inflammatory stress response associated with increased capillary permeability. This facilitates the extravasation of intravascular fluid into the extracellular space (see Fig. 34–17). Fluid sequestered in this way does not remobilize until the stress response resolves. In these circumstances, up to 80% of crystalloid solutions used as volume replacement collect in extravascular tissues (see Fig. 34–16). This leads to weight gain and tissue edema, particularly in lax tissues and in the abdomen. Oxygen delivery is reduced and the cumulative effect may be worsened perioperative outcomes.[16] In addition to increased capillary permeability, there is a reduction in plasma oncotic pressure in surgery, trauma, and critical illness as a result of reduced circulating albumin concentrations, because of dilution, extravasation, and reduced hepatic production (negative acute-phase response).

High-molecular-weight solutions are use widely as plasma substitutes. These have the purported advantages of remaining in the intravascular space, plugging leaky capillaries and increasing colloid oncotic pressure, thus expanding intravascular volume. As compared to crystalloid solutions, lower volumes are required to achieve hemodynamic goals.[16]

Colloids are homogenous noncrystalline substances, consisting of large molecules or ultramicroscopic particles of one substance dispersed through a second substance.[132] Colloid solutions remain in the intravascular space because of their large molecular size, which leads to relative membrane impermeability (Fig. 34–20). The principal biologic colloids are plasma proteins, primarily albumin and globulin. These proteins impart two distinct forces: an osmotic pressure and a Gibbs-Donnan effect. This refers to an electrochemical effect of the protein: the protein is negatively charged and positively charged cations are held in plasma. The combined effect is a pressure that draws water out of the interstitium and into the plasma: the colloid oncotic pressure (COP). The COP is approximately 50% greater than would be expected from the plasma proteins alone.

Albumin, with a molecular weight of 69,000 kDa and a significant negative charge, normally accounts for nearly two-thirds of the plasma COP. Serum albumin falls in the perioperative period and during inflammation from tissue injury or sepsis. Many clinicians mistakenly ascribe hypoalbuminemia as the cause of cause of the edema of critical illness. However, edema occurs secondary to increased capillary permeability and fluid overload. In addition, albumin production falls as a consequence of "hepatic reprioritization" toward inflammatory proteins. The result is maintenance of COP despite low levels of albumin.[39] Thus serum or plasma protein concentration is an unreliable predictor of COP. Globulins are larger molecules than albumin, and impart significantly less osmotic effects. COP can be measured

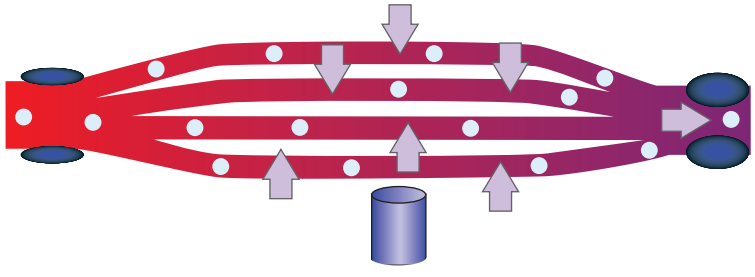

FIGURE 34–20. Colloid therapy. Colloids are hypothesized to remain intravascular despite the presence of widespread capillary leak. Fluid (represented by *pink arrows*) is drawn back into the circulation as a consequence of increased colloid oncotic pressure.

in a laboratory using a colloid osmometer (i.e., oncometer); however, this is rarely measured in modern clinical practice.

It is important to note that although colloids have an important role in maintaining intravascular volume, the oncotic effect is significantly less important vis-à-vis extracellular volume than the osmotic effect of electrolytes, such as sodium or chloride. This is a result of the significantly lower total number of osmotically active particles involved. The COP is only one of several factors that determine the fluid flux across a vascular membrane. The Starling equation describes the movement of fluid across the capillary endothelium:

$$Qf = k1[(P_c - P_i) - \delta(\pi_c - \pi_i)]$$

where Qf indicates transcapillary fluid flux, k1 is the fluid filtration coefficient, P_c indicates capillary hydrostatic pressure, P_i indicates interstitial hydrostatic pressure, π_c indicates intravascular oncotic pressure, π_i indicates interstitial oncotic pressure, and is the reflection coefficient.

The reflection coefficient in the Starling equation is a function of the permeability and surface area of the capillary bed. The numeric value varies from 0 to 1. For example, the reflection coefficient of the pulmonary endothelium is normally 0.7, but may fall to 0.3 or 0.4 in conditions that increase microvascular permeability.

Increased Capillary Permeability

The forces responsible for normal or abnormal fluid flux are the net colloid and hydrostatic pressures on either side of the capillary membrane (Fig. 34–21). The capillary hydrostatic pressure is the driving force for fluid moving out of the intravascular compartment. Because the interstitial hydrostatic pressure is usually negative or zero, the plasma COP is the force primarily responsible for counterbalancing the capillary hydrostatic pressure. Any increment in the forces that enhance filtration may induce changes that then retard further transcapillary fluid loss (e.g., increased tissue hydrostatic pressure, increased plasma COP, and decreased tissue COP). In addition, the lymphatic system provides a means for returning filtered capillary water and protein back to the intravascular compartment. The rate of lymphatic flow appears linked to the filtration characteristics of the capillary wall and interstitium, and the net flow of transcapillary fluid. When these protective adaptations are overwhelmed, the rate of interstitial fluid accumulation may surpass the rate of lymphatic drainage and edema will result.

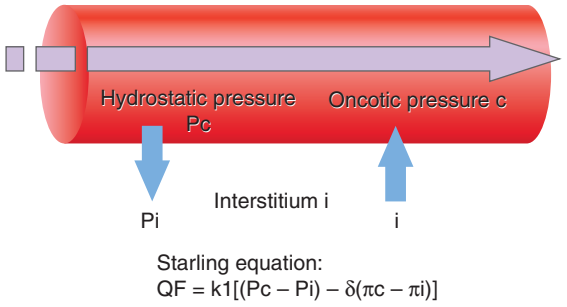

FIGURE 34–21. The Starling hypothesis.

During tissue injury, sepsis, or surgery, there is a significant increase in capillary permeability, with leakage of protein-rich fluid into the interstitial space (see Fig. 34–17). Thus the reflection coefficient of the Starling equation changes and fluid accumulates in lax tissues, leading to edema. The rate of edema formation varies linearly with the volume of crystalloid administered. Colloidal solutions (Table 34–29) are purported to remain intravascular in conditions of widespread capillary leak (see Fig. 34–20). There is some evidence to support this contention.[133,134] This leads to more rapid achievement of hemodynamic goals, volume expansion equal to or greater than the volume administered, and reduction in tissue edema.

Despite these logical arguments there is a strong counterargument that colloid solutions are expensive, probably leak into the extracellular space, and impact blood coagulation. Three influential meta-analyses were published in the late 1990s that suggested that colloid solutions may actually worsen patient outcomes.[135–137] There is reason to be skeptical of the results of these reviews. A myriad of compounds labelled "colloid" were included, many no longer administered. The studies accrued data over a 30-year period during which fundamental changes occurred in the practices of anesthesia, trauma, and critical care. Moreover, the end points listed in the reviews (principally mortality) were not necessarily end points measured in the studies. The majority of these studies were not carried out in the controlled operating room environment, did not use specific goals for resuscitation, and tended to compare isolated crystalloid resuscitation with isolated colloid resuscitation, not in combination. Most studies of colloids have compared one agent against another, rather than against crystalloid solutions.

There is an emerging body of evidence to support the limited use of colloid solutions in perioperative medicine. These data are discussed in the final section of this chapter. The following sections review the most frequently prescribed colloid solutions.

TABLE 34–29.

Properties of Colloid Solutions

Fluid	Weight (Average Molecular Weight)	Number (Average Molecular Weight)	Colloid Osmotic
5% Albumin	69,000	69,000	19
25% Albumin	69,000	69,000	78
Plasma	119,000	88,000	21
6% Hetastarch	450,000	70,000	30
10% Pentastarch	264,000	63,000	40
6% Pentafraction	280,000	120,000	28
10% Dextran 40	40,000	26,000	148
6% Dextran 70	70,000	41,000	60

Intravenous Albumin

Albumin is commercially available in concentrations of 5% (250-mL and 500-mL vials) and 25% (50-mL and 100-mL vials). These monodisperse solutions are derived from pooled human blood, serum, or plasma, and have been pasteurized at 140°F (60°C) for 10 hours. In addition, these preparations contain no clinically important antibodies and may be administered without regard to the recipient's blood group or Rh factor. The more frequently used 5% solution contains 50 mg of albumin per milliliter of physiologic salt solution, whereas the 25% solution has an albumin concentration of 250 mg/mL. All commercial albumin products contain 130–160 mEq of sodium per liter of solution. The 5% solution is isoncotic with respect to human plasma; the 25% solution is 4–5 times more oncotically active than is an equivalent volume of normal plasma. Albumin has a very low incidence of allergic reactions (0.5–1%) and these are usually mild (rash, fever, chills, nausea). Albumin solutions do not appear to directly alter blood coagulation.

Albumin administration is associated with a rapid but unpredictable expansion of the plasma volume. In profoundly hypovolemic patients the interstitial compartment should be resuscitated first so the use of albumin should follow initial administration of crystalloid. Albumin has been widely used to minimize weight gain, prevent pulmonary edema, diminish ascites and reduce tissue edema. There is some evidence that this agent may have some impact on improving organ function and facilitating enteral nutrition.[138] Beyond this there is no evidence that albumin reduces mortality. Previous concerns that albumin may increase mortality,[139] appear to be unfounded. The Saline vs. Albumin Fluid Evaluation (SAFE) study, an Australian randomized controlled trial that recruited >7000 patients, showed no differences in outcome between patients treated with 4% albumin as their resuscitation fluid and those receiving saline.[140]

Dextrans

Dextrans are high-molecular-weight *d*-glucose polymers joined largely by α-1,6 bonds into linear-branched macromolecules. They are biosynthesized commercially from sucrose by the B512 strain of *Leuconostoc mesenteroides*, using the enzyme dextran sucrase. For clinical purposes, dextrans are designated by their weight-average molecular weights, because these solutions are polydisperse colloids containing both large and small molecules. Dextran 40, with a weight-average molecular weight of 40,000 Da (range: 10,000–90,000 Da), is available in 0.9% sodium chloride or 5% dextrose, as is dextran 70, which has a weight-average molecular weight of 70,000 Da (range: 20,000–200,000 Da). Dextrans have a strong colloidal osmotic effect: 1 g of dextran 40 retains 30 mL of fluid.

Following administration, the lower-molecular-weight particles are rapidly cleared by the kidney. The threshold for the renal excretion of dextran is a molecular weight of roughly 50,000 Da. Particles weighing less than 15,000 Da are rapidly filtered and not reabsorbed. The remainder are excreted through the gut or phagocytosed by cells of the reticuloendothelial system. Within 24 hours after infusion, approximately 70% of dextran 40 and 50% of dextran 70 is excreted unchanged in the urine. Severe renal dysfunction (creatinine clearance <30 mL/min) prolongs the intravascular half-life and causes an accumulation of the smaller dextran molecules.

In most instances the dextran preparations produce an expansion of plasma volume that is approximately equal to the volume of solution infused. Acutely, dextran 40 will produce a greater increment in plasma volume as compared with dextran 70, because of the greater number of molecules and the more powerful osmotic effect. Intravascular volume expansion is generally more prolonged with dextran 70.

Dextrans are known to have a significant impact on coagulation. When more than 1.5 g/kg is administered, bleeding time is prolonged. The observed hemostatic abnormality is similar to that seen in von Willebrand syndrome. Dextran also impairs the polymerization of fibrin. Dextrans have been traditionally used for postoperative thromboembolic prophylaxis in vascular and plastic and reconstructive surgery.

Dextran 40 may interfere with the cross-matching of blood if a proteolytic enzyme technique is employed. Dextran 70 can induce erythrocyte aggregation and rouleaux formation that may also impede cross-matching. Both solutions can produce a factitious hyperglycemia, and the lower-molecular-weight dextran solution can increase serum transaminase (aspartate aminotransferase and alanine aminotransferase) levels. Dextran 40 can produce highly viscous urine that may actually obstruct the renal tubules and cause acute renal failure.

Dextrans are associated with a relatively high incidence of anaphylactoid and anaphylactic reactions. Anaphylactoid reactions are caused by dextran-reactive immunoglobulin G antibodies.[141] The best available data suggests that the risk of a major anaphylactoid reaction is 13 per 100,000 doses sold for dextran 40 and 25 per 100,000 doses sold for dextran 70.[142] Severe anaphylactoid reactions can nearly always prevented by preinfusing dextran 1 (Promit, Meda AB Pharmaceuticals, Solna, Sweden), a low-molecular-weight (1000 Da) dextran moiety.[141] Dextran 1 acts to prevent severe anaphylactoid reactions by competitively inhibiting dextran from binding to IgG antibodies.

Hydroxyethyl Starches

Hydroxyethyl starches (hetastarch) are modified natural polysaccharides, derived from amylopectin, that structurally resemble glycogen. Solutions of starch are unstable as they are rapidly hydrolyzed by α-amylase. The solution is stabilized by hydroxylethylation. This results in hydroxyethyl substitutions, predominantly at carbon 2 (c2), but also at c3 and c6, in the glucose ring (Fig. 34–22). The pharmacokinetics of these starches is determined by the degree and type of hydroxylation. A higher c2/6 substitution ratio results in slower enzymatic degradation. The molecular weight of the compound impacts its side effects. The main route of elimination is urinary. A fraction is taken up by the reticuloendothelial system from whence it is slowly eliminated. Hetastarches contain molecules of variable molecular weights, the average weight is usually that listed. After infusion of hetastarch the dispersion of molecular weights changes: first the small molecules are rapidly eliminated, then the large molecules are partially hydrolyzed to middle-size molecules.

Hetastarch products can be divided into three classes by their weight-averaged molecular weight: high molecular weight (450–480 kDa), medium molecular weight (approximately 200 kDa),

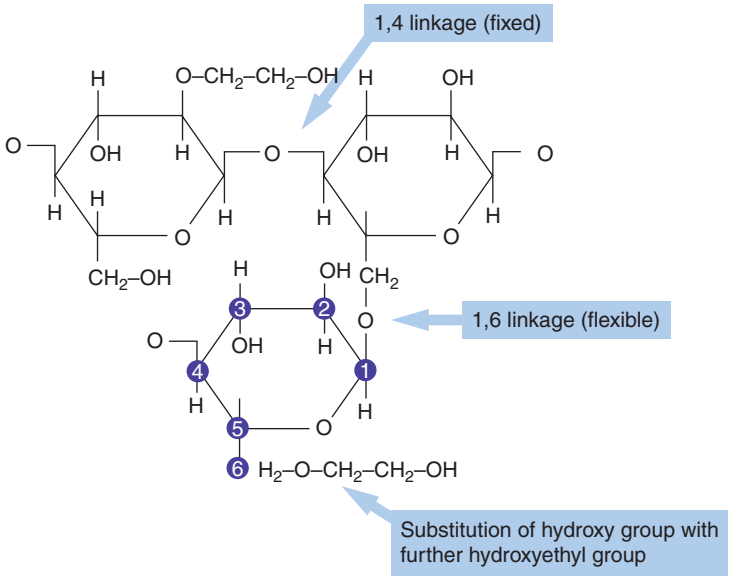

FIGURE 34–22. Hydroxyethyl starch structure.

and low molecular weight (70–130 kDa). Examples of commercially available starches are 6% high-molecular-weight hetastarch in saline (Hespan), 6% high-molecular-weight hetastarch in balanced electrolytes (Hextend), medium-molecular-weight pentastarch in saline (Pentaspan, EloHAES, HAES-steril), and low-molecular-weight tetrastarch in saline (Voluven).

The most commonly used hydroxyethyl starch in the United States, Hespan, is a high-molecular-weight hetastarch, with an average molecular weight of 450,000 Da and a number-average molecular weight of 70,000 Da; 80% of the polymers fall in the range of 30,000–2,400,000 Da. This hetastarch is usually formulated in 0.9% sodium chloride. The COP of this solution is approximately 30 mm Hg, and each gram of hetastarch has a water-binding capacity of 20 mL. On average, 46% and 64% of the dose is excreted in the urine within 2 and 8 days, respectively. Average terminal half life is 17 days. Plasma volume expansion persists for at least 48 hours,[143] with 40% of the peak effect persisting after 24 hours. Hetastarch produces a significantly greater increase in plasma COP than does an equal volume of 5% albumin.

Serum amylase may increase significantly after infusion of hetastarch because of the formation of a stable hetastarch-amylase complex that retards amylase excretion. Allergic reactions to hetastarch are uncommon.

Hetastarch solutions have varying effects on coagulation that are dependent on the molecular weight of the polypeptide molecule. This appears to occur principally with high-molecular-weight hetastarches that dilute coagulation factors and induce abnormalities on thromboelastography, but not standard coagulation tests. Hetastarch appears to induce an abnormality of platelet function by impairing von Willebrand factor and factor VIIIc. The effect on hemostasis appears to be dose related. Large volumes of hetastarch in vitro and in vivo produce progressive abnormalities in thrombelastogram studies. However, it is unclear if this translates into an increased risk of perioperative bleeding. Many clinicians assert that the dose of hetastarch should be limited to 20 mL/kg/d. Lower-molecular-weight hetastarch and pentastarch solutions appear to be associated with a reduced risk of coagulopathy,[144] as does formulation in balanced salt solution rather than saline.[145]

Gelatins

Gelatin solutions are widely used in Europe, in particular in the British Isles. Currently, no gelatin is licensed for administration in the United States. The colloidal compounds are derived from hydrolysis of bovine collagen. Gelatins are medium-size compounds, with a molecular weight of 30,000–40,000 Da. The two most common preparations are succinylated gelatin (Gelofusin), presented in a carrier solution of Na 154 mmol and Cl 120 mmol, and urea-linked gelatin (Hemaccel), presented in a carrier solution of isotonic saline plus K 5.1 mmol and Ca 6.25 mmol/L. Care should be used when administering the latter product in patients who require blood transfusion. The presence of calcium in the fluid-giving set may cause blood coagulation. Administration of gelatin is followed by intravascular volume expansion of an equivalent volume, although after 4 hours, up to 50% of the volume expansion will have been lost. Thus use of gelatins is limited to cases in which rapid volume expansion is required, but the source of the problem is rapidly reversible. An example of this situation would be acute vasoplegia associated with epidural analgesia.

The pharmacokinetics of gelatins are not well understood. Gelatins are cleared principally by glomerular filtration, but may also be broken down by proteases in the reticuloendothelial system. The impact of these compounds of coagulation is unclear; however, urea-bridge gelatins may result in a reduction of platelet aggregation. The incidence of allergic reactions is relatively high compared with hydroxyethyl starches. The bovine origin of these products has led to significant discussion about the risk of transmission of bovine spongiform encephalopathy to humans.[146] However, there are no reported cases of new variant Creutzfeldt-Jakob disease associated with pharmaceutical-grade gelatins to date.

MONITORING FLUID REPLACEMENT

Limitations of Crystalloid Resuscitation

Traditional approaches to perioperative fluid management had emphasized the use of careful calculation of fasting fluid deficits, insensible losses, third space loss, blood loss, and maintenance requirements. Fluid replacement regimens have been formulaic, centered on crystalloid resuscitation in the belief that dehydration and excessive third space loss will lead to adverse outcomes. However, there is an emerging movement that questions these assumptions.[16] For example, the human body evolved many processes to sustain itself in the face of inadequate hydration. Hence the renin–angiotensin–aldosterone–vasopressin axis developed to maintain homeostasis until a source of water became

available. Conversely, the human body does not appear to be able to store water. Consequently, few mechanisms appear to be in place to deal with significant hypervolemia. Moreover, advocates of aggressive crystalloid resuscitation have tended to ignore the impact of this fluid on tissue compartments (a dramatic increase in interstitial fluid volume), water dissociation (acid–base balance), electrolyte composition, colloid balance, and coagulation. Proponents of an alternative system for perioperative fluid balance, goal-directed resuscitation, use dynamic flow-directed physiologic end points that emphasize timing rather than total volume for fluid administration.

Resuscitation with crystalloid fluids may actually reduce oxygen delivery and tissue perfusion. Funk et al.[147] undertook a laboratory experiment of isovolemic hemodilution of awake Syrian golden hamsters. The hamsters were given either lactated Ringer solution or dextran 60 to replace blood loss. Four times the volume of blood loss was replaced with lactated Ringer solution to maintain mean arterial pressure, central venous pressure, and heart rate. Tissue perfusion and Pao_2 were unchanged in the colloid group, but reduced by 62% and 58%, respectively, in the crystalloid group. Lang et al. investigated the impact of colloid fluid replacement versus crystalloid therapy on tissue oxygen tension in major abdominal surgery.[148] Forty-two patients were randomized to receive 6% hydroxyethyl starch plus lactated Ringer solution or lactated Ringer solution alone for 24 hours targeted to a central venous pressure of 8–12 mm Hg. The investigators measured tissue oxygen tension in the deltoid muscle: a LICOX oxygen monitoring device was placed after induction of anesthesia. Patients in the crystalloid group had received significantly more fluid by the end of surgery (5940 mL ± 1910 mL vs. 3920 mL ± 1350 mL, $p < 0.05$) and at the end of 24 hours (11,740 ± 2630 mL vs. 5950 mL ± 800mL, $p < 0.05$). The patients in the combined crystalloid–colloid group had significantly greater tissue perfusion (oxygen tension increased from baseline) than did the crystalloid-only group (oxygen tension reduced from baseline).

An ideal resuscitative fluid would maintain intravascular volume without expanding the interstitial space. Ernest et al. investigated the volume of distribution of NaCl 0.9% versus albumin 55 in cardiac surgical patients.[149] Plasma and extracellular fluid volumes were measured by dilution of radiolabeled albumin and sodium. Administration of isotonic saline increased plasma volume by 9 ± 23% of the volume infused. Administration of 5% albumin increased plasma volume by 52 ± 84% of the volume infused. Albumin increased cardiac index significantly more than saline, and had an equal impact of hemoglobin dilution. In the saline treatment group, the mean net fluid balance (fluid infusion + fluid losses) was approximately double the mean increase in extracellular fluid volume, which on average was distributed equally between the plasma volume (PV) and interstitial fluid volume (ISFV). In contrast, in the albumin treatment group, the net fluid balance approximated the mean increase in extracellular fluid volume, which approximated the mean increase in PV.

The tendency for crystalloids to extravasate may lead to relative hypoperfusion. Wilkes et al. studied saline-based intravenous fluids (crystalloid and hetastarch) versus balanced salt solution-based fluids (crystalloid and hetastarch) on acid–base status and gut perfusion, which were estimated using gastric tonometry.[34] Patients who received saline were significantly more acidotic and had a lower gastric mucosal pH (indicative of gut perfusion), compared with the patients receiving balanced salt solutions. This was strongly related to increases in serum chloride.

Pro- and Antiinflammatory Effects of Intravenous Fluids

Conventional wisdom holds that intravenous fluids impart adverse effects consequent of increases in hydrostatic pressure, leading to pulmonary edema, tissue edema, and interference with oxygen perfusion into tissues. However, there is emerging evidence that intravenous fluids may have indigenous pro- and antiinflammatory properties. In a pig model of volume-controlled hemorrhagic shock, Rhee et al. demonstrated a significant increase in neutrophil activation and oxidative burst activity, associated with the administration of lactated Ringer solution.[150] This solution activated inflammation regardless of whether blood was shed or not. This did not occur when volume was replaced with whole blood or 7.5% hypertonic saline. Similar findings were reported with isotonic saline, dextran, and hydroxyethyl starch but not with albumin (5% or 25%), blood, or anesthesia.[151]

Lactated Ringer solution administration was associated with expression of adhesion molecules that were increased in lung and spleen whether or not hemorrhage took place. This was not seen if the animal was either not resuscitated or was resuscitated with fresh blood.[152] However, when preceded by shock, lactated Ringer resuscitation was associated with histologic evidence of pulmonary edema and inflammation.[152]

Ketone-buffered intravenous fluids such as ethyl pyruvate may have opposite antiinflammatory effects. In a rat model, the use of ethyl pyruvate versus lactated Ringer solution resulted in significantly less pulmonary cellular apoptosis.[151]

Flow/Goal-Directed Volume Resuscitation

As a result of significant limitations regarding formulaic approaches to fluid resuscitation, concerns about overresuscitation, and the need for a scientific approach based on the dynamics of the stress response, there is an emerging body of evidence supporting the use of goal-directed volume resuscitation that combines crystalloid and colloid in perioperative medicine and critical illness.[153] The modern approach to goal-directed volume resuscitation involves the use of specific "normal" end points of blood flow and tissue perfusion.

The goal-directed approach involves the use of specific monitors that measure input (fluid loading), tissue blood flow, and response (Fig. 34–23). Arterial and central lines are placed and goals for resuscitation are set: these include a central venous pressure (CVP) of 8–12 cm H_2O, a mean arterial pressure (MAP) of >65 mm Hg, and, if the appropriate device(s) is(are) placed, a mixed venous oxygen saturation of >70% and a stroke volume of between 0.7 and 1.0 mL/kg (ideal body weight). The purpose of stroke volume monitoring is to construct Starling curves, using one of a variety of surrogates of end-diastolic volume as an index of cardiac preload. These include central venous pressure, pulmonary artery oc-

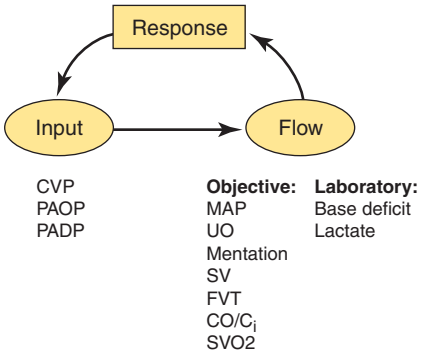

FIGURE 34–23. Principles of goal-directed resuscitation. FIGURE 34–24. Stroke volume monitoring.

clusion pressure, and pulmonary artery diastolic pressure (Fig. 34–24). Changes in stroke volume are more sensitive to changes in circulating volume than changes in cardiac output or cardiac index.[10]

A variety of other devices that measure surrogates of stroke volume or cardiac output are available. These include esophageal Doppler monitors, lithium dilution cardiac output, Fick principle CO_2 rebreathing cardiac output (noninvasive cardiac output), bioimpedance cardiac output, and echocardiography. An alternative approach is to directly measure tissue perfusion, or measure surrogates of blood flow. This includes gastric tonometry and tissue oxygen monitoring probes, such as LICOX.

Central venous pressure can be used to ensure precise perioperative hydration. Moretti et al.[154] randomized 90 patients who were undergoing major elective (noncardiac surgery) to receive either 6% hetastarch in normal saline, 6% hetastarch in balanced salt solution, or lactated Ringer solution on the basis of a resuscitation algorithm. CVP was used for therapeutic goals (Fig. 34–25). Patients who received colloid received significantly less fluid than did those who received crystalloid alone and had significantly lower incidence of postoperative nausea and vomiting, requirement for rescue antiemetics, severe pain, periorbital edema, and double vision.

A number of studies have used esophageal Doppler monitoring (EDM) stroke volume to guide perioperative fluid administration. Mythen and Webb[155] studied 60 patients who were undergoing cardiac surgery and randomly assigned to a protocol that included 200-mL boluses of colloid throughout to specified stroke volume using EDM or control. The volume administration approach in the control group was at the anesthesiologist's discretion. Patients in the EDM group had higher splanchnic perfusion, and at the end of surgery, fewer major complications and shorter intensive care and hospital stays.

Gan et al.[156] studied 100 patients who were undergoing major elective surgery with an anticipated blood loss of greater than 500 mL and who were randomly assigned to a control or protocol group. The protocol included EDM-guided plasma volume expansion (with colloid) to maximize stroke volume. The protocol group had a significantly shorter duration of hospital stay, tolerated solid oral food earlier, and had significantly less postoperative nausea and vomiting.

Venn et al.[157] randomized 90 patients into three groups: one that received conventional fluid management (based on formulae), a second that received colloid fluid challenges with a CVP line, and a third that received colloid fluid challenges with EDM. Patients were deemed medically fit for discharge more rapidly in the esophageal Doppler monitored group than in the CVP group, and in the CVP group than in the conventional fluid management group.

Sinclair and Singer[158] randomized 40 patients who were undergoing repair of proximal femoral fracture to receive conventional fluid management versus EDM and colloid fluid challenges, again to a specific stroke volume goal. Patients in the esophageal Doppler monitored group were deemed medically fit for discharge earlier than those in the conventional therapy group.

Wakeling et al.[159] randomized 128 consecutive patients who were undergoing colorectal surgery to EDM-guid-

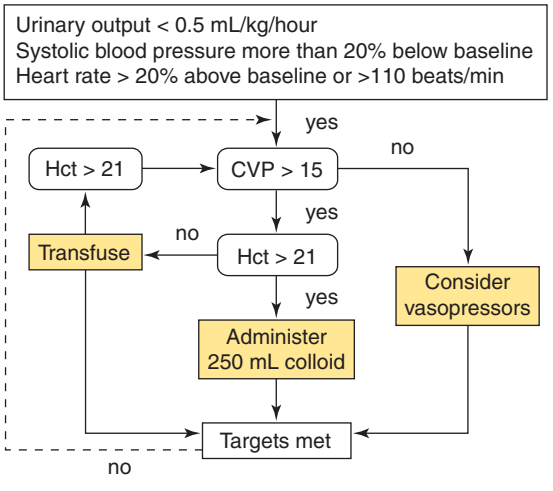

FIGURE 34–25. Use of central venous pressure as part of goal-directed volume resuscitation.

ed or CVP-based (conventional) intraoperative fluid management. The CVP-guided protocol aimed at a CVP of 12–15 mm Hg. There was a significant reduction in postoperative stay, shorter time to resuming full diet, and lower incidence of gastrointestinal morbidity in the patients randomized to EDM-guided therapy.

Noblett et al.[160] recruited 108 patients who were undergoing elective colorectal resection and inserted esophageal Doppler monitors in all. The patients were randomized into fluid therapy that was at the discretion of the anesthesiologist versus protocolized fluid therapy that included colloid boluses. The intervention group had a reduced postoperative hospital stay, fewer intermediate or major postoperative complications, and tolerated diet earlier. In addition, there was a reduced rise in perioperative level of the cytokine interleukin 6 in the intervention group.

An alternative approach to flow monitoring, derived from the seminal work of Shoemaker,[161] is to use oxygen consumption (or its surrogate, mixed venous oxygen saturation [SVO_2]) to determine tissue oxygen flow. Low SVO_2 is indicative of excessive extraction per unit volume, which is strongly suggestive of hypovolemia. Rivers et al.[162] studied early goal-directed therapy in sepsis, in 263 patients who were randomized to "standard" therapy versus aggressive goal-directed therapy that included the use of an oximetric central venous pressure line. This measured SVO_2 in the superior vena cava distribution. The patients in the study group received significantly more fluid than did patients in the control group in the first 6 hours, more red cell transfusions overall, and an equivalent volume of intravenous fluid over the first 72 hours. There was a 16% decrease in 28-day mortality (number needed to treat: 6). The implication of this study is that early aggressive volume resuscitation ensures tissue blood flow. Once goals are met, further resuscitation is not helpful and may be harmful (Fig. 34–26).

Taking these data together, it appears that perioperative patients who are undergoing major nonvascular surgery, require early, aggressive, goal-targeted volume resuscitation. Stroke volume monitoring appears to be more effective than CVP, which appears to be more effective than the use of standard formulaic approaches. Patients appear to do better if resuscitated on the day of surgery, and if colloids are administered to achieve volume goals (Fig. 34–27).

Fluid Restriction

One question that arises from these data is whether the convention of administering postoperative maintenance fluids to patients who have undergone major abdominal surgery is helpful or hurtful. Brandstrup et al.[163] performed a randomized, observer-blinded, multicenter trial (8 Danish Hospitals) that included 172 patients randomized to restrictive or standard perioperative fluid regimen. All of the patients underwent colorectal surgery. The restrictive therapy received no volume preloading, no adjustment for third space loss, and hetastarch or blood to replace blood losses. Postoperative fluid management was adjusted to prevent weight gain of more than 1 kg. The standard therapy group received formula-driven volume replacement. There was a significant reduction in postoperative (including cardiopulmonary and wound healing) complications in the restrictive therapy group.

In another study, 152 patients, with an American Society of Anesthesiologists physical status of I–III who were undergoing elective intraabdominal surgery, were randomized to receive intraoperatively either liberal or restrictive amounts of lactated Ringer solution.[164] The liberal protocol group received 10 mL/kg followed by 12 mL/kg/h. The restrictive protocol group received 4 mL/kg/h and no bolus. The majority of patients underwent lower gastrointestinal surgery. The median volume of fluid administered to the restrictive group was 1230 mL versus 3670 mL in the liberal group. The number of complications was lower in the restrictive protocol group. Return of bowel function was later in that group and their hospital stay was longer.

Another group randomized 10 patients who were undergoing surgery for colonic cancer to receive liberal postoperative fluids (≤ 3L water and 154 mmol sodium per day) and 10 to receive a restricted intake (≤ 2 L water and 77 mmol sodium per day). Patients in the fluid-restriction group, that is, a weight gain of less than 3 kg, had an earlier return of gastrointestinal function and shorter duration of hospital stay. A similar study by Tambyraja et al. demonstrated a significant relationship between postoperative sodium and water gain and complications after colonic surgery.[165]

Summary

Perioperative fluid management is a complex process that must take into account the patient's preexisting disease, preoperative volume status, physiologic reserve, degree of perioperative stress, and perioperative fluid losses.

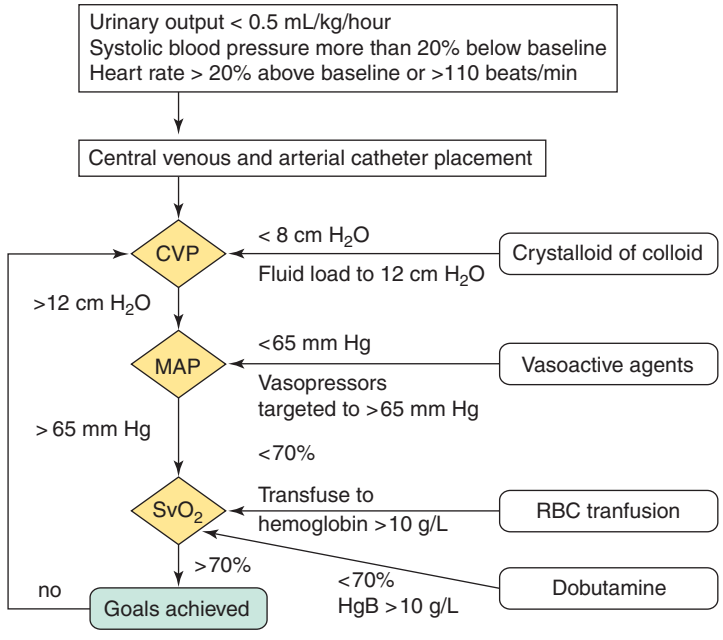

FIGURE 34–26. Use of SVO_2 (mixed venous oxygen saturation) as part of goal-directed resuscitation.

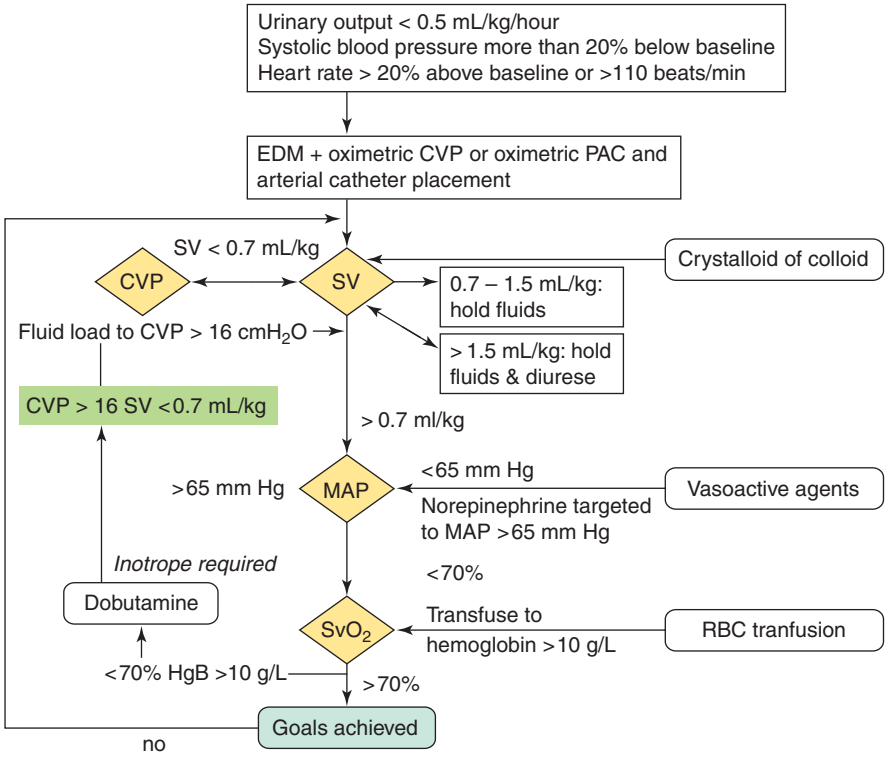

FIGURE 34–27. Use of stroke volume and SVO_2 (mixed venous oxygen saturation) as part of goal-directed resuscitation. CVP, central venous pressure; EDM, esophageal Doppler monitor; MAP, mean arterial pressure; PAC, pulmonary artery catheter; SV, stroke volume .

For the majority of patients, prehydration with 2 mL/kg/h fasting or 30 mL/kg crystalloid, prior to or at the time of induction, will reduce postoperative nausea, vomiting, pain, and lightheadedness. For patients who are undergoing minor surgery or ambulatory surgery without appreciable blood loss, this is all the intravenous fluid that is required. There is little data available with respect to youthful patients with low American Society of Anesthesiologists physical status scores. A formula-based approach to perioperative fluid management appears reasonable for low-risk patients who are undergoing moderately traumatic surgery (e.g., laparoscopic operations, peripheral vascular surgery, neurosurgery). However, management of patients who are undergoing extensive or high-risk surgery requires a more elegant approach. Patients who underwent bowel resection appear to have worse outcomes when overresuscitated with crystalloid. Patients who underwent major vascular surgery, hip surgery, or extensive upper abdominal operations appear to benefit from a dynamic, flow-based, goal-directed approach to volume resuscitation. This can be achieved (in increasing order of invasiveness) using CVP (volume responsiveness; see Fig. 34–25); CVP and mixed venous oxygen saturation (volume responsiveness and tissue flow; see Fig. 34–26) or stroke volume and mixed venous oxygen saturation (dynamic volume responsiveness and tissue flow; see Fig. 34–27). In the latter approach, stroke volume is targeted to 0.7–1 mL/kg of ideal body weight. A stroke volume in excess of 1.0 mL/kg is indicative of overresuscitation and fluids are withheld until the stroke volume drifts back into normal range. If the stroke volume exceeds 1.5 mL/kg, serious consideration should be given to the administration of diuretics. Respiratory pulse pressure variation is gaining popularity and may emerge as a simple surrogate for stroke volume.[166] Intraoperative blood loss should be replaced 1:1 with blood or colloid or with 4:1 with crystalloid; crystalloid requirements to replace blood increase geometrically as blood loss continues. Patient outcomes appear to be optimal when the patient is resuscitated fully on the day of surgery or injury and resuscitation efforts rapidly decelerate.

Postoperative fluid management remains a controversial area. Although transcompartmental fluid sequestration continues for a day or two following surgery or injury (longer if a septic source remains uncontrolled), continued administration of crystalloid leads to increasing tissue edema and weight gain. Conversely, intravascular dehydration may lead to hypoperfusion organ injury, particularly to the kidney. A prudent approach to postoperative fluid administration is recommended. Maintenance fluids are probably unnecessary, unless the period of fasting is prolonged. Evidence of tissue hypoperfusion, as evidenced by low urinary output, low SVO_2, or low stroke volume, should be treated with fluid boluses, keeping in mind that lower volumes of colloid are required to achieve the same hemodynamic goals. Once spontaneous diuresis commences, continuous fluid infusions should be discontinued and attention directed toward repletion of intracellular ions, potassium, magnesium, and phosphate. A reasonable goal for perioperative fluid management is restoration of normal body weight by day 7 postoperatively.

SECTION B

MANAGING THE AIRWAY

CHAPTER 35

Airway Management

P. Allan Klock, Jr., MD, and
Andranik Ovassapian, MD

The airway conducts gases between the atmosphere and the alveoli. Effective airway management keeps the airway free of secretions, contamination, and obstruction while minimizing complications. Critical illness often causes weakness and obtundation sufficient to impair air exchange. The sedative, narcotic, anesthetic, and relaxant drugs that facilitate surgery predictably compromise airway patency and protection. The Closed Claims Study of the American Society of Anesthesiologists (ASA) Committee on Professional Liability reveals that tragic and costly complications of anesthesia frequently are tied to problematic airway management.[1] Some of the most important roles of the anesthesiologist include ensuring that the patient is adequately oxygenated and ventilated and that airway patency is maintained.

Mastery of the airway demands familiarity with normal and variant anatomy and the alterations caused by abnormal states. Essential attributes for the expert airway manager include knowledge, sound judgment, skills for a range of techniques, and planning for conceivable contingencies.[2,3]

APPLIED ANATOMY OF THE AIRWAY

To ensure adequate gas exchange, anesthesiologists must continually assess the patency and alignment of the air passages and their ability to accommodate airway devices. Key are the relationships of the pharynx to surrounding structures, the architecture of the larynx, and the mobility of the tissues.

The Pharynx

Extending from the sphenoid bone to C6, the pharynx parallels the vertebrae, which are covered by the anterior longitudinal ligament and fascial layers beneath the mucosa and constrictor muscles.[3,4] Between the more

KEY POINTS

1. Tracheal intubation can be accomplished using a direct visual (rigid laryngoscopy), indirect visual (fiberoptic laryngoscopy), guided blind (laryngeal mask airway, retrograde, lightwand), or a complete blind (blind nasal) technique. Each technique has its preferred indication and risks and benefits.
2. Airway management without tracheal intubation is becoming more popular with the introduction of the laryngeal mask airway.
3. General anesthesia and muscle relaxants are used to facilitate tracheal intubation. A rapid-acting muscle relaxant is used during rapid sequence induction and intubation.
4. Soft-tissue upper airway obstruction is common after induction of anesthesia. Oropharyngeal airway insertion and application of jaw thrust often are successful for overcoming soft-tissue airway obstruction.
5. Securing the airway under topical anesthesia with or without sedation (an "awake intubation") provides the optimal approach for patients with severely compromised or difficult airways.
6. Awake intubation should be encouraged, taught, and practiced regularly so that anesthesiologists are comfortable and skilled with the elements of this technique.
7. The availability of a difficult airway cart should be assured for every anesthetizing location.
8. Major anesthetic complications are frequently associated with airway mismanagement, including inadequate ventilation or oxygenation and unrecognized esophageal intubation.
9. Laryngospasm is common with patient stimulation during light anesthesia. Stridor indicates partial blockade of the airway. Lack of stridor may indicate complete closure of the larynx with no air exchange.
10. In patients in whom the upper airway is obstructed, establishing emergency ventilation through the use of a laryngeal mask airway, Combitube, cricothyrotomy, or transtracheal jet ventilation is a must and should be applied as soon as possible to prevent brain injury and death.
11. Esophageal intubation to establish emergency ventilation is more likely to succeed since the introduction of the Combitube.
12. Trauma to laryngeal structures can leave patients with vocal cord paralysis and major voice dysfunction.
13. Airway compromise has been reported during patient extubation. Planned and prepared extubation is a must to minimize airway-related complications.

superficial buccopharyngeal fascia and the prevertebral fascia, the retropharyngeal space permits free movement of the pharynx during deglutition. Retropharyngeal abscesses may infiltrate through this space and enter the superior mediastinum.

The anterior communications of the pharynx give names to its subdivisions (Fig. 35–1). The nasopharynx extends from the skull base to the soft palate at the caudal aspect of the atlas (C1). From here to the caudal aspect of C3 lies the oropharynx, whose forward limit is the junction between the anterior two thirds and posterior third of the tongue. The laryngopharynx or hypopharynx merges at C6 with the esophagus (Fig. 35–2). There, the cricopharyngeus (lower fibers of the inferior constrictor), originating on the cricoid cartilage, encircles the esophagus to form its upper sphincter. In anesthetized patients, the same function is mimicked by pressing the cricoid ring against C6 (Sellick maneuver).[5]

Nasopharynx and Nose

The pharyngobasilar fascia anchors the pharynx superiorly to the occipital and the sphenoid bones. In the presence of basilar skull fractures, passage of nasotracheal and nasogastric tubes may result in their entry into the cranium. Superficial to these bones that roof the pharynx and C1 lies the pharyngeal tonsil (called *adenoids* when hypertrophied), a site of potential obstruction or hemorrhage during nasal intubation. In patients whose large tongues fill their oral cavities, face mask ventilation permits entry of gas through the nasopharynx into the lungs, but the soft palate, posterior pharyngeal wall, and tongue often form a unidirectional valve that blocks exhalation. Exhalation block is prevented by periodic release of the mandible or by insertion of an artificial airway.

Anteriorly, the nasopharynx opens through the choanae, nasal passages, and nostrils. Consequent to septal deformity or mucosal congestion, one passage is commonly smaller than the other. The filtration and humidification functions of the nose are well served by the convoluted surfaces of the three turbinates on each lateral wall (Fig. 35–3). Their fragility assures that intubation attempts will cause epistaxis unless the tube is guided parallel and adjacent to the hard palate and perpendicular to the face

through the channel beneath the inferior turbinate.

Oropharynx and Mouth

The posterior third of the tongue, muscular for mastication and deglutition, forms the anterior wall of the oropharynx. In the sleeping or anesthetized patient in the supine position, muscle relaxation combined with gravity moves the base of the tongue toward the posterior oropharyngeal wall, causing varying degrees of airway obstruction. Partial airway obstruction is aggravated by negative inspiratory pressure collapsing the loose pharyngeal walls inward. Much of successful airway management amounts to preventing airway obstruction at this level.

In the absence of artificial airways, airway patency may be improved by extending the neck or subluxing the mandible anteriorly. This anterior displacement, through stretching of the mylohyoid, geniohyoid, and genioglossus muscles, indirectly relieves oropharyngeal obstructions (Fig. 35–4). Mandibular mobility depends in turn on the hinging and gliding motions of the temporomandibular joint. Successful rigid laryngoscopy requires anterior displacement of the tongue to allow visualization of the larynx.

The oropharynx opens to the oral cavity at the palatoglossal folds, marking the division between the anterior two thirds and posterior one third of the tongue. The palatoglossal folds and the more posterior palatopharyngeal folds form bilateral triangles, called the *fauces,* which contain the tonsils. Hypertrophy of the tonsils and their confluence with the adjacent soft palate, uvula, and tongue base can challenge an anesthesiologist attempting mask ventilation or intubation. Full visualization of all structures at the faucial isthmus between the oropharynx and oral cavity, in the seated patient with tongue protruding, suggests easy direct laryngoscopic intubation.

Anterior to the fauces is the oral cavity proper, separated from the vestibule by the teeth and gums. Maxillary teeth, especially if prominent, bucked, or capped, can interfere with laryngoscopy and intubation.

Laryngopharynx and Larynx

Three single cartilages (epiglottis, thyroid, cricoid) and six smaller, paired cartilages (arytenoid, corniculate, cuneiform) and their mucosal coverings shape the larynx (Fig. 35–5). Presenting the appearance of an obliquely cut vent pipe originating out of a steep roof, the larynx protrudes into the laryngopharynx. The laryngeal inlet or aditus is formed by the cephalad border of the epiglottis, the aryepiglottic fold, and the mucous membranes covering the cuneiform and corniculate cartilages. The rima glottidis is the elongated opening between the true vocal folds (anteriorly) and the arytenoid cartilages (posteriorly). The term *glottis* (vocal apparatus of the larynx) refers to the true vocal folds and the opening between them. Be-

tween the false and true vocal cords lie the laryngeal ventricles. The laryngeal vestibule includes the laryngeal inlet and the false vocal folds. The aryepiglottic folds curve caudally and medially into the larynx to form the vestibular folds or false cords.

To each side of the larynx and inferior to the aryepiglottic folds are the piriform recesses, which are separated by a prominence in the anterior laryngopharyngeal wall created by the lamina of the cricoid cartilage (Fig. 35–6).[3] The properly positioned laryngeal mask airway (LMA) seals against the cricoid cartilage and cricopharyngeus muscle inferiorly, the base of the tongue superiorly, and the piriform recesses laterally.[6] The superior laryngeal nerves, submucosal in these recesses, can be blocked with local anesthetic-soaked pledgets applied to the piriform sinuses. During blind nasal or lightwand intubation, tubes caught in the piriform recesses should be withdrawn a few centimeters and rotated to enter the larynx.

FIGURE 35–6. Fiberoptic endoscopic view of the larynx. The piriform recesses are represented by the deepest part of the hypopharynx lateral to aryepiglottic folds bilaterally. (From Ovassapian[3] with permission.)

The hyoid (Greek, "U-shaped") bone at C4 suspends the thyroid cartilage by the thyrohyoid membrane, which is penetrated when performing superior laryngeal nerve blocks (Fig. 35–7). Gentle lateral movements by the thumb and index finger applied to opposite sides of the hyoid allow palpation of the cornua of the bone. At C5, at the superior aspect of the 3-cm high thyroid cartilage, is the thyroid notch and laryngeal prominence (Adam's apple), an important landmark that may be subtle in women. The thyroid (Greek, "shield") cartilage sends superior cornua cephalad toward the hyoid bone and inferior cornua to articulate with the cricoid (Greek, "ring") cartilage. The cricoid cartilage resembles a graduation ring with its narrower portion facing posteriorly. In the midline at C6, the cricothyroid membrane (ligament) provides an easily palpated and avascular site for emergency cricothyrotomy or cannulation for instillation of local anesthetics, jet ventilation, or retrograde wire-guided intubation.

The vocal ligaments of the true cords attach anteriorly to the medial aspect of the thyroid cartilage, just 1 cm superior to the cricothyroid ligament, and posteriorly to the vocal processes of the arytenoid cartilages (Fig. 35–5).[3,4] Just superior to the anterior attachment of the vocal ligaments, the epiglottic cartilage is attached to the medial aspect of the thyroid cartilage. The superior edge of the epiglottis blends with the aryepiglottic folds. The tip of a curved (Macintosh) laryngoscope blade fits into the glossoepiglottic reflection. Two lateral valleculae in this reflection are created by the hyoepiglottic ligament, which keeps the resting epiglottis out of the laryngeal vestibule. Tracheal tubes caught in the valleculae during blind nasal or lightwand intubations may be directed into the larynx by changing their angle of approach or by pulling the epiglottis anteriorly with traction on the tongue. The epiglottic cross-section, crescent-shaped in adults, is more curved (omega-shaped) in infants.

Superior to the posterior cricoid lamina sit the paired arytenoid (Greek, "ladle") cartilages with superior, anterior, and lateral projections. The superior projections support the corniculate (Latin, "little horn") cartilages, and the anterior and lateral projections attach to the vocal cords and various intrinsic laryngeal muscles, respectively (Fig. 37–5). Corniculate and cuneiform cartilages embedded in the aryepiglottic fold form two prominences on the posterior part of rima glottidis. These prominences, commonly referred to as "the arytenoids," serve as important landmarks for intubation during suboptimal laryngoscopy.

Normal Vocal Cord Movements and Laryngeal Nerve Palsies

Normal vocal cord movements include abduction during inspiration, partial adduction during exhalation, and full adduction during phonation. All intrinsic muscles of the larynx are adductors or tensors, with the exception of the posterior cricoarytenoid muscles, which are the sole abductors. All intrinsic muscles of the larynx are innervated by the recurrent laryngeal nerve, with the exception of the cricothyroid, a tensor innervated by the external branch of the superior laryn-

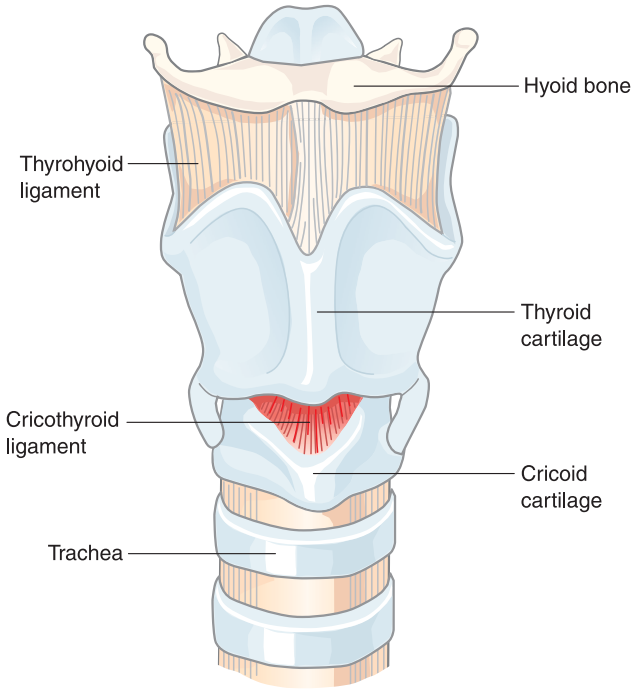

FIGURE 35–7. Diagrammatic illustration of the anterior view of the larynx. The larynx is suspended from the hyoid bone by the thyrohyoid ligament. The cricothyroid ligament provides easy and fast access to the larynx. Translaryngeal injection of local anesthetics and transtracheal jet ventilation are performed through this ligament. (Reprinted from Finucane BT, Santora AH. Principles of Airway Management. 2ed. St. Louis: Mosby Year Book, Inc., 1996, with permission from Elsevier.)

geal nerve. Laryngeal nerve palsies are classified as central or peripheral and unilateral or bilateral.[7] Simultaneous malfunction of the superior and recurrent laryngeal branches implies a central lesion or a high interruption of the vagus nerve. Central causes include posterior fossa surgery or brainstem infarctions. Peripheral lesions are more commonly caused by neck or cardiothoracic surgery than by endotracheal (ET) tube cuff pressure on the larynx. Damage to the superior laryngeal nerve or its external branch results in an inability to sound a high-pitched C note, but the inability improves over time as the contralateral muscle compensates. During phonation, the aryepiglottic folds and glottis are asymmetric. A complete unilateral recurrent laryngeal nerve injury causes hoarseness and a motionless cord that is joined during phonation by the contralateral cord crossing the midline. Brain infarction or a complete vagus nerve interruption causes the cord to assume a flaccid, wavy, partially abducted, or "cadaveric" position more commonly seen as a result of administering muscle relaxants.

Incomplete bilateral recurrent laryngeal nerve palsies result in a glottic opening so small that an emergency surgical airway may be needed. Bilateral complete recurrent laryngeal nerve palsies result in severe hoarseness, but because the cords neither adduct nor abduct, a safe glottic opening may remain. Paradoxical movement of vocal cords, often seen in young anxious female patients, may mimic vocal cord paralysis. Both vocal cords move, but they approximate during inspiration, closing the larynx and causing stridor and airway obstruction.[8]

Glottic and Laryngeal Closure

Three forms of laryngeal airway closure can be distinguished. First, during light anesthesia or phonation, the intrinsic laryngeal muscles approximate the vocal cords during exhalation, causing expiratory stridor or moaning. Second, if the vocal cords are edematous or are resting close together (encountered in some anxious patients), the Bernoulli effect draws the cords together during rapid inhalation, resulting in inspiratory stridor.[9]

The third kind of closure involves the entire larynx instead of simply the glottis; the thyrohyoid and other strap muscles contract in a forceful, longitudinal compression of the larynx.[10] During deglutition, Valsalva, or laryngeal spasm, the thyroid cartilage and hyoid bone approximate, bulging the epiglottis caudal into the vestibule against the false cords in a ball-valve fashion. Muscle relaxants and maneuvers to elongate the larynx (application of the sniff position, neck extension, and jaw thrust) tend to counteract such closure; in contrast, face mask positive pressure may expand the piriform recesses and compress the aryepiglottic folds, compounding laryngeal closure.

The Lower Airway

The lower airway includes the subglottic larynx, trachea, and bronchi. The subglottic larynx is 2 cm in length and extends from the true vocal folds to the lower border of the cricoid ring. The trachea extends from the lower border of the cricoid ring at C6 to the carina at T5, posterior to the angle of Louis (manubriosternal junction).[4]

A lightwand-fitted tracheal tube can be positioned with its tip at midtrachea by advancing the transilluminated spot to the sternal notch.[11] Neck flexion will advance an ET tube in a caudad direction, whereas Trendelenburg position or laparoscopic pneumoperitoneum can move the carina in a cephalad direction. All of these maneuvers can cause a properly located ET tube to move into a bronchus.[12] False reassurance that a tube tip is not in a bronchus often is given by a radiograph taken with the head transiently thrown into extension by removing the pillow while supporting the chest with a film cassette.

During fiberoptic examination, the trachea is distinguished from bronchi by its flat, muscular posterior wall, lending a D-shaped cross-section.

The right mainstem bronchus is approximately half as long as the 5-cm left mainstem bronchus. Being wider and more in line with the trachea, the right mainstem bronchus is more likely than the left bronchus to be unintentionally intubated. Also, foreign bodies, aspirated material, and suction catheters preferentially wind up in the right bronchus. Tracheobronchial anatomy and other features of the airway differ between infants and adults (Table 35–1).[4]

EVALUATION OF THE AIRWAY

A difficult airway can present as difficult mask ventilation, difficult rigid

TABLE 35–1.

Comparison of the Infant and Adult Airways

Feature	Infant (birth to 1 year)	Adult ≥8 years)
Cricoid–carina distance (cm)	5–6	10–20
Trachea–right bronchus angle	30°	20°
Trachea–left bronchus angle	45°	45°
Narrowest portion of airway	Cricoid cartilage	Glottis
Level of glottis	C3–4 interspace	C5
Inclination of vocal cords	Anteroinferior	Horizontal
Protrusion of corniculate and cuneiform tubercles into laryngeal aditus	Prominent	Minimal
Epiglottic cross-section	Omega-shaped	Crescent-shaped or flat
Glottic–epiglottic angle	Small	Large
Ease of mobilizing epiglottis to expose cords	Generally awkward, especially with curved blade	Usually easy with curved or straight blade
Height of thyrohyoid and cricothyroid ligaments	Almost nonexistent	Several millimeters
Preferred breathing route	Nasal	Nasal or oral
Prominence of occiput	Large (no headrest needed to attain the "sniff" position)	Small (headrest needed)

BOX 35–1.

Some Causes of Difficult Airway Management

Anatomic Features
- Short, muscular neck
- Limited neck mobility
- Prominent maxillary incisors
- Awkwardly placed, incomplete dentition
- Long, highly arched palate with narrow mouth
- Small mouth opening
- Receding chin

Abnormal States
- Anaphylactic airway edema
- Arthritis and ankylosis
  - Cervical spine
  - Temporomandibular joint
  - Larynx
- Congenital syndromes
  - Klippel-Feil (short, fused neck)
  - Pierre Robin (micrognathia, cleft palate, glossoptosis)
  - Treacher Collins (mandibulofacial dysostosis)
- Endocrinopathies
  - Obesity
  - Acromegaly
  - Hypothyroid macroglossia
  - Goiter
- Infections
  - Ludwig's angina (floor of the mouth abscess)
  - Peritonsillar abscess
  - Retropharyngeal abscess
  - Epiglottitis
- Mediastinal masses
- Myopathies demonstrating myotonia or trismus
- Scarring from burns or radiation
- Trauma and hematomas
- Tumors and cysts

Technical and Mechanical Factors
- Body cast
- Halo fixation or cervical collar
- Airway foreign bodies
- Leaks around a face mask
  - Edentulous
  - Flat bridge of nose
  - Large face and head
  - Whiskers, beard
  - Nasogastric tube
- Poor technique, inexperience, or haste

laryngoscopic intubation, difficult tracheostomy, or combination of all three. The major task during preoperative airway evaluation is to identify patients at risk for a "cannot intubate, cannot ventilate" situation, which is caused by congenital or acquired anatomic variations or by abnormal afflictions of the upper and lower airway (Box 35–1).[13,14] A search for these includes reviewing old records, taking a ventilatory history, examining the patient with reference to the normal and desired mobility of airway structures, and reviewing relevant laboratory and radiologic studies.[14] Inability to ventilate is a more urgent problem than is inability to intubate with adequate mask ventilation. Independent risk factors for difficult mask ventilation include age >55 years, body mass index >26 kg/m^2, facial hair, missing teeth, and a history of snoring.[15] Special attention should be paid to syndromes associated with a problematic airway. Details of the airway evaluation are given in Chapter 8.

It is important to have an airway management plan that addresses whether the patient will require an airway device such as a supraglottic airway or an ET tube. It also is important to consider whether the airway will be instrumented while the patient is awake or after induction of the anesthetic.

Despite a thorough evaluation of the airway, anatomic variants, including supraepiglottic cysts[16] and lingual tonsillar hypertrophy,[17,18] can lead to an unexpected difficult ventilation and/or intubation. In addition, the ever present possibility of instrument failure requires backup plans and familiarity with algorithms for handling unanticipated challenges.

VENTILATION DURING ANESTHESIA

Alveolar ventilation should deliver the oxygen (O_2) consumed by tissues while removing metabolic carbon dioxide (CO_2). The average anesthetized adult consumes approximately 250 mL/min of O_2 and produces 200 mL/min of CO_2. Because the normal alveolar effluent contains 5% (1/20) CO_2, removing 200 mL of CO_2 each minute requires 4 L/min (20 × 200 mL/min = 4000 mL/min) of alveolar ventilation. Because one third of minute ventilation is dead space (does not participate in gas exchange), the required total minute ventilation to maintain normocapnia is 6000 mL/min, or approximately 90 mL/kg/min. Unless the metabolic rate is reduced, alveolar hypoventilation results in hypercapnia.

Arterial oxygenation can be sustained during hypoventilation by increasing the fraction of inspired oxygen (FIO_2).

In the presence of opioids, sedatives, and inhaled anesthetics, the brain's normal compensatory responses to hypercapnia and hypoxemia are blunted. Thus, the spontaneously breathing patient during general anesthesia will become hypercapnic, although surgical stimuli offset ventilatory depression and tend to return $Paco_2$ toward normal. Spontaneous ventilation is acceptable during general anesthesia when muscle relaxants are avoided and airway patency is properly maintained.

The anesthesiologist assists ventilation by timing the compression of the reservoir bag to the patient's spontaneously initiated breaths, a task requiring considerable practice.[19] Assisted ventilation can test the quality of a face mask or laryngeal mask seal and offset the mechanical loading caused by partial airway obstruction. In the anesthetized patient, apnea may result either from hyperventilation until the $Paco_2$ drops below the apneic threshold or from a series of breaths large enough to elicit the Hering-Breuer inspiratory reflex. It has been shown that assisting breathing enough to lower the $Paco_2$ by 5 mm Hg reduces it below the apneic threshold. For this reason, assisted ventilation cannot generally reverse hypercapnia to a meaningful extent without becoming controlled ventilation. In the presence of muscle relaxants, unfavorable position, critical illness, or a requirement for hyperventilation, the anesthesiologist may choose to initiate controlled ventilation.

An inhalation induction is performed by allowing a patient to breathe volatile anesthetics, starting with concentrations low enough to avoid airway irritation and gradually increasing as the central effects of the vapors begin to depress cough reflexes. As alveolar ventilation drops off, breaths are assisted with increasing frequency, until ventilation is manually controlled. Inhalation inductions, popular for children, have some merit in adults when the ability to ventilate the patient after induction of anesthesia is uncertain.[19] If worsening of airway obstruction is encountered during inhalation induction, the anesthetic can be turned off, thereby awakening the patient. Historically, a well-performed inhalation induction was even used in patients at increased risk for regurgitation to deepen them enough to obliterate the vomiting reflex while preventing inspiratory attempts against a closed glottis.

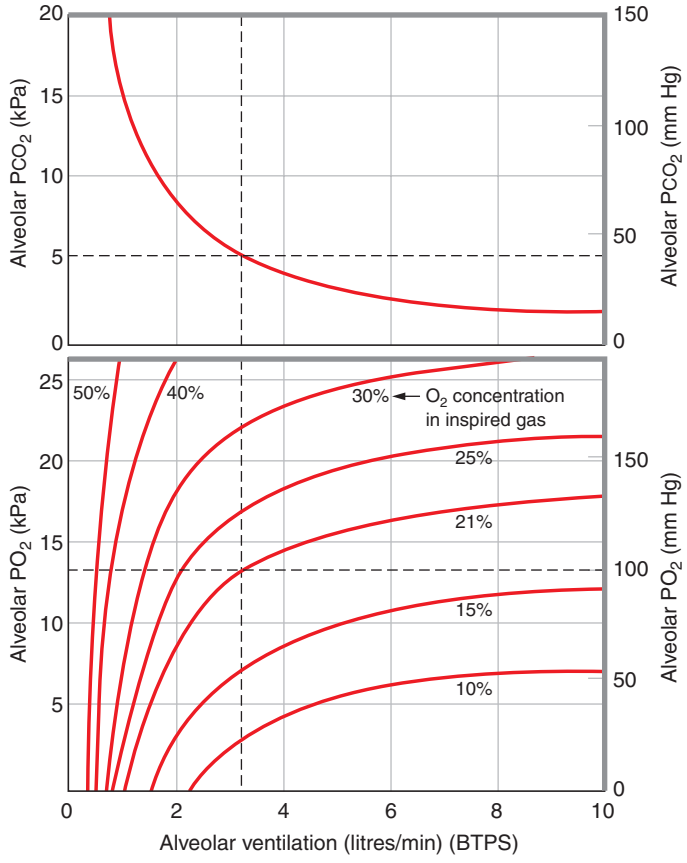

FIGURE 35–8. Dependency of alveolar oxygenation on alveolar ventilation at low FIO_2 values. Supplemental O_2 largely frees the PaO_2 of its dependency on alveolar ventilation. For example, the broken vertical line shows that a patient breathing room air with an alveolar ventilation of 3.2 L/min has a PaO_2 of 100 mm Hg, which would decrease to 50 mm Hg should the alveolar ventilation decrease by 50%. Yet even at the lower alveolar ventilation, increasing the FIO_2 to 0.4 elevates the PaO_2 to 200 mm Hg. (Reprinted from Nunn JF. Applied Respiratory Physiology. 3d ed. Boston: Butterworth, 1987, with permission from Elsevier.)

Hypoventilation

Hypoventilation, consequent to depressed ventilatory drive, laryngeal spasm, or most commonly supraglottic soft-tissue airway obstruction, results in hypercapnia and hypoxemia. Normally, although room air is 21% O_2, alveolar gas has an O_2 concentration of 16% because of the presence of water vapor and CO_2. Arterial O_2 desaturation of hypoventilating patients breathing room air occurs in part because increasing alveolar CO_2 displaces alveolar O_2. Small increases in FIO_2 elevate alveolar O_2 enough to maintain an acceptable arterial O_2 saturation in the presence of hypoventilation; large increments in FIO_2 can maintain close to normal arterial O_2 saturation despite profound hypoventilation (Fig. 35–8).

During apnea, arterial oxygenation can be sustained by apneic oxygenation.[20] In this technique, the patient breathes 100% O_2 long enough to wash nitrogen from the alveoli, leaving only O_2, CO_2, and 6% water vapor (47 mm Hg vapor pressure at 37°C). If 100% O_2 continues to be available to a patent airway, it will be drawn into the alveoli during apnea. Without exhalation, the alveolar CO_2 concentration increases 5 or 6 mm Hg the first minute (equilibration between venous and alveolar PCO_2) and 3 to 6 mm Hg/min thereafter (metabolic production). Ten minutes into apneic oxygenation that began with normocapnia, the alveolar composition of gases would be 47 mm Hg of water vapor, 72 mm Hg of CO_2, and 641 mm Hg of O_2. In the absence

BOX 35–2.

Conditions Aggravated by Hypercapnia

Preexisting metabolic acidosis (e.g., lactic acidosis, uremia)
Hyperkalemia
Elevated intracranial pressure
Pulmonary hypertension
Right-to-left cardiac shunts
Cardiac dysrhythmia
Poor myocardial contractility

of metabolic acidosis, the pH would be approximately 7.24.

In general, it is the risk of hypoxia that threatens to permanently harm the hypoventilating patient. This realization justifies the popularity of supplemental O_2 to lessen the likelihood of hypoxemia during hypoventilation. Except in selected conditions, the consequences of hypercapnia are well tolerated or reversible (Box 35–2).

Denitrogenation

Because it is impossible to assure the ability to ventilate any patient about to receive general anesthesia, proper preanesthetic denitrogenation should be undertaken. The 80% of the average 2.5-L adult functional residual capacity (FRC) that starts out as N_2 is replaced with O_2.[21] Should ventilation become impossible, this extra 2 L of O_2 may sustain vital organs for up to 8 minutes, which is enough time to establish another means of oxygenation.

Because it may make the difference between life and death for the patient, proper denitrogenation (Box 35–3) should be a top priority for an anesthesiologist preparing to induce a general anesthetic.[21,22]

BOX 35–3.

Proper Denitrogenation

Technique
High flow of O_2
Fully open pop-off valve
Leak-free mask fit to prevent entraining room air
Tidal breathing for 2–3 minutes or a series of four vital capacity breaths

Confirmatory Observations
Reservoir bags empties and refills
End-tidal CO_2 approaches 40 mm Hg
End-tidal O_2 approaches 85–90%

MONITORING THE ADEQUACY OF VENTILATION AND OXYGENATION

The gold standard for assessing the adequacy of ventilation and oxygenation is the measurement of the partial pressures of CO_2 and O_2 in sampled blood, that is, arterial blood gases. Because of cost and delay, a number of alternative technologies have become popular since 1980. Clinical observations remain invaluable to the anesthesiologist, who should constantly monitor the validity of pulse oximetric and capnographic data.

Clinical Observation

Airway management demands constant awareness of the patient's physiologic status, obtained through observations of skin color, vital signs, chest and abdominal movements, and use of accessory muscles. Even before arterial blood gases deteriorate, anesthesiologists usually are able to detect problems and make adjustments to maintain airway patency and gas exchange (Table 35–2).[4,19]

Pulse Oximetry

In the majority of patients, pulse oximetry affords reliable but noninvasive measurement of the arterial O_2 saturation. Provided that hemoglobin concentration and organ perfusion are acceptable, satisfactory arterial O_2 saturation makes organ hypoxia unlikely. The reassurance offered by pulse oximetry allows the anesthesiologist to proceed carefully instead of hurrying during intubation.[23] Pulse oximetry is not sensitive to hypoventilation in the presence of a high FIO_2 and gives late notification of esophageal intubation after denitrogenation.[24]

Most failures of pulse oximetry (e.g., movement artifact, vasoconstriction) are obvious. The anesthesiologist may incorrectly assume adequate oxygenation during carbon monoxide poisoning or illumination of the pulse oximeter's probe by lights of unusual wavelength.

Capnometry

Capnometry, using one of several detection methods, continuously displays the waveform of end-tidal PCO_2 ($PETCO_2$)

TABLE 35–2.

Reassuring and Worrisome Signs and Their Implications during Airway Management

Reassuring	Worrisome	Implication of Worrisome Sign
Concurrent pectoral and subcostal rising, alternating with falling	Stepwise expansion of subcostal region	Stomach filling with gas or unidirectional expiratory obstruction
No retractions	Subcostal expansion with concurrent pectoral collapse	Partial upper airway obstruction or intercostal weakness
No tug	Subcostal rocking with no chest expansion	Complete airway obstruction
Breathing without accessory muscles	Submandibular, intercostal, or supraclavicular retractions	Partial or complete upper airway obstruction
Normal breathing sounds heard with pretracheal stethoscopy	Inspiratory tracheal tug	Intercostal weakness with preserved diaphragmatic strength
Normal vital signs	Use of sternocleidomastoid and trapezius muscles	Respiratory muscle fatigue or weakness
Rebreathing bag quickly refills during exhalation	Stertor (snoring)	Soft-tissue obstruction
Volumeter indicates appropriate tidal volumes	Stridor (harsh, high pitched)	Laryngeal obstruction
Sequential fogging and clearing of plastic mask	Audible phonation or palpable purring	Light anesthesia or partial airway obstruction

sampled at the patient end of the breathing circuit. When the tidal volume is large enough, alveolar gas reaches the CO_2 sampling site, and the displayed $P_{ET}CO_2$ closely approximates P_{aCO_2}, affording a noninvasive, breath-by-breath method to judge the adequacy of ventilation. In patients with normal cardiopulmonary physiology, expiratory gas has a PCO_2 that is 2–5 mm Hg less than the arterial PCO_2.

Significant and common clinical events create PCO_2 gradients (arterial to alveolar) so that the P_{aCO_2} is normally higher than that displayed on the capnometer measured (Box 35–4). In most patients, end-tidal CO_2 suggests better alveolar ventilation than actually exists, resulting from significant amounts of CO_2-free inspired gas diluting the sample. For example, during spontaneous face mask ventilation of a patient with elevated intracranial pressure, the peak measured PCO_2 displayed by the capnometer may be only 18 mm Hg, but the first few breaths after tracheal intubation may show a PCO_2 of 30 mm Hg. The rapid, shallow ventilatory pattern prior to intubation prevented transport of undiluted alveolar gas to the capnometer.

An important application of capnometry is the confirmation of an intratracheal tube position by the appearance of stable CO_2 concentrations in sequential breaths immediately after intubation, as mandated, by the ASA Standards for Basic Anesthetic Monitoring.[25,26] Despite tracheal intubation, the expected levels of CO_2 may fail to appear if delivery of CO_2 to the lungs is limited by low cardiac output, hypovolemia, gas embolization, or cardiac arrest.

BOX 35–4.

Increased Gradient between $PaCO_2$ and $P_{ET}CO_2$

Arterial-to-End-Tidal Gradients
$PaCO_2$ increases, whereas $P_{ET}CO_2$ decreases (decreased perfusion relative to ventilation)
Decreased perfusion
- Embolization
- Pulmonary thromboembolism
- Air embolism
- CO_2 embolism (laparoscopic insufflation)

Hypovolemic shock
Right-to-left intracardiac shunting
Sudden increase in ventilation-to-perfusion ratio
- Bronchial intubation

$P_{ET}CO_2 > PaCO_2$ (reversed gradients)
- Chronic obstructive pulmonary disease

Alveolar-to-Sampled Gradient
Anatomic or apparatus dead space
- Rapid, shallow breaths
- Apparatus dead space (face mask)

Dilution at the sampling site of exhaled gas by fresh air

Sampled-to-Measured Gradients
Calibration errors
Slow capnometer response time with rapid breaths

AIRWAY MANAGEMENT WITHOUT TRACHEAL INTUBATION

The majority of airway-related deaths and severe neurologic morbidity result not from a failure to intubate the trachea but rather from a failure to ventilate and oxygenate.[1] Resourceful anesthesiologists command an array of techniques for ventilation without tracheal intubation when the latter is not indicated or has failed. These include face mask ventilation, oral airways, and supraglottic devices such as LMAs or esophageal devices.[4,19,27]

Face Mask Ventilation

Positioning to Facilitate Face Mask Ventilation

When the patient is in the supine position, gravity draws the relaxed tongue and epiglottis into configurations that can obstruct the airway. Patients recovering from anesthesia or obtunded and intoxicated emergency room patients may be best observed in a semilateral position, with the dependent leg straight and the other leg bent, the dependent arm flexed, and the dependent cheek on the bed (the tonsillar position). Gravity will draw the tongue away from the posterior pharyngeal wall, and blood or vomitus can drain out the mouth before being aspirated.

If the anesthesiologist suspects that gastric contents have entered the pharynx, he or she should turn the patient's head to the side and quickly position the table head down to maximize drainage while attempting to clear the pharynx with a Yankauer suction catheter.

Students of basic life support are taught to overcome upper airway obstruction by extending the head and neck and by anterior mandibular displacement with jaw thrust. Although these maneuvers move the hyoid and attached structures anteriorly, their effectiveness can be limited by two factors. Some vertebral columns can bow anteriorly and impinge on pharyngeal patency. More commonly, the forceful cervicooccipital extension tightens the strap muscles sufficiently to limit the anterior mobility of the larynx and the mandible. For these reasons, anesthesiologists often favor the sniffing position, in which the occiput rests on a firm pad approximately 10 cm anterior to the scapula. Atlantooccipital extension and jaw thrust maneuvers then are superimposed. The sternomental distance shrinks, so the hyoid and its attached structures can be moved away from the posterior pharynx without tightening the strap muscles. Greater comfort for the awake patient and preparedness for laryngoscopy are additional advantages of the sniffing position. It is provided naturally by the large occiput of infants and small children, obviating the need for a pad.

In some patients, the best airway patency is achieved by rotating the head to either side. Airway visualization and manipulation seem easier when the operating room table is elevated so that the patient's forehead is brought to the level of the anesthesiologist's xiphoid.

Achieving a Seal

The skill of sealing a mask to the face develops only after months of anesthesiology residency training. Although masks consist of a few basic designs, facial contours assume an endless variety (Fig. 35–9). Clear plastic masks with large-volume, low-pressure cushions seal easily to most faces (including patients with a flat nasal bridge) while affording a view of ventilatory condensation and evaporation cycles and early detection of regurgitated gastric contents. Being disposable, they are relatively expensive per use, provide little bracing for the mandible, and can be hard to seal on the furrowed face of an edentulous patient.

Black rubber anatomic masks have a formable body between their 22-mm connectors and inflatable cushions. A mask strap hooks around the connectors. These opaque masks may delay the recognition of regurgitation, albeit a rare event. As reusable items, they are inexpensive per use but require individual cleaning and high-level dis-

FIGURE 35–9. Face masks. Three adult universal masks on the left. The Rendell-Baker pediatric mask is shown on the far right.

infection between uses. Masks are only half of an ensemble that includes a mask strap, which is essential for achieving and sustaining a good fit (Box 35–5).

Concern of excessive apparatus dead space in patients with tiny tidal volumes led Rendell-Baker and Soucek to develop pediatric masks without cushions and made from molds of infants' faces. In contrast with the racial and ethnic variability displayed in later life, infants share uniformity of facial contours. Their full cheeks can be pulled up and around the rims of these masks. Undue submandibular pressure by the anesthesiologist's fingers tends to worsen airway obstruction. When providing mask ventilation for children, it is particularly important to ensure that the anesthesiologist's third through fifth fingers engage only the mandible and do not compress the soft tissues overlying the tongue.

Beards or broad mustaches may hinder a good mask seal, making controlled ventilation simply impossible. For edentulous patients too alert to tolerate airways, the lower margin of the mask can be placed against the mucosal reflection in the vestibule of the mouth while drawing the lower lip over the mask. By inserting an oropharyngeal airway, anesthesiologists can minimize the furrows in the cheeks of edentulous patients. Inserting an oral airway lengthens the distance between the supramental depression and the nasal bridge, necessitating substitution for the next larger mask size. For this reason, it is essential that small, medium, and large masks be available.[4,19]

Applying Positive Pressure

A functioning breathing system (a backup self-inflating resuscitation bag should be present at all anesthetizing locations) and a leak-free mask seal are essential for applying positive airway pressure. Anesthesiologists learn to adjust the pop-off valve and speed of reservoir bag compression to keep airway pressures below the 20–25 cm H_2O associated with gastric inflation.

Fit patients can tolerate generous doses of intravenous (IV) induction drugs without hypotension. An opioid, benzodiazepine, and hypnotic agent in combination act synergistically and generally render the airway nonreactive for several minutes, during which inhaled anesthetics can be introduced. Large vigorous breaths and rapid escalations in inspired anesthetic concentrations may precipitate hiccups, coughing, breathholding, laryngospasm, and delay induction. Increasing sevoflurane or desflurane vaporizer settings in 0.5% increments every five breaths allows depression of airway reflexes before irritating inspired concentrations are reached. Intubating doses of neuromuscular blockers eliminate upper airway reactivity in short intervals.

Positive pressure not only facilitates ventilation but may overcome minor degrees of soft-tissue obstruction of the airway. In a spontaneously breathing patient who is too lightly anesthetized to accept insertion of an airway, 5–15 cm H_2O of continuous positive airway pressure achieved by partially closing the "pop-off" valve may relieve airway obstruction and increase the minute ventilation. Well-synchronized intermittent positive-pressure breaths can achieve the same result. Inflation of the stomach with respiratory gases should be avoided because it decreases thoracic compliance and increases the risk of regurgitation.

Pharyngeal Airways

An inability to ventilate with a face mask despite proper positioning, jaw thrust, and a good mask seal may be caused by laryngeal spasm in response to light anesthesia or by soft-tissue upper airway obstruction resulting from deepening anesthesia and the onset of muscle relaxation (Box 35–6).[2,3] If an assessment suggests simple supraglottic obstruction, insertion of pharyngeal airway to separate soft tissues from the posterior pharyngeal wall is a logical next step (Fig. 35–10). Success confirms that the soft tissue had been obstructing the airway, whereas persisting or worsening obstruction often is indicative of active closure of the larynx that may be relieved by administering muscle relaxants or deepening the anesthetic depth with intravenous agents. The anesthesiologist should minimize the trap created by the pathologic causes of obstruction that may be worsened by the loss of muscle tone.

Until the arrival of the LMA and esophageal devices, oropharyngeal or nasopharyngeal airways were the best ways to relieve simple supraglottic obstructions. They remain inexpensive,

BOX 35–5.

Achieving a Seal with a Face Mask

1. Place the mask strap beneath the occiput.
2. Apply the mask's nasal groove to the low point of the nasal bridge to avoid pressure on the eyes.
3. Grip the left mandible with the third and fourth fingers of the left hand.
4. Lower the mask so that its inferior rim contacts the face between the lower lip and the mental prominence.
5. If there is a leak between the mask and the cheeks, consolidate the seal by dragging mobile tissue of the left cheek toward and under the mask cushion, stabilizing the tissue with the ulnar margin of the left hand.
6. Bracing the mentum against the mask, pull the mandible up and forward with the third through fifth fingers, while the thumb and index finger grip the mask above and below the connector.
7. Maintaining the left-sided seal, tilt the mask toward the right cheek, consolidating the seal by dragging the mobile tissue forward to the cushion and by keeping it there with one limb of the mask strap.
8. The other limbs of the mask strap may improve the seal, especially for anesthesiologists with small hands. Crossing the lower limbs of the mask strap prevents the mask from riding up the face.

BOX 35–6.

Causes of Inability to Ventilate

- Laryngeal spasm or vocal cord adduction
  - Light anesthesia
- Supraglottic soft-tissue relaxation (obstruction)
  - Soft palate and pharyngeal walls
  - Tongue
  - Epiglottis
- Chest wall rigidity
  - Breathholding
  - Narcotic-induced
- Pathologic, glottic, and subglottic
  - Foreign body
  - Enlarged lingual tonsil
  - Edema
  - Infection
  - Tumor and hematoma
  - Congenital
  - Superior vena cava syndrome
  - Bilateral vocal cord palsy
  - Tracheal stenosis
  - Tracheal and bronchial compression
    - Great vessel anomalies
    - Mediastinal mass
- Equipment failure
  - Selector valve accidentally in the "ventilator" position

safe, and generally effective.[19,27] Trial and error often are necessary for even the experienced anesthesiologist to select an oropharyngeal airway long enough to anteriorly displace the base of the tongue without pushing the epiglottis into the laryngeal inlet. The forward portion of the oropharyngeal airway separates the teeth or gums; its flange keeps the device from dropping into the hypopharynx. Displacing the tongue into the hypopharynx is avoided by drawing it anteriorly with a tongue blade held in the left hand while the right hand opens the mouth and inserts the oropharyngeal airway.

The onset of soft-tissue relaxation and airway obstruction usually heralds depression of cough and gag reflexes sufficient to tolerate pharyngeal stimulation. Swallowing or gagging triggered by a tongue blade or airway touching the base of the tongue suggests deferring insertion pending greater obtundation; the stimulus itself often restores airway patency. Coughing and breathholding after uneventful placement of an oropharyngeal airway suggest airway irritation by anesthetic vapors and may remit with turning down the vaporizer and temporarily abandoning attempts at positive-pressure ventilation or deepening the depth of anesthesia with intravenous agents.

A nasopharyngeal airway can be inserted in a patient with a clenched jaw, a need that often occurs when soft-tissue obstruction complicates premature extubation. Unfortunately, unless precautions are taken (Box 35–7), epistaxis may complicate the hasty introduction of an airway through the nasal passages. Because of alignment with the glottic opening, blind tracheal suctioning may be possible by passing a catheter through a nasopharyngeal airway, although the need for and tolerance of repeated tracheal suctioning usually are indications for intubation.

Laryngeal Mask Airway

Developed in the 1980s by Dr. Archie Brain,[6] the classic LMA (Fig. 35–11) has achieved great popularity for addressing simple, supraglottic airway obstruction in a variety of contexts.[28–30] Its unique capabilities (Boxes 35–8 and 35–9), relative ease of use, and low incidence of serious complications has assured the LMA a place in the anesthesiologist's armamentarium.[31–34] Several studies have indicated that trained but inexperienced resuscitators are more likely to be successful at proper placing an LMA than at tracheal intubation.[35] Lacking an experienced mentor, practitioners can initiate their own LMA experience based on the instructional videotape and manual that accompany the product.

BOX 35–7.

Precautions for Introducing Nasopharyngeal Airways

- Prepare the larger nasal passage with a vasoconstrictor
- Choose a soft, blunt-tipped nasopharyngeal airway
- Soften it by warming (not applicable for some materials)
- Lubricate the airway
- To protect the turbinates, point the bevel medially
- Direct the device directly posteriorly, parallel to the hard palate and beneath the inferior turbinate
- If resistance is encountered, withdraw, rotate 90°, and re-advance with gentle, steady pressure
- Ease difficult passage by using a soft suction catheter as an introducer

Becoming adept at proper LMA insertion requires consideration of anatomy, patience, and practice.[29,36] Even when using suboptimal insertion technique, providers will have a high success rate with the LMA, allowing many practitioners to develop poor habits. Adherence to proper technique will maximize success and reduce complications. The LMA should be deflated with finger pressure on the dorsal aspect of the cuff so that the totally flattened cuff curves away from the aperture (Fig. 35–12). Water-soluble lubricant smeared on the dorsal surface of the cuff should be kept from drying. The recommended technique for LMA placement is summarized in Figure 35–13.[37] When the epiglottis is dragged downward, the aperture bars of the LMA prevent impaction of epiglottis into the LMA and possible obstruction.

Obstacles to LMA insertion include the soft palate, uvula, tonsillar fauces, oropharyngeal angle, tongue, and epiglottis. These areas are negotiated by the sniffing position with marked cervi-

FIGURE 35–10. Artificial oropharyngeal and nasopharyngeal airways.

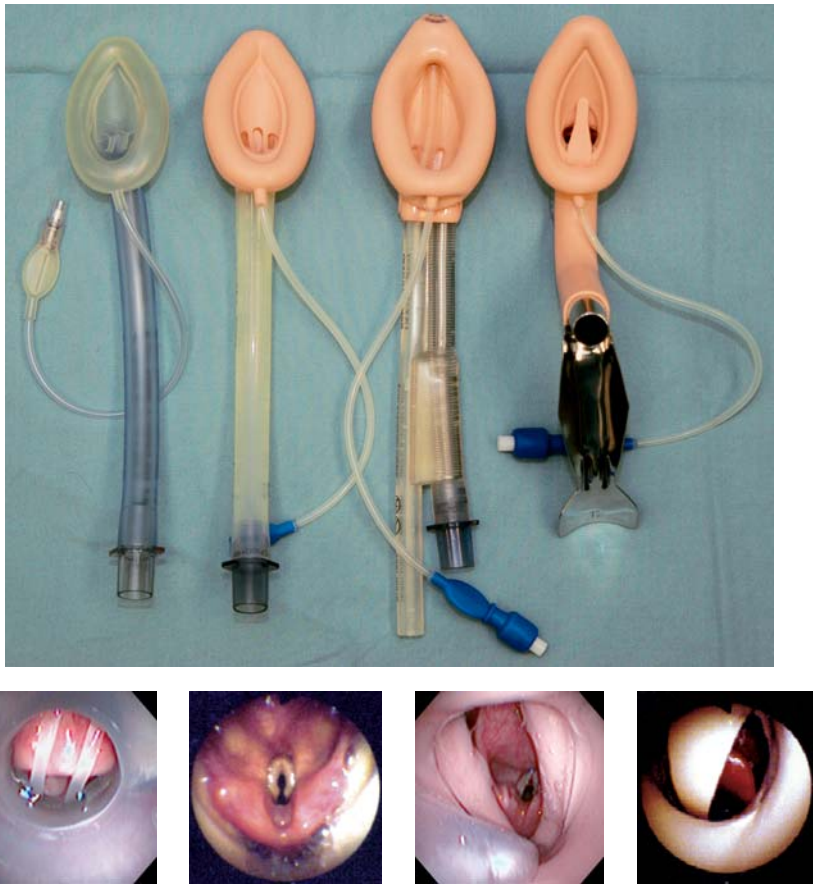

FIGURE 35–11. Various laryngeal mask airways and endoscopic views of them. Shown from left to right are the LMA Unique, Classic, ProSeal, and Fastrach. The two epiglottic bars of the LMA Unique and Classic prevent entry of epiglottis inside the lumen of LMA. The LMA ProSeal dose not have epiglottic bars, but the drain tube supports the epiglottis and prevents it from impacting inside the LMA tube. In the LMA Fastrach, the epiglottis bar elevates epiglottis as the endotracheal tube passes into the trachea.

cooccipital extension, permitting laryngeal structures to move forward and accommodate the mask. A gloved hand flattens the tip of the mask against the hard palate to start it on a path that will not engage the epiglottis. Intravenous propofol doses of 2–2.5 mg/kg usually provide an appropriate depth of anesthesia for LMA insertion, but insertion can proceed during *any* adequately deep general anesthetic or after topical anesthesia in conscious patients.

Although careful placement, cuff inflation, and adaptation time improve the seal, leakage often occurs at 20 cm H_2O airway pressure with the classic LMA. Obesity, head-down tilt, abdominal insufflation, airway obstruction, or any other conditions necessitating ventilation with high airway pressures increase the risk of hypoventilation, gastric insufflation, and regurgitation.

The *LMA Classic* is particularly well suited for the lightly anesthetized, spontaneously breathing ambulatory patient. Compared with face mask or endotracheal anesthesia, there seems to be less need for deep anesthesia beyond that required for the surgery itself.[29] Patients seem to tolerate a lighter depth of anesthesia with less chance of coughing, breathholding, stridor, or laryngeal spasm.[38] Increasing anesthetic depth usually manages episodes of movement, tachypnea, or hyperpnea. Finally, patients tolerate a return to consciousness with the ability to follow commands while the inflated LMA is still in place. Positive-pressure ventilation can be applied through the LMA; however, the tidal volume, respiratory rate, and inspiratory to expiratory ratio (I:E) should be adjusted to avoid high airway pressures. Newer anesthesia ventilators that can provide synchronized positive-pressure breaths are particularly well suited for use in the patient with a supraglottic airway in place.

The *LMA ProSeal* is an advanced form of the LMA Classic consisting of two tubes; an airway tube and a drain tube.[39] When properly positioned, the drain tube communicates with the upper esophageal sphincter and permits insertion of a gastric tube to decompress the stomach. The LMA ProSeal also has a second posterior cuff that provides a

BOX 35–8.

Clinical Use of Laryngeal Mask Airway

Indications

- Surgical anesthesia without intubation
- Repeated anesthetics
- Emergency ventilation when intubation has failed
- Improving airway seal without tracheal intubation
  - Patient with facial hair
  - Edentulous
- Assisting tracheal intubation
- Providing a patent airway with minimal changes in blood pressure, heart rate, intraocular or intracranial pressure, or bronchial tone

Contraindications

- High risk of aspiration (relative contraindication)
- Glottic or subglottic obstruction
- Supraglottic pathology interfering with its placement
- Extremely limited mouth opening or neck extension
- Prone position (relative contraindication)
- Need for high airway pressure ventilation

BOX 35–9.

Benefits and Limitations of Laryngeal Mask Airway (LMA)

Benefits

- Permits ventilation when face mask and intubation have failed
- Permits lighter anesthesia and faster emergence
- Facilitates blind or fiberoptic tracheal intubation
- Provides better airway for fiberoptic bronchoscopy
- Easier to learn than tracheal intubation

Limitations

- Proper position of the LMA may be difficult to achieve
- Probably gas leak with LMA Classic when airway pressure >20 cm H_2O
- Limited protection against aspiration
- No protection against laryngospasm

FIGURE 35–12. Diagram of a deflated laryngeal mask airway. The cuff of the laryngeal mask airway is deflated before its insertion. The rim of the cuff should evenly face away from mask aperture, with no folds near the tip.

better seal between the LMA and the larynx, allowing for positive-pressure ventilation with higher airway pressures than the LMA Classic.[29] The LMA ProSeal introducer is provided to aid insertion of the LMA ProSeal without the need to place fingers in the mouth. The technique of LMA ProSeal placement with the introducer is similar to LMA Fastrach placement.

Whereas the LMA Classic can be used with low-pressure positive-pressure ventilation, the LMA ProSeal has been designed for use with positive-pressure ventilation at higher airway pressures. The drain tube will direct the regurgitated fluid to the outside, minimizing the risk of aspiration of gastric contents.[29,40] One of the best emergency uses of the LMA ProSeal is to establish ventilation and to decompress the distended stomach when intubation has failed and the stomach is distended because of difficult face mask ventilation. The anesthetic can be continued with the ProSeal, or the

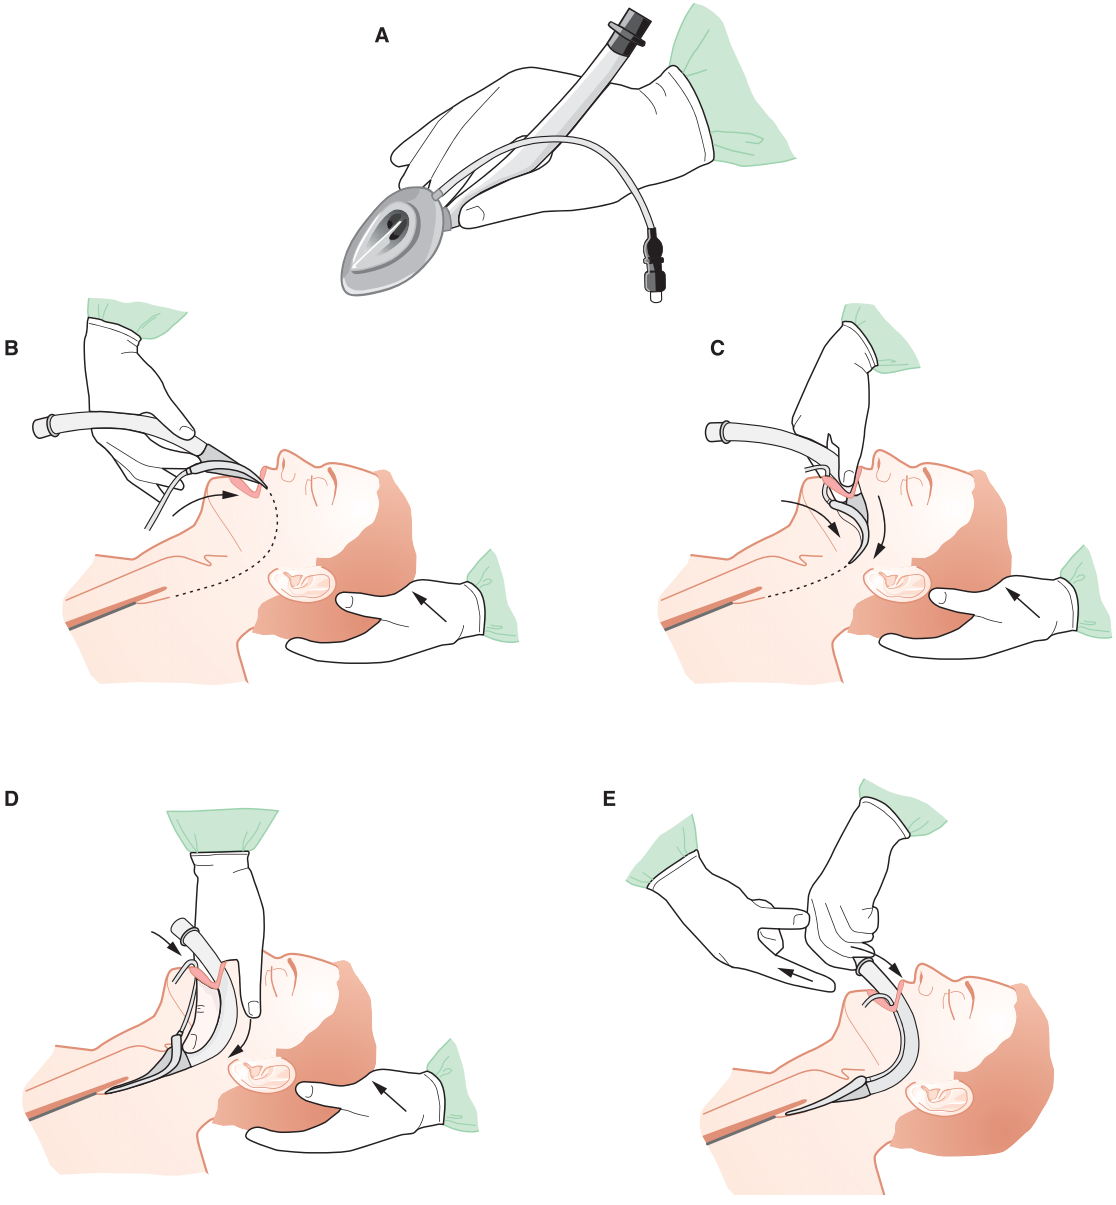

FIGURE 35–13. Technique for placing a laryngeal mask airway (LMA) described by Brain. **A.** The LMA is held by the index finger and the thumb facing the bowl of LMA caudally toward the larynx. The index finger is positioned between the shaft of the LMA and the deflated cuff. The occiput is stabilized with the left hand. **B.** The deflated and lubricated LMA is placed into the open mouth pressed against the hard palate. **C.** The LMA is advanced behind the tongue and into the oropharynx using the index finger. **D.** The LMA is pushed further down deep into the hypopharynx using the tip of the index finger. **E.** The index finger is removed. The LMA is pushed farther down to its final position by holding the tube of the LMA with the left hand. Without holding the tube of the LMA, the cuff is inflated with the recommended volume of air. The LMA may protrude slightly on inflation of the cuff. Final position of the LMA with cuff inflated. A bite block made of sponges is placed between molars and taped to the LMA tube to prevent patient biting. (LMA Airway Instruction Manual. San Diego: LMA North America, 2005. Courtesy of LMA.)

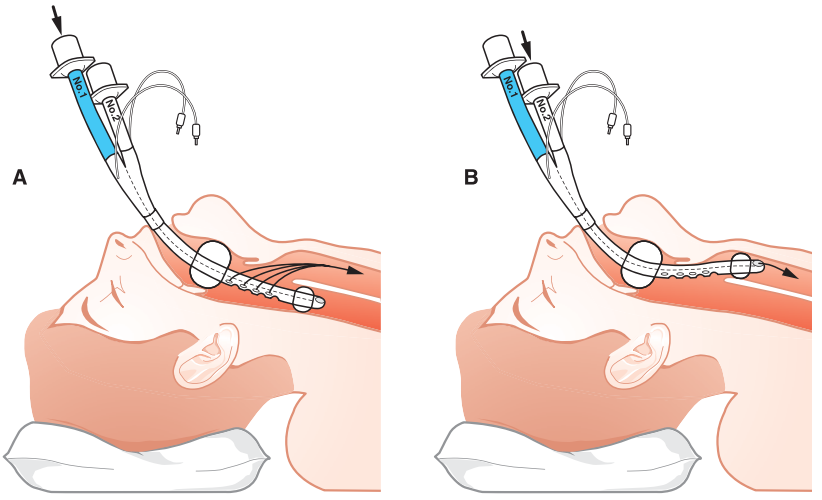

FIGURE 35–14. Combitube. **A.** Combitube positioned in the esophagus. Ventilation is performed via the blue lumen, marked number 1. **B.** Combitube positioned in the trachea. Ventilation is performed via the clear lumen, marked number 2. (From Ovassapian[3] with permission.)

device can be exchanged for an ET tube.

Using the LMA in an unfavorable setting increases the likelihood of unfortunate results. The LMA does not protect as effectively as an ET tube against pulmonary aspiration of gastric contents.[41,42] The incidence of aspiration with the laryngeal mask is reported to be similar to that of mask anesthesia and very close to that of ET intubation.[29,43] Application of cricoid pressure impedes placement of the LMA.[44] Reported but rare complications include twelfth cranial nerve paralysis,[45] unilateral hypoglossal nerve paralysis,[46] and transient bilateral vocal cord paralysis.[47]

Esophageal–Tracheal Airway

The esophageal–tracheal Combitube (ETC; Fig. 35–14) is intended for establishing emergency ventilation when there is simple, supraglottic obstruction or when the operator lacks the skills for face mask ventilation or tracheal intubation.[48–50] This device differs from the earlier esophageal obturator airway in that it permits ventilation whether it enters the esophagus or the trachea.

When the lubricated ETC is passed through the pharynx of a comatose or anesthetized patient, a neutral position or slight flexion of the neck generally directs the device to follow the posterior pharyngeal wall and into the esophagus. Approximately 4–6% of the time, the ETC enters the trachea. A large 100-mL balloon seals the oropharynx, and a smaller balloon seals the esophagus. The ETC has two channels. One lumen is open at the tip of the ETC. If the ETC enters into the esophagus, this channel can be used to decompress the stomach. If the ETC enters the trachea, this lumen can be used to ventilate the patient, avoiding the necessity of removal and reinsertion. The second lumen opens into multiple pharyngeal ports and is used to ventilate the patient during the more common scenario when the tip of the ETC is placed in the esophagus. Lifesaving ventilation has been provided by this device.[48]

Other Extraglottic Airways

After successful introduction of the LMA, several other extraglottic airway devices have been introduced. Some are commercially available, but none have been studied as extensively as the LMA. Examples are the laryngeal tube airway (VBM Medizintechnik, GmbH, Sulz, Germany), the streamlined pharyngeal airway liner, the intubation laryngeal airway developed by Cookgas, and the Cobra (see reference 29).

Complications of Nonintubated Airway Management

Improperly conducted and monitored airway management can result in hypercapnia and/or hypoxic organ damage, although supplemental oxygen and pulse oximetry reduce the incidence of the latter.[1] Hypercapnia is nearly always well tolerated; however, in rare situations hypercapnia can cause morbidity (Box 35–2).

Laryngeal spasm is an airway reflex that presents as a sustained, disinhibited glottic closure resulting from insufficient anesthesia and precipitated by instrumentation, fluid irritation, or ill-timed stimulation of the larynx or other body parts (e.g., moving or examining the patient at a light plain of anesthesia). The anesthesiologist should consider a wide variety of causes (Box 35–6) when treating a patient who is difficult to ventilate (Box 35–10).

Although anesthesia deep enough to obliterate airway reflexes eliminates active vomiting, passive regurgitation can occur anytime during the care of the anesthetized or critically ill patient. Repeated inspiratory efforts against an obstructed airway and gastric distension by air are predisposing factors to regurgitation.[51,52] When regurgitation occurs, liquids should be removed from the pharynx by rapidly lowering the head, turning it to the side, and suctioning with a rigid-tipped (e.g., Yankauer) catheter. Subsequent pulmonary aspiration of fluid, solid, or acid may result in bronchospasm and O_2 desaturation, tracheobronchial obstruction, and/or chemical pneumoni-

BOX 35–10.

Progression of Steps to Manage Difficulty in Ventilating a Patient

- Confirm that the machine's selector valve is set to "bag" and that the reservoir is not twisted
- Without exceeding 25 cm H_2O, increase airway pressure while intensifying jaw thrust and observing for ventilation or gastric distension
- If blood pressure is adequate and if awakening the patient is unnecessary, deepen anesthesia with a rapidly acting IV drug (e.g., thiopental, propofol)
- If depth of anesthesia is judged adequate, insert an oropharyngeal or nasopharyngeal airway
- If O_2 saturation decreases, maximize FIO_2
- Consider whether it would be safest to awaken the patient
- Administer 5–20 mg of IV succinylcholine
- Consider the wisdom of a full dose of relaxant to facilitate tracheal intubation
- Consider using laryngeal mask airway or Combitube
- Consider establishing a transcricothyroid airway

BOX 35–11.

Indications for Tracheal Intubation

Anesthesia
- Controls the airway
- Provides an unobstructed leak-free airway for prolonged ventilation
- Minimizes aspiration risk
- Facilitates resuscitation of the moribund patient
- Permits attention to complex diagnostic and therapeutic matters
- Has preemptive utility if it is feared that ventilation and intubation may later become impossible
- Ventilates with thoracoabdominal surgery
- Permits flexible positioning
- Affords the anesthesiologist distance from the head
- Allows full range of positions (e.g., prone, sitting, lateral, head down)
- Keeps blood and secretions out of the trachea during airway surgery

Critical Care
- Establishes airway patency
- Protects against pulmonary aspiration
- Facilitates tracheobronchial toilet
- Provides a route for airway pressure therapy (e.g., IPPV, IMV)

IPPV, Intermittent positive pressure ventilation; IMV, Intermittent mandatory ventilation.

tis. Although the ASA Closed Claims Study indicates that aspiration is rare in modern anesthetic practice, the consequences are significant enough to require that the possibility of aspiration be considered in every patient and that thoughtful planning and preparation be undertaken.[1]

Using a face mask with straps presents risk of traumatic pressure to the eyes or branches of the facial nerve. Upper airway laceration may precipitate mucosal bleeding severe enough to render laryngoscopy impossible.

AIRWAY MANAGEMENT WITH TRACHEAL INTUBATION

Tracheal intubation is undertaken for reasons of physiology, pathology, or convenience (Box 35–11). Reflecting an appreciation of the consequences of hypoventilation, hypoxia, and aspiration and the desire to free the anesthesiologist's hands for other tasks, the prevalence of tracheal intubation during anesthesia had increased until the introduction of the LMA in the 1980s, leading to a reduction in the proportion of anesthetics used with ET intubation.

Visualization of the pharyngeal and glottic structures assures the greatest likelihood of successful tracheal intubation. Tracheal intubation is optimally undertaken after setup in an operating room or critical care area with custom-stocked carts (Box 35–12). Alternative techniques of intubation and ventilation may be lifesaving when suboptimal circumstances prevent visualized tracheal intubation.

Endotracheal Tubes

Most ET tubes are disposable and made of clear, bioinert polyvinyl chloride (PVC) that molds to the contour of the airway after softening at body temperature. Lengths are marked in centimeters, and internal diameters are indicated in millimeters. Implantation testing in animals has shown these materials to be nonirritating by the standards of the American Society for Testing and Materials' Committee F-29 on Anesthetic and Respiratory Equipment. Because combustion of PVC in the presence of supplemental O_2 during airway laser surgery produces hydrochloric acid and other pulmonary toxins, tubes in this setting tend to be made of metal, metal-wrapped red rubber or silicone.[53]

Although the resistance of a small ET tube can impair the ventilatory weaning of a critically ill patient, it generally is not necessary in the operating room to use the largest possible tube. In many cases, a 7.0- or 7.5-mm internal diameter ET tube is chosen for female patients and an 8.0-mm ET tube is used for men. The clinical setting dictates even smaller tubes for patients with airway edema (e.g., preeclamptic), nasal intubation, and blind intubation. Pediatric ET tube sizes are predicted by an age-related formula and tested for leaks in situ. Use of cuffs often is avoided in children until they are 8 to 9 years old, when the cricoid ring ceases to be the narrowest, edema-prone portion of the airway. Cutting ET tubes renders them less obtrusive and easier to handle, but 26 cm of length should be sufficient for adult oral tubes, allowing 3 cm more for nasal tubes. The 15-mm adapter can be firmly affixed by wiping it with alcohol and twisting it firmly into place in the ET tube.

BOX 35–12.

Preparation for Tracheal Intubation

- Skilled assistance
  - Equipment for face mask ventilation
  - Source of positive-pressure oxygen
    - Anesthesia machine
    - Self-inflating bag
  - Tongue blade and oropharyngeal or nasopharyngeal airways
- Bright laryngoscope
  - Straight blade(s)
  - Curved blade(s)
- Stiff (tonsil-style) suction device
- Position and environment
  - Access to patient's head
  - Patient's face near anesthesiologist's xiphoid
  - Occipital elevation (sniffing position)
  - Adequate light
  - Monitors
- Intubation stylet or introducers
- Local anesthetics
  - Injectable
    - Nerve block
    - Laryngotracheal spray
    - Transcricothyroid spray
  - Topical
    - Spray
    - Ointment for tongue
    - Viscous
    - Nebulized
- IV access for
  - Sedation or anesthetic induction
  - Neuromuscular blockers
  - Relaxants
  - Volume administration
  - Cardioactive drugs (e.g., antiarrhythmic)
- Intubating (Magill) forceps
- Backup equipment for unanticipated difficult intubation or ventilation (difficult airway cart)

High-volume cuffs contact the trachea over a broad area, minimizing the pressure on the mucosa and improving the seal, which helps minimize aspiration risk. The pressure in the cuff is estimated by squeezing the pilot balloon, or the pressure is set to < 25 cm H_2O when measured by a manometer. With longer periods of intubation, it becomes important to minimize cuff overinflation by periodically measuring pressure or by injecting only 1 additional cc of air after the audible air leak has been sealed. A cuff initially inflated with air merits periodic checks to detect overinflation

TABLE 35–3.

Special Tracheal Tubes and Their Applications

Description	Use
Embedded wire (armored or anode)	Minimize chance of kinking
Endotrol with an intrinsic cable to flex the tip	Facilitate entry into the glottis
J-shaped laryngectomy	Fit into a tracheal stoma without entering the bronchus
Laser-adapted	Minimize change of ignition
Lumen-containing	Sample airway gas or medicate the airway (e.g., with lidocaine)
Microlaryngeal 4- to 6-mm inner diameter with adult length and cuff (microlaryngeal tube [MLT])	Pass a narrowed stretch of the airway
Preformed oral or nasal (Ring-Adair-Elwyn [RAE])	Avoid the field during head and neck surgery
Uncuffed	Prevent subcricoid edema in patients aged <8 years
Double lumen	Lung separation
Univent bronchial blocker	Lung separation

when nitrous oxide is used during an anesthetic course because nitrous oxide may enter the cuff and lead to increasing pressures.

The standard ET tube has a bevel that opens toward the patient's left when the concavity of the tube's curve faces anteriorly. The Murphy eye is a fenestration in the tip of the tube opposite the bevel, added to protect against obstruction. A variety of ET tubes are available for specific applications (Table 35–3, and Figs. 35–15 and 35–16).

Laryngoscopes

These instruments are designed to create a line of sight for passage of the ET tube by displacing the tongue and epiglottis anteriorly.[53] A battery-operated bulb may sit near the tip of the blade or in the handle itself, in which case illumination is directed by a fiberoptic bundle to the laryngeal structures. Blade-mounted bulbs will operate erratically if their contacts are not corrosion-free.

Laryngoscope blades require appropriate disinfection to kill vegetative organisms but do not necessarily need to be sterilized. They should be soaked and brushed clean in an enzyme detergent before disinfection. Autoclaving or soaking in glutaraldehyde will corrode the contact between the bulb and blade over time. Gas sterilization is effective but time consuming. Disposable plastic covers keep handles and blades free of saliva and blood and minimize cross-contamination.

Although innumerable laryngoscope blade designs have been used, only two remain popular: the straight Miller, which lifts the epiglottis directly, and the curved Macintosh, which does so with traction on the glossoepiglottic and hyoepiglottic ligaments (Fig. 35–17).

Stylets

Because of the position of the tongue and epiglottis, a glottic opening not exposed by routine laryngoscopy seems to hide anteriorly. Stylets are blunt-tipped, flexible tools used to give a different shape to the ET tube in order to facilitate tracheal intubation. Stylets are lu-

bricated and inserted in the ET tube but are not intended to protrude out of the tube (the distal tip of the stylet should be positioned inside the ET tube). The tip of the ET tube and stylet are often bent approximately 5 cm from the tip to achieve a "hockey stick" shape. The ET tube is passed beneath the epiglottis, and an assistant removes the stylet as the ET tube enters the trachea. Excessively stiff, carelessly placed, and improperly used stylets can cause life-threatening complications. A stylet that is used repeatedly may fracture during intubation.

Introducers

Introducers, exemplified by the angle-tipped Eschmann gum elastic bougie, can guide an ET tube into the trachea. Longer and less rigid than stylets, they are used to facilitate difficult intubation. The gum elastic bougie tip is guided into the trachea first, and the ET tube is threaded over it into the trachea.

A soft, flexible introducer can serve as tracheal tube exchanger and guide the blind insertion of a new tube if an exchange of tubes is necessary. Dedicated tube changers include models with Luer-Lok or 15-mm male adapters at the proximal end for oxygenating with jet ventilation until a new tube can be placed. An ET tube is least likely to hang up on the epiglottis or aryepiglottic folds if its internal diameter is not much larger than the introducer.

TRACHEAL INTUBATION

Tracheal intubation usually is performed after induction of anesthesia and muscle paralysis, but it is also easily accomplished in conscious patients. In some patients, muscle relaxants are avoided, and intubation is performed during general anesthesia with the patient breathing spontaneously.

An ET tube can be passed orotracheally, nasotracheally, or through a tracheostomy. Although passage of an ET tube through a mature tracheostomy requires no special instruments, intubating through the mouth or nose can be extremely difficult or impossible.

Many techniques exist to assist routine and difficult tracheal intubation (Box 35–13).[3,4,51] They vary in their level of sophistication, invasiveness, tendency for blood and secretions to obscure visualization, and potential for complications. In selecting a technique, the anesthesiologist weighs risks against the likelihood of success, keeping in mind a backup plan to deal with unexpected failure. Importantly, expertise may vary depending on when the anesthesiologist trained. For example, recent American trainees may not have extensive experience in blind nasal intubation (BNI), whereas those of an earlier vintage may be less comfortable with fiberoptic techniques. The ideals against which a technique can be judged are summarized in Box 35–14. Fiberoptic bronchoscopy scores high as a technique to manage difficult airways. Its shortcomings include its size, cost, potential for equipment damage, and susceptibility to obliteration of the view by blood and secretions. Compact, battery-powered light sources for bronchoscopes have proven advantageous when portability, compact size, or low weight are important.

  - Bougie
  - Augustine guide
- **Blind Nasal**
- **Combination of techniques**
- **Surgical**
  - Cricothyrotomy
  - Tracheostomy

BOX 35–14.

Desired Features of an Intubation Technique

- **Primary**
- High success rate in those with difficult airways
- Useful for upper and lower airway problems
- Useful for oral and nasal intubations
- Allows ventilation during intubation
- Performed with visual guidance
- Allows application of topical anesthesia
- Devoid of technique-specific complications
- Head and neck manipulation not crucial for success
- Useful in combination with other techniques
- Blood and secretions do not interfere with its use
- **Secondary**
- Avoids dental trauma
- Equipment easily cleaned and stored
- Portable
- Easily learned and mastered
- Cost-effective

TECHNIQUES OF INTUBATION

Rigid Laryngoscopy

Rigid laryngoscopy retains its popularity because of its simplicity, high success rate, and good visualization.[4,19,51] In adults, it is critical to elevate the occiput on a pad to flex the neck while permitting the atlantooccipital extension that will align the pharynx with the mouth and larynx (Fig. 35–18). If the patient has been given muscle relaxants, a neuromuscular blockade monitor is the best means to assure sufficient paralysis. Although succinylcholine provides the most rapid onset of relaxation, the effect of nondepolarizing relaxants can be hastened by using either large doses or the priming principle.

The left hand grasps the open laryngoscope with the fifth finger just above the blade. Although simply extending the neck adequately opens some mouths, the best access is achieved by pushing on the right mandibular premolar with the right thumb while stabilizing the maxillary teeth with the third finger. With barrel-chested or obese patients, extra elevation of the head and shoulders or directing the laryngoscope handle to the left (rather than keeping it in a sagittal plane) avoids

interference from the sternum while inserting the blade in the mouth. The laryngoscope blade can then be slid along the right side of the tongue so that its flange displaces the tongue leftward. Passing the right fauces, the blade is directed medially to the epiglottis, a key landmark. The tip of a curved blade, placed in the midline of the glossoepiglottic reflection, will be able to maximally lift the epiglottis to expose the glottis. Straight blades are slid beneath the epiglottis to lift it directly (Fig. 35–19). Elevation of the tongue and epiglottis is accomplished with the left hand pulling up and away from the anesthesiologist, keeping the left elbow close to the anesthesiologist's side. Levering the laryngoscope with the maxillary teeth as a fulcrum is to be avoided. The view of the glottis may be improved by applying the right thumb and index finger to the thyroid cartilage to provide either lateral or backward, upward, and rightward pressure (the BURP maneuver).[51] Initiated by the laryngoscopist, laryngeal pressure can be maintained by an assistant during intubation. In small children, the relatively large occiput eliminates the need for a pad, and the more cephalad glottis increases the importance of laryngeal pressure.

Common avoidable causes of difficult visualization during laryngoscopy include improper positioning of the head, inadequate opening of the mouth, selecting the wrong blade, allowing the tongue to hang over the right side of the blade, applying leverage rather than traction, and obscuring the line of vision with the ET tube during its insertion. If the epiglottis is not seen, the blade may have been inserted too far, providing a view of the esophagus. Slowly withdrawing the laryngoscope may let the epiglottis drop into view. Selecting too short a blade will prevent the tip from reaching the glossoepiglottic reflection.

Particular situations may call for either a straight or a curved blade. The Macintosh curved blade with its effective flange and panoramic exposure of the anatomic features is recommend to those learning intubation. It does a good job retracting large tongues and prominent lips of edentulous patients. Because a curved blade avoids contacting the sensitive laryngeal surface of the epiglottis, it is well suited for intubation in conscious patients. In patients with micrognathia, a floppy epi-

glottis, or an anteriorly hidden glottis, the ability of the straight blade to lift the epiglottis affords a superior view of the larynx. The Miller straight blade, with its small cross-section, is especially useful in the right corner of the mouth in patients with prominent maxillary teeth or limited temporomandibular mobility.

Nasotracheal intubation guided by rigid laryngoscopy can be used in oral and maxillofacial surgery or in the intensive care setting. Introduced through the right corner of the mouth so as not to block laryngoscopic visualization, a Magill intubating forceps directs the tip of the ET tube to the glottis while an assistant advances the tube on command.[51,54] The tube commonly hangs up on the anterior laryngeal structures and may require twisting or occipitocervical flexion for it to enter the trachea.

Intubation in the Conscious Patient

In patients who have a difficult airway or are at high risk for aspiration, serious consideration should be given to securing the airway before inducing anesthesia.[2,3] Intubation in the conscious patient is certainly the choice when both risk of aspiration and difficult airway factors coexist. To assure maximum cooperation, preanesthetic preparation should include an explanation of the procedure and appropriate premedication.

Sedation to an extent that apnea or airway obstruction is produced should be avoided. Opioid-induced analgesia and depression of airway reflexes increase the risk of aspirating gastric contents but facilitate oropharyngeal instrumentation while permitting the patient to follow commands. Protective reflexes remain more active when a benzodiazepine is used, but the patient may be less cooperative and reacting more vigorously to instrumentation. A combination of fentanyl and midazolam (1.5 μg/kg and 30 μg/kg, respectively in divided doses) has been used successfully.[55] To assure that these synergistic drugs have reached their peak effect, 3–5 minutes is allowed to elapse between doses. Continually asking the patient to take deep breaths helps avoid oversedation and hypoxemia.

Glycopyrrolate 0.2–0.3 mg IV minimizes secretions and improves the effectiveness of topical anesthetics. Patients may benefit from medications that increase gastric fluid pH or enhance gastric emptying.

FIGURE 35–20. Proper application of cricoid pressure during rapid sequence induction and intubation to prevent passive regurgitation of gastric contents.

Topical anesthesia is achieved by an oropharyngeal spray of 4% lidocaine and translaryngeal injection of 3 mL of 4% lidocaine.[56,57] Topical anesthesia with lidocaine begins to work within 30 seconds after its application and is fully active within 2 minutes, but it lasts only 20–30 minutes. For nasotracheal intubation, 4% cocaine or a 3-mL mixture of 4% lidocaine with 1 mL of 1% phenylephrine more commonly used today provides anesthesia while shrinking mucosae.[58] Use of lidocaine jelly before application of other anesthetics to normal mucosa increases patient satisfaction.[59]

During rigid laryngoscopy in the conscious patient, the anesthesiologist continually instructs and reassures the patient while proceeding gently. Time may be required to spray more topical anesthetic on the tongue base or epiglottis. Laryngeal pressure by an assistant is particularly helpful, and lingual nerve block may decrease refractory gagging.

Rapid Sequence Induction and Intubation

Preoxygenation, avoidance of mask ventilation, and compression of the cricoid cartilage (Sellick maneuver; Fig. 35–20) to resist passive regurgitation of gastric contents into the oropharynx are elements of a traditional rapid sequence induction.[5,19,51] The anesthetic begins with a rapid injection of propofol or thiopental, followed by succinylcholine and intubation as soon as muscle relaxation is confirmed. An assistant maintains cricoid pressure from the onset of hypnosis until tracheal intubation is confirmed, and the cuff is inflated. Other induction agents and nondepolarizing muscle relaxants are alternatives for induction.

Appropriate cricoid pressure, as described by Sellick, should be firm enough to prevent the esophagus from slipping laterally but not so firm as to obstruct ventilation.[5,60] This may be difficult to attain because the 30-N force currently recommended may obstruct the view of the larynx.[61] Sellick also described neck extension, but pursuing such extension at the expense of the sniffing position sacrifices the goal of smooth easy tracheal intubation. Application of cricoid pressure is a safe and effective maneuver, with one reported case of esophageal rupture in the presence of vomiting. Complete anesthesia and paralysis, confirmed with a blockade monitor, eliminates the chance of active vomiting. With this knowledge, the anesthesiologist can be confident in having the assistant maintain cricoid pressure until the tracheal position of the tube is certain.

Should intubation fail, the anesthesiologist should keep in mind that the risk of asphyxia may exceed the risk of aspiration. Mask ventilation with maintained cricoid pressure was described by Sellick[5] in 1961. If mask ventilation proves difficult, the patient should be placed in 5° of head-down tilt and the cricoid pressure decreased incrementally until it is released. If

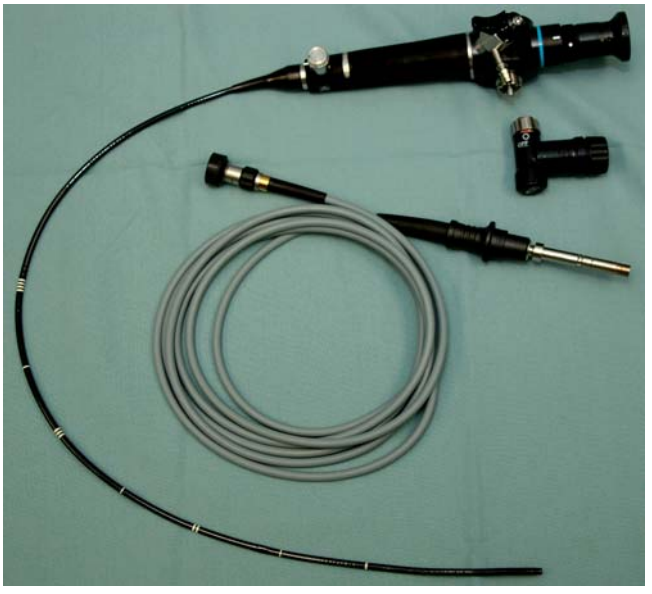

FIGURE 35–21. Olympus LF-GP bronchoscope. This bronchoscope can use a battery-powered, self-contained, or standard halogen light source.

mask ventilation is improved, intubation may proceed without cricoid pressure. If mask ventilation is impossible, the possibility of airway obstruction caused by improperly applied cricoid pressure[60] or previously unsuspected pathology (e.g., hypertrophic lingual tonsils) should be considered.

Any factor that increases the intragastric to esophageal pressure gradient predisposes to regurgitation of stomach contents. Factors that elevate this pressure gradient include inflation of the stomach with air, steep head-down position, high intraabdominal pressure, and spontaneous respiratory efforts against a fully or partially obstructed airway (which lowers the intraesophageal pressure). Airway pressures <15 cm H_2O during mask ventilation rarely inflate the stomach, whereas in adults without cricoid pressure, the minimum airway pressure required to push air into the stomach is reported to be 20 cm H_2O.

In infants and children, appropriate application of cricoid pressure prevents gastric gas insufflation during mask ventilation with an airway pressure up to 40 cm H_2O.[62] Complete airway obstruction is one of the complications of improperly applied cricoid pressure and is more likely to occur in infants and children because of their more pliable trachea.

FIGURE 35–22. Advanced carcinoma of the larynx.

Fiberoptic Intubation

A fiberscope (Fig. 35–21) can be used for routine and challenging intubations in patients with airway tumors or infections or cervical spine fractures or fixation (Fig 35–22).[3,63–68] Indications for fiberoptic tracheal intubation are summarized in Box 35–15.

Fiberoptic intubation is easier in the conscious patient because the tongue and epiglottis are less likely to obscure the vocal cords, and the patient can assist by phonating or protruding the tongue. Haste is unnecessary given that the patient is breathing. The patient with a history of failed intubation, upper airway abnormality, or expected difficult intubation may benefit from an awake fiberoptic intubation. Proper topical anesthesia and sedation ease the task.

With experience, topical anesthesia of the larynx and trachea can be achieved by spraying local anesthetic through the working channel of the fiberscope. Inhalation of nebulized lidocaine may minimize coughing.

Oral Fiberoptic Approach

After applying topical anesthetic to the tongue and oropharynx, a special oropharyngeal airway is inserted to prevent biting on the fiberscope, to keep the instrument in the midline, and to restrain the tongue (Fig. 35–23).[3] The oropharynx is suctioned, and the lubricated ET tube is placed 4–5 cm inside the airway. The fourth and fifth fingers of the right hand stabilize the ET tube, while the index finger and thumb insert the fiberscope through it (Fig. 35–24). If the fiberscope is accidentally passed through the Murphy eye of the ET tube, it will prevent subsequent intubation, even after the fiberscope is successfully guided into the trachea.

As the fiberscope is advanced toward the oropharynx, the soft palate and uvula come into view. With entry into the oropharynx, the tip is deflected anteriorly to expose the epiglottis and vocal cords. To separate a floppy epiglottis from the posterior pharyngeal wall, extending the head at the atlantooccipital joint or applying tongue traction or a jaw thrust is effective. In obese patients and in those with a difficult airway, the sitting position has merit.

After the glottis is exposed, it is maintained in the center of the field of view by fine manipulations of the control lever. The fiberscope is advanced into the midtrachea, as confirmed by observation of the carina and flat posterior wall (Fig. 35–25). The ET tube is slipped over the fiberscope and advanced with a twisting motion into the trachea. The tip of the ET tube is positioned 3–4 cm above the carina.

In many patients, even though the fiberscope has entered the trachea, the

Indications for Fiberoptic Intubation

- Routine intubation (teaching and learning)
- Difficult intubation
  - Anticipated
    - History of difficult intubation
    - Physical evidence of difficult intubation
  - Unanticipated
- Compromised airway
  - Upper airway abnormality
  - Tracheal stenosis and compression
- Extension of neck to be avoided
  - Unstable neck
  - Vertebral artery insufficiency
- High risk of dental damage
  - Poor, loose, or fragile teeth
  - Extensive dental restoration
- Conscious intubation

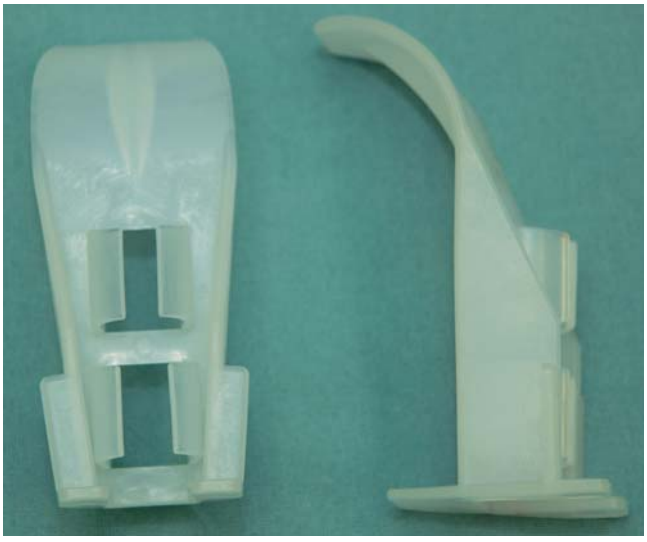

FIGURE 35–23. Ovassapian fiberoptic intubating airway.

ET tube catches on laryngeal structures and cannot pass.[69] The ET tube is pulled back, twisted until the leading ledge of the bevel is oriented anteriorly, and readvanced during a deep inspiration. In some patients, this maneuver may have to be repeated two or three times, particularly when a large discrepancy exists between the size of the fiberscope and the ET tube. Using a larger size fiberscope,[70] an anode tube,[71] or a special tube with tapered tip,[72] such as the tube used to intubate through the LMA Fastrach (Fig. 35–26), minimizes the incidence of difficult advancement of the tube through the larynx.

Laryngospasm may prevent ET tube advancement. Additional topical anesthesia applied through the fiberscope usually remedies this problem.

Nasal Approach

In the conscious patient, fiberoptic nasotracheal intubation often is easier than an oral approach.[3] Minimal pressure on the base of the tongue leads to less gagging, and the patient cannot bite the tube. By creating a "straight shot," passing the fiberscope through the nose facilitates locating the glottis and advancing the fiberscope and tube into the larynx. A warmed, softened, lubricated tube, advanced into the pharynx through a nasal passage prepared with anesthetic with or without a vasoconstrictor, serves as a channel to suction the pharynx and to find the glottis with a fiberscope. Laryngeal anesthesia and intubation proceed as described for the oral approach. The gag reflex is not stimulated by nasal intubation, so no oropharyngeal topical anesthesia is needed. If the tube does not make the bend, it is pulled back, rotated 90°, and reintroduced. If this maneuver fails, the ET tube is withdrawn to allow the lubricated fiberscope to guide it into the oropharynx.

It is important to avoid passing the tube too far into the oropharynx because this may direct the fiberscope into the esophagus or away from the midline, preventing laryngeal exposure. The oropharynx is suctioned thoroughly through the ET tube before the lubricated fiberscope is inserted through it. In most patients, the epiglottis and vocal cords are seen immediately with minimal manipulation of the fiberscope tip. In heavily sedated or edentulous patients, the tongue and pharyngeal tissues may block exposure of the glottis, necessitating head extension, jaw thrust, or tongue traction. The fiberscope is advanced into the midtrachea, followed by the ET tube.

Asleep Fiberoptic Intubation

Fiberoptic oral and nasal intubation in the anesthetized patient require an assistant to monitor the patient and apply jaw thrust.[3] Intubation attempts are interrupted to ventilate the patient as needed. With oral and nasal approaches, the ET tube is loaded on the fiberscope before intubation is attempted. The fiberscope then is passed through the nostril or intubating airway in the mouth and advanced through the glottis into the trachea. The ET tube then is advanced over the fiberscope into the trachea (Fig. 35–27).

Failed rigid laryngoscopic intubation, during a rapid sequence induction, leaves the patient vulnerable to aspiration. If the patient can be ventilated via face mask, then oral fiberoptic intubation, while maintaining cricoid pressure, is an effective technique that should be seriously considered. The ability to perform rapid fiberoptic intubation may play an important role in preventing airway problems. Repeated unsuccessful attempts at BNI or rigid laryngoscopy traumatize the airway, converting a manageable airway into one that is difficult to ventilate.

In a rapid sequence induction incorporating fiberoptic intubation, one assistant maintains cricoid pressure while another applies jaw thrust (Fig. 35–28). Excessive cricoid compression may block the endoscopist's view of the glottis by folding the epiglottis posteriorly.

Intubation Through an LMA

The LMA Classic can be used to manage a "cannot intubate, cannot ventilate" situation or to facilitate tracheal intubation.[73–76]

Three distinct techniques exist for tracheal intubation through the LMA Classic or LMA Unique: blind passage of a 6.0-mm inner diameter or smaller ET tube,[29] blind insertion of a guide to facilitate the threading of a large ET tube after LMA removal,[75] or fiberoptic-assisted tracheal intubation through the LMA. With ideal LMA position, the aperture lies opposite the glottic inlet, allowing blind insertion of an ET tube or guide. When the epiglottis partially blocks the laryngeal inlet, fiberoptic assistance is needed. The Aintree intubation catheter (Cook Critical Care, Bloomington, IN) has a 4.7-mm internal diameter and a 56-cm length. It is specifically designed to facilitate intubation when an LMA is in place. A fiberoptic bronchoscope is placed through the catheter. The scope and catheter are directed through the LMA into the trachea. With the catheter left in place, the fiberoptic scope is removed, and the LMA is removed over the catheter. The trachea is then intubated over the catheter.

The distance from LMA aperture bars to the vocal cords is 3.5 cm.[77] If the length of a 6-mm ET tube is limited to 26 cm, the cuff of the ET tube will be positioned inside the larynx just beyond the vocal cords, which may increase the possibility of a laryngeal nerve palsy.

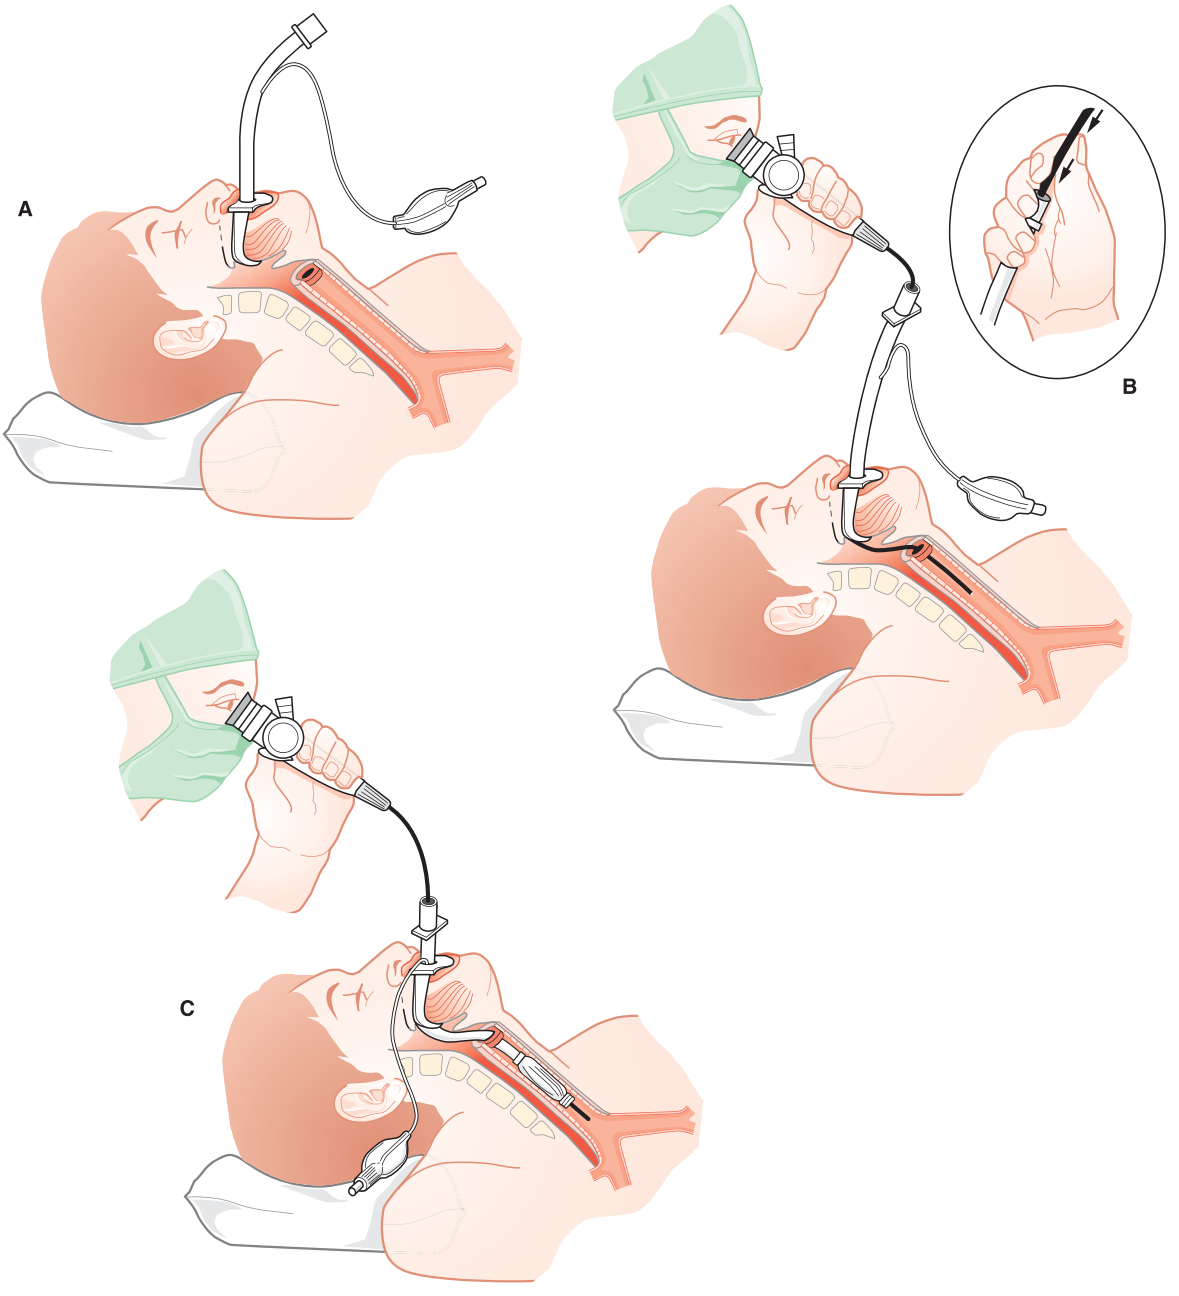

FIGURE 35–24. Fiberoptic orotracheal intubation during sedation and topical anesthesia. **A.** After sedation and application of topical anesthesia, an Ovassapian intubating airway is placed, and the oropharynx is suctioned. **B.** The endotracheal tube is removed from a warm water bath, lubricated, and placed inside the airway. The fiberscope is advanced through the endotracheal tube into the oropharynx, under the epiglottis, and inside the trachea. Care should be exercised to avoid passing the fiberscope through the Murphy eye. **C.** The endotracheal tube is slipped over the fiberscope into the trachea. The distance between carina and tip of the endotracheal tube is measured using the fiberscope before it is removed. (From Ovassapian[3] with permission.)

The Fastrach intubating LMA (LMA North America, San Diego, CA) is unique among airway management tools because it is the only device designed to assist with ventilation and intubation.[78] The Fastrach LMA was introduced as an intubation device in 1997. It is designed to facilitate blind or fiberoptic-aided tracheal intubation with a large size ET tube while maintaining the ventilatory properties of the classic LMA. It is available in three sizes and has a rigid anatomically curved tube made of stainless steel with a standard 15-mm connector and an epiglottic elevating bar. The caudal end of the epiglottic elevating bar is not fixed, allowing it to elevate the epiglottis when an ET tube is passed through the aperture. The tube is large enough to accept a cuffed 8-mm ET tube and is short enough to ensure passage of the cuff of the ET tube beyond the vocal cords. The tube is fitted with a rigid handle to facilitate one-handed insertion, removal, and adjustment of the device's position during intubation.

The Fastrach LMA permits single-handed insertion without moving the head and neck from a neutral position. Because a direct line of sight is not required, the person performing the

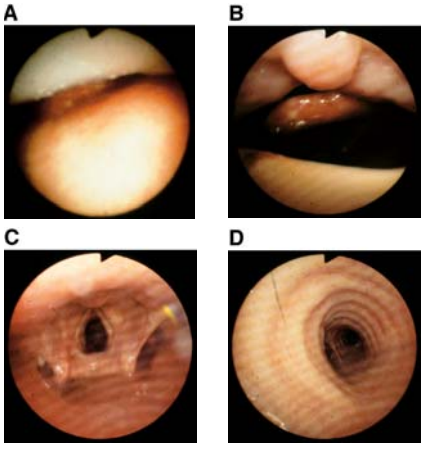

FIGURE 35–25. Endoscopic view during orotracheal intubation. **A.** As the fiberscope enters the intubating airway, the white laryngeal surface of the Ovassapian airway is seen at the top of the circle. The soft palate is visualized in the lower half of the slide. **B.** When the tip of the fiberscope is advanced to the oropharynx, the distal end of the Ovassapian airway can be seen covering the base of the tongue, and the epiglottis is in the center of the view. **C.** With the tip of the fiberscope passed beneath the tip of the epiglottis, the glottic opening is visualized. **D.** The tip of the fiberscope is located in the lower third of the trachea, revealing the carina.

intubation does not need to be behind the patient's head, an advantage when the patient is contained in a small space or is in unusual position, such as

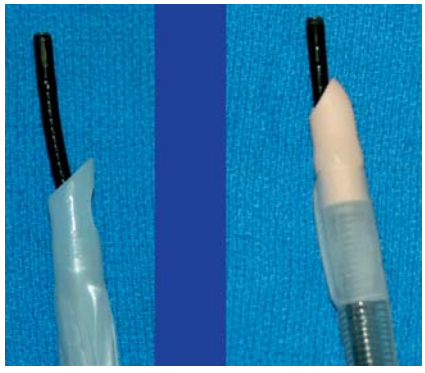

FIGURE 35–26. Endotracheal tubes over a 4.0-mm flexible bronchoscope. The tube designed for intubation through the Fastrach LMA (right) has a curved tip, which eases passage of the tube into the trachea.

victim trapped in a motor vehicle accident. Ventilation and oxygenation can be continued during intubation to prevent desaturation.

Tracheal intubation has been achieved successfully under many difficult situations, including in patients with cervical spine diseases. One series of 254 patients with difficult to manage airways showed that 96.5% of patients had successful blind intubation via the LMA. The remaining patients were intubated using a flexible bronchoscope placed through the LMA.[79]

The most recent development in the evolution of the LMA is the introduction of the LMA CTrach (LMA North America; Figure 35–29). The general shape of the device is similar to the Fastrach but has added features of fiberoptic light and image transmission bundles and a small monitor that is mounted on the CTrach to display the view of the larynx during intubation.

Light Wand

This technique uses a lighted stylet to transilluminate the anterior neck, guiding an ET tube into the trachea. The Trachlight light wand has a bright light and stylet long enough to be used with an uncut ET tube. A clip holds the ET tube in place. The Trachlight has been used successfully in patients with routine or difficult oral intubations.[80]

The light wand is lubricated and inserted into the distal tip of the ET tube. The styletted tube is bent proximal to the cuff at a 90° angle. After induction of anesthesia and muscle relaxation, the tongue is grasped with a sponge and pulled forward. The light wand is introduced into the mouth and posterior to the tongue in the midline.

When light is seen in the anterior neck above the thyroid notch, the tip of the tube is in the vallecula. If the tube enters the esophagus, the light

FIGURE 35–27. Fiberoptic orotracheal intubation during general anesthesia. **A.** The patient is paralyzed, the intubating airway is in place, and the oropharynx has been suctioned. The operator receives the fiberscope from an assistant and inserts the tip of the fiberscope inside the intubating airway. **B.** The assistant applies a jaw thrust as soon as the fiberscope has been passed to the operator. The operator looks through the fiberscope and advances the insertion cord through the airway and vocal cords into the trachea. The tube is rotated 45–90° if resistance is encountered during advancement through the vocal cords. Note the position of the endoscopist's right hand.

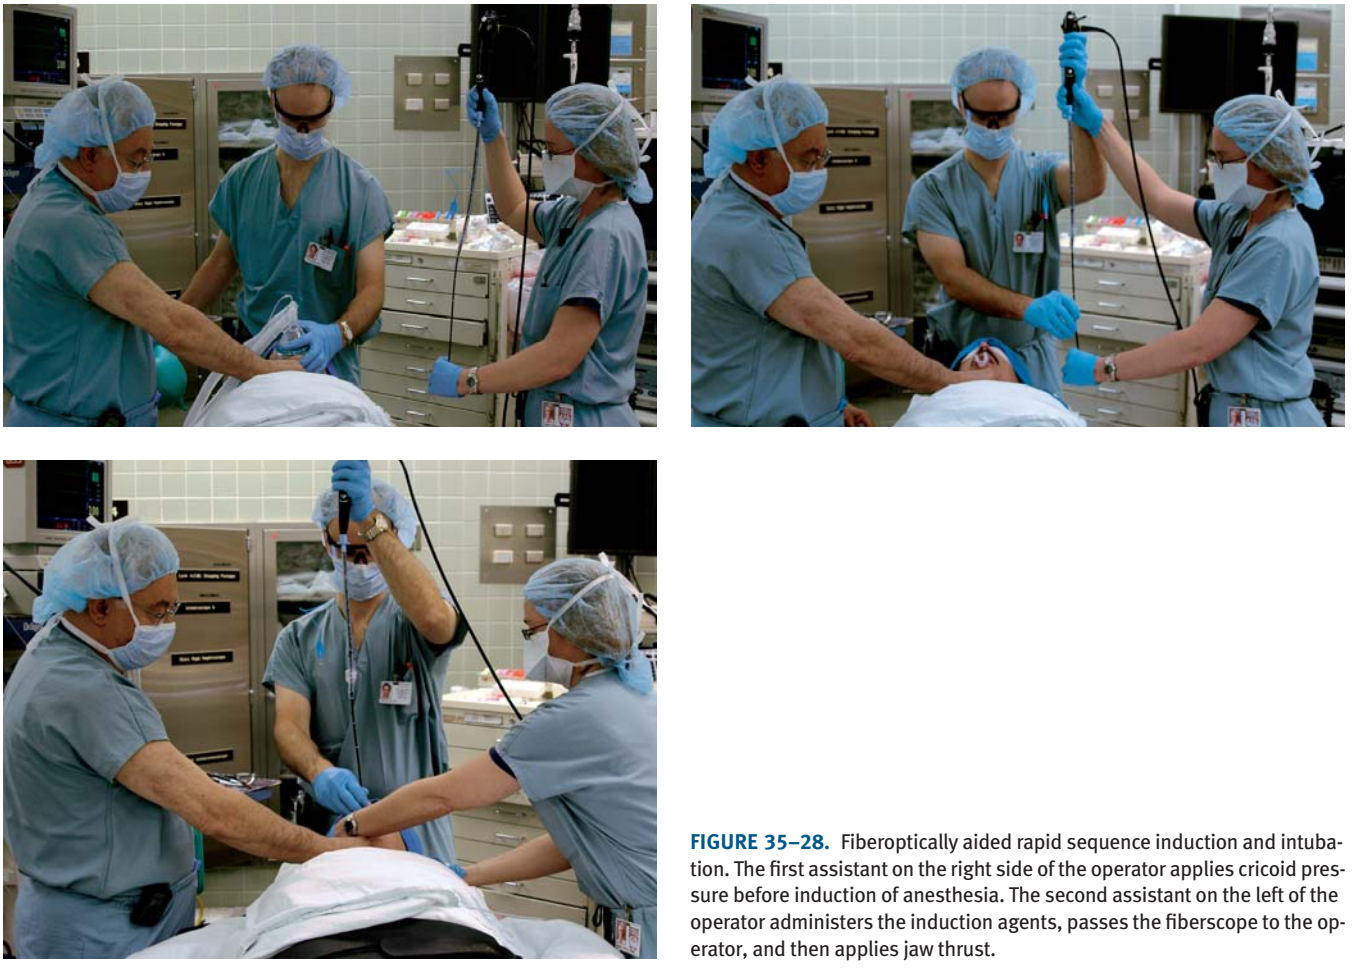

FIGURE 35–28. Fiberoptically aided rapid sequence induction and intubation. The first assistant on the right side of the operator applies cricoid pressure before induction of anesthesia. The second assistant on the left of the operator administers the induction agents, passes the fiberscope to the operator, and then applies jaw thrust.

dims or disappears. Off-midline transillumination indicates the tip is in a piriform recess, requiring withdrawal and rotation into the midline. When the tip of the tube enters the larynx, the light is visible below the cricoid cartilage, at which time the stylet is withdrawn to allow the tube to be threaded into the trachea.

The light wand orotracheal intubation technique has been used successfully in patients with unstable cervical vertebrae, burn strictures of the neck, and congenital airway problems, such as Treacher Collins and Pierre Robin syndromes.

Retrograde Intubation

Retrograde intubation involves passing a guidewire through a needle percutaneously inserted into the larynx and delivering the wire through the mouth or nose to serve as a guide for the ET.[81–83] Dedicated kits (Cook Retrograde Intubation Set, Bloomington, IN) are available for pediatric and adult use.

The supine patient is placed in the sniffing position. The oropharynx is topically anesthetized. An 18-gauge needle attached to a syringe containing 2 mL of 4% lidocaine is inserted through the cricothyroid membrane in a cephalad direction into the larynx. Aspiration of air confirms correct placement of the needle, and the local anesthetic is injected into the larynx. The guidewire is threaded through the needle into the pharynx, and the tip is delivered through the mouth.

A guide is passed over the wire through the mouth, cords, and into the trachea. Then the ET tube is advanced over the guide into the trachea (Fig. 35–30).

A fiberscope loaded with an ET tube can be advanced over the guidewire or next to the guidewire to assist retrograde intubation.[81,82] A technique that involves passing the guidewire through the suction channel of the fiberscope has greatly improved the success rate of retrograde intubation.

The most common complication with the retrograde technique is bleeding in and around the airway. Bleeding usually is minor and does not require special treatment. Other complications are trauma to the airway, pneumomediastinum, and failed intubation.[83]

Blind Nasal Intubation

BNI is a valuable technique in the patient who is uncooperative, unable to open the mouth, or has a fair amount of secretions or blood in the airway.[51,84,85] The nasal mucosa is prepared with a cocaine or a mixture of vasoconstrictor and local anesthetic. If sedation is needed, ketamine, which allows maintenance of an airway with spontaneous ventilation, has been used to provide sedation or induce general anesthesia to facilitate BNI.

The head is placed in the sniffing position, and a lubricated ET tube is advanced gently into the oropharynx. If resistance is encountered when entering the oropharynx, the tube is withdrawn approximately 2 cm, rotated 90°, and readvanced. If still unsuccessful, a suction catheter or a nasogastric tube passed through the ET tube into the oropharynx serves as a guide. The intensity of breath sounds and bulging produced in the neck guide maneuvers.[84] As the tube is advanced toward

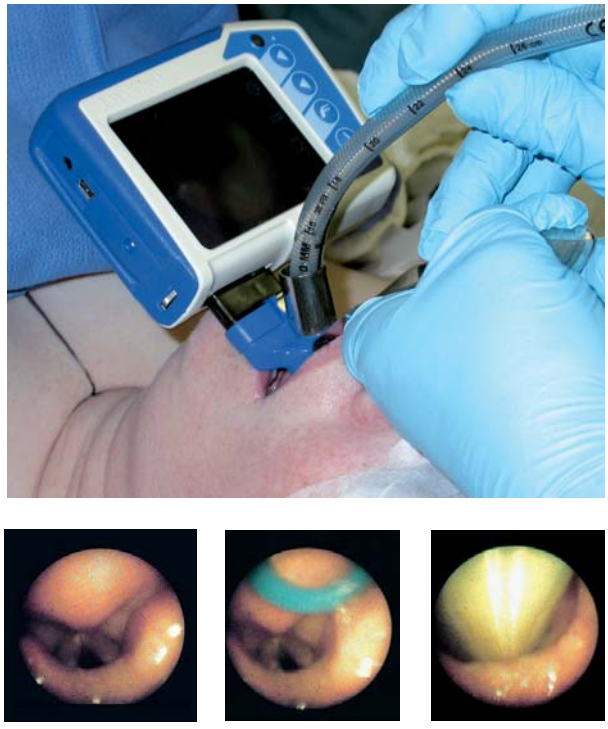

FIGURE 35–29. Latest addition to laryngeal mask airway families, the LMA CTrach. Views observed on the monitor during intubation. Shown from left to right are the glottic view showing the green epiglottic elevator bar pushing the epiglottis up and the endotracheal tube passed through the larynx.

the larynx, the breath sounds become louder. To help pass through the cords, the patient is encouraged to breathe deeply and rapidly, and the tube is advanced quickly during inspiration. Successful intubation is confirmed by continued breath sounds through the tube and the patient's inability to phonate. Coughing is common when topical anesthesia is omitted.

If breath sounds are lost, the tube has not entered the trachea. It may be in the esophagus, valleculae, or one of the piriform recesses. A loss of breath sounds without resistance to passage indicates esophageal placement. In this case, the tube should be withdrawn and readvanced after further elevating and extending the patient's head. Inflating the tracheal tube cuff with 15 mL of air may accomplish the identical end.[85] The tube is advanced 1–3 cm before the cuff is deflated and advanced further into the trachea. Entry into a piriform recess is corrected by withdrawal and rotation. Obstruction by the epiglottis necessitates neck flexion and jaw thrust or application of traction on the tongue.

Success rates between 86% and 97% have been reported for BNI. Success rates in emergency room patients have been reported as approximately 90%.[86] BNI is less successful when the larynx is distorted by a mass, edema, or scarring from previous surgery. Contraindications to BNI include nasal pathology, coagulopathy, thrombocytopenia, severe midface trauma, and prior transsphenoidal surgery; the latter two contraindications may allow the ET tube to pass into the cranium in some patients.

Complications of BNI include trauma to the nasopharyngeal mucosa, entering the submucosal plane of the pharynx, dislodging nasal polyps, pushing foreign bodies into the larynx, and nasal bleeding.[84,86] Difficulty advancing the tracheal tube into the oropharynx may be a result of septal deviation, a turbinate spur, hypertrophied inferior turbinates, or nasopharyngeal lymph nodes. Use of a smaller tube or of the other nostril may remedy these problems.

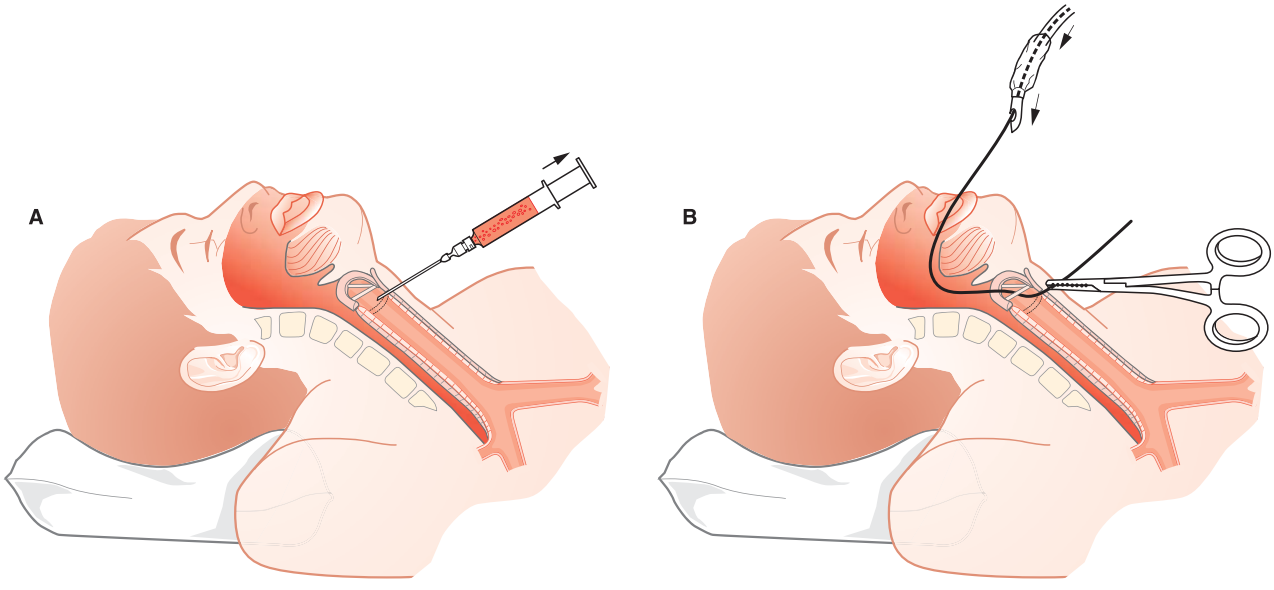

FIGURE 35–30. Retrograde intubation. **A.** Needle attached to a syringe filled with lidocaine is passed through the cricothyroid membrane into the larynx. Free aspiration of air confirms correct placement of the needle. Lidocaine is injected to provide topical anesthesia of the airway. **B.** The guidewire is passed into the needle, retrograde through the larynx, and up into the oropharynx. The guidewire is retrieved through the mouth using a hook or forceps. The endotracheal tube is advanced over the guidewire into the trachea. (From Ovassapian[3] with permission.)

Cricothyrotomy and Tracheostomy

In patients with upper airway obstruction or failed tracheal intubation, surgical establishment of the airway through the anterior neck is indicated. Cricothyrotomy involves entering the larynx through the cricothyroid membrane, allowing passage of a small ET tube or a special cricothyrotomy tube into the trachea. Cricothyrotomy is preferred to tracheostomy when an airway must be established promptly. Cricothyrotomy is faster, is easier to perform, and is farther away from the mediastinum than tracheostomy. Several kits are available for percutaneous cricothyrotomy including the Melker cricothyrotomy system (Cook Critical Care). Applying the Seldinger technique for cricothyrotomy is easy for nonsurgeons faced with a patient who has a difficult airway.[87] Cricothyrotomy usually is performed during emergency situations and in less than optimal conditions, increasing the chances for laryngeal injury. Once the patient is stabilized, the wound and the larynx should be examined.

Percutaneous Transtracheal Jet Ventilation

Placement of a large-bore catheter through the cricothyroid membrane (needle cricothyrotomy) into the trachea provides rapid access to the airway and can be lifesaving when mask ventilation and tracheal intubation have failed.[88,89]

The incidence of malfunctioning of thin-walled 16- or 14-gauge IV catheters caused by kinking or dislodgment is high and can cause major complications. This problem is more likely to occur in an awake, struggling patient. The Arndt emergency cricothyrotomy catheter set (Cook Critical Care) may minimize these problems. The set features a 3-mm, kink-resistant catheter with a 15-mm Luer-Lok connector. A hollow, tapered-tip dilator is provided to assist with placement of the catheter into the trachea. Once in place, the airway catheter and its 15-mm adapter can be connected to the common gas outlet of the anesthesia machine or Ambu bag, or directly to a jet ventilator through the Luer-Lok adaptor. The relatively large size tracheal catheter permits effective high-pressure jet ventilation. Bag-valve manual ventilation provides some oxygen delivery but ineffective ventilation with a progressive increase in CO_2 concentration.

Rupture of the lungs may produce a pneumomediastinum, pneumothorax, or other complications. In the event of total upper airway obstruction, percutaneous transtracheal jet ventilation requires establishment of an exit airway. Inadequate exhalation time or inability of gas to escape can lead to "breath stacking" or pulmonary tamponade. The resultant impairment of venous return can lead to hypotension and even pulseless electrical activity similar to that seen with a tension pneumothorax. It is prudent to practice the technique initially on a mannequin and gain expertise during controlled patient care conditions before applying it to emergency situations.

Percutaneous transtracheal jet ventilation has been used as an interim means of oxygenation during a difficult intubation.[89]

CARE AFTER TRACHEAL INTUBATION

Confirmation of Tracheal Intubation

Visually observing the position of the ET tube between the cords after passage is a reliable indicator of tracheal intubation. Immediately after intubation, the cuff is inflated, and the anesthesiologist should observe the sequential rise and fall of the chest while auscultating over each midaxillary line and the epigastrium to assure that the trachea, not the esophagus or bronchi, has been intubated. Because breath sounds have misled even skilled clinicians, the ASA's intraoperative monitoring standards mandate confirming tracheal intubation by detecting consistent levels of exhaled CO_2 in successive breaths.[25,26] Carbon dioxide can be sampled while ventilating the esophagus, but exhaled CO_2 concentrations fall after a few breaths (Fig. 35–31).[26] During circulatory shock, exhaled CO_2 levels may be very low despite proper tracheal tube position. If no sustained CO_2 levels are detected and the patient has a perfusing rhythm, the tracheal tube should be removed and the lungs ventilated by mask, particularly if there is a low risk for aspirating gastric contents.

The self-inflating bulb (Ambu TubeChek B, Ambu Inc., Glen Burnie, MD) relies on anatomy rather than the physiology of CO_2 in exhaled gases. The device reinflates within 5 seconds if the tube is in the trachea but should remain collapsed if the tube is in the esophagus. (Fig. 35–32).[90]

When an ET tube is ideally positioned, the tip of the ET tube is placed 3–4 cm above the carina and the tube cuff is positioned below the cricoid ring. The practice of taping the ET tube at 21 cm in women and 23 cm in men at the teeth level may place the tube cuff inside the larynx in some patients and should be discouraged. To avoid endolaryngeal placement of the ET tube cuff, the superior border of the ET tube cuff should pass 2.5–3 cm beyond the level of the true vocal cords. Some ET tubes identify this depth by placing a black dot or circle on the tube 2.5–3 cm above the tube cuff. Nasotracheal tubes should be inserted 3 cm deeper.

Maintaining the Tracheal Tube

To avoid tracheal mucosal ischemia, many clinicians fill the cuff so that there is a small audible leak at peak airway pressure. During prolonged intubation, regular checks are conducted to prevent overinflation.

Tracheal tubes usually are secured with adhesive tape. Tincture of benzoin or other skin adhesives may improve stability. An oropharyngeal airway or roll of gauze sponges placed between the teeth keeps the patient from biting

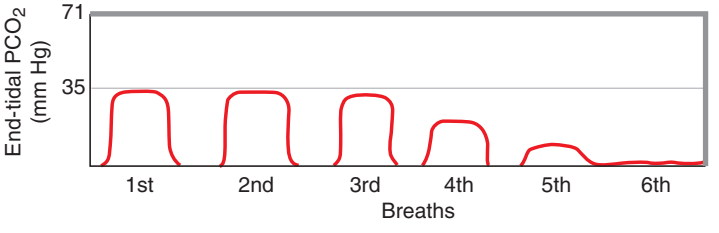

FIGURE 35–31. CO_2 waveform after esophageal intubation. The first three breaths may look like normal waves but will decrease in amplitude quickly. With tracheal intubation, the CO_2 level remains constant. (From Sum Ping[26] with permission.)

FIGURE 35–32. Self-inflating bulb fitted with a standard 15-mm adapter used as an esophageal detector device. Disposable CO_2 detector showing the green color change to yellow color with CO_2 exposure.

the tube. Nasotracheal tubes should be taped securely while avoiding pressure on the nares. The position of the tube should be verified each time the patient's position changes.[12]

MANAGING THE DIFFICULT AIRWAY AND THE ASA DIFFICULT AIRWAY ALGORITHM

Patients difficult to intubate often can be ventilated by face mask. When intubation has failed but ventilation is adequate, the anesthesiologist should weigh the available options, assuring that each new maneuver represents a logical, substantive change from steps that have failed. Repeated rigid laryngoscopy may cause bleeding and rapidly evolving airway edema that frustrate subsequent attempts and may render mask ventilation difficult.[91] Therefore it is essential to anticipate patients at risk so that they can benefit from a controlled awake intubation. Proper preparation includes optimal positioning, thorough denitrogenation, glycopyrrolate pretreatment, and ensuring the presence of proper tools and personnel. Only two or three rigid laryngoscopy attempts generally are indicated before changing techniques.[2,3,91] A simple algorithm for tracheal intubation using two attempts at direct laryngoscopy with a Macintosh blade and fiberoptic intubation has been reported to have a 99.96% success rate when the two techniques are used regularly.[92] A return to spontaneous ventilation may be the wisest course. Experienced assistance is invaluable.

Morbidity and mortality related to airway management prompted the ASA's Difficult Airway Task Force to develop a management algorithm (Fig. 35–33).[91] Subsequent to the publication of the ASA guidelines, other organizations have published guidelines for airway management.[93,94]

Key features of the ASA guidelines include three management choices made before initiating the anesthetic: (1) Should the airway be secured with the patient awake or after induction of general anesthesia; (2) Should the initial technique be noninvasive or should it include invasive elements? (3) Should spontaneous ventilation be maintained or abolished? If problems are encountered after induction of general anesthesia, the algorithm distinguishes between difficult ventilation (life-threatening) and difficult intubation (rarely life-threatening). The LMA plays a prominent role in the 2003 revision of these guidelines because it can be used to establish or maintain ventilation and oxygenation, and it may also facilitate intubation.[91]

Because any patient may unexpectedly prove difficult to intubate or ventilate, proper denitrogenation before induction of general anesthesia should be routine. Maintaining skills at techniques of ventilation without tracheal intubation and mastering a variety of methods for tracheal intubation are a must for every anesthesiologist.[2,3] Each anesthetizing location should have rapid access to a difficult airway cart, including equipment to deal with a cannot ventilate, cannot intubate scenario.

EXTUBATING THE TRACHEA

The Routine Airway

Extubation of the easily intubated patient who did not undergo airway surgery is performed as soon as extubation criteria are met (Box 35–16).[4,19,51] Breathholding and coughing elevate pulse, blood pressure, intracranial pressure, and intraocular pressure (Box 35–17).[95,96] Intravenous lidocaine and esmolol are popular adjuncts to minimize coughing and the cardiovascular responses to laryngeal stimulation by the ET tube during emergence from anesthesia.[97]

Extubation of the trachea during deep anesthesia minimizes the cardiovascular response,[98] although ventilatory depression, upper airway obstruction, and difficulty with mask ventilation may be problematic. In patients who were difficult to intubate or in those at high risk for aspiration, extubation during deep anesthesia usually is contraindicated. Even properly treated asthmatic patients tolerate conscious extubation.

Laryngospasm and airway obstruction may occur after extubation, especially in children.[99] Although mild laryngeal spasm presents with stridor, a severe episode results in complete airway obstruction and silence. Management of laryngeal spasm includes applying positive-pressure oxygen, suctioning oropharyngeal secretions, and providing jaw thrust. In patients with severe episodes, intravenous succinylcholine 0.1 mg/kg will relieve the spasm, permitting mask ventilation without apnea.[100] On rare occasions, reintubation may be necessary.

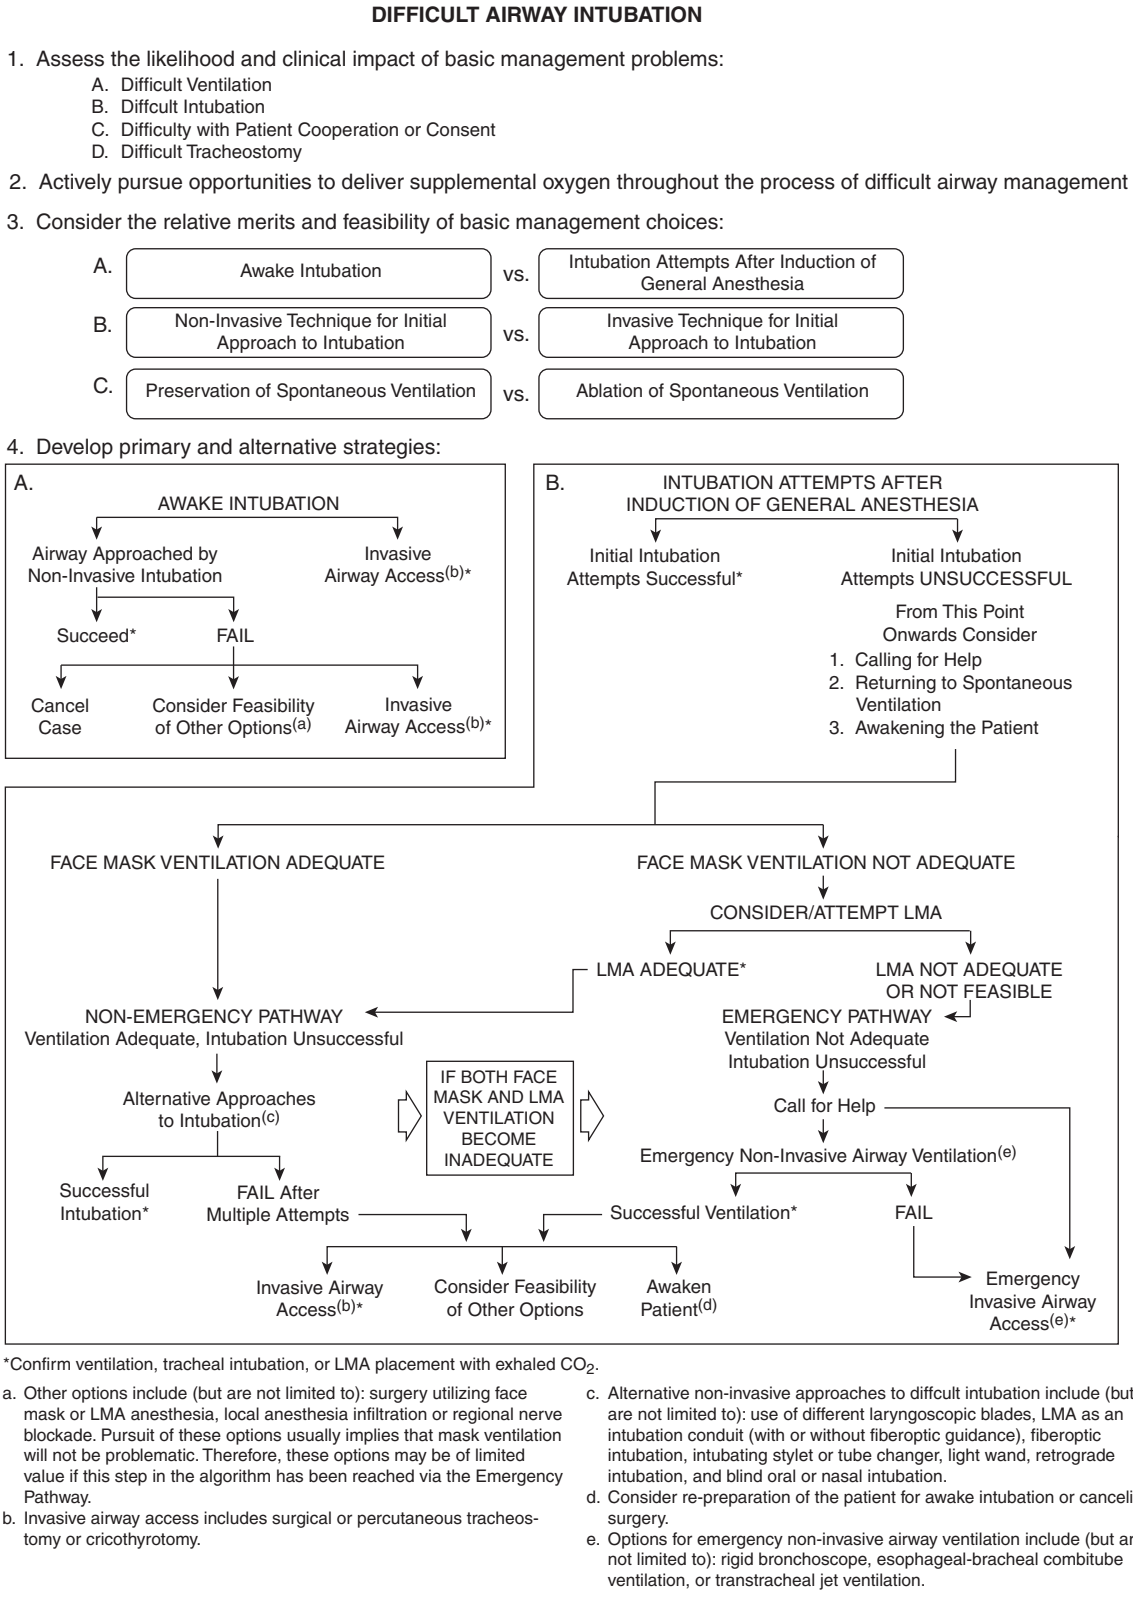
Laryngeal edema should be suspected when postextubation inspiratory stridor develops within 30–60 minutes after extubation.[101] Laryngeal edema caused by intubation is uncommon in adults. Overhydration, prolonged Trendelenburg position, and an allergic reaction to medications given before or during surgery should be considered. Management includes the head-up position, humidified oxygen, racemic epinephrine, dexamethasone, and reintubation.

Acute pulmonary edema may complicate tracheal extubation when severe airway obstruction coexists with vigorous spontaneous attempts at inspiration.[99,102] The negative intrathoracic pressure and possibly associated hypoxemia contribute to the development of pulmonary edema. Management consists of relieving the obstruction and administration of supplemental oxygenation while the congestion resolves.

Tracheomalacia caused by thyroid disease may cause airway obstruction after extubation.[101,103]

The Difficult Airway

A closed claims analysis showed that since the introduction of the ASA



*Confirm ventilation, tracheal intubation, or LMA placement with exhaled CO_2.

a. Other options include (but are not limited to): surgery utilizing face mask or LMA anesthesia, local anesthesia infiltration or regional nerve blockade. Pursuit of these options usually implies that mask ventilation will not be problematic. Therefore, these options may be of limited value if this step in the algorithm has been reached via the Emergency Pathway.

b. Invasive airway access includes surgical or percutaneous tracheostomy or cricothyrotomy.

c. Alternative non-invasive approaches to diffcult intubation include (but are not limited to): use of different laryngoscopic blades, LMA as an intubation conduit (with or without fiberoptic guidance), fiberoptic intubation, intubating stylet or tube changer, light wand, retrograde intubation, and blind oral or nasal intubation.

d. Consider re-preparation of the patient for awake intubation or canceling surgery.

e. Options for emergency non-invasive airway ventilation include (but are not limited to): rigid bronchoscope, esophageal-bracheal combitube ventilation, or transtracheal jet ventilation.

FIGURE 35–33. The American Society of Anesthesiologist's difficult airway algorithm. (From American Society of Anesthesiologists Task Force on Management of the Difficult Airway[91] with permission.)

practice guidelines for management of difficult airways in 1993, there has been a reduction in airway-related claims associated with the induction of anesthesia. However, there has been no change in the rate of claims related to airway misadventures during the maintenance, emergence, or recovery from an anesthetic. The authors call for the development of additional management strategies during these phases.[104]

Patients who were difficult to intubate, who had major head and neck operations, or in whom airway access is

BOX 35–16.

Tracheal Extubation in Patients with Uncomplicated Airways

Criteria for Extubation
- No indication to keep patient intubated
- Spontaneous ventilation is adequate
- Muscle relaxant is fully reversed (demonstrated with strong head lift or hand grip)
- Airway reflexes are recovered
- Patient follows commands

Technique of Extubation
- Suction oropharynx before patient is reactive
- Administer 100% oxygen for several minutes
- Remove tape
- Deflate the cuff
- Apply positive pressure to the breathing bag, and gently remove the tracheal tube
- Suction again if secretions are present
- Apply mask with high-flow oxygen
- Check for airway patency and adequacy of ventilation

BOX 35–17.

Complications Related to Extubation

During Extubation
- Hypertension, tachycardia, arrhythmias
- Coughing, breathholding, cyanosis
- Difficult extubation

Postextubation
- Laryngospasm
- Airway obstruction
  - Soft-tissue obstruction
  - Laryngeal edema
  - Edema of stenotic trachea
  - Vocal cord malfunction
    - Bilateral palsy
    - Unilateral palsy
    - Dysfunctional vocal cords (paradoxical adduction during inspiration)
  - External compression
    - Hematoma
    - Bleeding
  - Laryngotracheomalacia
- Negative-pressure pulmonary edema
- Aspiration of gastric contents
- Ventilatory depression
- Laryngeal incompetence
- Dysphonia, aphonia
- Dislocation of arytenoid
- Laryngotracheal stenosis
- Sore throat

BOX 35–18.

Challenges of Immediate Reintubation
- Known difficult airway
- Surgical distortion
- Limited access
- Edema
- Uncooperative, combative patient
- Emergent nature
- Blood and secretions
- Hematoma
- Cervical immobilization or instability
- Maxillomandibular fixation
- Head and neck dressing
- Halo vest
- Inadequate experience
- Difficult mask ventilation
- Risk of aspiration
- Poor oxygenation and ventilation
- Poor topical anesthesia as a result of secretions
- Occurrence during transportation
- Unavailability of equipment

restricted are at high risk after extubation. The timing of extubation, equipment availability, and presence of a skilled anesthesiologist are vital in these patients. Should emergent reintubation be required, these patients are likely to be hypoxic, hypercapnic, and uncooperative, with gastric distension from failed ventilatory attempts (Box 35–18).[105]

Possible approaches to these patients include extubating them when fully awake, extubating after edema or hematoma has resolved, extubating after assuring a leak around a deflated cuff (cuff-leak test),[54] or extubating over an introducer, fiber scope, or jet stylet.[106–108] The presence of a leak around a deflated ET tube cuff usually predicts that glottic edema will not complicate extubation in adult patients. Exchange for an LMA or extubation in front of an LMA likely will be the most common technique to bridge to extubation (Fig. 35–34).[109,110]

LMA-assisted extubation is beneficial in several situations. Some examples include prevention of upper airway obstruction in obese patients; in head and neck operations to avoid severe hypertension and bleeding; for head and neck free flap and skin graft operations to avoid damage to the new flap; in intraocular operations to prevent pressure on the eye caused by face mask ventilation; and to provide a conduit for fiberoptic assessment of the vocal cord function after thyroidectomy. The exchange is performed while the patient is anesthetized and before the muscle relaxant effect is reversed. The ET tube tape is moved to the lower lip, and a size 3 or 4 deflated LMA Classic is placed behind the ET tube. It is advanced to its position using either the standard finger technique or by bringing the shaft to parallel to the chest and advancing the LMA against the hard palate in a cephalad and downward direction. Anesthesia is then discontinued, and the ET tube is removed as soon as spontaneous ventilation has begun. The LMA is removed when the patient is fully awake and responds to the LMA. At this stage, patients usually maintain good air exchange and do not require any airway support after the device is removed.

Extubation Over a Jet Stylet

The jet stylet, an airway exchange catheter, or a bougie can be left in the trachea to facilitate reintubation.[106,108] Should reintubation fail, the jet stylet can be used to oxygenate and ventilate patients.[106] The jet stylet can be positioned in the lower trachea using centimeter markings along its length. Tissue trauma from catheter whip or direct injury from the air jet is a major concern. Side holes placed along its distal 5 cm help minimize tissue trauma from these causes.

The Difficult Extubation

Iatrogenic causes and mechanical failure on rare occasions can render extubation difficult or impossible.[108,111,112] Extubation may be difficult in patients with laryngeal abnormalities or in those who bite the ET tube. Difficult extubation with a deflated cuff has been reported, resulting from folding of the ET tube cuff below the vocal cords and from laryngeal edema caused by difficult intubation. Persistent fixation of the tra-

BOX 35–19.

Complications of Tracheal Intubation

Physiologic Responses to Laryngotracheal Stimulation
Cardiovascular
Tachycardia, hypertension, myocardial ischemia
Reflex bradycardia
Bronchospasm and bronchorrhea
Intracranial hypertension
Intraocular hypertension or extrusion of vitreous humor
Trauma
Abrasion of the cornea
Laceration of the lips, gums, tongue, pharynx
Epistaxis
Perforation of pharyngeal or esophageal mucosa
Chipping or avulsion of teeth or dental appliances
Persisting subluxation of the mandible
Laryngotracheal penetration with subcutaneous emphysema
Pneumothorax
Injury to the vocal cords and arytenoid cartilages
Tube Malposition
Prolonged or failed intubation
Insufficient insertion
Bronchial intubation
Airway Foreign Bodies
Teeth
Laryngoscope bulbs
Stylets
During Tracheal Tube Maintenance
Unintended extubation
Obstruction
Unrecognized disconnection
Changes in position
With Extubation
Physiologic responses (same as previous)
Difficult or impossible extubation
Laryngeal spasm
Negative-pressure pulmonary edema
Common Sequelae of a Mild Nature and Lasting <48 Hours
Hoarseness
Sore throat
Complications of Prolonged Intubation
Infections
Laryngotracheobronchitis
Sinusitis
Pneumonia
Laryngeal ulceration
Vocal cord granuloma
Tracheomalacia
Tracheal stenosis
Vocal cord paralysis

cheal tube with surgical wires, sutures, and screws also has been reported.

FOLLOWUP OF A DIFFICULT AIRWAY

For optimal airway management in the future, patients with proven difficult airways should be informed and identified. Immediate application of a temporary wristband or flagging the medical record will alert healthcare providers to these patients' special requirements.

A written statement with pertinent airway management information should be given to the patient, with a copy of the statement filed in the patient's medical record.

For future reference and availability of information for other healthcare organizations, the patient with a difficult airway can be enrolled in the Medic Alert Difficult Airway/Intubation Registry.[113]

COMPLICATIONS OF INTUBATION

The difficulties and complications related to tracheal intubation are numerous and can be related to the act of intubation, maintenance of the ET tube, or extubation (Box 35–19).[7,114–117] A closed claims analysis found that the larynx, pharynx, and esophagus were the most common sites of airway injuries. Pharyngoesophageal perforation injuries were the most severe. Early signs of perforation were present in only 51% of the claims. The authors recommend that patients in whom tracheal intubation has been difficult should be observed for and instructed to watch for signs and symptoms of retropharyngeal abscess, mediastinitis, or both.[115]
