The surgical condition may result in part or entirely from the endocrine disorder, for example, vasoocclusive disease in the patient with DM requiring peripheral vascular surgery. Alternatively, the surgery may directly target endocrine tissue, either for biopsy or for excision. The pathophysiologic implications of the endocrine lesion and of surgical manipulation of the diseased tissue must be understood in the context of anesthetic and perioperative management. The most common endocrine surgery involves the thyroid gland.

This chapter reviews the immediate perioperative implications of major endocrine disorders and addresses the specific issues encountered in surgery for common endocrine pathologies.

DIABETES MELLITUS

DM is a condition with an absolute (type 1) or a relative (type 2) deficiency of insulin. Chapter 12 reviews the complex physiology of DM. A fundamental concept in perioperative management is that the *type 1 diabetic patient has an absolute requirement for continuous exogenous insulin,* which can be supplied in several different preparations.[1] In the absence of insulin, despite a normal or low blood sugar concentration, the patient with type 1 DM will develop *ketoacidosis,* a metabolic derangement that interferes with basic cellular metabolism and drug responses. The pharmacokinetic profiles of the various insulin preparations warrant careful consideration (Table 59–1).[2] Without a source of glucose in the perioperative period, a patient may develop hypoglycemia from the residual effects of a long-acting insulin preparation.

In the immediate perioperative period, it is generally recommended that patients receive regular insulin by intravenous (IV) bolus or IV infusion. The uptake of intramuscular or subcutaneous insulin may be unpredictable in the perioperative period because of changes in tissue perfusion.

Patients with type 2 DM can be managed with diet alone, with oral agents alone, with insulin, or with a combination of oral agents, one of the newer injectable drugs (incretin mimetics), and insulin. The pharmacokinetic and pharmacodynamic profiles of oral hypoglycemic agents differ markedly (Table 59–2). Some oral agents (e.g., sulfonylureas) remain active for 24 hours, predisposing the patient to hypoglycemia during fasting. Other oral agents act as insulin sensitizers, improving the postreceptor action of insulin. Insulin sensitizers and incretin mimetics do not cause hypoglycemia when used in single-agent therapy. Some of these agents are newly introduced into clinical practice, so experience with their use in surgical patients during the perioperative period is minimal.

Clinical Features of DM

Although both major types of DM can share a number of clinical features, such as the presence of neuropathy, vascular and renal disease, and a predisposition to infection (see Chapter 12), an appreciation of the essential and distinctive features of each type is important.

Type 1 DM

The patient with type 1 DM usually is first diagnosed at a young age, but the disease may occur at any stage of life. The patient is generally thin or of normal body habitus. The patient with type 1 DM has an absolute requirement for chronic insulin therapy to prevent diabetic ketoacidosis (DKA). As a general rule, patients with type 1 DM are extremely sensitive to the effects of insulin compared to patients with type 2 DM and therefore receive relatively small doses of insulin to both control blood sugar levels and prevent DKA. Acute medical or surgical conditions can precipitate DKA

KEY POINTS

1. Endocrine diseases are common comorbid conditions in surgical patients.
2. The patient's type of diabetes mellitus must be known and the differing therapies of types 1 and 2 appreciated.
3. Frequent monitoring of glucose levels is a mainstay in the management of the diabetic patient undergoing anesthesia and surgery.
4. Hypothyroid patients may exhibit sensitivity to sedative and hypnotic drugs used perioperatively. Hemodynamic instability should be anticipated.
5. Hyperthyroid patients may exhibit hemodynamic instability and are at particular risk for tachydysrhythmias and metabolic decompensation.
6. The airway is a key consideration in patients undergoing thyroid surgery.
7. Pheochromocytoma patients require careful preoperative preparation, and plans must be made to manage hemodynamic extremes during surgery.
8. Glucocorticoid deficiency in patients at risk for adrenal suppression should be anticipated.
9. The implications of growth hormone excess (acromegaly) and adrenal steroid excess (Cushing disease) should be considered when preparing patients for pituitary surgery.

TABLE 59–1.

Insulin Preparations for Management of Diabetes Mellitus Therapy

Agent	Time to Onset (h)	Peak (h)	Duration of Action (h)
Insulin (subcutaneous administration)			
Lispro (Humalog)	0.1–0.25	1–2	4–6
Aspart (NovoLog)	0.1–0.25	1–2	4–6
Glulisine (Apidra)	0.1–0.25	1–2	4–6
Regular	0.5–1	2–4	6–10
Semilente	0.5–3	2–10	12–16
NPH	2–4	6–12	12–18
Lente	1–3	6–15	22–28
Protamine zinc	1–6	14–24	≥36
Ultralente	2–8	10–30	≥36
Glargine (Lantus)	2–4	"Peakless"	20–24
Detemir (Levemir)	2–4	"Peakless"	20–24
Insulin (inhaled)			
Exubra	0.1–0.25	1	4–6

Regular insulin can be administered intravenously. The biologic effect of receptor-bound insulin lasts approximately 1 hour. The circulating half-life of unbound insulin is a few minutes. Renal insufficiency prolongs the half-life of circulating insulin.

(diagnostic criteria are listed in Table 59–3). Consequently, these patients may arrive urgently in the operating room requiring surgical intervention (i.e., due to trauma, acute abdomen, abscess, ischemic limb) but may have a concurrent metabolic derangement. Therefore, intraoperative anesthetic management of the patient with type 1 DM may include treatment of DKA.

Diabetic Ketoacidosis

Features of DKA (Table 59–3) include circulatory depression, as acidosis and metabolic derangements can reduce cardiac contractility and peripheral vascular tone. Hyperglycemia with attendant hyperosmolarity produces osmotic diuresis resulting in hypovolemia. Abnormalities often include hyperglycemia (although glucose usually is < 500 mg/dL), intracellular dehydration, hyperkalemia, and hyponatremia. Dehydration frequently is severe because of poor oral intake due to the primary illness, exacerbated by hyperglycemia-induced osmotic diuresis. Plasma potassium (K^+) levels can be elevated because metabolic acidosis drives K^+ out of cells. Insulin concentrations are insufficient to maintain intracellular K^+ levels, so total body K^+ actually is depressed (reduced by 3–10 mEq per kilogram body weight). Measured sodium (Na^+) concentrations are

TABLE 59–2.

Other Agents Used for Treatment of Type 2 Diabetes

Agent	Route of Administration	Mechanism of Action	Major Side Effects	Time to Onset (h)	Duration of Action (h)
Chlorpropamide	Oral	Increases insulin secretion	Hypoglycemia	1	60
Glimepiride				1	24
Tolbutamide				≤0.25	6–12
Tolazamide				1	10–24
Glyburide				1	6–12
Glipizide XL				1	3–4
Nateglinide				1	24
Repaglinide				1	3–4
Byetta (exenatide)	Subcutaneous	GLP1 mimetic, increases insulin secretion only with hyperglycemia	No risk for hypoglycemia as single agent, delays gastric emptying, nausea, anorexia	≤0.25	6–12
Symlin (pramlintide)	Subcutaneous	Suppresses postprandial glucagon secretion	Hypoglycemia when given with insulin, delays gastric emptying, nausea	≤0.25	2–4
Januvia (sitagliptin)	Oral	DPP4 inhibitor increases GLP1		1	24
Rosiglitazone	Oral	Insulin sensitizer	Peripheral edema, abdominal obesity congestive heart failure, anemia, hepatotoxicity	1	24
Pioglitazone				1	24
Metformin	Oral	Decreases hepatic glucose output, insulin sensitizer	Lactic acidosis, diarrhea	1	8–12
Acarbose	Oral	Decreases gastrointestinal glucose absorption	Malabsorption, flatulence, diarrhea	Immediate	<0.3
Miglitol				Immediate	<0.3

Incretin-mimetics and insulin sensitizers in single-agent therapy do not predispose to hypoglycemia even in the fasting state.

TABLE 59–3.

Criteria for Diagnosis of DKA and HONK

Laboratory Parameter	DKA	HONK	Mixed
Serum glucose (mg/dL)	>300	>600	>600
Serum bicarbonate (mEq/L)	<15	≥15	<15
Serum osmolarity (mOsm/L)	≤320	>320	>320
pH	<7.3	≥7.3	
Urinary ketones	>3+	[a]	[b]
Serum ketones	+	[a]	[b]

[a]Trace to small amounts of ketones may be present.
[b]Ketones may be present.
DKA, diabetic ketoacidosis; HONK, hyperglycemic hyperosmolar nonketotic coma.

artificially lowered ~1.6 mEq/L for every 100 mg/dL that the glucose level is elevated above 100 mg/dL. Thus, the serum Na^+ level of a severely hyperglycemic patient may not reliably reflect the degree of dehydration. Plasma hypophosphatemia and hypomagnesemia commonly result from excessive urinary losses in DKA.

Management of DKA includes repletion of intravascular volume with salt and water to resolve fluid deficits and help restore blood pressure, tissue perfusion, and glomerular filtration. Initial volume resuscitation usually is accomplished with normal saline. Vigorous hydration also decreases glucose levels by 20–40%. Insulin therapy (regular insulin by IV bolus and subsequent infusion) is crucial in treating DKA. Insulin inhibits gluconeogenesis and ketone production in the liver and decreases lipolysis in adipose tissues. Insulin administration must be continued if acidosis or ketosis persists, even though glucose levels have normalized. During administration of insulin, an infusion containing 5% dextrose (e.g., D_5NS, 100 mL/h) will prevent hypoglycemia when plasma glucose concentrations decrease to <250 mg/dL. Blood glucose levels should be monitored every hour, with frequent electrolyte determinations.

Potassium and phosphate replenishment are essential for insulin's action. These electrolytes should be replaced carefully, after first verifying that the patient has normal renal function and adequate urine output. Potassium can be replaced with an equal mixture of potassium chloride and potassium phosphate.

Serum K^+ <3 mEq/L, give K^+, 40 mEq/h

Serum K^+ <4 mEq/L give K^+, 30 mEq/h

Serum K^+ < 5 mEq/L, give K^+, 20 mEq/h

Serum K^+, ≥5 mEq/L, no replacement

Consideration should be given to bicarbonate therapy only for severe acidosis (e.g., when arterial pH falls to <7.0) or hemodynamic instability, or for patients with cardiac rhythm disturbances. Following administration of bicarbonate, arterial pH levels should be monitored.

An emerging form of diabetes associated with obesity and presenting with ketoacidosis is called *Flatbush type 2 DM.* Most or almost all of these patients can be treated with oral agents after initial management with intensive insulin therapy. Initial treatment of ketoacidosis in the patient with Flatbush type 2 DM is the same as for the typical type 1 DM patient.

Type 2 DM

Patients with type 2 DM generally are older, obese, and subject to metabolic syndrome, a complex pathophysiologic state characterized by hypercholesterolemia, hypertriglyceridemia, hyperglycemia, hypertension, and DM.[3,4] In patients with metabolic syndrome, the cardiovascular risk of anesthesia and surgery may elevate markedly. Hypercoagulability is one feature of metabolic syndrome potentially relevant to these patients, who may be prone to thrombosis as a result of their surgical conditions or the consequences of surgery and anesthesia.[5] Of burgeoning clinical importance is the growing population of young, typically obese, patients with type 2 DM. The practitioner encounters a juvenile or adolescent patient with the combined anesthetic management challenges of youth, obesity, and diabetes. Type 2 DM may occur in young, nonobese, adolescents (maturity-onset diabetes of the young [MODY]) because of autosomal dominant inheritance of a mutation in the glucokinase gene that results in impaired hepatic glucose uptake and reduced insulin secretion.

A fundamental concept of type 2 DM is that patients with the condition usually produce sufficient insulin to avoid DKA, the severe metabolic consequence of absolute insulin deficiency seen in patients with type 1 DM. However, patients with type 2 DM have reduced cellular response to insulin binding to its receptor. Patients are described as being resistant to the hypoglycemic actions of insulin and may require large insulin doses to achieve normal glucose levels.

Initial medical therapy for type 2 DM includes administration of agents to increase endogenous insulin release, reduce intestinal uptake of carbohydrates, or increase peripheral sensitivity to insulin. When these measures are insufficient, insulin therapy can be initiated, but patients may require very high insulin doses. A new class of therapeutic agents, currently represented by pramlintide, has been approved by the US FDA for reducing postprandial glucagon secretion and suppressing hepatic glucose release.

Hyperglycemic Hyperosmolar Nonketotic Coma

Hyperglycemic hyperosmolar nonketotic coma (HONK), also known as *hyperglycemic hyperosmolar syndrome,* is a clinical syndrome encountered in some type 2 diabetic patients with decompensated DM. As the name implies, features include hyperglycemia, hyperosmolarity, and dehydration (typical water deficit 10–12 L). Severe ketosis is rare, but mild acidemia can be caused by inadequate circulation and lactic acidosis (Table 59–3). The precipitating factors for HONK are similar to those of DKA (Table 59–4). Patients presenting for surgery, especially urgent procedures, may have HONK as a comorbid condition requiring management during administration of their anesthetics. The classic presentation of patients with HONK includes fatigue, blurred vision, polydipsia, polyuria, leg cramps, and weight loss. The laboratory findings of HONK are related to dehydration and hypovolemia. Derangements in serum electrolyte levels occur, and

TABLE 59–4.

Precipitating Factors for Hyperglycemic Hyperosmolar Nonketotic Coma

Precipitating Events	Pharmacologic Agents	
Infection (pneumonia, urinary tract infection, sepsis)	Amphetamines	Niacin
Noncompliance with insulin regimen	β-Blockers	Pentamidine
First presentation of diabetes mellitus	β-Agonists	Protease inhibitors
Dehydration	Diuretics	Salicylates
Impaired renal function	Glucocorticoids	Sympathomimetics

hemoconcentration causes increases in blood levels of hemoglobin, protein, calcium, amylase, lactate dehydrogenase, and transaminases. Some patients present a mixed picture, with features of both DKA and HONK (Table 59–3).

Fluid administration in the setting of HONK is crucial. The rate of fluid administration depends on the patient's volume status, total body water deficit, serum osmolarity, and renal and cardiac function. Normal saline (2–3 L) is an appropriate fluid bolus in a patient with adequate cardiac and renal function and serum osmolarity < 320 mOsm/L. Even larger fluid boluses may be required if serum osmolarity is > 320 mOsm/L. In hypotensive patients who do not respond to aggressive crystalloid administration, colloidal or vasopressor infusions are additional treatments. Central venous pressure or pulmonary arterial monitoring may help guide therapy, especially in patients with HONK who are elderly and at significant risk for concomitant cardiovascular disease.

Medical therapy for HONK includes a low-dose, continuous, IV infusion of insulin. If no decrease of glucose levels occurs over the first 2–4 hours, doubling the insulin infusion rate every hour until a response occurs is recommended. Potassium chloride usually is administered as part of the fluid regimen. The total body potassium deficits encountered in HONK are modest compared to DKA because of the absence of acidosis (see guidelines for potassium replacement in DKA). Potassium acetate and/or potassium phosphate can be used in order to avoid excessive chloride levels. Bicarbonate need not be given unless lactic acidosis causes arterial pH to decrease to < 7.0. Thrombotic/embolic events are common complications of HONK. Prophylaxis against thrombosis warrants consideration. Should thrombosis occur, an anticoagulating dose of IV heparin or low-molecular-weight heparin anticoagulation is indicated.

Perioperative Insulin/ Glucose Management

As a rule, long-acting oral hypoglycemic agents (sulfonylurea drugs) should not be given before surgery to reduce the risk of hypoglycemia, signs and symptoms of which may be masked by general anesthesia. However, it is unlikely that insulin sensitizers or incretin mimetics will produce hypoglycemia. Theoretically, inhibitors of glucagon secretion may lead to hypoglycemia in the fasting state. Patients with type 2 DM treated with insulin are at risk for hyperglycemia if their insulin is withheld completely. Typically, these patients receive about half of their usual morning insulin dose in the form of long-acting insulin preparations, such as NPH insulin. Short-acting insulins are omitted. *Patients with type 1 DM must receive some insulin.* In this population, half of the usual morning dose of long-acting insulin may be appropriate before surgery. One key to management is frequent monitoring of glucose levels in all patients with DM. As a general rule, diabetic patients should undergo their anesthetic and surgical procedures as early in the day as possible. This limits the perturbations caused by prolonged fasting and disruption of customary diabetes medical regimens.

Recently, patients have been chronically managed with a portion of their insulin requirements supplied by continuous infusion delivered with a pump. Recommendations for the perioperative period for patients with pumps include (1) maintaining the basal infusion rate of insulin, (2) omitting any preprandial insulin boluses in the fasting patient, (3) monitoring of glucose levels at frequent intervals, and (4) resuming the usual diet and insulin therapy regimen as soon as possible.[6] However, the anesthesiologist must recognize that these pumps deliver the insulin dose subcutaneously. Uptake of the drug from this depot may be affected by alterations (usually reductions) in tissue perfusion that are commonly encountered during surgery or the perioperative period. Consequently, depending on the surgical circumstances, it may be advantageous to interrupt the continuous subcutaneous administration of insulin by pump and to substitute carefully titrated IV infusions of insulin. To decide on the initial IV insulin infusion rate, first determine the total 24-hour basal insulin dose typically administered by the subcutaneous infusion. Divide this basal dose by 24. Start the IV infusion with this number of units of regular insulin per hour, again with close monitoring of blood glucose and serum potassium levels.

Intraoperative Insulin Therapy

A variety of regimens exist for IV infusion of regular insulin in the operating room. For the routine surgical population, the "Vellore Regimen" has been evaluated.[7] Other schemes also are acceptable,[8] as long as glucose and potassium levels are closely monitored and treated when necessary. Table 59–5 outlines one practical method of insulin administration in the operating room that is used at our institutions. Cardiac surgical patients[9] and pediatric surgical patients[10] may benefit from regimens tailored to the special needs of these particular populations.

A growing consensus holds that in some surgical situations (e.g., neurovascular procedures or carotid endarterectomy) associated with significant risk for cerebral ischemia, blood glucose levels should be more tightly controlled to avoid hyperglycemia. Unlike the situation with critically ill patients for whom outcome studies provide data supporting tight glucose control (blood glucose target typically < 110–120 mg/dL), clinical outcome studies establishing optimum intraoperative blood glucose levels for more routine surgical patients do not yet exist. Coursin and Prielipp[11] conclude that the optimum insulin regimen for a given surgical situation and the ideal range of blood glucose levels for routine anesthetics remain undetermined.

TABLE 59–5.

Perioperative Intravenous Regular Insulin Regimens

A. Initial regular insulin IV bolus: 0.05–0.1 U/kg

Dose additional boluses based on glucose levels

B. Regular insulin infusions (1 U regular insulin/mL normal saline)

Initial Regular Insulin Infusion Rate (U/h)	
Type 1 DM (female)	0.5
Type 1 DM (male)	1.0
Type 2 DM (male or female)	1.0

Notes on IV Regular Insulin Action

1. Onset is immediate
2. Duration is ~ 1 h.
3. Duration of action prolonged in renal insufficiency.

Adjustment of IV Regular Insulin Infusion Rate (U/h)

Glucose (mg/dL)	Rate Change	Other Rx
<70	Hold 30 min	Give D_{50}, 15–20 mL. Recheck blood glucose level after 30 min. Give more dextrose until blood glucose level >70 mg/dL.
70–120	↓ 0.3 U/h	
121–180	No change	
181–240	↑ 0.3 U/h	
241–300	↑0.6 U/h	
>300	↑ 1.0 U/h	

Notes on IV Regular Insulin Dosing

1. Insulin guidelines assume patient is fasting and is not in diabetic ketoacidosis.
2. DOSING MUST BE INDIVIDUALLY TITRATED BASED ON FREQUENT BLOOD GLUCOSE MONITORING.

DM, diabetes mellitus.

Metformin

Metformin is an oral hypoglycemic agent of the biguanide class with an important role in type 2 diabetes therapy, particularly because of its favorable effects on cardiovascular mortality.[12] This drug, which has multiple pharmacologic effects, has also been associated with the serious side effect of lactic acidosis, which may become life threatening. Whether metformin causes lactic acidosis or exacerbates lactic acidosis resulting from other conditions remains undetermined.[13] When administered according to guidelines and avoiding contraindications including renal and hepatic insufficiency and a history of alcohol abuse, the incidence of lactic acidosis is very low.[12] In conditions where tissue hypoxia already exists (including circulatory failure) or circulatory insufficiency is anticipated (e.g., major surgery), it is prudent to withhold metformin. In anticipation of IV radiologic contrast exposure, metformin should be stopped and not restarted until the creatinine level has been checked to confirm baseline renal function. Recognizing that conclusive data do not exist to support their suggested guidelines, Jones et al.[14] and Vreven and De Kock[15] proposed that metformin be withdrawn 2 days before general anesthesia and reinstated when renal function is demonstrated to be stable. Metformin should not produce hypoglycemia in the fasting preoperative patient.

Steroid (Glucocorticoid) Therapy: Implications for DM

Administration of pharmacologic doses of glucocorticoids increases resistance to insulin action by inhibiting glucose uptake into muscle and fat.[16] In many patients, the effect is primarily postprandial hyperglycemia. Thus, morning fasting glucose levels are only mildly elevated, but glucoses levels rise substantially after meals in the afternoon and evening.

Glucose levels will increase in patients with known diabetes. Glucocorticoid therapy reveals previously undiagnosed insulin resistance in 25% of all patients receiving such treatment.[17] The hyperglycemia resulting from glucocorticoid therapy can be managed with insulin, oral hypoglycemic agents, or combination therapy. When glucocorticoid therapy is tapered, insulin resistance decreases with a lag of 1–3 days. Hyperglycemia therapies (e.g., insulin infusions) must then be reduced to avoid hypoglycemia. The complexities of the patient's regimen for controlling hyperglycemia must be considered when managing medications and glucose in the perioperative period.

Postoperative stress usually leads to excess endogenous glucocorticoid production and consequent insulin resistance. This may result in hyperglycemia lasting 1–3 days after the procedure or for as long as significant infection or pain-related stress is present. Treatment of this manifestation of hyperglycemia is accomplished by administering a long-acting insulin plus a short-acting insulin at mealtime in the patient who is able to eat. Other patients may require regular insulin administered by IV infusion.

Counterregulatory Hormones

Glucagon

Glucagon is a 29-amino-acid polypeptide secreted by the alpha cells of the pancreatic islet. Glucose is the most important regulator of glucagon secretion. Hyperglycemia decreases glucagon secretion. Hypoglycemia stimulates glucagon secretion via direct effects on islets and via central nervous system pathways activated by hypoglycemia. β-Adrenergic receptor activation stimulates glucagon secretion.[18] Glucagon acts primarily on the liver to increase both glycogenolysis and gluconeogenesis. Increased glucose output balances glucose utilization during the fasting state to maintain euglycemia.[19] Patients with hepatic or pancreatic insufficiency are theoretically at risk for hypoglycemia as a result of lack of glucagon effects. In addition, β-blocker therapy potentially reduces glucagon secretion. The implication for anesthetic management is the need to monitor glucose levels frequently in patients at risk and to intervene as needed.

Epinephrine

Epinephrine and glucagon are the most important hormones maintaining eu-

glycemia during the fasting state.[20] The central nervous system reacts to hypoglycemia by stimulating secretion of epinephrine. Activation of pancreatic α-adrenergic receptors by epinephrine inhibits insulin secretion. β-Adrenergic receptor activation stimulates secretion of glucagon. Epinephrine, via β_2-adrenergic receptors, also acts directly on the liver to increase glycogenolysis and gluconeogenesis. Therefore, patients at risk for blunted sympathetic responses, either following neuraxial anesthesia or from receiving β-blocker therapy, may fail to react normally to hypoglycemia. The implication for anesthetic management is, again, a need to anticipate potential hypoglycemia, with close monitoring of glucose levels in patients at risk, and to treat as needed.

Glucocorticoids and Growth Hormone

Growth hormone (GH) and cortisol play minor roles in the restoration of euglycemia after hypoglycemia. Prevention of cortisol secretion and GH deficiency does not inhibit restoration of euglycemia after hypoglycemia.[21] The hyperglycemic response to the combination of glucagon, epinephrine, and cortisol is larger than to each of these hormones given individually, suggesting that synergism contributes to normal physiologic responses to hypoglycemia.[22]

Hypoglycemic Unawareness

Some patients with long-standing DM and frequent bouts of hypoglycemia lose their normal sympathetic response to low blood sugar levels. The failure to consciously recognize low blood sugar levels is known as "hypoglycemic unawareness." Fasting in the perioperative period, particularly in the setting of continued insulin therapy administered by infusion pump, may predispose these patients to potentially dangerous hypoglycemia. The anesthesiologist cannot rely on such patients to symptomatically monitor their own blood glucose levels and to respond appropriately, even when managed with regional anesthesia and minimal sedation. Assessment of glucose levels by glucometer or laboratory methods, and appropriate therapy, is essential for these patients.

DM: Implications for Anesthesia

Although general anesthesia may be mandatory for some surgical procedures, other options (including regional anesthesia or neuraxial anesthesia) exist for some situations.[23] Neuraxial anesthesia may provide an advantage by blocking "stress responses" to surgery involving counterregulatory hormones such as epinephrine and glucocorticoids. Regional or neuraxial block anesthetic techniques may allow some diabetic patients to return to their customary diets earlier than they would if given general anesthesia, facilitating resumption of chronic diabetes regimens. Metabolic control in the diabetic patient may be improved by regional anesthetic techniques, at least in some patient populations.[24] Regional anesthesia or neuraxial techniques may also be useful for patients with diabetic gastroparesis, who are at elevated risk for aspiration under general anesthesia, or who may be difficult to intubate because of stiff joints (including the temporomandibular joints and the cervical spine) associated with their disease. However, the effects of neuraxial techniques are complicated by their effects on gut motility and absorption. In addition, preexisting autonomic neuropathy may compound the effects of sympathectomy produced by neuraxial block. There is some concern that patients at risk for diabetic neuropathy may be more likely to develop peripheral nerve injury in association with regional or neuraxial techniques. No published studies in readily identifiable sources support or refute this possibility.[25] McAnulty and Hall[26] conclude that no body of evidence indicates that regional anesthesia alters overall surgical morbidity and mortality in the diabetic patient population. Consequently, a well-conducted anesthetic, regardless of specific technique, probably is the most important factor in the care of the diabetic patient. Of note, general anesthesia often masks the autonomic response to hypoglycemia, and changes in vital signs can easily be misinterpreted as a response to increased surgical stimulation rather than hypoglycemia. Consequently, close monitoring of glucose levels in patients at risk for hypoglycemia and appropriate therapy are essential.

Specific Surgical Procedures and Glucose Homeostasis

Total pancreatectomy eliminates insulin-producing islet cells as well as cells secreting the counterregulatory hormone glucagon. This surgery renders the patient as having type 1 DM with an absolute requirement for insulin therapy. The biologic effect of insulin molecules bound to cellular receptors lasts for approximately 1 hour, but the chemical half-life of insulin in the circulation is just a few minutes. Consequently, following a total pancreatectomy, the need for insulin therapy to prevent DKA begins within 60 minutes of devascularizing the pancreatic islets.

Surgery for insulinoma or glucagonoma poses no particular management challenges as long as glucose levels are monitored closely and the means for treating hypoglycemia are readily available.

THYROID DISEASE

Thyroid diseases compose the second most common endocrine conditions appearing as comorbidities in patients presenting for surgery of any kind. Hypothyroidism and hyperthyroidism have significantly different implications for anesthetic management. Where possible, assessment of the current status of the patient's thyroid condition provides information useful for predicting sensitivity to drugs commonly administered in the perioperative period, hemodynamic responses during surgery and anesthesia, and physiologic perturbations potentially requiring investigation and treatment, such as electrolyte disorders and adrenal insufficiency.[27] It is important to recognize that medical treatment of altered thyroid function (hypothyroidism or hypothyroidism) may require several weeks to achieve a new steady state. In general, mildly hypothyroid patients can proceed to elective surgery without delay. Postponement of elective surgery may be indicated to allow evaluation and treatment of hyperthyroidism and to allow medical management of hypothyroid patients with more than mild to moderate thyroid insufficiency.

Implications of Hyperthyroidism

The clinical features of hyperthyroidism result from excess thyroid hormone and enhanced β-adrenergic activity.[27,28] Etiology, manifestations, and medical management of thyroid disorders are discussed in detail in Chapter 12. Endocrinologists distinguish *thyrotoxicosis*, which is a general term for excessively elevated thyroid hormone of any cause (including excessive exogenous thyroid

TABLE 59–6.

Clinical Features of Thyroid Disease

Hyperthyroidism/Thyrotoxicosis	
Volume depletion	Eyelid retraction
Tachycardia or atrial fibrillation	Lid lag, stare
Systolic hypertension	Elevated liver function tests
Congestive heart failure	Decreased cholesterol
Hyperthermia and increased perspiration	Exophthalmos (Graves disease only)
Adrenocortical insufficiency	Warm, moist skin
Proximal muscle weakness	Hypercalcemia
Motor hyperkinesis	Tremor
Hypothyroidism	
Decreased spontaneous respiration	Hypothermia
Reduced plasma volume	Enlarged tongue
Hypoglycemia	Slow movement
Hyponatremia	Slow speech
Impaired hepatic drug metabolism	Hoarseness
Hypometabolic state	Elevated creatine phosphokinase
Adrenocortical insufficiency	Dry, sallow skin
Obesity	Periorbital edema
Enlarged cardiac silhouette on radiography	Nonpitting edema (myxedema)
Congestive heart failure	Delayed relaxation of deep tendon reflexes
Bradycardia	
Hypertension (especially diastolic)	Low-voltage electrocardiogram
Depressed mental state	Elevated cholesterol
	Ileus

hormone), from *hyperthyroidism,* in which thyroid gland hypersecretion is the reason for excessive thyroid hormone activity. The clinical features of hyperthyroidism or thyrotoxicosis that are particularly relevant to anesthetic management of thyroid surgery, or of nonthyroid surgery that cannot be postponed until the patient is rendered euthyroid, are summarized in Table 59–6. Atrial dysrhythmias, including atrial fibrillation, and premature atrial contractions, tachycardia, systolic hypertension, ischemic cardiac disease, and congestive heart failure, should be specifically considered when planning an anesthetic for the hyperthyroid patient.[29] Muscle weakness may impair perioperative respiratory reserve. β-Adrenergic blockade is the mainstay of anesthetic management. High doses of β-blockers may be required to control cardiac manifestations of hyperthyroidism in the immediate perioperative period.

Implications of Hypothyroidism

The clinical features of hypothyroidism result from a deficiency of thyroid hormone action.[27,30] Etiology, manifestations, and medical management are discussed in detail in Chapter 12. The clinical features that are particularly relevant to the anesthetic management of thyroid or nonthyroid surgery that cannot be postponed until the patient is rendered euthyroid are summarized in Table 59–6. Bradycardia, diastolic hypertension, congestive heart failure (systolic and diastolic dysfunction), pericardial or pleural effusions, seizures, depressed mentation or frank coma, hypothermia, coagulopathy, and ileus should be specifically considered when evaluating for suspected hypothyroidism. The patient may have a blunted hypercapnic or hypoxic ventilatory drive. Adrenal cortical insufficiency may impair normal stress responses. Laboratory findings include hyponatremia and hypoglycemia.

Pharmacologic Implications

Minimum Alveolar Concentration

Conventional anesthetic wisdom holds that thyroid status does not alter the minimum alveolar concentration. Data from studies of experimental animals using agents such as halothane and cyclopropane support this assertion.[31,32] Data from studies of humans or of any species on the interaction of thyroid status with minimum alveolar concentration for newer potent inhalational agents such as desflurane and sevoflurane have not been reported. As demonstrated in rats, thyroid status may alter the metabolism of the older potent inhalational anesthetics halothane, enflurane, and methoxyflurane,[33] but the clinical relevance of this finding for commonly used, newer agents is not reported.

Altered Drug Metabolism/Sensitivity

Conventional wisdom holds that hypothyroidism increases the sensitivity to sedative, analgesic, and anesthetic medications.[30] Evidence supporting this concept is limited to older drugs without recent studies.[34] One case report cites the accumulation of midazolam in prolonged sedation of a critically ill patient with hypothyroidism as a comorbid condition.[35] Whether this observation can be generalized to all hypothyroid patients or to use of other commonly administered sedative, hypnotic, and analgesic agents remains unproven.

Amiodarone

Amiodarone is widely used for the management of atrial and ventricular dysrhythmias. The amiodarone molecule contains approximately 37% iodine by weight, resulting in the delivery of large amounts of iodine to patients receiving standard doses of the drug. The effects of amiodarone therapy on thyroid function are complex, and patients may become either hypothyroid or hyperthyroid when their cardiac electrophysiologic disturbances are treated with amiodarone.[28,36,37] Consequently, patients presenting for surgery who are receiving chronic amiodarone therapy may warrant consideration of their risk for thyroid dysfunction in the perioperative period.

Exophthalmos: Anesthetic Implications

Exophthalmos, a clinical feature of Graves disease, results from the accumulation of retroorbital fat and swollen ocular muscles resulting in proptosis (Fig. 59–1). The eyelid may not cover the globe, and the exposed cornea and prominent globe are subject to mechanical trauma, including pressure injury.

Management of Severe Hyperthyroidism or Thyroid Storm in Urgent Surgery

Severe hyperthyroidism is a relative contraindication to anesthesia and sur-

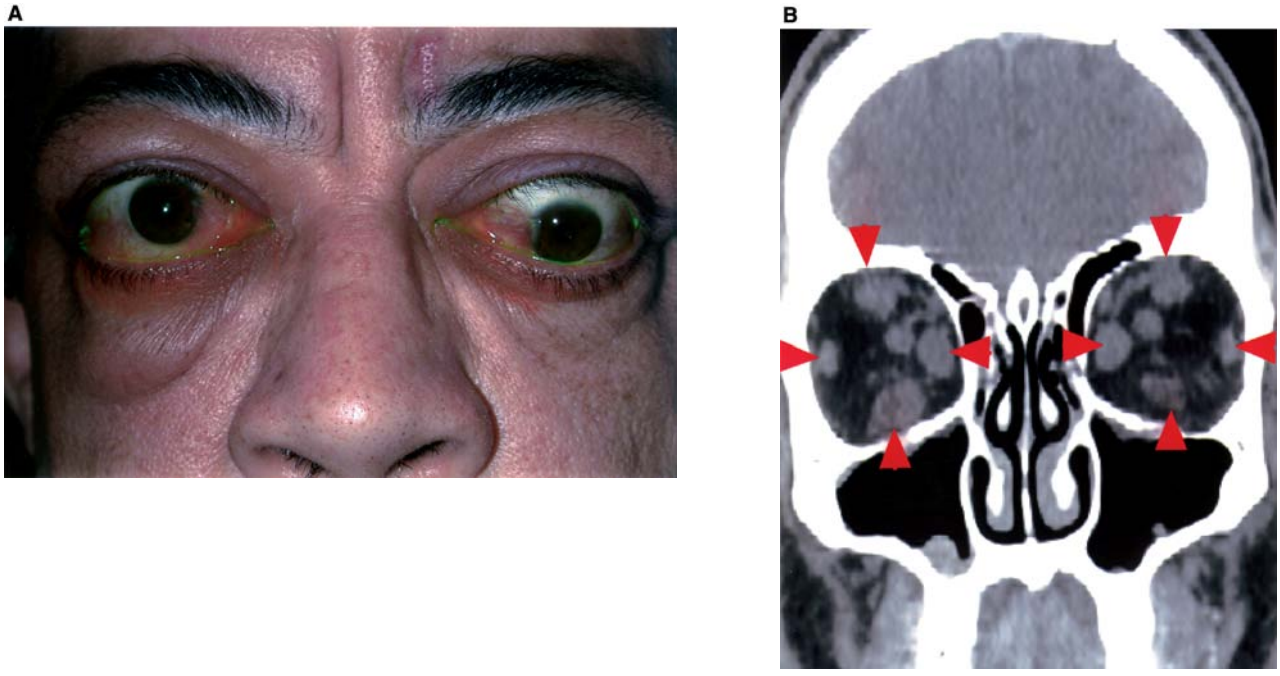

FIGURE 59–1. Graves ophthalmopathy with exophthalmos. **A.** Photograph of the face. Note the protuberant orbits and disconjugate gaze caused by accumulation of tissue in the retroorbital area, and edema and fibrosis of the extraocular muscles. **B.** CT scan through the orbits of a different patient showing extraocular muscle edema (*arrows*).

gery. When extreme hyperthyroidism progresses to physiologic decompensation with circulatory collapse, altered mental status, and hyperthermia, the diagnosis is thyroid storm, a life-threatening condition that ideally should be medically controlled before a patient is brought to surgery (Table 59–7). If the primary surgical condition itself is life-threatening and an operation cannot be delayed, the patient must be rapidly prepared in order to limit the effects of the endocrine disorder on the clinical course. Mainstays of therapy include medications to control the thyroid gland, β-adrenergic blockers to blunt sympathetic effects of the excess thyroid condition, glucocorticoids, and circulatory support.[38,39] Iopanoic acid is a valuable treatment option now available only in Europe. The drug may be particularly useful in the setting of amiodarone-induced thyrotoxicosis.[38,40] In the United States, saturated solution of potassium iodide (SSKI) may be used in combination with β-adrenergic blockers.[41,42]

Thyroid Surgery

Anesthetic Options

General anesthesia is commonly administered for thyroid surgery. General anesthesia has the advantages of patient comfort, amnesia, and immobility, along with control of the airway. Airway control often is achieved by intubation with a cuffed endotracheal tube. However, use of the laryngeal mask airway (LMA) has been considered an option for airway control because intraoperative inspection of vocal cord function and glottic structures can be accomplished with a fiberoptic scope.[43–48] Direct visualization may be particularly valuable if the surgical procedure places a recurrent laryngeal nerve (RLN) at significant risk. An advantage of the technique is that the RLN can be continuously monitored throughout the surgical procedure if the fiberoptic scope is left in place, allowing real-time identification of compromised RLN function. Because some patients may require endotracheal intubation but also benefit from continuous direct observation of glottic structures, Hillermann et al.[48] proposed the use of a small-diameter (5.0-mm inner diameter) endotracheal tube together with an LMA through which a fiberoptic scope was positioned. This setup allows control of the airway with a cuffed endotracheal tube while permitting visual monitoring of RLN function.

Muscle relaxants facilitate endotracheal intubation and may constitute one component of anesthesia maintenance. Muscle relaxants may interfere with motor monitoring of the RLN or other nerves placed at risk by the surgical procedure. Partial pharmacologic paralysis may permit motor nerve monitoring in some situations[49] if the level of muscle relaxation is closely monitored.

An alternative to general anesthesia is regional anesthesia with supplemental local anesthetic infiltration as needed.[50–52] A consideration in planning a regional anesthetic is that systemic absorption of epinephrine, a common additive to local anesthetic solutions, may exacerbate tachycardia or other tachydysrhythmias encountered in hyperthyroid patients. Thus, epinephrine should be given cautiously or avoided entirely.

Unilateral and bilateral deep cervical plexus block or superficial cervical plexus block with local supplementation has been described for thyroid surgery. Advantages of regional anesthesia include the ability to assess spontaneous respiration and the voice as indicators of RLN integrity during the procedure. In addition, regional anesthesia provides the possibility of early postoperative pain control with little or no need for systemic analgesics. Deep cervical plexus block carries the associated risk of anesthetizing the phrenic nerve with resulting diaphragm dysfunction. Unilateral or bilateral diaphragmatic dysfunction may

TABLE 59–7.

Treatment of Severe Hyperthyroidism or Decompensated Hyperthyroidism (Thyroid Storm)

Therapy to Control the Thyroid
- Thionamides (PTU, methimazole)
- Iodinated medications (iopanoic acid, stable potassium iodide, Lugol solution), Graves disease only
- Lithium carbonate

Therapy to Block Conversion of T_4 to T_3
- PTU
- Iopanoic acid
- Propranolol
- Corticosteroids

Therapy to Enhance Clearance of Thyroid Hormones
- Gastrointestinal clearance
  Cholestyramine
- Blood clearance
  Hemoperfusion
  Plasmapheresis

Therapy to Block the Effects of Thyroid Hormones
- β-Blockers to control heart rate
- Corticosteroids

Supportive Measures
- Antipyretics (acetaminophen)
- Cooling
- Meperidine (blocks shivering induced by cooling)
- Correction of dehydration
- Nutrition
- Oxygen
- Treatment of congestive heart failure

Therapy for the Precipitating Illness

PTU, Propylthiouracil; T_3, triiodothyronine; T_4, L-Thyroxine.

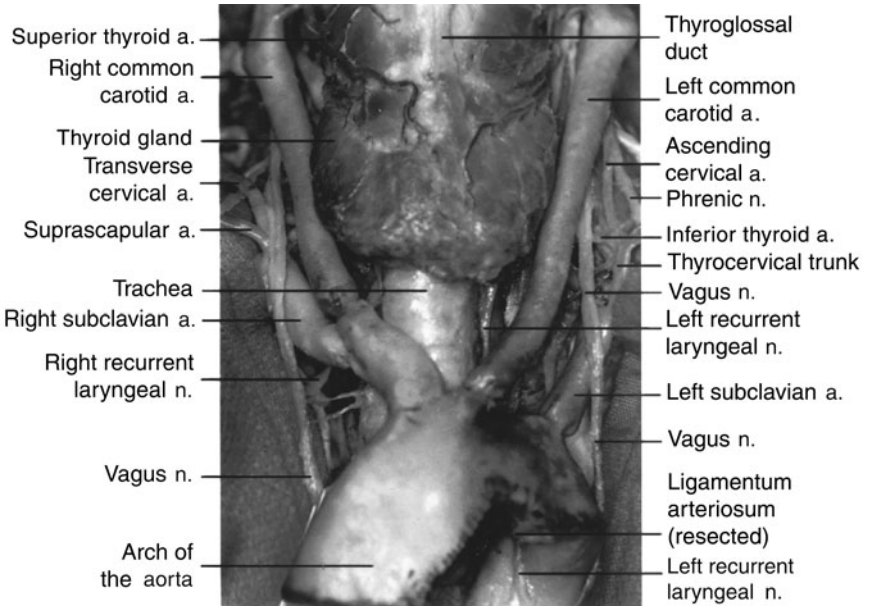

FIGURE 59–2. Anatomic relationships of the normal anterior neck. (From Monfared et al.[61] with permission.)

precipitate respiratory distress, especially if the surgical procedure disturbs RLN function with airway compromise. However, little or no change of the forced vital capacity (FVC) measured by incentive spirometry was detected in 21 patients undergoing thyroid surgery with bilateral deep cervical plexus block, and no patient experienced subjective respiratory distress.[51] A study that focused on the analgesic efficacy of cervical plexus block administered in conjunction with general anesthesia for thyroid surgery reported no subjective respiratory complaints among the 39 subjects.[53] However, the study did not include any quantitative objective assessments of respiratory function. Taken together, the findings of these small clinical studies suggest that bilateral cervical plexus block may be suitable for appropriately selected patients, but more definitive investigation, particularly of the incidence of perioperative respiratory complications, is needed.

Cervical epidural anesthesia has been used successfully for parathyroid surgery in patients maintained awake to evaluate their vocal cord function.[54] Significant decreases in FVC were encountered, but other measured respiratory variables remained stable, with minimal subjective respiratory compromise. Because the airway and respiratory considerations for thyroid and parathyroid surgery are comparable, the findings suggest that cervical epidural anesthesia may provide an anesthetic option for thyroid surgery where general anesthesia is not desirable.

Deep cervical plexus block may impair RLN function when the anesthetic spreads to block the vagus nerve. Although this would not affect direct stimulation of an RLN (as for electromyographic [EMG] monitoring) during surgery, the ability to assess spontaneous vocal cord function would be compromised by anesthetizing an RLN during the course of a deep cervical plexus block. Superficial cervical plexus block avoids the potential airway or respiratory problems of a deep cervical plexus block but may not provide sufficient analgesia for the deeper structures of the neck that may be involved in the surgery. Lack of airway control, in a situation where the location of the surgical site complicates establishing emergency airway control, is a disadvantage of this regional anesthesia technique. An analgesia option for thyroid surgery is placement of regional blocks intended to provide postoperative pain control in conjunction with administering general anesthesia for the operative period.[53,55]

Anatomic Concerns

Situated at the base of the anterior neck, the thyroid gland lies in close proximity to major vascular structures, including the internal jugular veins and the carotid arteries (Figs. 59–2 and 59–3).[56] Distortion of normal anatomic relationships, as in the case of a large goiter or a thyroid cancer, can complicate the insertion of an internal jugular catheter (Fig. 59–4). The thyroid gland wraps around the trachea in a nearly circumferential fashion. Direct extension of thyroid cancers into the trachea may obstruct the lumen. Large thyroid masses sometimes compress the tracheal lumen (Fig. 59–5) or distort the glottic or supraglottic airway (Figs. 59–6 and 59–7). Some thyroid masses penetrate or compress the esophagus with implications for the patient's nutritional status. Insertion of nasogastric or orogastric tubes also may be complicated.

Emergency airway algorithms contain a provision for establishing a surgical airway, either by cricothyrotomy or by tracheostomy. Extension of

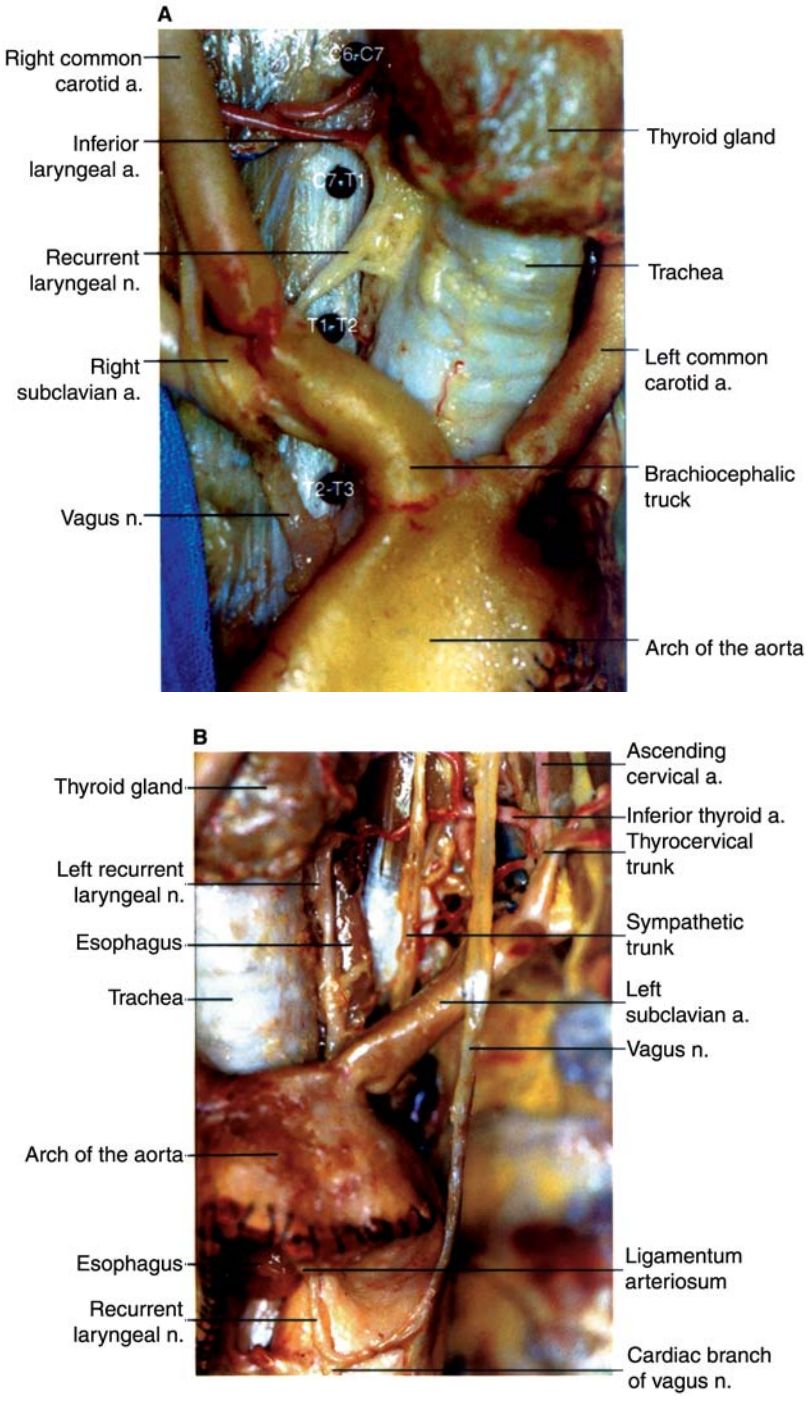

FIGURE 59–3. Anatomic relationships of the thyroid gland. The recurrent laryngeal nerve branches from the vagus and ascends in a groove between the trachea and the esophagus. **A.** Right exposure. **B.** Left exposure. (From Monfared et al.[61] with permission.)

thyroid tissue rostrally over the cricothyroid membrane, or caudally toward the sternal notch, positions this highly vascular tissue directly in front of the airway. Thyroid isthmus tissue may be encountered even in routine tracheostomy placement.[57] A cadaver study reported a high incidence of percutaneous tracheostomy catheters malpositioned so as to puncture the thyroid isthmus.[58] Complications of surgical airway insertion related to thyroid tissue or vessels have been reported.[59] Hemorrhage can easily complicate attempts to establish a surgical airway.

Other structures in close proximity to the thyroid gland include the parathyroid glands, which are placed at risk during thyroid surgery, and

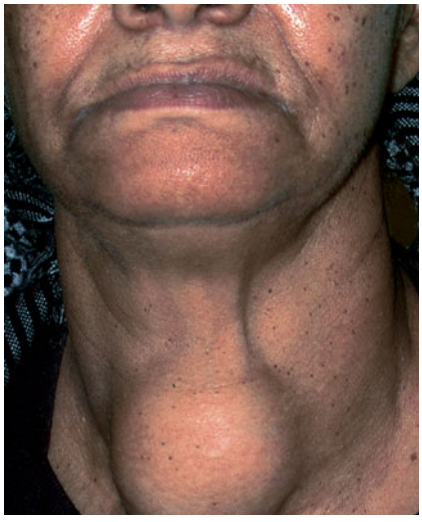

FIGURE 59–4. Large recurrent goiter overlying the anterior and right neck in a patient with a previous partial thyroidectomy.

the recurrent and superior laryngeal nerves, which supply the larynx.[60,61]

Airway Concerns

Airway management is a principal anesthetic concern in thyroid surgery. Thyroid masses can affect the airway in the supraglottic region. Lingual thyroid tissue arising from the base of the tongue may obstruct the oropharynx, compromising spontaneous respiration,[62] mask ventilation, and direct laryngoscopy. Thyroid masses invading or compressing the glottis potentially compromise visualization of the glottic opening or passage of an endotracheal tube through the vocal cords. Bouaggad et al.[63] studied 320 patients scheduled for thyroidectomy in an analysis of potential factors helpful for predicting difficult endotracheal intubation. Endotracheal intubation was found to be easy in 36.9% of patients, and the investigators encountered only minor difficulties in 57.8% of the study group. The study concluded that the presence of a large goiter is not of itself predictive of a difficult endotracheal intubation. However, multivariate analysis identified the presence of Cormack grade III or IV view and the presence of a cancerous mass as independent predictors of a difficult oral intubation. Potential risk factors for difficult airway management include the body mass index, Mallampati class, thyromental distance, neck mobility, and airway compression.

Thyroid masses within the thorax compromise the airway in the subglottic region by external compression of

the trachea or direct extension into the airway. Preoperative imaging studies[64] and flow–volume loops may provide information useful for planning the approach to the airway.

Laryngeal Nerve Monitoring: Anesthetic Implications

Several methods have been described to monitor the function of the RLN, which controls the function of the vocal cords and other nerves at risk, such as the external branch of the superior laryngeal nerve, which supplies the cricothyroid muscle and therefore regulates voice pitch.[65,66] Most attention has been devoted to monitoring the RLN. Monitoring techniques generally require some form of direct RLN stimulation. Function following stimulation usually is detected by (1) direct visualization of the cords via a fiberoptic scope (see above), (2) palpation of the larynx during RLN stimulation,[67] (3) EMG monitoring using recording electrodes inserted directly into the laryngeal muscles,[68] or (4) EMG monitoring via endotracheal tubes fitted with external sensing electrodes.[69] Nerve monitoring often impacts anesthetic management by the need for a special method of airway control (e.g., LMA vs. cuffed endotracheal tube) or the need to avoid muscle relaxants as part of the anesthetic technique.

Perioperative Complications of Thyroid Surgery

Laryngeal Nerve Injury

A major complication of thyroid surgery that usually appears early (immediately or within hours) in the postoperative period is airway obstruction attributable to RLN injury with resultant narrowing of the glottic opening. A unilateral RLN palsy would not produce significant respiratory compromise if the contralateral nerve and vocal apparatus function normally. However, bilateral nerve palsy, as from a new unilateral RLN injury in the setting of a preexisting deficit on the other side, can produce complete closure of the glottis and respiratory obstruction. Prompt endotracheal intubation may be lifesaving.

Estimates of the overall incidence of unilateral temporary RLN palsy after major thyroid surgery range from 1.2–1.4% to 5.1–8.7%.[70–74] Estimates of the incidence of permanent lesions range from 0.4–0.6% to 0.9–1.4%.[70–74] Factors associated with an increased likelihood of RLN injury include surgery for thyroid cancer or Graves disease, reoperation, and extensive neck and lymph node dissections. Positive identification of the RLN and documentation of its integrity during the course of surgery are associated with a reduced likelihood of palsies in the postoperative period. Overall, despite extensive investigation, intraoperative RLN monitoring has not been shown to confer protection against RLN injury after surgery.[73,75–77] RLN monitoring correlates with a reduced incidence of RLN injury only for initial procedures for benign goiter.[78] Monitoring may facilitate visual identification of the RLN, as in cases of reoperation or anatomic variants of nerve position. Of note, endotracheal intubation alone may account for 7–11% of all RLN paralyses.[79]

Hypocalcemia

Damage to parathyroid glands during thyroid surgery can cause reduced secretion of parathyroid hormone (PTH), resulting in hypocalcemia. Positive identification of the parathyroid glands at the time of surgical dissection can prevent postoperative hypocalcemia. Estimates of the prevalence of temporary hypocalcemia range from 8.3–27.5%, and estimates of permanent hypocalcemia range from 1.7–5.1%.[70,71] Patients with acute hypocalcemia can present with paresthesias, muscle cramps, stridor, dysrhythmias, or seizures. Some studies suggest that the circulating PTH level obtained during surgery or in the immediate postoperative period is predictive of laboratory or symptomatic evidence of hypocalcemia.[80,81]

Hemorrhage

The thyroid bed is extremely vascular. Inadequate hemostasis may result in formation of hematomas. Rapid onset of life-threatening airway obstruction is a known complication of thyroid (and parathyroid) surgery. Consideration should be given to prompt intubation to preserve airway patency, even before a return to the operating room for neck exploration. Decompression of the neck at the bedside by opening the wound is a potentially lifesaving option.[65] Use of surgical drains is advocated, at least in selected circumstances, to prevent accumulation of blood or serous fluid in the closed potential space of the neck.[75]

Obstruction of venous drainage from the head by large intrathoracic thyroid masses sometimes results in superior vena cava syndrome (Fig. 59–8). Resec-

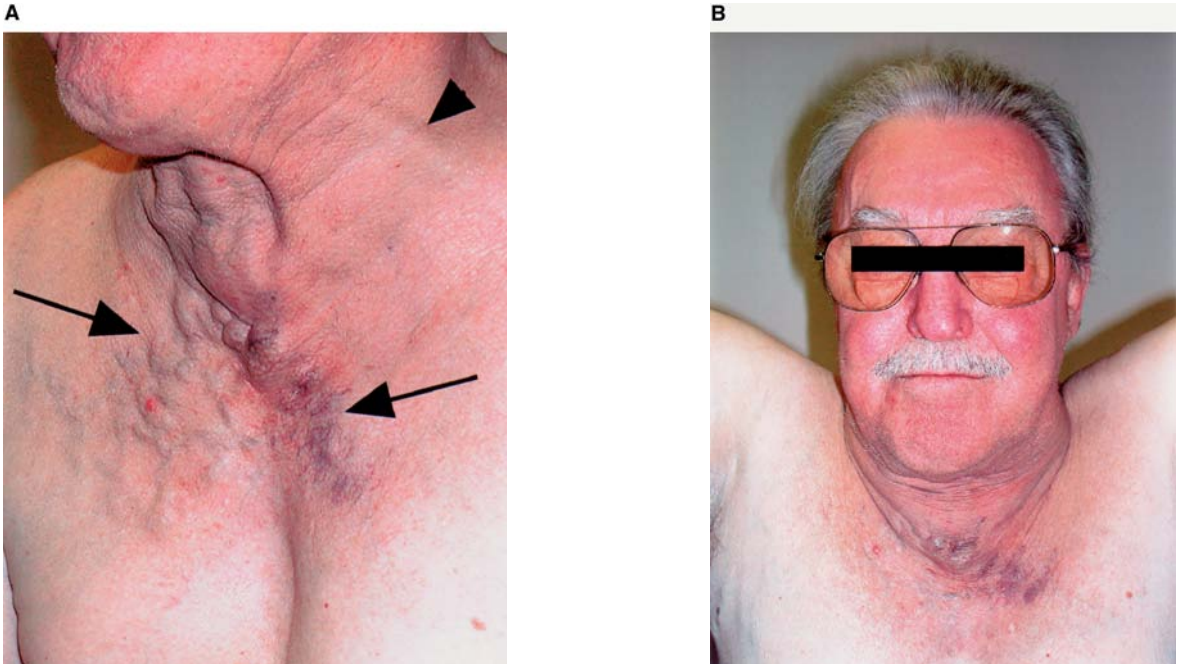

FIGURE 59–8. Large cervical and intrathoracic goiter obstructing venous drainage from the head. This patient lost >5 L of blood during surgery to resect the thyroid mass.

tion of such lesions may be compromised by substantial blood loss.

Positioning Injuries

Thyroid surgery typically is accomplished with the patient in the supine position with the neck extended and the arms wrapped and supported at the patient's side (Fig. 59–9). Cervical spine conditions may limit the ability to extend the patient's neck safely or comfortably. A pressure injury to the occipital nerves has been described in a patient with the potential risk factors of obesity and DM undergoing thyroid surgery.[82] Risk of ulnar neuropathy related to positioning of the arms at the sides with the potential for pressure on the elbow should be considered. In addition, patients with proptosis from Graves ophthalmopathy may be at particular risk for corneal abrasions or pressure injuries to the globe.

PARATHYROID DISEASE AND DISORDERS OF CALCIUM METABOLISM

Patients may present for surgery to treat parathyroid disease (parathyroidectomy) or require surgery in the setting of disorders of calcium homeostasis. Anesthetic considerations for parathyroidectomy substantially overlap with many of the issues encountered in thyroid surgery. These concerns include monitoring of RLN function, risks of postoperative hypocalcemia and postoperative neck hematoma, and positioning.[75,83] Manifestations of renal insufficiency are particularly important for patients presenting for parathyroidectomy to treat secondary or tertiary hyperparathyroidism.

Advanced preoperative imaging techniques facilitate identification of abnormal parathyroid tissue, sometimes permitting less invasive surgery with achievement of therapeutic goals.[52,75,84] However, failed explorations persist as a surgical problem. Rapid intraoperative immunoassay for PTH can assist the surgeon in determining whether pathologic parathyroid tissue has been identified and removed.[85] Propofol does not interfere with the intraoperative PTH assay.[86]

Anesthesia options for parathyroid surgery include general anesthesia with or without endotracheal intubation, and regional anesthesia techniques.[51,54,75,87] One advantage of regional anesthesia is the avoidance of nausea and vomiting, which is common following parathyroid surgery.[88]

Implications of Hypocalcemia

Hypocalcemia is a feature of many medical conditions (Table 59–8). Of particular relevance to the anesthesiologist planning to take a hypocalcemic patient to the operating room are critical illness conditions, including pancreatitis or fat embolism syndrome, hepatic or renal failure, and rhabdomyolysis. Detection of hypocalcemia should provide an impetus to comprehensively evaluate the overall condition of a patient to ascertain whether other significant disorders are present.

Features of hypocalcemia (Table 59–9) of particular relevance to perioperative management include a pre-

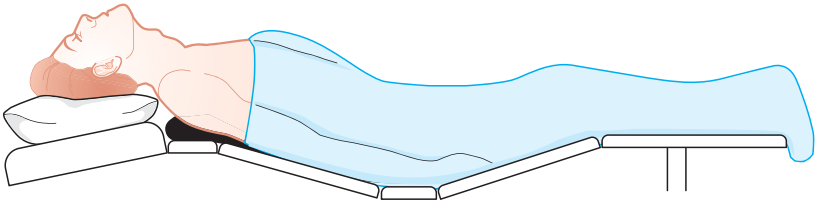

FIGURE 59–9. Patient positioning for thyroid and parathyroid surgery. The patient lies supine with the neck extended, usually by an inflatable pouch positioned under the scapulae ("thyroid bag"). The arms are tucked at the sides or rest on the abdomen. The anesthesiologist has little access to the patient once surgical drapes are placed.

- Massive transfusion (citrate intoxication with chelation of calcium)

disposition to laryngospasm, cardiac dysrhythmias, muscle weakness, hypotension, congestive heart failure, altered mental status, and coagulopathy. Massive transfusion with attendant citrate intoxication, especially in the setting of hepatic insufficiency, is a commonly encountered clinical situation with a significant risk for hypocalcemia that may exacerbate the hemodynamic and metabolic disturbances of complicated surgery. Hypocalcemia should be considered in the differential diagnosis of altered mental status following emergence from a craniotomy.

Treatment of hypocalcemia in the perioperative setting is best accomplished with IV calcium chloride, although calcium gluconate is another option. Clinicians should recognize that 1 g of calcium chloride solution provides three times the amount of elemental calcium present in 1 g of calcium gluconate. Serial blood ionized calcium measurements should guide therapy.

Implications of Hypercalcemia

Hypercalcemia is a feature of many medical conditions (Table 59–10). Detection of hypercalcemia warrants evaluation for the possible presence of other major physiologic disturbances, including pheochromocytoma, adrenal insufficiency, and acromegaly. Hypercalcemia should be considered in the differential diagnosis of altered mental status in the perioperative period.

Features of hypercalcemia of particular relevance to perioperative management include a predisposition to cardiovascular disturbances, such as dysrhythmias and hypertension (Table 59–11). Muscular weakness caused by hypercalcemia can exacerbate respiratory insufficiency. Positioning should take into account the risk of fracturing osteopenic bone. Urgent treatment of hypercalcemia may be required in the operating room or in the immediate perioperative period. First-line therapy includes IV hydration and diuresis. Treatment modalities are summarized in Table 59–12.

PHEOCHROMOCYTOMA AND PARAGANGLIOMA

Pheochromocytomas are neuroendocrine tumors arising from chromaffin

cells in the adrenal medulla.[89] These tumors may be benign or malignant. Secretion of vasoactive substances, including the catecholamines (dopamine, norepinephrine, and epinephrine), leads to clinical manifestations of the tumors. Neuroendocrine chromaffin tumors that arise outside of the adrenal medulla are referred to as *paragangliomas.*[90,91] Because the clinical presentation and management issues are similar, the anesthetic implications of pheochromocytoma and paraganglioma are discussed together. Several excellent reviews of the pathophysiology, presentation, and perioperative management of pheochromocytoma appear in the literature.[89–92]

Clinical Manifestations of Pheochromocytoma

As reviewed in Chapter 12, the clinical manifestations of a pheochromocytoma in a patient depend on the profile of catecholamine secretion. Tumors secreting primarily norepinephrine are associated with hypertension. If epinephrine is the major secreted catecholamine, tachycardia, tachydysrhythmias, and hypotension often result. Dopamine is the major catecholamine secreted by some tumors, and hypotension is the significant clinical feature. However, the overall manifestations of pheochromocytoma are variable, often paroxysmal or episodic, and sometimes similar to other conditions such as severe hyperthyroidism[90,91] or preeclampsia.[89] If a patient is diagnosed with pheochromocytoma, rapid, extreme, perturbations in hemodynamics or other signs and symptoms can be anticipated and should be promptly and appropriately managed in the operating room, postanesthesia care unit (PACU), or ICU. The undiagnosed patient poses a significant management challenge in the perioperative period because the differential diagnosis of extreme physiologic perturbations is so extensive and treatments differ markedly.

For the anesthesiologist, particularly salient clinical features of pheochromocytoma are hypertension, tachycardia and dysrhythmias, cardiac ischemia or myocardial dysfunction, hyperglycemia, intravascular volume depletion, and lactic acidosis. Patients may present in shock, caused by either the secreted products of the tumor or some complication of the disease, such as myocardial infarction, cardiac failure, or dissected/ruptured aorta. Acute manifestations of an unsuspected pheochromocytoma must be considered in the differential diagno-

TABLE 59–12.

Medical Management of Symptomatic and/or Severe Hypercalcemia

Mode of Action	Measure/Substance	Indication	Side Effects/Complications
Intravenous hydration	Isotonic saline administration at 200–300 mL/h (4–6 L/d)	Universal	Volume expansion, hypokalemia, hypomagnesemia
Loop diuretic	Furosemide 20–40 mg, q6–12h, up to 500 mg/d or continuous infusion 100 mg/h	Universal in cases of fluid retention	Hypokalemia, hypomagnesemia
Bisphosphonates	Pamidronate 60–90 mg IV over 4 h Zoledronate 4 mg IV over 15 min Repeat every 2–3 wk[a]	Universal (preferred in HHM)	Fast administration → renal insufficiency Fever, myalgia
Calcitonin	200–500 IU/d subcutaneously	Universal (adjuvant)	Nausea, vomiting, tachyphylaxis
Steroids	Prednisone 40–100 mg/d for 3–5 days	Vitamin D intoxication, sarcoidosis (rarely HHM)	Iatrogenic Cushing syndrome
Hemodialysis (if renal failure)	Ca^{2+}-free dialysate	Hypercalcemic crisis and renal insufficiency	Dialysis related
Diet low in Ca^{2+}/ Vitamin D	<100 mg Ca^{2+} per day	Universal	None

HHM, Humeral hypercalcemia of malignancy.
[a]Reduce bisphosphonate doses in renal insufficiency.

sis of many intraoperative clinical scenarios.

Preoperative Preparation

A patient with a known pheochromocytoma scheduled for tumor resection undergoes extensive preparation for the procedure. Preoperative medical management has been reviewed.[89,90,93] The major concerns are as follows:

1. Control of elevated blood pressure
2. Repletion of intravascular volume
3. Assessment of end-organ consequences of the disease (e.g., cardiomyopathy)
4. Recognition of the potential impact of conditions associated with a pheochromocytoma (e.g., multiple endocrine neoplasia type II, von Hippel-Lindau syndrome)
5. Normalization of glucose and electrolyte levels

A number of regimens have been reported to reduce blood pressure in the preoperative period in preparation for surgery to resect the pheochromocytoma. α-Adrenergic blockade has been widely used. Phenoxybenzamine, a nonselective, noncompetitive, α-adrenergic blocker that covalently binds to α-adrenergic receptors, has been a mainstay of therapy.[89,94] Competitive blockers selective for the α_1 subtype of α-adrenergic receptors (e.g., doxazosin) have been used to successfully prepare patients for surgery.[95]

A potential advantage of competitive, selective α_1-blockade is that once the tumor has been resected and excess catecholamine release eliminated, α-adrenergic receptors can return quickly to normal function, for example, in regulating vascular tone and blood pressure. A disadvantage of competitive α-adrenergic blockade is the possibility that massive concentrations of catechols released by the tumor can overwhelm the competitive receptor antagonist, resulting in clinical manifestations including hypertension. Covalent, noncompetitive deactivation of α-adrenergic receptors, as with phenoxybenzamine, can withstand a surge in circulating catechol levels. However, following resection of the tumor and removal of excess circulating catecholamines, permanent deactivation of α-adrenergic receptors by phenoxybenzamine may result in hypotension refractory to α-adrenergic agonists for days until new receptors are synthesized.[90,91,96]

Tachycardia is one consequence of elevated catecholamine levels. β-Adrenergic blockade is commonly used to control tachycardia. However, β-blockade must not be instituted before initiation of α-blockade so that α-adrenergic activation would be unopposed in the vasculature.[97] α-Adrenergic blockade is physiologically complex because activation of α_2-adrenergic receptors, which are presynaptic, reduces catecholamine secretion, whereas activation of α_1-adrenergic receptors, which are postsynaptic, causes vasoconstriction. A theoretical advantage of drugs such as doxazosin lies in their selectivity for α_1-adrenergic receptors so that the normal regulatory activities of presynaptic α_2-receptors are not impaired, as in the case with the nonselective agent phenoxybenzamine. Urapidil, another selective α_1-antagonist deliverable by IV infusion, provides similar advantages.[98]

Other approaches to preoperative control of blood pressure use calcium channel blockers such as nicardipine,[99] the mixed α- and β-receptor antagonist labetalol,[100] infusions of magnesium,[92,101–103] and treatment with metyrosine,[104] which inhibits catecholamine biosynthesis. The aims of preoperative preparation are to prevent an acute hypertensive crisis before entering the operating room and then to minimize catecholamine-induced hemodynamic changes during anesthesia and surgery. With adequate preoperative preparation, which has been defined as a systemic blood pressure stabilized below 160/90 mm Hg with only modest orthostatic hypotension, rare ventricular extrasystoles, and no electrocardiographic evidence of ischemia, perioperative mortality from pheochromocytoma has dropped to <3%.[91,94] However, intraoperative hemodynamic lability (both hypertension and hypotension) requiring treatment remains a persistent challenge.[94]

Anesthesia for Pheochromocytoma Resection

Laparoscopy is currently the favored surgical approach for abdominal pheochromocytoma resection.[89,91,105–107] However, open surgery may be required depending upon the exact location of the lesion (e.g., neck paraganglioma) or the anatomic features of an abdominal tumor. Epidural anesthesia provides one option for hemodynamic control.[102] Infusions of nitroprusside, nitroglycerin, magnesium sulfate, esmolol, fenoldopam, phentolamine, urapidil, dexmedetomidine, and nicardipine are reported to successfully control hemodynamics in a readily titratable fashion (Table 59–13).[96,98,99,103,108] Case reports suggest that remifentanil infusions fail to blunt episodes of hemodynamic lability.[109,110] Careful reading of various publications advocating the advantages of particular agents for controlling hemodynamics during pheochromocytoma surgery reveals that, in fact, multiple drugs of different classes often are administered in combination. Appropriate sedation contributes to hemodynamic control in the perioperative period.[89]

During administration of the anesthetic, the usual triggers for hemodynamic activation, such as laryngoscopy, may result in exaggerated hemodynamic responses in a patient with pheochromocytoma. Insufflation of the abdomen with CO_2 for laparoscopy may stimulate release of catecholamines from tumors,[90] and direct manipulation of the tumor may precipitate rapid secretion of vasoactive substances.[89,111] Once the major draining vein of the tumor is ligated, plasma catecholamine levels generally decline precipitously. Hypotension often ensues. Volume repletion, infusions of α-adrenergic agonists such as phenylephrine, and cessation of vasodilators can be used to support hemodynamics. However, as discussed in the section on Preoperative Preparation, phenoxybenzamine produces sustained deactivation of α-adrenergic receptors, which limits the response to phenylephrine. Vasopressin may circumvent this problem.[112] Hypoglycemia should be specifically anticipated and treated as needed.[89,91]

No particular anesthetic technique is specifically indicated, or contraindicated, for pheochromocytoma surgery. Agents known to cause the release of catecholamines, such as ketamine, ephedrine, meperidine, and desflurane, should be used with care or avoided entirely. Whereas neuraxial anesthesia produces sympathectomy (thereby blunting physiologic autonomic responses to surgical stimulation) and may be a useful adjunct to general anesthesia, especially for postoperative analgesia, the release of catecholamines from tumor cells is not prevented by spinal or epidural anesthetics.

TABLE 59–13.

Medications Used in Perioperative Management of Pheochromocytoma

Drug	Dose	Indication
Phentolamine	2.5–5 mg IV at 1 mg/min, repeated every 5 minutes until blood pressure is controlled. Constant infusion, 100 mg/500 mL D_5W, infusion rate adjusted to targeted blood pressure	Treatment of acute hypertensive crisis
Nitroprusside	0.5–10 mcg/kg/min IV, infusion rate adjusted to targeted blood pressure	Treatment of acute hypertensive episodes
Nitroglycerin	0.5–10 mcg/kg/min IV, infusion rate adjusted to targeted blood pressure	Treatment of acute hypertensive episodes
Doxazosin	2–16 mg/d, orally	Preoperative preparation
β-Blockers	Atenolol, metoprolol, propranolol, esmolol, labetalol, dose titrated to effect	Used preoperatively only after complete α-adrenergic blockade is achieved. Used intraoperatively for treatment of acute hypertensive episodes or tachycardia
Phenoxybenzamine	20–30 mg/d initially, then can be increased to 60–250 mg/d (1 mg/kg/d in 3 divided doses) until blood pressure is controlled	Preoperative preparation may be achieved in 10–14 days Used for prevention of hypertensive crisis
Nicardipine	20–60 mg/d, 3 divided doses, orally 0.5–10.0 mcg/kg/min IV infusion rate adjusted to targeted blood pressure, or IV bolus 1–2 mg	Preoperative preparation and intraoperative hemodynamic control
$MgSO_4$	Bolus 2–4 g IV Infusion 1–2 g/h IV	Preoperative control of hypertensive crisis Control of intraoperative hemodynamics
Fenoldopam	0.02–0.1 mcg/kg/min IV infusion	Control of intraoperative hemodynamics
Urapidil	10–15 mg/h IV infusion	Preoperative preparation and intraoperative hemodynamic control
α-Methyl-para-tyrosine	Start at 250 mg orally, 4 times per day Increase to maximum of 4 g/d	Preoperative depletion of catecholamine stores by inhibiting catecholamine synthesis at rate-limiting enzyme. Maximal effect in 2–3 days, start 7–14 days preoperatively

The choice of monitors and vascular access should take into account the need to assess volume status and cardiac performance and the utility of a central route for delivering vasoactive or inotropic drugs. An arterial line likely will be useful.[94] Central venous access and pulmonary arterial catheter insertion remain important considerations. Prys-Roberts[90] reported few pulmonary arterial catheter insertions in a large series of pheochromocytoma resections. Volume loss due to surgical bleeding during pheochromocytoma resection typically is on the order of a few hundred milliliters, although plans for volume access should take into account potential overall volume depletion, especially in the patient who has not been well prepared for surgery. General preparations should include planning for postoperative care in a setting capable of monitoring and treating volume, hemodynamic, and metabolic concerns.

ADRENAL CORTEX AND PERIOPERATIVE MANAGEMENT OF GLUCOCORTICOIDS

Surgeons approach lesions of the adrenal cortex by both laparoscopic and open methods. Anesthetic considerations resemble those for other procedures in the abdomen or retroperitoneum (see Chapters 55, 60). The physiology of adrenal cortical hormones and pathophysiologic conditions of the adrenal cortex are covered in Chapter 12. In general, an excess or deficiency of the mineralocorticoid aldosterone and of adrenal sex steroids have little impact on perioperative anesthetic management, as long as their existence is recognized and medical management is appropriate, including control of blood pressure and treatment of any electrolyte imbalances.

Adrenalectomy for Primary Adrenal Hypercortisolism

For the patient undergoing surgery on one adrenal cortex for primary hyperadrenal cortisolism, anesthesia considerations include the consequences of prolonged production of excess cortisol. Relevant features of this condition are summarized in Table 59–14. Hypertension may be particularly difficult to treat during surgery. Plasma glucose levels are likely to be high, requiring therapy. Prolonged excess cortisol levels affect body habitus and can potentially complicate airway management, positioning, and vascular access. Osteopenia renders the patient at risk for fractures, even with minimal mechanical stress.

TABLE 59–14.

Clinical Features of Glucocorticoid Excess or Deficiency

Glucocorticoid Excess	
Proximal myopathy	Osteoporosis
Muscle wasting	Truncal obesity
Glucose intolerance, diabetes mellitus	Inhibited wound healing
Hypertension	Immunosuppression
Coronary artery disease, peripheral vascular disease	Bowel perforation
Hypervolemia	Gastric ulcers
Hypernatremia	Pancreatitis
Hypokalemia	Behavioral disturbances
Hypercalciuria	Depression
Hypercoagulability	Easy bruising
Glucocorticoid Deficiency	
Postural hypotension	Anorexia
Weakness/fatigue	Nausea/vomiting
Depressed catechol responses	Abdominal pain
Fever	Diarrhea, constipation
Weight loss	Hyperpigmentation

In general, mineralocorticoid function is preserved in primary adrenal hypercortisolism. Following unilateral adrenalectomy, mineralocorticoid replacement probably is unnecessary. Because the function of the opposite normal adrenal cortex may be suppressed, glucocorticoid replacement will be required in the early postoperative period until the hypothalamic–pituitary–adrenal (HPA) axis recovers. This may take several weeks. Because the half-life of cortisol is several hours, an addisonian crisis likely will not develop in the operating room. However, glucocorticoid replacement therapy must be started early in the postoperative period.

If the patient undergoes bilateral adrenal resection, replacement of both a glucocorticoid and a mineralocorticoid ultimately will be necessary.[113]

Adrenal Insufficiency

As reviewed in Chapter 12, native adrenal cortex function may be absent or suppressed by a variety of conditions. Administration of exogenous glucocorticoid is the most common reason for native adrenal suppression. Key features of adrenal insufficiency are summarized in Table 59–14. Of particular relevance in the perioperative period, adrenal insufficiency warrants consideration in the differential diagnosis of refractory hypotension.

In the 1950s, case reports described perioperative deaths of patients who were chronically treated with glucocorticoids and found to have adrenal atrophy.[114] The concept emerged that patients at risk for adrenal insufficiency should receive glucocorticoid supplementation in the perioperative period. Risk factors for adrenal suppression and perioperative adrenal insufficiency include prolonged glucocorticoid therapy and doses of steroids exceeding prednisone 5–7.5 mg/d or equivalent for 3 weeks or longer.[115] Table 59–15 lists the relative potencies of a variety of common glucocorticoids and their mineralocorticoid activities. Recovery from adrenal cortical suppression is variable but may take up to 1 year. Thus, patients treated with glucocorticoids within 12 months of surgery are considered to be at risk for adrenal suppression. Provocative testing with cosyntropin may help identify patients at risk for adrenal suppression, but such evaluation is expensive and cumbersome, and the biochemical results may not correspond to clinical events.[116]

An accepted regimen for perioperative patients that was developed without formal clinical trials calls for the administration of hydrocortisone in "stress" doses. Typically, at least three doses of hydrocortisone, 100 mg IV, are administered every 8 hours, followed by tapering of the dose over several days to the patient's baseline steroid regimen. However, this commonly accepted stress dose steroid regimen has been questioned, based on an increased understanding of physiologic stress responses and glucocorticoid secretion.[116] Baseline normal cortisol production may be as low as 10–15 mg/d,[117–119] rather than 30 mg or more as once believed.[120] Thus, even if extreme surgical stresses result in a 10-fold increase of cortisol production,[121] 100–150 mg of exogenous cortisol or glucocorticoid equivalent should suffice to sustain hemodynamics and metabolism in the absence of any endogenous HPA axis activity. Of note, Leopold et al.[122] did identify larger increases in glucocorticoid production in a group of joint replacement patients; however, these elevations were transient.

The requirement for exogenous glucocorticoid support has been tested in controlled clinical studies of patients chronically treated with steroids.[123–125] The chief end points in these studies were blood pressure or heart rate. With-

TABLE 59–15.

Relative Potencies of Glucocorticoid and Mineralocorticoid Hormones

Steroid	Gluco-corticoid	Mineralo-corticoid	Equivalent dose (mg)	Duration (h)
Short-acting				
Cortisol	1.0	1.0	20	8–12
Cortisone	0.8	0.8	25	8–12

TABLE 59–16.

Suggested Perioperative Steroid Supplementation with Hydrocortisone in Patients with Chronic Adrenal Insufficiency

Anticipated Surgical Stress	Preoperative	Intraoperative	Postoperative
Minor[a]	25 mg or usual dose	None, unless complications	Resume usual replacement POD 1
Moderate[b]	50–75 mg or usual steroid dose, whichever is higher	50 mg IV	20 mg IV q8h on POD 1, then resume preoperative replacement dose on POD 2
Major[c]	100–150 mg or usual steroid dose, whichever is higher, within 2 h of start of procedure	50 mg IV q8h after initial dose	50 mg IV q8h, or 150 mg continuously over 24 h for 2–3 days, then reduce dose by 50% per day until preoperative regimen is reached.

[a]Inguinal herniorrhaphy, minor urologic or gynecologic procedures, oral surgery, plastic surgery
[b]Total joint replacement, open cholecystectomy, lower extremity revascularization
[c]Thoracotomy, cardiac surgery, major abdominal surgery
POD, Postoperative day
Note that these guidelines may not meet the requirements of all patients, and perioperative or stress steroid replacement should be individually tailored.

holding steroid supplementation resulted in minimal evidence of hemodynamic instability. Based on these results and the limited number of similar studies in animals and humans, a graded approach to steroid supplementation has been recommended for patients believed to be at risk for adrenal insufficiency in the perioperative period. Recommendations take into account the anticipated magnitude of surgical stress. Table 59–16 combines the recommendations from several sources.[97,116,126] Of note, prolonged tapering of exogenous glucocorticoid therapy does not appear to be essential, as long as baseline therapy is resumed within a few days of surgery.[127] These recommendations should not necessarily be taken to apply to critically ill patients who come to the operating room from an ICU setting. Some evidence suggests that adrenal insufficiency occurs in at least some critically ill patients,[115] particularly those with sepsis. Such patients may require large doses of supplemental steroids for prolonged periods.

Etomidate

The favorable hemodynamic properties of the IV induction agent etomidate give this drug an important place in the anesthesiologist's armamentarium. However, unique among all anesthetic agents, etomidate inhibits the mitochondrial enzyme 11β-hydroxylase, an essential enzyme in the biosynthetic pathway for steroids. An induction dose of etomidate reduces cortisol and aldosterone production for approximately 8 hours. Repeated doses or infusions of etomidate have more prolonged suppressant effects on steroid production, which may become clinically relevant. Consequently, the use of etomidate should be evaluated in the context of the patient's adrenal reserve.

PITUITARY DISEASES AND PITUITARY SURGERY

Anatomy of the Pituitary Gland

The pituitary gland lies within a recess of the sphenoid bone, the sella turcica. The gland is composed of two major subdivisions, the anterior pituitary and the posterior pituitary. Magnetic resonance imaging (MRI) readily visualizes these structures because the posterior pituitary appears as a bright spot on T1-weighted images, as shown in the sagittal view in Fig. 59–10A. Structures next to the pituitary are shown in the coronal view in Fig. 59–10B.

The posterior pituitary contains axon terminals of specialized neurons arising within the supraoptic and paraventricular nuclei of the hypothalamus. These nerves secrete oxytocin and vasopressin (antidiuretic hormone [ADH]). Thus, the posterior pituitary is a direct extension of the brain. In contrast, the anterior pituitary derives embryologically from the Rathke pouch; it is composed primarily of epithelial cells. It does not have direct neuronal connections to the brain. The anterior pituitary is dependent upon a vascular conduit, the pituitary portal plexus, which directly links the hypothalamus to the anterior pituitary gland. The portal plexus is a venous plexus and is the major source of blood flow to the anterior pituitary, which has little or no arterial blood supply. The major cell types and secretory products of the anterior pituitary gland are listed in Table 59–17.

Pituitary Lesions

Pituitary lesions can be placed in broad categories according to their functional effects. Lesions can cause mass effects, anterior pituitary hyperfunction, or anterior pituitary hypofunction.

Pituitary adenomas arise from anterior pituitary cells; therefore, they almost always are located in the sella turcica. They compose approximately 10–15% of all intracranial neoplasms. Adenomas < 1 cm in diameter typically are referred to as *microadenomas,* whereas adenomas with diameters ≥1 cm are commonly referred to as *macroadenomas.*[128,129] Macroadenomas and some microadenomas can be visualized by MRI following IV infusion of gadolinium. Autopsy studies reveal that 25% of individuals have asymptomatic pituitary adenomas. Only adenomas with endocrine syndromes as a result of hyposecretion or hypersecretion, or which cause symptomatic mass effects on adjacent brain structures, come to medical attention. The prevalence of diagnosed pituitary adenomas is 8.9:100,000.[129]

In addition to pituitary tumors, many other masses appear in the sella

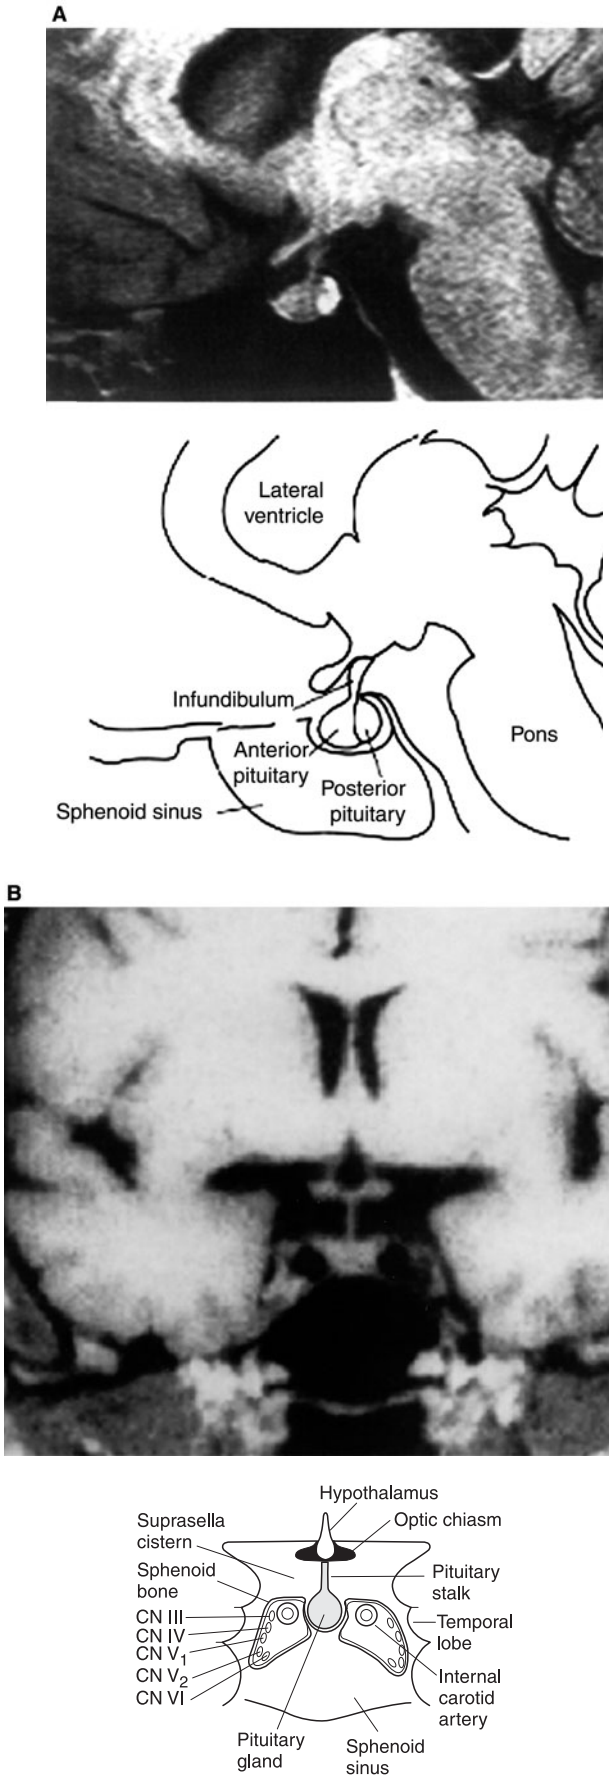

FIGURE 59–10. Anatomic relationships of the normal pituitary gland. **A.** Sagittal view. **B.** Coronal view.

or parasellar region.[128,130] Meningiomas, craniopharyngiomas, chordomas, and metastatic carcinomas occasionally appear as pituitary masses. Benign sellar cysts derive primarily from the Rathke cleft; they frequently are asymptomatic and are found incidentally. Infiltrative diseases mimicking masses in the pituitary include sarcoidosis, lymphocytic hypophysitis, histiocytosis X, and tuberculosis.

Classification of Pituitary Adenomas

Pituitary adenomas are classified by either their hypersecretory product or their lack of hormonal secretion (nonsecretory pituitary adenomas).[128,130] Some tumors secrete more than one pituitary hormone (plurihormonal adenomas). The most common combination seen in these tumors is GH and prolactin.[131] Other pituitary adenomas do not secrete bioactive hormone but may secrete the α- or β-subunits of the glycoprotein hormones luteinizing hormone (LH), follicle stimulating hormone (FSH), or thyroid stimulating hormone (TSH). Table 59–18 lists the most common types of pituitary adenomas, their most abundant secretory products, and their relative frequency.

Clinical Symptoms of Pituitary Masses

Because the pituitary gland lies adjacent to the cavernous sinus, temporal lobes, and sphenoid sinus (Fig. 59–11), the presentation of pituitary lesions occasionally includes other clinical symptoms (Table 59–19). Palsies of extraocular muscles, sensory disturbances in the first and second branches of the fifth cranial nerve, temporal lobe seizures, and cerebrospinal fluid (CSF) rhinorrhea may bring a patient to medical attention.[128] Disorders of both the hypothalamus and pituitary can compress or infiltrate the optic chiasm, resulting in a variety of visual field abnormalities affecting peripheral vision (superolateral visual field defect).

Pituitary Hypofunction: Causes, Presentation, and Treatment of Hypopituitarism

Causes of Deficient Pituitary Hormone Secretion

Many disorders cause hypopituitarism by affecting either the hypothalamus or the pituitary gland. Pituitary adenomas are the most common cause of

TABLE 59–17.

Major Cell Types and Secretory Products of the Anterior Pituitary Gland

Cell Type	Secretory Products	Cell Population (%)

hypopituitarism.[128,132] Other less common causes are listed in Table 59–20.

Symptoms of Deficient Pituitary Hormone Secretion

Specific symptoms associated with the loss of individual pituitary hormones are listed in Table 59–21. Although a diagnosis of some pituitary deficiencies can be inferred based on history and clinical findings, demonstrating hormone deficiencies by biochemical testing is essential to establishing the diagnosis of hypopituitarism. A more detailed description of hypothyroidism and cortisol insufficiency can be found in the thyroid and adrenal sections of Chapter 12. A variety of tests can be performed to evaluate the reserve of each of the pituitary hormones. It is extremely important to make the diagnosis of adrenocorticotropic hormone (ACTH) and/or TSH deficiency, because these anterior pituitary hormones are essential to surviving perioperative stress.[128,132] Destruction of the posterior pituitary, stalk compression, or stalk section results in a complete or relative lack of ADH. ADH causes the renal tubules to reabsorb water. Lack of ADH results in failure to concentrate urine, producing dilute urine (low specific gravity and low osmolality) despite dehydration with an elevated blood osmolality. Urine output can exceed 1–2 L/h, resulting in severe dehydration, hypernatremia, and vascular collapse.[132]

Treatment of Deficient Pituitary Hormone Secretion

The aim of treatment is to replace the hormonal deficiencies needed for normal function and to treat the underlying disease process.[128,133] In most instances, replacement of hormone deficiencies can be accomplished by oral, IV, cutaneous (skin patch), subcutaneous, or nasal administration of deficient hormones. The dose usually is the same from day to day, with the exception of glucocorticoid replacement, which must be increased during times of stress (see Adrenal Cortex

TABLE 59–19.

Clinical Signs and Symptoms of Pituitary Lesions

Direction of Tumor Expansion	Neighboring Structures	Symptoms of Compression
Upward	Optic pathways	Visual field cuts, blindness
	Hypothalamus	Disturbed temperature autoregulation
	Olfactory nerve	Anosmia
Lateral	Cavernous sinus	Proptosis, eyelid edema

and Perioperative Management of Glucocorticoids for a detailed discussion of baseline and stress doses of glucocorticoids). Table 59–22 lists the common drugs used for hormone replacement therapy in hypopituitarism. As a general rule, glucocorticoid replacement therapy should be given first. Thyroid hormone replacement therapy should never be given before glucocorticoids have been replaced in order to avoid precipitating an addisonian crisis.[128,133]

Pituitary Hypersecretion and Neoplasia

Pituitary hypersecretion may occur physiologically, for example, when LH and FSH rise during menopause with the loss of feedback inhibition by gonadal steroids, or when ACTH secretion increases during stress. Pathophysiologic causes of pituitary hormone hypersecretion include hyperplasia of one or more cell types in the anterior pituitary, driven by excessive production of hypothalamic releasing factors. Tumors in the hypothalamus (hamartomas, gangliocytomas) or in the periphery (carcinoids, islet cell tumors) may secrete these factors. However, the most common cause for pathologic hypersecretion of anterior pituitary hormones is pituitary adenoma.[128,130] The most common pituitary adenoma is a prolactinoma.[134] The lesions with greatest significance for anesthetic management are corticotroph and somatotroph adenomas.

Prolactinomas

The prolactinoma is the most common pituitary adenoma.[134] In women, the majority of tumors present as microadenomas, whereas in men, macroadenomas predominate. Symptoms due to compression of local structures thus are generally found in men.[128] Signs and symptoms associated with hyperprolactinemia mainly relate to reproductive tissues and function, including amenorrhea and impotence.

Treatment of patients with a prolactinoma depends upon the size of the adenoma and the degree of symptoms. If the adenoma is small and endocrine consequences are minor, management is conservative because most lesions will not enlarge. Adenomas requiring therapy generally respond to medical management with the dopamine agonists bromocriptine or cabergoline.[128,134]

FIGURE 59–12. Patient with acromegaly: bony tissue changes. **A.** Face view. Note coarsening of the features with jaw prominence and distortion of the tooth occlusion. Also note large nose and tongue. **B.** Hand view of acromegalic patient (*left*) and normal adult (*right*).

By stimulating D_2 receptors on the adenoma, these drugs cause a reduction in tumor size and inhibit prolactin synthesis and secretion. Most adenomas will regrow, however, if therapy is stopped. If tumors resist medical therapy, transsphenoidal (TSP) surgery is performed. Surgical success rates are high for microadenomas (>70%), but postoperative recurrence may reach 50% over 5 years.[134] Macroadenomas are difficult to cure by surgery, with success rates of ~30%. Radiotherapy is not very effective and is used as a last resort.[128,134]

Somatotroph Adenomas

GH is primarily under the regulation of two opposing hypothalamic peptides, growth hormone-releasing hormone (GHRH) and somatostatin. GH stimulates insulin-like growth factor-1 (IGF-1), which exerts feedback effects on the hypothalamus and pituitary to inhibit both GHRH and GH secretion, respectively. GH secretion is stimulated by hypoglycemia, amino acids, exercise, and stress. Glucose inhibits GH secretion.

Random GH determinations are generally not helpful in diagnosing acromegaly. Nighttime GH levels at the peak of a GH spike can be within the range of an individual with acromegaly. Conversely, normal GH levels may be found in individuals with acromegaly, but these individuals lose the normal pulsatile rhythm of GH.[128,130]

GH hypersecretion is almost always due to a pituitary adenoma. Rarely, excess GH secretion results from hyperplasia of anterior pituitary somatotrophs as a result of ectopic secretion of GHRH. GH hypersecretion causes gigantism in children and adolescents (before closure of the epiphyses) and acromegaly in adults.

Acromegaly, largely a disorder of middle age, has a peak incidence between ages 40 and 50 years. If untreated, it is associated with a 2- to 3-fold increased mortality due to cardiovascular disease (hypertension, cardiomyopathy, arrhythmias, stroke), cancer (especially adenocarcinoma of the colon), and respiratory impairment.[130]

Acromegaly leads to profound physical deformity due to skeletal overgrowth (bone and cartilage) and fibroblast proliferation under the influence of IGF-1. This is particularly manifest in the facial bones, where enlargement of the mandible results in protrusion of the jaw (prognathism), dental malocclusion, and often an increased space between the teeth (Fig. 59–12). Facial features are thickened, coarsened, or swollen, making skin creases very pronounced, partly due to sodium and water retention and increased glycosaminoglycan accumulation in the skin. The lips, tongue, and tissue in the posterior pharynx become very large (Fig. 59–13). Increased cartilaginous growth contributes to the very prominent nose. Enlargement of the hands and feet result in the common complaint that ring, glove, and shoe sizes increase. Arthralgias are particularly common (75%) due to cartilaginous overgrowth in the joints resulting in misalignment and destabilization of the joints and ultimately joint destruction. Other manifestations of acromegaly are listed in the Table 59–23. It is important to make the diagnosis of acromegaly early to prevent irreversible, devastating complications.[128]

Because of the insidious nature of the disease and delays in diagnosis, almost all individuals with acromegaly have macroadenomas when they come to medical attention. Approximately 30% have microadenomas. TSP surgery successfully removes approximately 80% of microadenomas. Only approximately 30% of individuals with macroadenomas have a surgical cure.[128] Radiation therapy is only partly successful in reducing GH hypersecretion to normal, although preliminary data using radiosurgery therapy suggest a 60% cure rate over 4 years. Several medical treatments have become available to control GH hypersecretion and, in some cases, tumor growth. These medications, which include somatostatin analogues and blockers of dopamine receptors, can be given singly or in combination.

Successful treatment of acromegaly results in reduction of left ventricular

FIGURE 59–13. Soft-tissue changes in a patient with acromegaly: tongue enlargement. **A.** Before treatment. The large tongue obstructs the airway. The patient received a tracheostomy. **B.** After treatment. Soft-tissue changes have substantially reversed, allowing decannulation of the tracheostomy.

hypertrophy and some improvement of diastolic function (increase in transmitral peak flow velocity and decreased isovolumic relaxation time).[135,136] However, skeletal and soft-tissue changes persist and may pose challenges when patients require surgery and anesthesia for conditions other than their pituitary disease.

Corticotroph Adenoma

Pituitary secretion of ACTH normally is under negative feedback inhibition by circulating cortisol. ACTH-secreting pituitary adenomas are partially autonomous; feedback inhibition by cortisol remains but at a higher set point. Hence, ACTH and cortisol can be suppressed in individuals with ACTH-secreting pituitary adenomas when they receive sufficiently large doses of exogenous glucocorticoids. Dexamethasone, a semisynthetic steroid, is often used for this purpose because it does not interfere with cortisol radioimmunoassays. By administering graded doses of dexamethasone (Liddle test) to individuals suspected of having Cushing syndrome and measuring ACTH and cortisol levels, it is possible to distinguish individuals having ACTH-secreting adenomas, adrenal adenomas, and ectopic ACTH secretion (e.g., oat cell carcinoma, medullary thyroid carcinoma, islet cell tumors, pheochromocytoma) from individuals who simply are obese.

Alternatively, measurement of a late night plasma or salivary cortisol level can be used to distinguish individuals with Cushing disease from normal individuals. This discrimination is based on the normal physiologic diurnal variation of cortisol levels, which peak at around 8 AM and have their nadir at around midnight. Thus, a normally suppressed midnight cortisol level excludes the diagnosis of Cushing disease. In some patients, midnight cortisol levels are elevated, but MRI fails to demonstrate a pituitary adenoma (60% of cases due to the small size of ACTH-secreting pituitary adenomas; macroadenomas are rare). In this situation, a corticotropin-releasing hormone (CRH) stimulation test can be performed with sampling of venous blood draining the pituitary gland. However, a skilled invasive radiologist is needed to catheterize each inferior petrosal sinus vein.

Some individuals have clinical and biochemical findings consistent with Cushing disease but instead are diagnosed with a condition called pseudo-Cushing syndrome. Pseudo-Cushing syndrome may result from alterations in the set point for feedback inhibition of CRH or ACTH by cortisol. The con-

dition is associated with excessive alcohol intake, depression, severe obesity, and severe illness. Preservation of the normal cortisol circadian rhythm distinguishes pseudo-Cushing syndrome from true Cushing disease. In pseudo-Cushing syndrome, the abnormal endocrine findings revert to normal with correction of the precipitating cause. Table 59–14 summarizes clinical characteristics relevant to perioperative management

Treatment of Cushing disease is primarily surgical, with removal of the pituitary adenoma by TSP surgery. For individuals not cured by surgery, treatment options include conventional radiation or radiosurgery therapy, with or without medical therapy. Medications used in the management of Cushing disease and their mechanisms of action are summarized in Table 59–24.

Thyrotroph Adenomas

Thyrotroph adenomas are rare pituitary adenomas.[128,130] The vast majority of these tumors are macroadenomas; therefore, they may be associated with mass effects. Their principal clinical presentation is thyrotoxicosis due to excessive TSH secretion. A goiter occurs in >90% of cases. Graves disease is often misdiagnosed in these patients. Inappropriately elevated TSH levels (for the levels of thyroid hormones) and the absence of ophthalmopathy allow differentiation between the two disorders. Resistance to thyroid hormone because of mutations of the thyroid hormone receptors also can result in inappropriately elevated TSH levels despite the high circulating levels of thyroid hormones. This unusual condition can be differentiated from thyrotroph adenoma because the adenoma secretes an excess of α-subunit compared to intact TSH.

Surgery is the primary therapy for a thyrotroph adenoma, but complete removal often is difficult because of the large size of these tumors. Radiation therapy and/or medical therapy with octreotide are used for treating persistent disease. Octreotide is very effective in reducing TSH secretion to normal and reversing thyrotoxicosis but is not very effective in shrinking tumors.

Nonsecreting Adenomas

The majority (90%) of nonsecreting pituitary adenomas are actually glycoprotein hormone-producing adenomas, manufacturing various subunits of glycoprotein hormones including α-subunit, β-LH, and β-FSH.[131] Because these subunits are biologically inactive, clinical syndromes usually are not observed. As a result, most of these tumors come to medical attention because of mass effects and/or hypopituitarism.

Treatment depends upon the size of the adenoma. Small adenomas do not necessarily require treatment if they do not compress local structures or cause hypopituitarism. Periodic MRI can assess their rate of growth. Large tumors are treated by TSP surgery. Complete resection of the tumor is not necessary. Relief of compressive symptoms is adequate. If hypopituitarism persists following surgery or is caused by surgery, replacement therapy is given. Occasionally, anterior pituitary function recovers after decompression of the residual normal anterior pituitary cells.[128]

Anesthetic Considerations for Pituitary Surgery

Most sellar lesions are accessible by a TSP approach.[137–139] The nares is the preferred route for entering the sella (Fig. 59–14A). However, this approach may not be anatomically feasible, so the surgeon may achieve adequate exposure by dissecting over the palate with an incision above the maxillary teeth (sublabial approach; Fig. 59–14B). Consequently, the surgeon and anesthesiologist share the head during TSP surgery. General endotracheal anesthesia is indicated. To prevent accumulation of secretions, blood, or CSF in the airway or stomach, a throat pack typically is inserted.

Preoperative assessment requires an understanding of the implications of the patient's endocrine condition. Nonsecreting adenomas, prolactinomas, and the rare adenomas secreting glycoprotein hormones generally have little impact on anesthetic management. Patients with Cushing disease may have all the features of sustained cortisol excess. Potential anesthetic concerns with these patients include airway management, positioning, glucose and electrolyte disturbances, and control of blood pressure. Some patients with Cushing disease have refractory hypertension that poses a significant treatment challenge.

Patients with acromegaly have a propensity for ischemic cardiac disease as well as myocardial dysfunction. Cardiac status should be specifically assessed before surgery. Because of the skeletal and soft-tissue effects of sustained exposure to GH, patients with acromegaly may present substantial challenges in airway management. Mask ventilation and conventional direct laryngoscopy may be difficult or impossible (Fig. 59–15). Advanced airway management devices may be required. Consideration should be given to awake fiberoptic intubation in selected patients.

For most patients undergoing TSP surgery, standard monitoring and routine IV access suffice. Addition of an arterial line may be indicated for patients with comorbidities, or Cushing disease or acromegalic patients with refractory hypertension or cardiac issues. Volume loss likely will be minimal, so large-bore IV access usually is unnecessary. However, the sella is situated near major vascular structures, and the need to augment IV access may develop during surgery.

TABLE 59–24.

Medical Therapy for Cushing Disease

Drug	Mechanism of Action
Ketoconazole	Antifungal agent. Blocks cholesterol side-chain cleavage to reduce cortisol.
Metyrapone	Inhibits 11β-hydroxylase to reduce cortisol. May cause hypertension and hypokalemia due to increase in 11-deoxycorticosterone and hirsutism due to increased androgens.
Aminogluteth-imide	Often used with metyrapone to reduce side effects. Inhibits cholesterol side-chain cleavage and 11-/18-hydroxylation.
Mitotane	Destructive to adrenal cortex. Frequent adverse reactions.
Mifepristone (RU-486)	Glucocorticoid antagonist (not available in the United States).

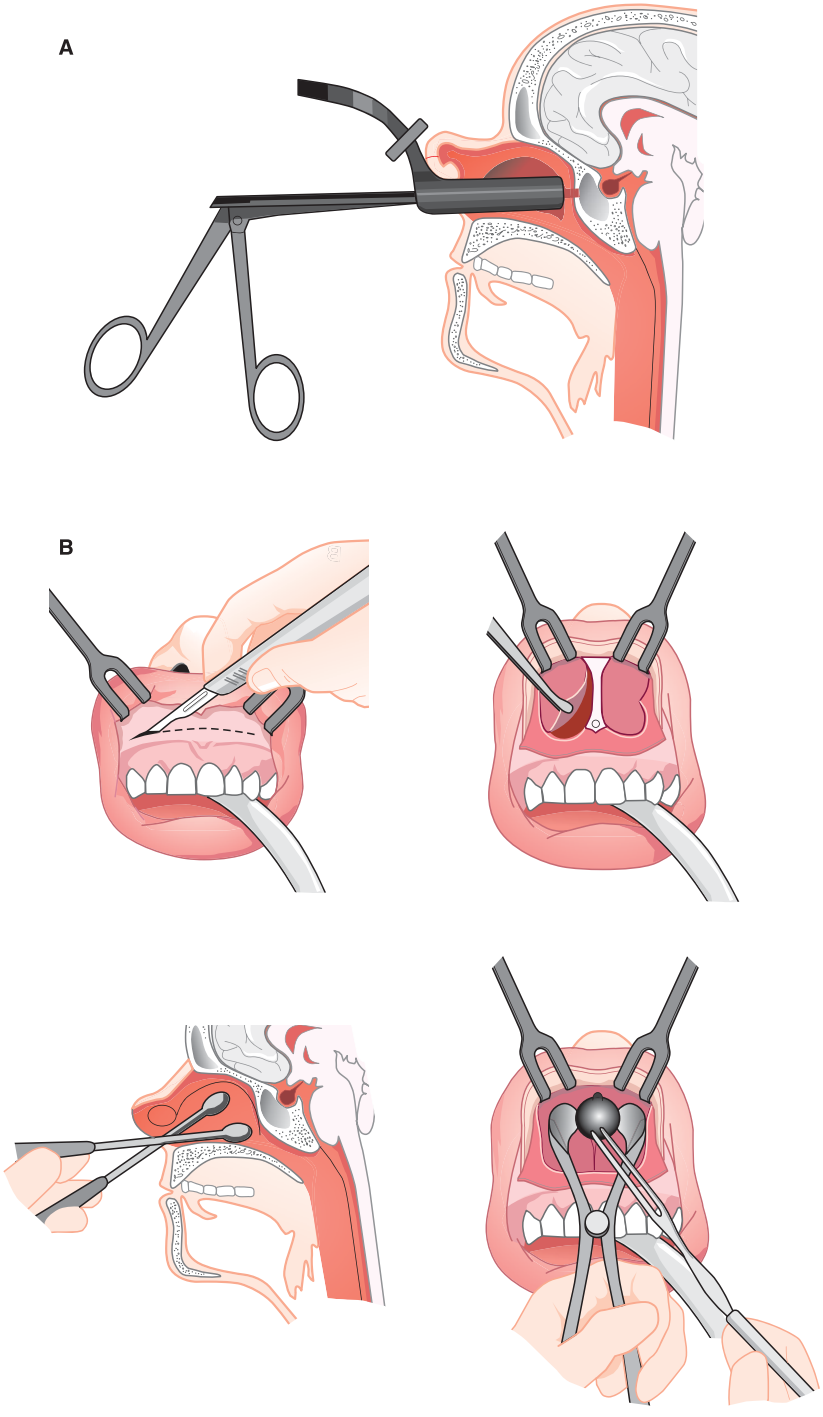

FIGURE 59–14. Transsphenoidal approach to the sella turcica for pituitary surgery. **A.** Following induction of general anesthesia, the surgeon inserts a speculum into the nares. Instruments are manipulated through the speculum. The sphenoid bone is breached to expose the sella and the pituitary gland within. **B.** If a nasal approach is not anatomically feasible, the sella can be accessed over the roof of the mouth (sublabial approach) following an incision above the maxillary teeth. (From Molitch[141] with permission.)

The transnasal TSP surgical procedure is only moderately stimulating, and postoperative pain control requirements are modest.[132] Early hypertension during the surgical procedure may be a result of the application of vasoconstrictors to the nasal mucosa by the surgeon, with subsequent systemic effects. Surgical procedures generally terminate abruptly, so the anesthesiologist must titrate drugs carefully to permit a prompt and smooth emergence. It is highly desirable for the patient to be able to maintain his/her own airway without support or the need for bag-mask positive-pressure ventilation following extubation. The dura has been opened at the surgical site, which now communicates with the nasal passages. Positive-pressure ventilation can, in theory, cause the introduction of air or infectious material through the dural opening into the CSF space.

Some centers use intraoperative MRI techniques to assist the surgeon in gauging the extent of dissection or resection. This poses some additional concerns for easy access to the patient's airway. In addition, preparations include ensuring the availability of MRI-compatible equipment (e.g., monitoring devices and the anesthesia machine itself).

Postoperative Care after Pituitary Surgery

Patients are at risk for diabetes insipidus immediately after surgery.[140] Monitoring includes frequent determinations of serum sodium levels and meticulous recording of daily weight and fluid balance, with hourly measurement of urine output and assessment of urine specific gravity every 4 hours. A triphasic course is often seen. Early ADH deficiency is attributed to immediate perioperative neuronal damage, followed a few days later by excess ADH release and associated hyponatremia from retrograde neuronal death and release of ADH stores. Finally, permanent deficiency of ADH develops with return of diabetes insipidus.

The vasopressin analog desmopressin should be administered postoperatively when urine output exceeds fluid intake and the serum sodium level rises. Careful monitoring of body weight, fluid balance, urine specific gravity, and plasma sodium level should continue daily to avoid electrolyte abnormalities. Desmopressin therapy starts with a single dose at bedtime in a patient diagnosed with partial central diabetes insipidus to avoid hyponatremia. Patients with acromegaly can have salt and water diuresis after successful tumor removal. Such patients should not be immediately treated with vasopressin.

With the exception of patients with Cushing disease, all patients undergoing pituitary surgery should be placed on steroids appropriate for surgical stress. The rate of decrease in steroid dose should be guided by clinical and hemodynamic status after

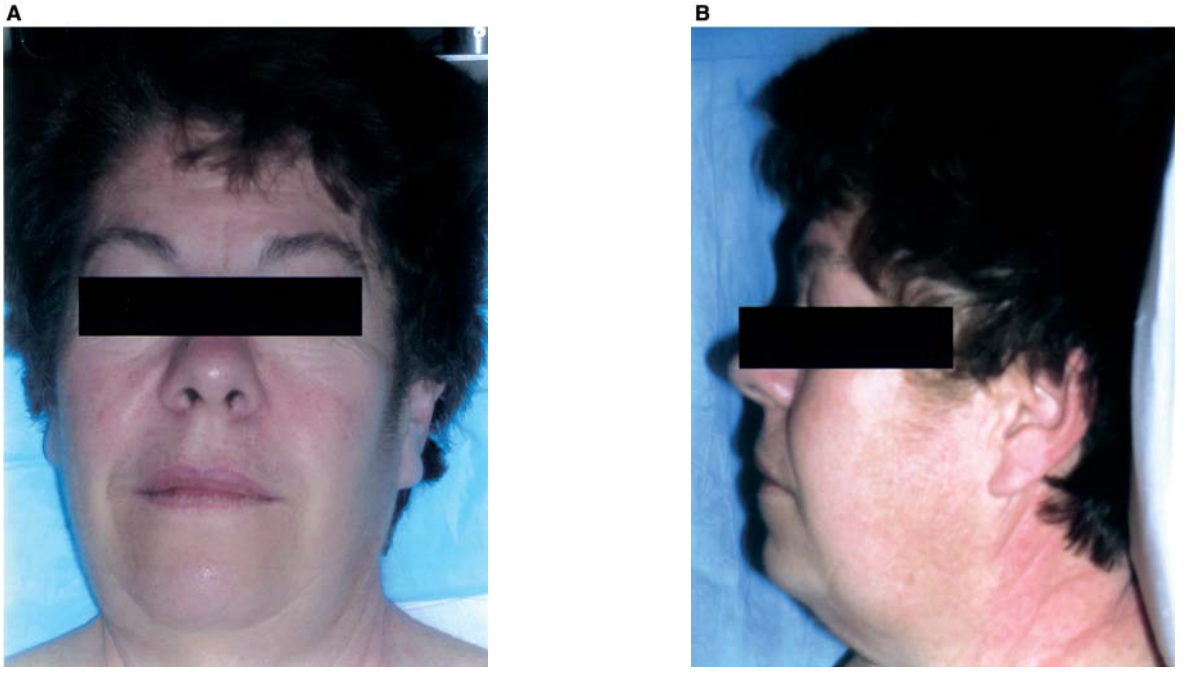

FIGURE 59–15. Patient with acromegaly who could not be intubated by conventional means. This woman lacked symptoms of airway obstruction. There was little external evidence of excessive airway soft tissue. With induction of general anesthesia, a mask airway was established with only moderate difficulty. Attempts at direct laryngoscopy by experienced anesthesiologists with different blades failed to produce any view of recognizable glottic structures. Excess soft tissue prevented insertion of a fiberoptic scope into the trachea. The patient emerged from anesthesia without airway compromise; the planned surgery was cancelled. **A.** Frontal face photograph. **B.** Profile photograph.

surgery. In an uncomplicated postoperative course, taper steroids to physiologic replacement doses over 2–3 days. Patients with Cushing disease should not be placed on hydrocortisone immediately after surgery, but cortisol levels should be checked every 6 hours and replacement therapy initiated as needed.

CHAPTER 60

Anesthetic Considerations for Genitourinary and Renal Surgery

Maurizio Cereda, MD, and Sean Kennedy, MD

Urologic surgery includes a broad variety of procedures of varying complexity, ranging from endoscopic diagnostic procedures to major cancer surgery. Patients who undergo urologic surgery often are of advanced age and have several comorbidities, which may render their perioperative management rather complicated. The anesthesiologist should have background knowledge of the indications, technical aspects, and complications of the major procedures used in urologic surgery in order to formulate a sound anesthetic plan. Additionally, complex patient positions may lead to complications such as nerve damage. The addition of laparoscopic and robotic surgery has further expanded the horizons of urologic surgery. Although the use of minimally invasive procedures may simplify anesthetic and perioperative management, they likely will permit surgery on patients who, because of comorbidities, are not good candidates for traditional procedures. This situation ultimately will render the perioperative management of these patients more challenging for the anesthesiologist.

MACROSCOPIC ANATOMY OF THE URINARY TRACT

Kidney

The kidneys are located in the retroperitoneal space between T12 and L4, along the medial borders of the psoas muscles. Positioned inferior to the liver, the right kidney lies slightly lower than the left kidney. The kidneys are surrounded by the perirenal fat and are enclosed in the perirenal or Gerota fascia. The adrenal glands lie on top of each kidney, also contained by Gerota fascia. Diaphragmatic movement transmits to the kidneys, causing physiologic excursion of 4–5 cm with each respiration. Upon section, the kidney is composed of a cortex and a medullary section. The medulla is divided into several pyramids whose tips, the papillae, are indented with the minor calices. The latter converge in the major calices, then drain into the renal pelvis, which tapers into the ureter.

Each kidney receives its blood supply from a single renal artery, although variants with multiple arteries are encountered occasionally. The renal arteries originate just inferior to the superior mesenteric artery and enter the kidney at its hilum. The right artery crosses the midline behind the vena cava. The renal veins run in front of the arteries, with the left vein crossing the midline anterior to the aorta. The lymphatic circulation of the kidney drains into lymph nodes located in the lumbar region.

The kidneys receive vegetative (adrenergic and cholinergic) innervation (Fig. 60–1) from the renal plexus, which receives fibers mainly from the celiac plexus and the vagus nerve. Sympathetic vasoconstrictor and afferent fibers originate from T8 to L1. For this reason, kidney pain typically is perceived in the costovertebral angle and below the twelfth rib. Anesthesia for kidney surgery requires effective blockade of the nerve roots between T8 and L3 to allow incision through the overlying skin and abdominal wall.

Ureters

The ureters originate from the renal pelvis and run along the course of the

KEY POINTS

1. Patient positioning is important in urologic surgery because of the variety and complexity of the positions used. Knowledge of the physiologic implications and the possible complications of these positions is critical to preventing untoward outcomes.
2. For most endourologic procedures, rapid anesthetic onset and recovery are desired. These goals can be reached with either general or neuraxial anesthesia, provided appropriate pharmacologic choices are made.
3. Use of neuraxial anesthesia for transurethral resection of the prostate (TURP) does not have proven outcome benefits over general anesthesia, but it may facilitate the detection of TURP syndrome. This is the most severe complication of TURP, although its frequency has decreased with the use of current irrigation fluids.
4. For extracorporeal shock wave lithotripsy, intravenous sedation can be effective when lower intensity waves are used. Intrathecal narcotics seem to be a valid alternative.
5. Epidural analgesia may offer some advantages when added to general anesthesia for radical prostatectomy and cystectomy, but no outcome benefits have yet been demonstrated.
6. Blood loss is a significant concern in urologic cancer procedures such as prostatectomy, cystectomy, nephrectomy, and lymph node dissections. A variety of techniques have been used to limit blood loss and transfusion requirement, but their clinical and financial advantages are unclear. Hemodynamic monitoring and volume status assessment are important during these procedures.
7. Patients undergoing surgery for testicular cancer usually are young and in relatively good health, but they may suffer from complications of previous chemotherapy and radiation therapy.
8. Protection of residual kidney function is one of the major concerns during radical nephrectomy. Other than maintenance of hemodynamic stability and use of partial resections, no "renal protection" strategy has proved to be effective in preventing postoperative renal dysfunction.
9. Minimally invasive and robotic urologic surgeries are likely to become common in the future because of their advantages in patient satisfaction and faster recovery. The anesthetic plan for these procedures should account for the physiologic alterations caused by laparoscopy, prepare for possible conversion to a traditional open procedure, and provide patient comfort and faster recovery times.

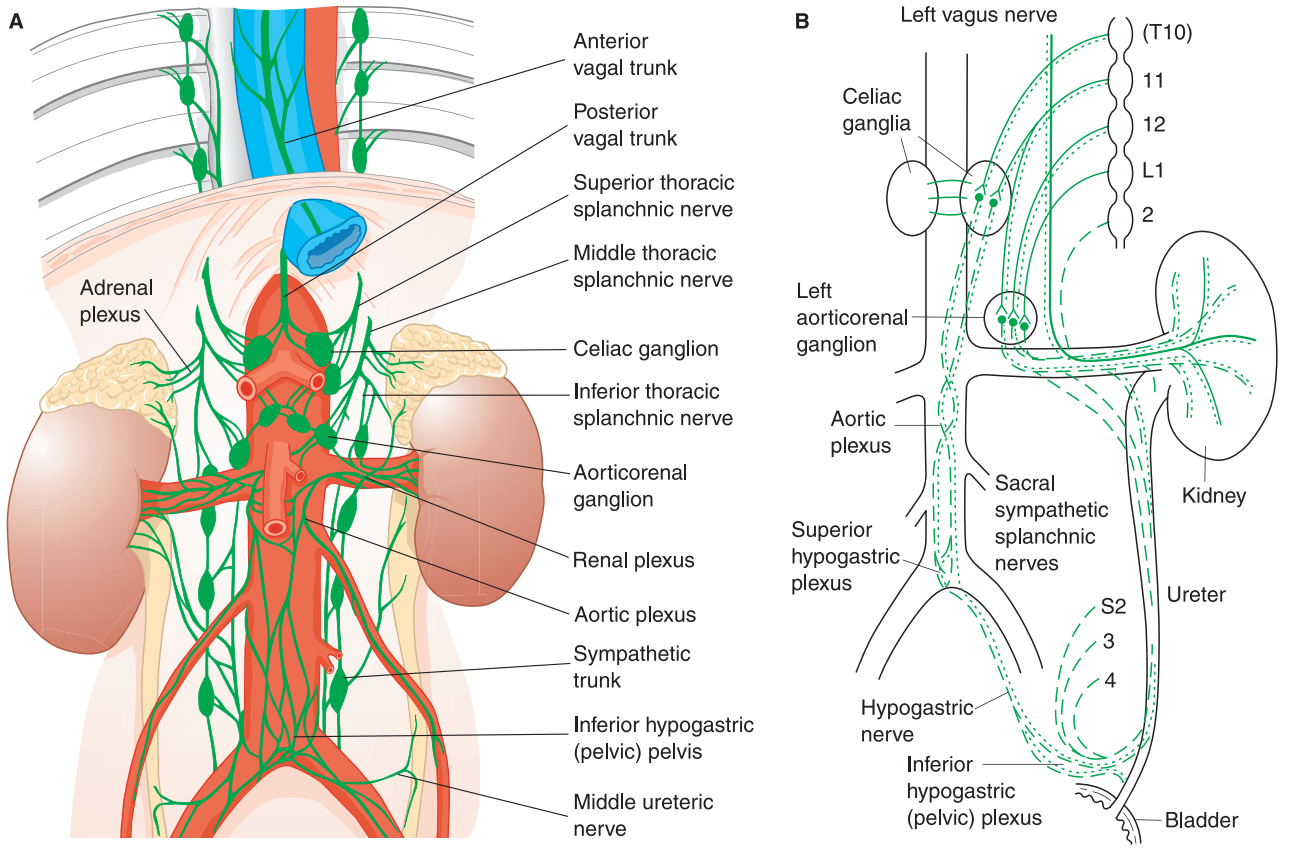

FIGURE 60–1. **A.** Gross anatomy of the kidneys. **B.** Autonomic and sensory nerve supply. (From Bonica JJ. Management of Pain. Philadelphia: Lea & Febiger, 1990, with permission.)

psoas muscle. They cross the course of the common iliac arteries and swing laterally in the lower pelvis, entering the base of the bladder. The ureteral blood supply derives from the renal arteries in their upper tract, from the spermatic or ovarian arteries in their midportion, and from hypogastric and vesical arteries in their terminal tract. Ureteral innervation originates from the renal, hypogastric, and pelvic plexuses. Sympathetic afferent fibers enter the spinal cord at T10 through L2 for the upper ureteral portion, whereas parasympathetic afferents reach the S2 through S4 levels. This distribution explains why pain from a ureteral stone is perceived in different locations depending on the position of the stone in the ureter.

Bladder

The bladder is a hollow organ with a capacity of 400 to 500 mL and a wall mainly composed of smooth muscle tissue. When empty, the bladder lies behind the pubic symphysis, anterior to the rectum in males or to the vagina in females. When the bladder is full, it rises significantly above the pubic bone and becomes palpable. The ureters enter the bladder posteriorly and emerge into the bladder cavity 2.5 cm apart, constituting the base of the vesical trigone. The dome of the bladder is covered by peritoneum, whereas the inferior portion lies on top of the prostate and seminal vesicles.

The blood supply of the bladder is provided mainly by the superior, middle, and inferior vesical arteries, arising from the hypogastric artery. The venous blood collects in a plexus located at the bladder neck, which drains into the hypogastric vein. This plexus is also joined by the prostatic venous plexus and by the deep dorsal vein of the penis, making this region prone to marked bleeding during surgical dissection. The lymphatics of the bladder drain in lymph nodes located near the iliac vessels.

The bladder receives its nerve supply from the hypogastric plexus (Fig. 60–2). Sympathetic fibers from lumbar splanchnic nerve fibers originate at T11 to T12. Parasympathetic innervation originates at S2 to S4 and is carried by the pudendal nerves. Afferent fibers follow both the sympathetic and parasympathetic pathways. Somatic afferents are carried by the pudendal nerves to the sacral spinal cord. Efferent sympathetic stimulation relaxes the bladder muscle fibers and causes contraction of the involuntary internal bladder sphincter. Parasympathetic stimulation contracts the bladder muscle fibers and relaxes the internal sphincter. Additionally, the external (striated) bladder sphincter is under voluntary control through the somatic fibers of the pudendal nerves originating at S2 to S3. Although bladder function is mainly under autonomic control, there is voluntary control through descending pathways originating in suprapontine centers. Therefore, micturition and urine storage can be altered not only by lesions at various levels of the spinal cord but also by cerebral lesions.

Prostate and Seminal Vesicles

The prostate gland has a strong fibromuscular component and normally weighs approximately 20 g. It is surrounded by a thick fibrous capsule and is located just beneath the bladder, behind the pubic symphysis, anterior to the rectum. The prostate contains

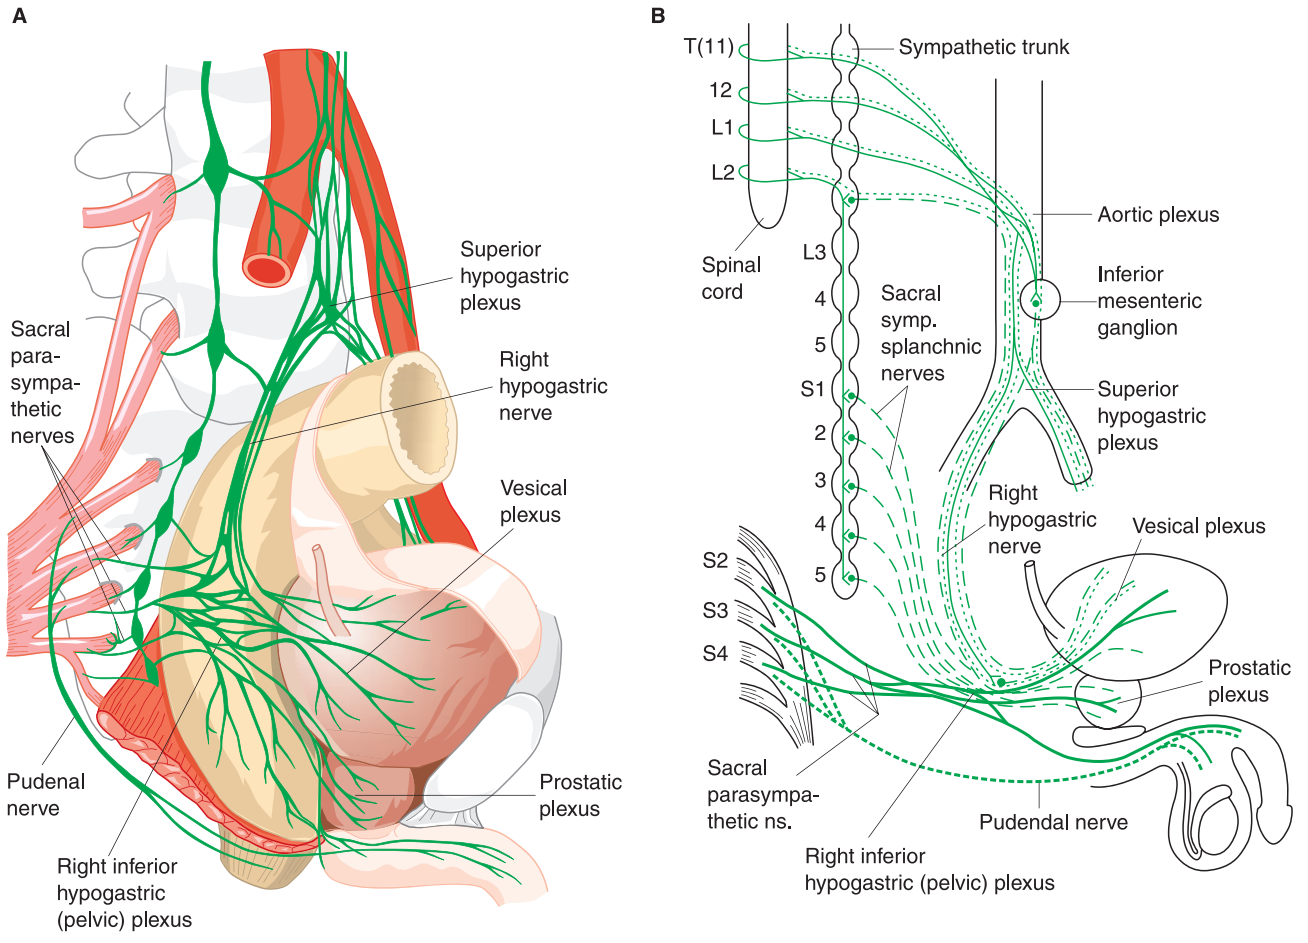

FIGURE 60–2. **A.** Gross anatomy of the bladder and the prostate. **B.** Autonomic and sensory nerve supply. (From Bonica JJ. Management of Pain. Philadelphia: Lea & Febiger, 1990, with permission.)

the prostatic portion of the urethra, which is approximately 2.5 cm long. The prostate can be seen as composed of five lobes (anterior, posterior, median, right lateral, left lateral). An alternative classification divides the prostate into a peripheral zone, a central zone, a transitional zone, an anterior segment, and a preprostatic sphincteric zone. The transitional zone is the closest to the urethra and is the zone where symptomatic prostatic adenomas usually are located.

Blood supply to the prostate derives from the inferior vesical arteries and drains into the prostatic venous plexus, which is in continuity with the vesical plexus and the dorsal vein of the penis. The prostate receives efferent sympathetic nerve supply from T11 through L2 through the hypogastric plexus and parasympathetic afferent fibers that run through the pelvic splanchnic nerves to reach S2 through S4 (Fig. 60–2).

The lymphatic circulation of the prostate drains into the hypogastric, sacral, and external iliac lymph nodes.

The seminal vesicles are located under the base of the bladder, immediately above the prostate, anterior to the rectum. They join the ipsilateral vas deferens, forming the ejaculatory duct, which then perforates the prostate to empty into the prostatic urethra. The blood, nerve, and lymphatic distribution are in common with the prostate.

Testes

The testicle is separated by connective tissue into approximately 250 lobules. It is covered by a dense fascia called the *tunica albuginea,* which is invaginated posteriorly and forms the mediastinum testis. The testicle is capped by the epididymis, composed of a convoluted tubule connected to the testis through the efferent ducts and, at its other end, continues in the vas deferens. The latter continues its ascent within the spermatic cord together with spermatic arteries and the venous pampiniform plexus. As a result of its embryogenesis near the kidneys, the blood and nerve supply of the kidneys and testicles are closely associated.

The arteries of the testicle originate from the aorta, below the renal arteries, and reach the testes after running near the ureters then through the spermatic cord. The venous blood ascends the spermatic cord through the pampiniform plexus, which forms the spermatic vein at the internal inguinal ring. The spermatic vein then drains into the vena cava on the right side and into the left renal vein on the left side. The testicular nerve supply originates at T10 and reaches the testis after joining the aortic plexus, located near the kidney. The anterior scrotum is supplied by the ilioinguinal nerve and by the genital branch of the genitofemoral nerve, with fibers originating from T12 through L2. The posterior face of the scrotum is supplied by fibers that originate at S1 through S4 and travel through branches of the perineal nerve and of the posterior femoral cutaneous nerve. Regional anesthesia for testicular surgery requires blockade up to the T10 level. The testicular lymphatic circulation drains into the lumbar nodes, which are con-

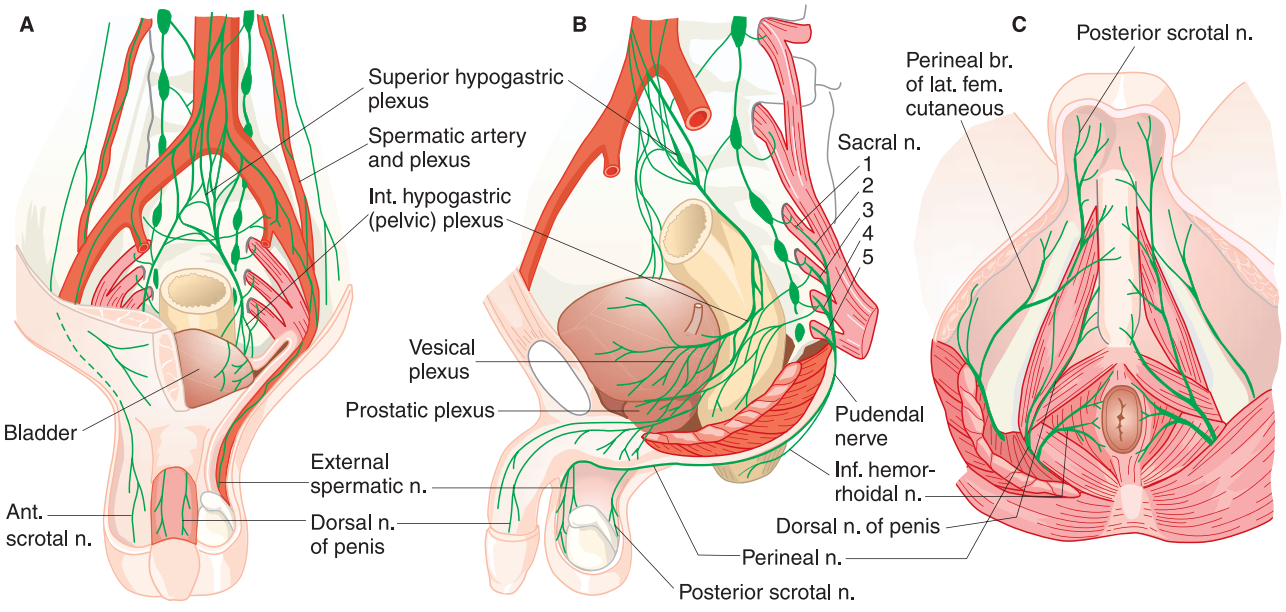

FIGURE 60–3. Gross anatomy and nerve supply of the male genitalia. **A.** Anterior view. **B.** Sagittal view. **C.** Transperineal view. (From Bonica JJ. Management of Pain. Philadelphia: Lea & Febiger, 1990, with permission.)

nected with the mediastinal nodes. The scrotal lymph circulation drains into the superficial inguinal and subinguinal nodes.

Urethra and External Genitalia

The penis is composed of the corpus spongiosum, which contains the urethra, and two corpora cavernosa. Each of these elements is contained in the tunica albuginea. They are distally capped by the glans and proximally attached to the pelvic bone. Arterial blood supply to the penis is delivered by the two deep internal pudendal arteries, which divide in the deep artery of the penis, the dorsal artery, and the bulbourethral artery. Venous blood runs through the superficial and deep dorsal vein of the penis, which reaches the internal pudendal vein through the pudendal plexus. The ilioinguinal nerve innervates the root of the penis, whereas the body and glans are supplied by the paired dorsal nerves of the penis, a continuation of the pudendal nerves (Fig. 60–3). Parasympathetic and sympathetic innervation originate from S2 through S4 and from L1 to L2, respectively. Erection is promoted by parasympathetic stimulation that causes arterial vasodilatation.

The female urethra is much shorter than that of the male and is located between the pubic symphysis and the vagina. Its arterial supply derives from the inferior vesical, vaginal and internal pudendal arteries, whereas venous blood drains into the internal pudendal veins.

PATIENT POSITIONING IN UROLOGIC SURGERY

Patient positioning often is complex during urologic surgery, and some of the positions adopted may result in important complications such as nerve injury and rhabdomyolysis. The anesthesiologist must have detailed knowledge of these positions and their consequences in order to avoid significant morbidity.

Lithotomy Position

The lithotomy position (Fig. 60–4) is used particularly for patients undergoing

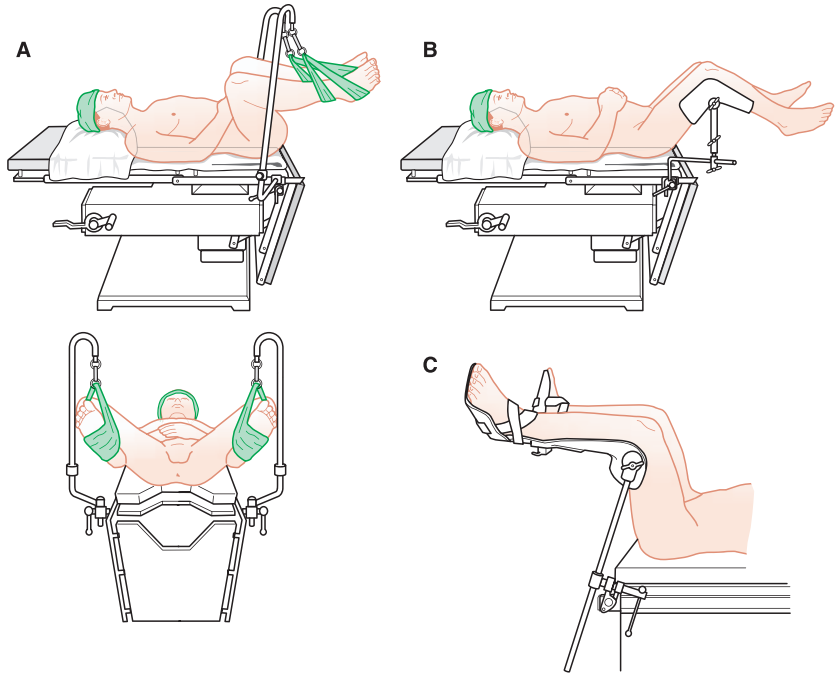

FIGURE 60–4. Lithotomy position. **A.** Strap stirrups. **B.** Bier-Hoff stirrups. **C.** Allen stirrups. (Modified and reprinted from Martin JT. Positioning in Anesthesia. Philadelphia: WB Saunders, 1988, with permission from Elsevier.)

transurethral procedures, for bulbar urethral reconstructions, and occasionally for transperineal prostatectomy. In the lithotomy position, the patient is supine and the lower extremities are flexed at the hips and knees. The leg rest of the operating table is lowered. In the standard position, the hips are flexed approximately 90° and the legs are parallel to the floor. In the low lithotomy position, the hips are flexed only 30–45°, and in the extreme position the legs are extended and the hips are flexed on the trunk with the goal of having the perineal floor almost parallel to the ground. A variety of leg and foot supports are used, including ankle straps, boot supports, and knee supports. The lithotomy position often is associated with a degree of head-down tilt to increase perineal exposure.

The lithotomy positions have physiologic consequences on both the respiratory and cardiovascular systems. The increased intraabdominal pressure and the cephalad shifting of abdominal contents decrease chest wall and lung compliance, functional residual capacity, and vital capacity. The head-down position enhances these effects. Hypoxemia due to atelectasis may be observed. Although it is often said that both the head-down position and leg elevation increase venous return, cardiac output, and left ventricular work, little evidence indicates that these positions affect cardiac output.[1] Increases in arterial blood pressure are more likely caused by increased systemic vascular resistance.

Lower extremity neuropathies have been reported after surgery in the lithotomy position. In a prospective study of 991 patients, Warner et al.[2] reported a 1.5% incidence of neuropathy. All neuropathies were sensory only and resolved within 6 months. Placement in the lithotomy position for more than 2 hours was a risk factor for neuropathy in this study. Additionally, the onset of symptoms was within 4 hours of the end of the surgery, suggesting intraoperative factors may have been important. In a retrospective analysis of 1170 patients, Gumus et al.[3] reported 12 (1.02%) cases of neuropathy, of which only two were reversible. Older age and operative time were risk factors. Compression of the superficial peroneal nerve[2] on leg support, strain of the obturator and lateral femoral cutaneous nerves, and stretching of the sciatic plexus probably contribute to the genesis of postoperative neuropathies in the lithotomy position. An American Society of Anesthesiologists (ASA) task force recommended that, during lithotomy, hip flexion >90° be avoided to limit sciatic and femoral neuropathy.[4]

Back pain is reported as a relatively common complication of the lithotomy position, probably caused by the loss of lumbar lordosis in susceptible patients. Finger injury from trapping in the operative bed is possible when the leg rest of the operating table is lowered. "Well leg" compartment syndrome with rhabdomyolysis is considered an unusual but severe complication of lithotomy position. In a survey of 261 urologists, 61 cases of compartment syndrome were reported, the majority following radical cystectomy and procedures lasting longer than 4 hours.[5] These results suggest that this complication may be more severe than initially thought. Prolonged surgery, extreme lithotomy, and compressive leg supports seem to predispose to the development of compartment syndrome. The genesis of this complication seems to be related to a decrease in arterial pressure in the lower extremity, which, combined with an increased pressure in the muscle compartments, results in muscle hypoperfusion, ischemia, and subsequent swelling. Arterial pressure is decreased by leg elevation, and the change can be dramatic in hypotensive patients. At the same time, the use of leg or calf supports increases muscle pressure significantly, as opposed to ankle supports, which do not increase muscle pressure.[6,7] When hypoperfusion is prolonged, compartment syndrome may occur. Awareness of this complication in the postoperative period should prompt careful observation of the patient's lower extremity for swelling, hypoperfusion, and paresthesias, because loss of peripheral pulse is a late sign of compartment syndrome. Acute renal failure may result if fasciotomies are not performed in a timely manner. Well-padded leg or ankle supports will help prevent this complication during prolonged surgery.

Head-Down Position

The head-down, Trendelenburg position is often used in urologic surgery to improve perineal exposure or facilitate lower abdominal laparoscopy. This position has physiologic consequences, particularly when a pronounced head-down posture is adopted. Cephalad shifting of abdominal viscera limits diaphragmatic excursion, reduces lung volumes, and predisposes to atelectasis. Blood pooling in the upper part of the body increases intracranial pressure and should be avoided in patients with intracranial space occupying lesions.[8] Although this position has long been used to treat hypovolemia, its hemodynamic consequences are far from clear. It has long been assumed that venous return and cardiac output increase in the head-down position. However, the amount of blood shift from the lower extremities to the central circulation seems to be minimal in this position.[9] Sibbald et al.[10] demonstrated no beneficial hemodynamic effects in a study of critically ill patients with hypotension. The head-down position may predispose patients to venous air embolism, a complication occasionally reported during urologic procedures.[11] With pronounced head-down positioning, shoulder braces are often used to prevent downward displacement of the patient. Use of these devices has been associated with brachial plexus injuries.[12] This complication may result from increased stretching of the brachial plexus by the brace, particularly when the shoulder is simultaneously abducted.[13] Based on these considerations, an ASA task force has discouraged use of these devices.[4] When a shoulder brace cannot be avoided, the arms should not be abducted and should be left resting at the sides of the patient to avoid brachial plexus stretching.

Lateral Position, Flexed Position, and Kidney Rest

In order to facilitate access to the kidney, a lateral position with flexion and kidney rest elevation is often used (Fig. 60–5). The patient is placed on the side with the dependent iliac crest on the break point of the table, where the kidney rest is located. The table top is angled approximately 30°, and the kidney rest is then elevated to raise the lower iliac crest and enhance exposure of the non dependent flank. An "axillary roll" is placed between the upper chest and the table to prevent brachial plexus compression. The dependent leg is flexed at the knee, while the other leg is left extended, to stabilize the patient on the table. Alternatively, a "bean bag" can be used.

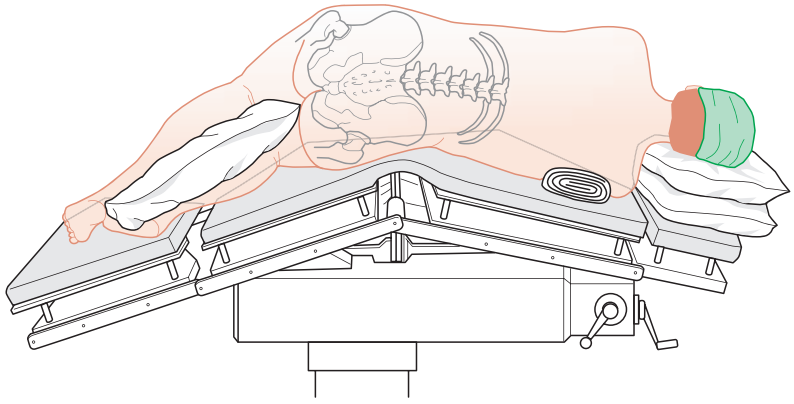

FIGURE 60–5. Kidney rest position commonly used for renal surgery. (Modified and reprinted from Martin JT. Positioning in Anesthesia. Philadelphia: WB Saunders, 1988, with permission from Elsevier.)

Similar to other types of lateral positioning, this position may have effects on respiratory physiology, with dependent atelectasis and maldistribution of the ventilation/perfusion ratio. Hemodynamic consequences of the kidney position include decreased systemic arterial pressure, cardiac output, and renal arterial pressures. These changes have been specifically ascribed to the kidney position because they have not been detected in nonflexed lateral positions. Although the exact mechanism of these hemodynamic effects is not clear, decreased blood flow in the vena cava due to its compression and stretching is likely. Additionally, the right heart is placed at a higher level than the lower extremities in this position, a position that could transiently reduce venous blood flow. When this position is used, one should be aware of its hemodynamic effects. Hypotension should be promptly treated with fluid and, if severe, with immediate decrease of flexion.

Compartment syndrome and rhabdomyolysis have been reported with the nephrectomy position, likely related to excessive compression of the gluteal compartment.[14]

Hyperextended Supine Position

This position is commonly used during retropubic prostatectomy to improve access to the pelvic organs (Fig. 60–6). The patient is supine with the iliac crests placed over the break of the operating table, which is then extended to increase the distance between the iliac crest and the ribs. The patient usually is placed in a head-down position, maintaining the operative field parallel to the floor. For thoracoabdominal incisions, the patient is placed in a semisupine position with the shoulder on the operative side raised by a roll to approximately 30°, and the ipsilateral arm placed on an armrest. The nonoperative leg is semiflexed, while the contralateral leg is kept extended.

When the patient is placed in hyperextended position, nerve and back injuries are possible but probably are relatively rare. Similar to any head-down position, the hyperextended position has the potential for venous air embolism, which should be considered in case of otherwise unexplained hemodynamic instability.[11]

ENDOUROLOGIC PROCEDURES

Cystoscopy and Transurethral Resection of Bladder Tumors

Cystoscopy and transurethral resection of bladder tumors are among the most common urologic procedures performed, particularly in the elderly population. These procedures are most commonly used to diagnose and resect bladder tumors in patients who have hematuria or voiding disturbances. Cystoscopy also is used to evaluate and treat other causes of urinary obstruction, to place ureteral stents, and to remove bladder and ureteral stones. Depending on the purpose of the procedure, the urologist may use either a rigid or a flexible cystoscope.

Complications

Bladder Perforation Perforation of the bladder is one of the most serious complications of cystoscopy. It occurs more often as an extraperitoneal tear and, in this case, manifests as poor return of irrigation fluid. Patients who are conscious may complain of nausea and lower abdominal pain. When an intraperitoneal rupture occurs, alert patients may have diffuse abdominal pain. In patients who are undergoing general anesthesia, bladder perforation may present only as hemodynamic instability. High irrigation pressures can predispose to perforation by overdistending the bladder. The onset of obturator reflex can also predispose to bladder perforation. Obturator nerve stimulation by the electrocautery may provoke adduction and extrarotation of the thigh, which may cause perforation of the bladder by the cystoscope. The most reliable ways to prevent the obturator reflex are either by delivering general anesthesia and muscle relaxation or by performing a nerve block of the obturator nerve.

Autonomic Hyperreflexia Autonomic hyperreflexia is a life-threatening hypertensive emergency that may occur in patients with spinal cord injuries above the sixth thoracic vertebra. Up to 85% of patients with this type of lesion have symptoms of autonomic hyperreflexia, and with significantly improved survival from spinal cord injury, an increasing number of patients with autonomic hyperreflexia present for procedures. This syndrome is particularly frequent in spinal cord injury patients who undergo urologic procedures, particularly cystoscopy, because bladder overdistension is the most common trigger. In addition to surgical procedures, rectal impaction, intercourse, and labor and delivery can trigger this syndrome. Afferent stimu-

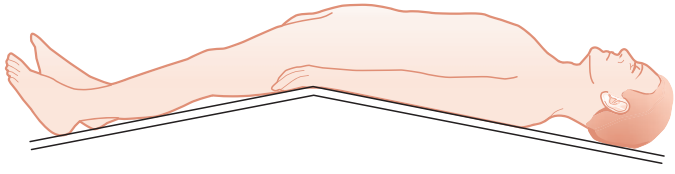

FIGURE 60–6. Hyperextended supine position commonly used for prostate and bladder surgery to facilitate pelvic exposure. (Modified and reprinted from Skinner DG, Lieskovsky G. Diagnosis and Management of Genitourinary Cancer, Philadelphia: WB Saunders, 1988, with permission from Elsevier.)

lation from the bladder and, less frequently, from the rectum and lower extremities ascends to the brain through the spinothalamic tract and dorsal columns. Interneurons project to sympathetic neurons between T5 and L2, causing reflex vasoconstriction, visceral contraction, and piloerection. Normally, these reflexes are inhibited by higher nervous centers and by control mechanisms originating in the carotid and aortic baroreceptors. However, in patients with a high spinal cord injury, inhibitory efferents cannot reach the thoracic sympathetic neurons, and the response to stimulation from the lower body cannot be modulated, resulting in uncontrolled vasoconstriction that can have catastrophic consequences if not corrected in a timely manner (Fig. 60–7). Hypertension can be dramatic, although an increase in blood pressure of only 50 mm Hg is required to diagnose autonomic hyperreflexia.[15] The clinical manifestations of autonomic hyperreflexia are headache, chest tightness, and piloerection ("gooseflesh") in the body below the level of the lesion. Above the lesion, flushing, sweating, mucous membrane congestion, and conjunctival erythema due to a parasympathetic response to the hypertension are visible. For the same reason, bradycardia usually is observed.

Other than early recognition, there is no definitive recommendation guiding the management of autonomic hyperreflexia. When possible, moving the patient to the sitting position may provoke an orthostatic decrease in blood pressure. Antihypertensive drugs with rapid onset and short duration of action should be chosen. Calcium channel blockers such as nifedipine and nicardipine, hydralazine, nitroglycerine, α- and β-blockers, and sodium nitroprusside usually achieve rapid blood pressure control.[15] Magnesium infusion also has been reported effective in controlling hypertension in autonomic hyperreflexia.[16]

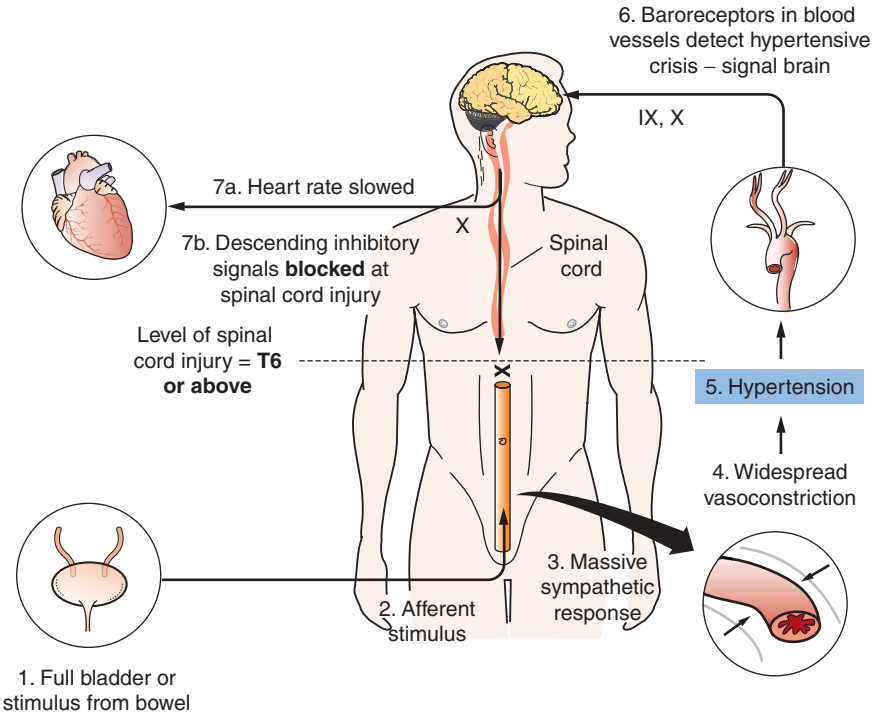

FIGURE 60–7. Mechanisms of autonomic hyperreflexia. In patients with spinal cord injury above T6, stimulation from the lower body triggers a sympathetic response that cannot be controlled by descending inhibitory efferents. Hypertension is accompanied by bradycardia caused by vagal response. (Blackmer J. Rehabilitation medicine: 1. Autonomic dysreflexia. CMAJ 2003;169:931–935, by permission of the publisher. © 2003 CMA Media Inc.)

Anesthetic Management

The choice of anesthetic technique for cystoscopy depends on patient sex, age, medical condition, and type of procedure performed. Female patients are more likely to tolerate topical anesthesia for diagnostic studies. Males more often require regional or general anesthesia, particularly for operative procedures. Subarachnoid (spinal) anesthesia is popular for endourologic procedures. The patient population is older and has multiple comorbidities. A common perception is that regional anesthesia affords better hemodynamic stability and potentially avoids cardiovascular complications compared with general anesthesia. However, no outcome studies have shown a significant difference in morbidity or mortality between regional and general anesthesia for cystoscopy. Indications for regional versus general anesthesia are clear for only a few circumstances. General anesthesia may be required for resections performed in the area of the obturator nerve. Patients who are prone to autonomic hyperreflexia may benefit from a neuraxial anesthetic, which can block the transmission of afferent impulses and prevent triggering of uncontrolled reflex vasoconstriction. However, performing a neuraxial block can be difficult in patients who have spinal deformities.

Most endourologic procedures are of short duration and are performed in an outpatient setting. The choice of anesthetic technique should be directed at allowing rapid onset and emergence and early discharge from the recovery room. Even though most urologic patients are elderly, these goals can be achieved when appropriate anesthetic decisions are made. Whether the choice between regional and general anesthesia has an effect on the time of recovery and discharge is not clear. With general anesthesia, avoidance of muscle relaxation and relatively rapid induction can be accomplished with a laryngeal mask airway. The choice of inhaled anesthetic agent may have a role in achieving rapid recovery times. In a randomized controlled study of elderly patients undergoing short urologic procedures, significantly more patients reached criteria for postanesthesia care unit bypass when desflurane was used as a maintenance agent compared with isoflurane.[17] When spinal anesthesia is chosen, the anesthetic agent should allow rapid resolution of motor block with early ambulation and discharge. Lidocaine has been the drug of choice for these procedures for many years. The recent demonstration of an association of lidocaine with postoperative neurologic symptoms has decreased the appeal of this drug. Transient neurologic symptoms (TNS) is a spectrum of symptoms, characterized by pain and dysesthesia in the lower extremity after spinal anesthesia, that usually resolves within 72 hours. Although this complication is

transient and is not associated with abnormal nerve function by electromyography,[18] it causes significant patient discomfort and some functional impairment in a small percentage of patients.[19] TNS initially was observed after spinal anesthesia using 5% lidocaine, but the incidence of this complication is similar when either 5% or 1% lidocaine is used.[19] Alternative drugs and doses to achieve rapid resolution of spinal anesthesia for urologic surgery without using lidocaine have been investigated. Kuusniemi et al.[20] randomized 80 patients undergoing various urologic procedures to receive bupivacaine at different doses with or without the addition of intrathecal fentanyl. In this study, 5 mg bupivacaine with fentanyl 25 mg achieved a comparable block level (higher than T7) and similar anesthetic quality with shorter lasting motor block compared to 10 mg plain bupivacaine.[20]

Transurethral Resection of the Prostate

Preoperative Considerations

Benign prostatic hyperplasia (BPH) is the most common benign tumor in males. Its prevalence is age related and reaches 90% in men older than 80 years.[21] BPH develops in the transition zone, the part of the prostate closest to the urethra, and is histologically characterized by increased cellularity in a nodular pattern.[21] Not all patients with an enlarged prostate are symptomatic. The extent of symptoms is affected by the size of the gland, the extent of intrusion into the urethra, and the effect of α-adrenergic tone. The presence of symptomatic BPH significantly affects quality of life and, if left untreated, predisposes to frequent urinary tract infections, development of bladder diverticula, and hydronephrosis and may cause nonreversible renal damage.

Patients with mild symptoms can be managed with watchful waiting because some patients improve spontaneously.[21] Pharmacologic treatment with selective and nonselective α-blockers and with 5-α-reductase blockers is effective in patients with more significant symptoms. Both classes of drugs are more effective than placebo in improving lower urinary tract symptoms and, when used in combination, slowed the progression of disease and reduced the need for surgery.[22] Surgical treatment is chosen in patients who do not respond to medical therapy. Open prostatectomy has the highest success rate in increasing urinary flow, but it also has the highest rate of complications and is performed in only 5% of cases.[21] Transurethral resection of the prostate (TURP) currently is considered the gold standard for prostate resection, reducing symptoms in 88% of cases. However, it has a small but significant risk of morbidity and mortality, including 5–10% risk of sexual dysfunction. Minimally invasive therapies for BPH have been recently introduced. These approaches include transurethral needle ablation (TUNA), transurethral microwave therapy, and interstitial laser therapy.[23] All these techniques use high energy to heat the prostate and cause tissue necrosis. Minimally invasive therapies are advantageous for older men for whom TURP has a considerable perioperative risk and for young patients who are sexually active. Minimally invasive therapy improves symptoms and quality of life without requiring general or neuraxial anesthesia or hospitalization. However, these techniques have a higher rate of recurrence of obstruction and of reoperation, compared with TURP. For these reasons, minimally invasive BPH treatment cannot yet be considered a replacement for TURP.

Complications

Mortality from TURP is estimated between 0.1% and 0.2%, with a reported morbidity of 9.5%. Postoperative morbidity is related to patient age, operative time, and amount of tissue resected.[24] Patients undergoing TURP usually are of advanced age and have multiple risk factors for cardiovascular, respiratory, and renal morbidity.

TURP Syndrome TURP is performed by resecting prostatic tissue using a cautery loop introduced through a special cystoscope. Bladder distension with irrigation fluid is required. During the resection, venous sinuses are opened, and the irrigation fluid can be absorbed into the systemic circulation. As a result, a complication known as *TURP syndrome* may develop. TURP syndrome is potentially fatal. It has multiple manifestations, characterized by fluid overload, hypoosmolality, hyponatremia, and neurologic disturbances. The reported rate of TURP syndrome is between 2% and 10%.[25] Asymptomatic hyponatremia has been observed in 50% of patients undergoing TURP.[26]

Onset of TURP syndrome may occur as early as 15 minutes after the beginning of the procedure, but later onset has been observed. The syndrome may be due to fluid absorption through the peritoneal and retroperitoneal space. Delayed-onset TURP syndrome due to bladder rupture and transperitoneal fluid absorption has been reported after cystoscopy.[27]

Clinical signs of fluid overload include hypertension and reflex bradycardia. Patients with poor cardiac reserve are more likely to present with heart failure and pulmonary edema. In patients under general anesthesia, signs of fluid overload may be the only hint of the occurrence of TURP syndrome. Neurologic manifestations are common during TURP syndrome and in patients under regional anesthesia may be the first signs and allow early diagnosis. Otherwise, they may be observed at emergence (Table 60–1).

The manifestations of TURP syndrome depend on the type and amount of fluid absorbed. Fluid absorption is difficult to control but seems to be related to the duration of the procedure, number of vascular spaces opened, hydrostatic pressure in the bladder,[28] and elevation of the irrigation fluid container above the patient level. Regional anesthesia may increase the absorption of irrigation fluid compared to general anesthesia with mechanical ventilation because of lower bladder pressures when spontaneous breathing is maintained.[29] The irrigation fluid is chosen based on its electrical conductivity. Electrolyte solutions disperse cautery current and cannot be used for TURP, although they would be better tolerated in case

TABLE 60–1.

Signs of Transurethral Resection of the Prostate Syndrome

Coma	Desaturation
Seizures	Delayed emergence

of systemic absorption. Distilled water was commonly used in the past and was associated with the highest morbidity. Absorption of significant amounts of distilled water leads to intravascular hemolysis and pronounced hypoosmolality, causing acute renal failure and cerebral edema. The cerebral edema is severe because intracellular compensation mechanisms do not have time to act. Nausea, restlessness, confusion, coma, seizures, and hemispheric herniation may occur.

Since the adoption of alternative irrigation fluids, the incidence of TURP syndrome has decreased by 50%.[30] Solutions with near-physiologic osmolality, such as 1.5% glycine and 2.7% sorbitol with 0.54% mannitol are now routinely used. Plain sorbitol, mannitol, dextrose, and urea solutions also can be used. The osmolality of these solutions ranges from 195 mOsm/L to isotonic. Because some of these fluids are relatively hypotonic, plasma hypoosmolality still may occur when irrigation fluid is absorbed in large amounts. Neurologic manifestations still may occur, even when serum osmolality is not significantly affected. It is commonly thought that hyponatremia is the main cause of the neurologic manifestations of TURP syndrome. However, low sodium levels do not cause cerebral edema if serum osmolality is maintained. Additionally, nerve conduction and transmembrane potentials are little altered, even in the presence of significant hyponatremia.[31] Direct toxic actions of some of the solutes used in irrigation fluids have been implicated. Glycine is the likely causative agent of postoperative blindness and seizures observed in some TURP patients. Variable but extremely elevated glycine blood levels have been observed in patients with neurologic symptoms of TURP syndrome. Glycine is an inhibitory neurotransmitter in the cortex and retina. In patients who have visual impairment after TURP, the pupillary reflexes often are sluggish or absent, unlike cortical blindness where reflexes are maintained. This finding suggests that the mechanism of blindness in these patients is direct inhibition of retinal potential transmission. Blindness resolves with decreasing blood levels of glycine.

Glycine metabolism in the liver produces ammonia. Hyperammonemia has been observed after TURP with glycine solutions and can be prevented by intravenous administration of L-arginine. However, whether hyperammonemia has a significant role in the genesis of TURP syndrome is not clear.

Absorption of sorbitol can result in the development of hyperglycemia and lactic acidosis related to sorbitol metabolism.[32] Metabolic acidosis has been reported in patients who absorbed a significant amount of irrigation fluid during TURP. This effect was related to a decrease in the strong ion difference, as a result of relative dilution of sodium chloride, and plasma protein.[33] Although acidemia was modest in this study, a more significant disturbance may develop following absorption of higher volumes of fluid.

Management of TURP syndrome should rely on a high level of suspicion, especially when the patient is unconscious (Table 60–2). No monitors of irrigation fluid absorption are clinically available. Adding ethanol to the fluid and measuring its expired concentration enables detection and quantification of irrigation fluid absorption,[34] but this tool has not found wide use outside of clinical research. Hemodynamic changes that cannot be otherwise explained may be the only available clues. Once TURP syndrome is suspected, the procedure should be stopped. Serum sodium and potassium levels and measured osmolality should be obtained. The latter value is essential to distinguish between true hypoosmolality and hyponatremia in the presence of circulating solutes such as glycine. Hemoglobin measurement should be obtained because it is an index of the extent of fluid absorption. Although rare, hemoglobinuria can occur even with glycine irrigant absorption and should be ruled out by urinalysis.

Hyponatremia need not be treated aggressively when it is not accompanied by hypoosmolality or when it occurs in the absence of neurologic symptoms. If hyponatremia must be treated, rapid correction should be avoided because it can cause pontine myelinolysis. Hypertonic saline should be used only in the presence of life-threatening manifestations such as coma and seizures. Otherwise, sodium levels can be increased by administration of normal saline in combination with a loop diuretic or mannitol. Sodium correction should never exceed a rate of 1–1.5 mEq/L/h. A diuretic also is used to treat fluid overload. Patients who had bladder perforation may have signs of hypovolemia due to transperitoneal loss of sodium and may require volume resuscitation.[27]

Myocardial Ischemia A relatively high frequency of myocardial ischemic events has been observed in TURP patients. Wong et al.[35] reported an 18% rate of ST-segment changes during the immediate postoperative period in patients undergoing TURP. Edwards et al.[36] observed a 26% rate of ischemic electrocardiographic (ECG) changes in patients undergoing TURP. The clinical relevance of these studies is unclear, and whether these ECG changes are associated with worsened clinical outcomes is not certain. The rate of ischemic events was greater in patients with increased risk factors for myocardial ischemia, suggesting that the high rate of comorbidities and the advanced age of the patient population contrib-

TABLE 60–2.

Management of Transurethral Resection of the Prostate Syndrome

- Inform surgeon
- Stop procedure
- Obtain electrolytes, arterial blood gases, hemoglobin, measured serum osmolality
- Support breathing and circulation
- Treat fluid overload
- If symptomatic hypoosmolality:
  - Start 0.9% normal saline infusion
  - Administer furosemide and/or mannitol
- In patients with convulsions or coma:
- Give hypertonic saline
- Consider ventilatory support if severe pulmonary edema
- Consider invasive hemodynamic monitoring if severe heart failure
- Monitor electrolytes q1h
- Limit sodium correction to < 1.5 mEq/L/h
- Maintain negative fluid balance in patients with fluid overload
- Consider hemodialysis/ultrafiltration in symptomatic patients with poor urine output

ute to the higher rate of myocardial ischemia during and after TURP.

Other Complications The risk of bleeding is related to prostate size and duration of resection. Estimation of intraoperative blood loss has been reported between 3 and 5 mL/min.[37] Blood for possible transfusion should be promptly available for patients with a very enlarged prostate. The amount of bleeding probably is not affected by the type of anesthesia.[38] Coagulopathies have been observed in 6% of patients undergoing TURP.[39] Disseminated intravascular coagulation arises occasionally, probably as a result of thromboplastin release by prostatic tissue.[37] Bladder perforation during TURP is possible, and its clinical aspects have been discussed in the section on Cystoscopy and Transurethral Resection of Bladder Tumors.

Anesthetic Management

Neuraxial anesthesia probably is the anesthetic technique most commonly used for TURP and is preferred over general anesthesia. However, a paucity of data supports a specific anesthetic choice. Given the low mortality of this procedure, it is highly unlikely that an effect of anesthesia on outcome can be demonstrated. No association between anesthetic technique and morbidity of TURP has been reported. Although patients undergoing TURP have an increased risk of myocardial ischemia by ECG changes, the choice of regional versus general anesthesia did not affect the rate of this complication in a randomized study by Edwards et al.[36] Choosing a particular anesthetic technique may have an effect on outcomes such as patient satisfaction, postoperative pain and comfort, and discharge times. However, no data suggest that anesthetic choices affect these variables. In a matched cohort study of 267 patients undergoing TURP, the choice of general or regional anesthesia had no effect on the length of recovery room stay or on patient satisfaction with analgesia.[40] Therefore, TURP likely can be safely performed under either general or regional anesthesia. However, several theoretical advantages to regional anesthesia make it appealing for use with this procedure. Onset of the TURP syndrome can be recognized from its neurologic symptoms, and bladder perforation can present with abdominal or shoulder pain if the patient is allowed to remain awake. Earlier recognition of these complications may allow interruption of the procedure and early treatment, which theoretically may translate into better outcome. Regional anesthesia may be associated with less blood loss than general anesthesia.[41] This effect has been attributed to the lower venous pressure during spontaneous breathing than during mechanical ventilation. However, a similar reduction of venous pressure can be obtained during general anesthesia if spontaneous breathing is allowed.

There is speculation that anesthesia depresses the immune system and predisposes to nosocomial infection and, in oncologic patients, to cancer recurrences. In patients undergoing TURP, a randomized controlled trial showed that spinal anesthesia and general anesthesia had opposite effects on T-helper lymphocyte populations, an effect that may suggest less immunosuppression with spinal anesthesia.[42] The clinical significance of these results is unclear.

Regional anesthesia may help reduce the incidence of deep vein thrombosis (DVT) after prostatectomy, but there is no evidence of this effect following TURP.

When general anesthesia is chosen, avoidance of muscle relaxation and relatively fast times of induction can be accomplished with a laryngeal mask airway. Although patients undergoing TURP usually are older and have significant comorbidities, a significant portion of these patients may have relatively short recovery times after general anesthesia, particularly if short-acting anesthetic agents are used.[17]

When a regional anesthetic technique is chosen, subarachnoid anesthesia usually is preferred to epidural for TURP because it allows better relaxation of the pelvic floor and reliable anesthesia of the sacral roots. Blocks higher than T9 are generally avoided because they do not allow the perception of pain due to rupture of the prostatic capsule, whereas a T10 level of sensory loss is required to avoid the sensation resulting from bladder distension from the irrigation fluid. Bladder sensation is conducted by sympathetic afferent fibers of the hypogastric plexus, which originate from T11 through L2. Lower-level blocks are possible as long as bladder pressure is monitored and maintained at a low level. Beers et al.[43] showed that a level higher than L1, obtained with intrathecal hyperbaric bupivacaine 7.5 mg, is acceptable as long as bladder pressure is monitored and maintained below 15 mm Hg. This level of block had the advantage of less decrease in blood pressure and may be considered in patients with significant hemodynamic compromise. Monitoring bladder pressure is cumbersome and may not be convenient. An alternative approach to a low block is intrathecal administration of a small dose of local anesthetic together with a narcotic. In a randomized study of 45 patients undergoing TURP, administration of 4 mg intrathecal tetracaine with 10 mg fentanyl achieved a block level comparable to that of 8 mg plain tetracaine, but more hypotensive episodes occurred in the patients who received 8 mg tetracaine.[44] The combination of 5 mg bupivacaine with fentanyl 25 mg achieved a sensory block higher than T7 in 50% of patients anesthetized with this dose.[20] Adequate anesthesia for TURP also has been obtained with only 4 mg bupivacaine and 25 mg fentanyl.[45]

Prolonged postoperative analgesia may be beneficial after TURP as patients often complain of pain from detrusor muscle spasm. Intrathecal morphine along with a local anesthetic effectively provided postoperative pain in a trial on patients undergoing TURP.[46] In this study, 0.1 mg intrathecal morphine was as effective as 0.2 mg but had a lower incidence of nausea and vomiting. Compared to other types of surgical procedures, relatively small doses of intrathecal morphine seem to be effective during TURP. In a randomized controlled trial, 0.05 and 0.1 mg intrathecal morphine had similar effect in controlling post-TURP pain, but the incidence and intensity of pruritus were lower with the lower dose.[47] Alternative agents have been used in an attempt to avoid the side effects of intrathecal morphine, such as respiratory depression. Tramadol provides postoperative analgesia when administered epidurally.[48] However, compared to plain bupivacaine intrathecal tramadol with bupivacaine did not provide additional pain relief after TURP.[49]

Extracorporeal Shock Wave Lithotripsy

Nephrolithiasis ranks third in frequency among the conditions affecting the

urinary tract, following infections and prosthatic diseases.[21] The presence of urinary stones causes pain, urinary obstruction, hematuria, and infection. Although the mechanisms of formation are incompletely understood, the management of urinary stones has progressed greatly in the last 20 years. Surgical stone extraction has become an uncommon procedure, particularly since the introduction of extracorporeal shock wave lithotripsy (ESWL).

Preoperative Considerations and Technical Aspects

ESWL uses acoustic shock waves to fragment stones. These waves are unharmonic and generate high-amplitude pressure oscillations that transfer impressive amounts of energy when the density of the medium changes significantly, such as at the interface between tissue and stones or between tissue and air. Stones are fragmented through erosion by cavitational forces at the entry and exit sites of the waves, and through shattering by energy absorption within the body of the stone. Application of this physical principle was developed by the German aeronautic company Dornier while studying supersonic aircraft. The Dornier HM3 lithotripter was the first commercially available machine.

Two types of shock wave generators are used clinically. Supersonic generators release high energy in a small space using a spark gap electrode, creating a small underwater explosion. The shock waves are then focused on the target stone using an ellipsoid reflector. Finite-amplitude generators create an acoustic wave by displacing a surface. This can be accomplished using piezoceramic emitters, where thousands of ceramic components placed on a spheric surface are elongated by an electric discharge, or by using electromagnetic systems, where an electric impulse displaces a metal membrane, similarly to loudspeaker woofers. An acoustic lens then focuses the waves on the target stone.

A key element of all lithotripters is the coupling that allows shock waves to progress from the site of formation to the surface of the patient's body. In waterbath models, the patient sits on a chair and is immersed in a tub full of heated water. Newer models transmit waves through a water cushion placed against the patient's skin, often with the interposition of a layer of coupling gel. Inadequate coupling, particularly when air is entrapped between the skin and the coupling membrane, may result not only in insufficient wave transmission but also in skin ecchymosis and breakdown.

Stone localization and aiming of the shock waves can be accomplished by fluoroscopic imaging or by ultrasound. Successful stone fragmentation depends on stone size, location, and composition. Calcium oxalate dihydrate stones are generally easier to fragment than cystine and calcium oxalate monohydrate stones.[21] Larger stones may require percutaneous access or placement of ureteral stents prior to the procedure.

Complications

Cardiac Arrhythmias Shock waves have the potential to trigger ventricular arrhythmias when they coincide with the repolarization period of the cardiac cycle. For this reason, ECG synchronization and shock delivery 20 ms after the R wave have been used. The onset of significant arrhythmias probably is rare, and many lithotripter models do not synchronize with ECG. Supraventricular arrhythmias may occur even with ECG synchronization.[50] Some machines synchronize with the respiratory cycle, to avoid loss of aim with respiratory movement of the kidney.

Shock waves occasionally inhibit or reprogram cardiac pacemakers. To avoid this complication, the patient should be positioned so that the pacemaker is not in the path of the wave. Resuscitation equipment, including an external pacemaker, should be available.[51]

Hemodynamic and Respiratory Effects Immersion in a waterbath can have hemodynamic effects, particularly in patients with heart failure or coronary artery disease. Increased hydrostatic pressure on the lower extremities and the abdomen may shift blood to the intrathoracic vessels, precipitating congestive heart failure in susceptible individuals. Systemic vascular resistance may increase during immersion, which could increase left ventricular work and precipitate ischemia.[52] Immersion in water increases intraabdominal pressure with consequent upward shifting of the diaphragm, increased work of breathing, and decreased tidal volume and arterial oxygenation.

Renal Injury Gross hematuria, which is the routine after ESWL, usually resolves within 1 week. Severe abdominal pain should alert for the rare presence of perinephric hematoma. Management is generally conservative but may require laparotomy in case of hypotension. A bleeding diathesis is a relative contraindication to ESWL, and coagulation times usually are checked routinely prior to the procedure.

Other Complications Patients with a high stone burden are prone to obstruction by fragments after ESWL. "Steinstrasse," the columnation of fragments along the ureter, may require nephrostomy drainage or endoscopic stone extraction to relieve obstruction. Fever and sepsis are possible after ESWL and are more common in patients with an infected urinary tract prior to the procedure. Pneumothorax may occur if the wave path crosses the lung and is more likely in children.

Anesthetic Management

ESWL causes pain at the skin, where the waves enter the body, and at the visceral level, where the waves dissipate. Subjective pain reported by unanesthetized patients during ESWL is higher than during endoscopic urologic procedures.[53] The Dornier HM3 machine generates high-intensity waves and requires deeper levels of analgesia and anesthesia than required by newer models that generate lower-intensity waves and are tolerable with minimal or no analgesia. These newer machines are ideal for the ambulatory setting, although stone fragmentation may be less effective and requires longer procedure times. The goals for anesthesia are not only to provide patient comfort during and after the procedure but also to achieve rapid recovery times, as ESWL is performed as an outpatient procedure in the majority of cases. Additionally, postoperative pain usually is mild and, for these reasons, short-acting anesthetic and analgesic techniques usually are preferred.

Even after many years, the best anesthetic approach for ESWL is still a topic of debate. General anesthesia with muscle relaxation offers the advantage of optimizing stone targeting by avoiding patient movement and controlling respiration, but it is thought to prolong recovery times. Additionally, positioning of anesthetized and intubated patients in the waterbath can be complex

and presents some safety risks. For these reasons, epidural and spinal anesthesia have been widely used for ESWL. However, these techniques have longer induction times and may not accelerate recovery. Timing of recovery likely is more affected by pharmacologic choices than by the type of anesthesia delivered. A randomized comparison between epidural anesthesia with lidocaine and general anesthesia showed markedly longer recovery times in the group that received epidural anesthesia.[54] The results of this study may be explained by the fact that general anesthesia included the administration of propofol and nitrous oxide (N_2O) and the use of a laryngeal mask airway, but no narcotics were given. Intrathecal lidocaine has been widely used for short procedures such as ESWL because of its rapidity of onset and of recovery. However, safety concerns have made the use of this technique less appealing. A possible alternative approach to the use of intrathecal local anesthetics is the injection of plain narcotics. In a randomized controlled study, intrathecal sufentanil was as effective as lidocaine in controlling pain during ESWL performed with the Dornier HM3 machine.[55] In this study, recovery times were strikingly shorter in the group of patients who received sufentanil compared to the group that received lidocaine. In a subsequent study, intrathecal sufentanil doses of 15–17.5 μg provided the best effectiveness/safety profile.[56] Intravenous analgesia and sedation with short-acting agents is widely used and presents several advantages in the ambulatory setting, particularly rapid recovery time. Deeper levels of sedation are required if high-intensity shock waves are used, and, consequently, side effects such as respiratory depression are more likely. Compared with desflurane general anesthesia through a cuffed oropharyngeal airway, sedation with propofol and remifentanil infusion was associated with more episodes of desaturation and greater narcotic requirement during ESWL performed with the Dornier HM3.[57] The time to discharge was no different in patients who received general anesthesia compared to those who received sedation. The success of a sedation regimen depends on the type of medication used. Use of propofol together with a short-acting narcotic is common. Remifentanil infusion is gaining popularity because of the drug's rapid clearance with faster recovery times than with fentanyl and its other derivatives.[58] Remifentanil and sufentanil also have been used for single-agent sedation. The two drugs have similar analgesic properties, but remifentanil had lower incidences of respiratory depression and nausea than did sufentanil in a randomized controlled study.[59] Remifentanil infusion at 0.05 μg/kg/min with patient-controlled supplementation of 10-μg boluses has been effective in controlling pain during ESWL with a Dornier Lithotripter S machine.[60] No difference between infusion of remifentanyl alone and continuous infusion of propofol combined with intermittent fentanyl boluses has been reported.[61] In fact, patients who received remifentanil had a higher incidence of nausea and prolonged times to discharge. These results might be due to the relatively high rate of remifentanil infusion (0.2–0.4 μg/kg/min).

An alternative sedative technique for ESWL is patient-controlled sedation. Drugs with rapid onset and fast elimination allow the patient to titrate the level of sedation in the face of rapidly varying levels of discomfort. Patient-controlled sedation with remifentanil alone or with remifentanil and propofol were compared.[62] Both techniques had high effectiveness and comfort level; however, fentanyl with propofol had a higher incidence of respiratory depression. Remifentanil alone also had a higher incidence of nausea and vomiting, an effect that seems to be common with use of this drug and is effectively prevented by serotonin ($5\text{-}HT_3$) antagonists.[63] Alternative anesthetic techniques, such as use of eutectic mixture of local anesthetics (EMLA) cream, skin infiltration with local anesthetics, and paravertebral blocks, have been proposed but are of dubious efficacy. In summary, no evidence supports any specific anesthetic choice for use with ESWL. The selection should be based on patient characteristics, machine type, and local preferences. Intravenous sedation provides adequate comfort in most patients, particularly if low-intensity waves are used. If neuraxial anesthesia is chosen, a technique that affords rapid resolution is preferred. Use of plain intrathecal narcotics is promising. Inhalation anesthesia via a laryngeal mask airway but without neuromuscular relaxants also provides good operating conditions and rapid recovery in a predictable manner.

CANCER SURGERY

Surgery for Prostate Cancer

Preoperative Considerations

Epidemiology Radical prostatectomy is one of the most common major surgical procedures in the United States, with approximately 60,000 performed yearly. Prostate cancer is the most common cancer and is the second leading oncologic cause of death in men. The incidence increases progressively with age, has no definite peak age, and reaches 17% in men between 60 and 79 years old.[64] Probably as a result of prostatic-specific antigen screening and rectal examination, the mortality from prostate cancer has decreased during the last few years.[65] The histologic diagnosis is adenocarcinoma in 95% of cases, with most of the remaining cases being transitional cell carcinomas. The most popular grading system used for prostate carcinoma is the Gleason score, which assigns a grade to the appearance of the glandular architecture based on its level of differentiation.[21]

Therapeutic Choices Prostate cancer has a broad spectrum of activity that ranges from indolent to highly virulent. For this reason, management decisions often are difficult. The best management, particularly for patients with early localized disease, is unclear. Older patients tend to have well-differentiated cancers with a slow progression. At the same time they have significant comorbidities and increased surgical risk. Therefore, watchful waiting often is offered to this patient population. In a randomized trial, radical prostatectomy was compared to watchful waiting in a group of 695 patients with early prostate cancer.[66] During a 10-year followup, prostatectomy resulted in a 26% decrease in mortality and a 40% decrease in the rate of distant metastases compared to watchful waiting. However, the beneficial effects of surgery on mortality were limited to patients younger than 65 years. These results suggest that radical prostatectomy probably is the best option in this group of patients. Radical prostatectomy often is preceded by dissection of pelvic lymph nodes to stage the dis-

ease accurately. Patients with positive nodes are very likely to have distant metastases. These patients and patients with locally advanced disease are candidates for nonsurgical treatments such as endocrine therapy, radiation therapy, and chemotherapy. In patients with localized disease in whom prostatectomy is not desirable or is contraindicated, alternative forms of radiation therapy, such as brachytherapy, are becoming popular. This technique involves implanting radioactive needles or "seeds" into the prostate, guided by transrectal ultrasound.

Of the different approaches to prostatectomy, radical retropubic prostatectomy (RRP) currently is the most common. The prostate is approached through a low, midline abdominal incision. The whole prostate is removed together with the seminal vesicles, the ejaculatory ducts, and a section of the bladder neck. The bladder neck is then anastomosed to the urethra. At this stage, indigo carmine often is injected to identify the ureters. Injection of this drug can cause hypertension.[67] Among the long-term complications of RRP, the most frequently occurring probably is sexual dysfunction. A "nerve-sparing" prostatectomy is performed by approaching the prostate gland from the bladder side while preserving the neurovascular bundle, with the advantage of less postoperative sexual dysfunction. This procedure may result in a higher rate of cancer recurrence if extracapsular extension is present.[21]

Radical perineal prostatectomy is used only rarely. This technique does not allow simultaneous dissection of the perineal lymph nodes and, when performed in the extreme lithotomy position, is associated with a relatively high risk of musculoskeletal and neurologic injuries.

Complications

Bleeding Hemorrhage is the most common complication and occurs more frequently with the retropubic approach. Bleeding during RRP can be substantial and is related to the operator, prostate size, anatomy, and technical factors such as division of the dorsal venous complex. Various techniques have been proposed to limit the amount of bleeding or the need for blood transfusion. Avoidance of red blood cell transfusion is desirable because of high cost, risks of immunologic and infective complications, immune suppression that may predispose patients to nosocomial infections and cancer recurrence,[68] and its negative outcome effects.[69] Preoperative autologous donation (PAD) is among the most popular transfusion-sparing techniques for use with radical prostatectomy; however, its cost-effectiveness has been questioned. In particular, PAD has a high cost and does not eliminate the risk of transfusion errors. Additionally, a significant amount of PAD blood units are discarded when moderate blood loss makes transfusion unnecessary. Acute normovolemic hemodilution (ANH) has been advocated as a more cost-effective technique because it is as effective as PAD in avoiding allogenic transfusion but avoids the cost of blood storage and the waste of unused blood.[70] In a randomized study of patients undergoing radical prostatectomy, PAD was compared with ANH and with ANH combined with preoperative recombinant human erythropoietin administration.[71] The latter technique was the most effective in avoiding postoperative anemia, but the increased cost of erythropoietin eliminated the financial advantage of using ANH. Intraoperative cell salvage has been proposed as an alternative technique to PAD during radical prostatectomy because it has similar effectiveness but generally lower cost.[72] The concern of possibly spreading cancers cells in the circulation has limited the use of this technique. No evidence has indicated that use of cell salvage for prostatectomy affects cancer recurrence.[73]

Anesthetic Management

Monitoring No definite recommendations guide the choice of monitoring techniques used during prostatectomy. The accuracy of central venous pressures in estimating blood volume is questionable.[74] The routine intraoperative use of pulmonary arterial catheters has no documented outcome benefit.[75] Therefore, hemodynamic monitoring should be chosen based on characteristics of the individual patient and should be directed at specific hemodynamic goals, such as optimization of cardiac output and organ perfusion. Urine output cannot be used to assess renal perfusion during prostatectomy because it is not measurable while the continuity of the urethra is interrupted. Use of intraoperative transesophageal echocardiography (TEE) for hemodynamic and volume status monitoring may have a role in patients with renal disease.

Anesthetic Choice The choice of anesthesia may affect the rate of venous thromboembolism after RRP. Epidural analgesia maintained for 24 hours postoperatively significantly reduced the incidence of DVT compared with general anesthesia alone.[76] This effect probably is related to increased venous blood flow in the lower extremities occurring intraoperatively, detected by Doppler ultrasound.[77] Alternative hypotheses include local anesthetic effects on the hemostatic system, attenuation of the stress response, and direct effects on platelet aggregation and coagulation factors.[78]

Use of epidural anesthesia, alone or in combination with general anesthesia, has been reported to be associated with less blood loss during prostatectomy.[79] This effect has been ascribed to higher venous pressure during general anesthesia and mechanical ventilation, alleviated by the use of epidural anesthesia. Complication rates in patients who received either general anesthesia alone or general anesthesia in combination with epidural anesthesia were similar.[80]

Surgery for Bladder Cancer

Preoperative Considerations

Bladder cancer is the fourth most common malignant tumor in men and the ninth most common among women in the United states. The mortality rate is strongly influenced by the stage at diagnosis and ethnicity (Fig. 60–8).[64] For this reason, emphasis has been placed on early diagnosis and aggressive management of early-stage disease. The most important risk factors for cancer of the bladder are sex, age, smoking history, and exposure to arylamines. Fluid intake may influence the risk of bladder cancer, as suggested by a prospective study in which the consumption of water or other beverages was inversely related to the odds of developing bladder cancer in a 10-year followup.[81]

The majority of patients with bladder cancer present with hematuria or voiding disturbances. The standard diagnostic method is cystoscopy and biopsy. Subsequent management depends on the degree of invasiveness. The majori-

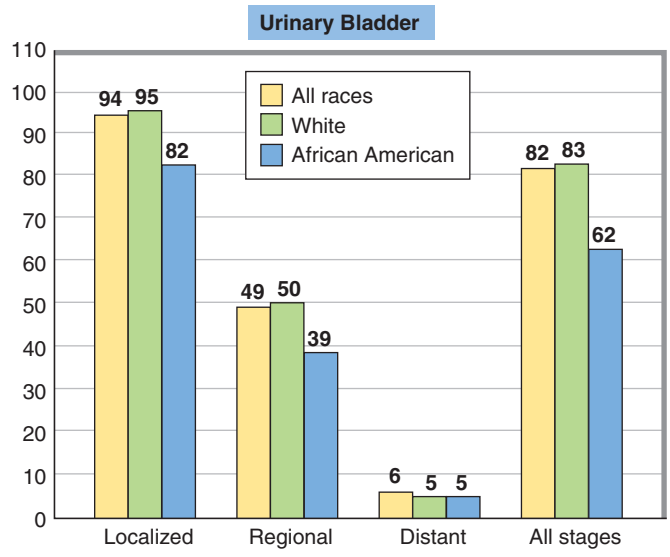

FIGURE 60–8. Five-year relative rate of survival from bladder cancer according to stage of presentation and ethnicity. (Modified from Jemal et al.[64] with permission.)

ty of patients will have superficial disease managed by transurethral resection, often followed by intravesical administration of adjuvant chemotherapy or of bacille Calmette-Guérin instillation.[21] The surgical and anesthetic management of patients undergoing transurethral resections has been described in the section on Endourologic Procedures.

Radical Cystectomy

Patients who have high-risk superficial tumors or who have invasive tumors are candidates for radical cystectomy, which is the most common procedure for invasive cancer of the bladder. Use of partial cystectomy has decreased considerably because of the high recurrence rate.[82] Radical cystectomy has a high rate of cure for patients with localized disease, with survival rates of approximately 70%. A significant portion of patients will have distant recurrence even after radical cystectomy; therefore, adjuvant or neoadjuvant chemotherapy often is given. A randomized study detected better survival rates in patients with locally advanced bladder cancer who received a course of chemotherapy prior to radical cystectomy as opposed to patients who underwent surgery alone.[83] During radical cystectomy, a low midline incision is performed, followed by removal of the bladder, peritoneum, perivesical fat, lower ureters, prostate, seminal vesicles, and, depending on tumor spread, the urethra. In women, the uterus, ovaries, tubes, urethra, and anterior vaginal wall are removed. Pelvic lymph node dissection usually is performed during radical cystectomy because it provides important staging and prognostic information. It also may contribute to improved control of disease and survival rates. Finally, a type of urinary diversion or bladder reconstruction is performed. Creation of an orthotopic neobladder using a segment of ileum or colon anastomosed to the native urethra is the first-line choice because of the resulting improved quality of life. This approach may not be possible in patients who have urethral or prostatic involvement. Alternative approaches include continent cutaneous diversion, where a reservoir is created from a bowel segment and open to the abdominal wall, and a noncontinent diversion, such as ileal loop or cutaneous urostomy. A continent diversion affords better quality of life compared to a noncontinent diversion but requires intermittent self-catheterization. All patients with intestinal pouches have chronic bacteruria and are subject to recurrent urinary tract infections and pyelonephritis.[84] A radically new approach to bladder reconstruction has been recently proposed. Biosynthetic bladders were fabricated using collagen scaffolds seeded with urothelial and muscle cells obtained from patient's own bladder. The engineered bladders were implanted, resulting in acceptable urodynamic characteristics. Although this approach has been used only in patients with myelomeningocele, the promising results suggest a possible future application of this technique for other indications, including cancer.[85]

Complications

Radical cystectomy is considered a relatively high-risk procedure. Patients commonly are males of advanced age who have significant risk factors for complications and comorbidities, such as history of smoking, chronic pulmonary, and heart disease. In an observational study of more than 2500 veterans undergoing cystectomy, independent predictors of postoperative morbidity included age, preoperative renal failure, elevated ASA status, use of general anesthesia, operative time, intraoperative transfusions, alcohol use, dyspnea, and dependent status.[86] According to a smaller observational study, surgical factors predisposing to complications include blood loss, operative time, type of diversion, and stage of cancer.[87] In this study, the overall rate of complications was reported to be approximately 30%. Postoperative ileus is the most common minor complication and results in increased hospital stay.[88] Unlike other types of major abdominal surgery, cystectomy is not associated with a particularly elevated risk of postoperative pulmonary complications, probably because the site of incision is far from the diaphragm.[89]

Anesthetic Management

Monitoring In spite of improvements in surgical technique, radical cystectomy continues to be associated with significant blood loss. In one study, blood transfusion was required in 30% of the cases. Female gender, preoperative anemia, and performance of ileal conduit were predictors of a higher need for transfusion.[90] Controlled hypotensive anesthesia has been advocated to reduce transfusion requirements, but the advantages of this practice should be critically compared to its risk in a population with significant cardiovascular risk.[91] The procedure is relatively lengthy, depending on the type of urinary diversion performed. Thorough monitoring of blood loss and attempts at estimating intravascular volume are necessary during the procedure. Invasive arterial blood pressure monitoring has the additional advantage of allowing frequent measurement of hematocrit levels. Volume status monitoring is hindered by the fact that the urinary tract is interrupted during most of the opera-

tion. In patients with heart dysfunction or renal disease, measuring central venous pressure may be indicated. Alternatively, monitoring blood pressure variations provides an accurate estimate of the need for fluid administration, with a predictive power superior to central venous and left atrial pressure monitoring in critically ill patients.[74] Pulmonary arterial catheters should not be used routinely but used only in selected cases to allow goal-directed hemodynamic management.

Anesthetic Choices Radical cystectomy usually is performed under general anesthesia, although use of neuraxial block is possible. Epidural anesthesia is more likely to be used in combination with general anesthesia because of the length of the procedure and patient discomfort during regional anesthesia alone. Use of epidural anesthesia together with general anesthesia has been reported to result in less blood loss and a lower transfusion rate compared with general anesthesia alone, but with no effect on the overall rate of complication, similar to radical prostatectomy.[92] In this study, postoperative pain control was also improved in patients who received epidural anesthesia. A large observational Veterans Health Administration study identified general anesthesia versus neuraxial block as a risk factor for complications after cystectomy.[86] No randomized controlled study has demonstrated an outcome benefit. A large well-conducted study on the outcomes of anesthetic choices in urologic surgery is needed.

Sympathectomy from neuraxial blockade promotes intestinal muscle spasm because of unopposed parasympathetic stimulation, which can render the fabrication of an ileal pouch technically difficult. Glycopyrrolate or papaverine has been used to obviate this problem.[93]

Surgery for Testicular Cancer

Preoperative Considerations

Malignant tumors of the testicle are relatively rare, with an incidence of 2–3 cases per 100,000 males each year.[21] Histologically, 95% of testicular cancers are germ cell tumors, of which 35 are seminomas. Nonseminomas, such as embryonal cell carcinomas, teratomas, choriocarcinomas, and mixed cell-type tumors, are clinically more invasive and require more aggressive management.[94] The incidence of germ cell tumors is highest in patients in their third and fourth decades and is heavily affected by ethnicity. Germ cell tumors occur significantly more frequently in whites than in people of Asian or African descent. The only known risk factors are a history of cryptorchidism or Klinefelter syndrome. Orchiopexy reduces the risk of testicular cancer if performed prior to puberty.[94]

Testicular tumors may present with a painless testicular mass or, more often, with testicular pain and swelling, which may be confused with orchitis or epididymitis. Occasionally patients have germ cell tumors that do not originate in the testicle. The diagnosis of testicular cancer is confirmed by testicular ultrasound. Abdominal CT scans usually are obtained for clinical staging. Metastatic spread of testicular tumors follows a characteristic stepwise pattern along the retroperitoneal lymphatics.[21]

Therapeutic Choices

Radical orchiectomy is required for all patients with testicular tumor. Further management depends on the extent of metastatic spread and tumor histology. The curability of germ cell tumors, particularly seminomas, is >90% with current management protocols. The stage at presentation and survival worsen with delay of recognition, which suggests the importance of early detection.[94] Low-stage seminomas are treated with retroperitoneal radiation therapy after orchiectomy, although observation only has been proposed. Nonseminomatous tumors are clinically more invasive and require more aggressive management, but the curability still is >90%. Retroperitoneal lymph node dissection (RPLND) is often used for these tumors, although observation also may be chosen because RPLND is often complicated by retrograde ejaculation and infertility. During RPLND, the lumbar sympathetic chain is ablated. Alternatively, a modified RPLND that spares the sympathetic nerves is used.[21] The response to therapy and the recurrence rate are evaluated following CT scan of the abdomen and the trend of biologic markers such as α-fetoprotein, human chorionic gonadotropin, and lactate dehydrogenase. Combination chemotherapy is the standard protocol for recurrent or high-stage testicular cancer. It incorporates cisplatin, etoposide, and bleomycin. Chemotherapy may be complicated by nerve and renal toxicity and by pulmonary fibrosis induced by bleomycin.

Orchiectomy Radical orchiectomy is performed by inguinal exploration, cross-clamping, and ligation of the spermatic cord at the internal inguinal ring. Transscrotal orchiectomy is not used because it predisposes to local and pelvic lymph node metastasis. This procedure can be safely performed with either general or regional anesthesia, depending on patient preferences.

Retroperitoneal Lymph Node Dissection Performed through a midline abdominal or thoracoabdominal incision, the standard RPLND involves removal of all lymphatic tissue between the ureters and between the superior mesenteric artery and the iliac vessels. The modified RPLND limits the extent of lymph node dissection and spares the sympathetic chain and hypogastric plexus on the side contralateral to the involved testicle. This technique preserves ejaculatory function in 80–90% of cases. General anesthesia is commonly used for this procedure. Pain management is particularly important for thoracoabdominal incisions and can be achieved with epidural anesthesia or intercostal nerve blocks. Blood and fluid losses can be significant during this procedure and should be replaced carefully. Large-bore intravenous access is strongly recommended.

Patients undergoing surgery for testicular cancer usually are young and do not have significant comorbidities; however, patients who have undergone combination chemotherapy before the procedure may suffer from the toxicities of the agents used. Bleomycin is associated with pulmonary toxicity. Patients at higher risk for this complication include those who received higher doses, are older, or have renal insufficiency. Acute respiratory distress syndrome has been reported after surgery in patients who had been exposed to bleomycin. according to evidence from animal studies and a series of patients, exposure to high concentrations of oxygen seems to favor the onset of this complication.[95] Little evidence indicates that a short exposure to high inspired oxygen results in acute pulmonary toxicity in patients with normal baseline pulmo-

nary function.[96] The lowest inspired oxygen concentration that achieves acceptable oxygen saturation values is a reasonable choice in patients who have been treated with bleomycin.[97]

During left-sided dissection, ligation of the intercostal arteries may lead to loss of circulation through the artery of Adamkiewicz, with consequent ischemia of the spinal cord. Therefore, motor function must be documented before and after surgery. When patients who received epidural anesthesia develop neurologic signs postoperatively, this diagnosis should be included in the differential.

Surgery for Renal Cancer

Preoperative Considerations

Renal carcinoma accounts for 2.6% of all cancers in the United States, and 85% of renal masses are renal cell carcinoma.[64] Only 2% of these cancers are associated with inherited conditions such as von Hippel-Lindau disease[98]; however, defects in the von Hippel-Lindau suppressor gene, an important regulator of cellular response to hypoxemia, may be responsible for a significant fraction of sporadic renal cell carcinomas. Tobacco smoking is an important risk factor for this disease. The peak incidence of renal carcinoma is 60 years, with a male-to-female ratio of 1.6:1.[64]

Approximately 50% of renal carcinomas are incidentally detected by abdominal imaging. A common presentation of this disease is hematuria, and its presence should always prompt further evaluation. The diagnostic and staging process includes contrast CT scan or gadolinium-enhanced MRI of the abdomen. In 5–10% of patients, tumor extension to the renal vein or vena cava occurs, worsening survival and complicating surgical management. Its presence and extent should be investigated.

Some patients present with paraneoplastic phenomena due to secretion of hormones by cancer cells. These conditions include erythrocytosis in 3–10% of patients, hypercalcemia in up to 20%, and hypertension refractory to medical treatment in up to 40%.[21] Determination of the prognosis of renal carcinoma in the individual patient is important in treatment and decision making. The survival rate worsens significantly with the stage of disease, from 95% at 5 years in tumors < 7 cm and limited to the kidney to 20% in tumors that extend beyond Gerota fascia or involve more than one lymph node.[98]

Nephrectomy

Radical nephrectomy is the standard approach to renal cell carcinoma because this tumor is not responsive to chemotherapy. During a radical nephrectomy, the renal artery and renal vein are ligated, and then the kidney is removed along with the adrenal gland, perinephric fat, Gerota fascia, and regional lymph nodes. Nephron-sparing partial resections had been performed mainly in patients at high risk for postoperative renal failure due to preexisting chronic kidney disease, diabetes, or hypertension because of concern that these limited resections may be associated with higher rates of tumor recurrence. Partial resection is becoming more popular and is now often chosen for smaller tumors.[99] In the last 10 years, minimally invasive laparoscopic nephrectomy has received increasing attention. The technique minimizes pain and reduces postoperative recovery time. It is particularly appealing for living donor nephrectomy. Robot-assisted nephrectomy has been introduced in the last 5 years and probably will be used more often as the technique is perfected.[100] Chemotherapy, interferon, and interleukin therapy are sometimes used in metastatic disease or as adjuvant therapy, although their effectiveness is unclear.

Anesthetic Management Preoperative evaluation of the nephrectomy candidate should follow the standard approach for patients undergoing intermediate-risk surgery of the upper abdomen and should focus on cardiovascular and pulmonary risk factors. A significant fraction of this patient population is composed of smokers and elderly persons at increased risk for cardiac and respiratory complications. Preexisting renal dysfunction should be noted because its presence may influence intraoperative and anesthetic management. The majority of patients undergoing nephrectomy are anemic, so an adequate amount of red blood cells should be available prior to surgery, particularly when the renal mass is large.

During nephrectomy, the kidney usually is approached through a flank incision, although subcostal and thoracoabdominal incisions are also used. The thoracoabdominal incision is the most commonly used if vena caval infiltration is known, because the flank incision allows adequate access only to the kidney and retroperitoneum but not to the vena cava. The most commonly used position for nephrectomy is lateral with kidney rest elevation. With the flank incision, the pleural space can be accidentally entered through a diaphragm tear, requiring chest tube placement. Routine postoperative chest radiographs should be obtained in the recovery room. With thoracoabdominal incision, a chest tube is placed routinely at the end of the procedure. Other intraoperative complications of radical nephrectomy are hollow viscus injuries and splenic lacerations.

Radical nephrectomy usually is performed under general endotracheal anesthesia. Both intraoperative and postoperative epidural analgesia also are used commonly, although little evidence suggests outcome benefits. Intercostal nerve blocks may be used for thoracoabdominal incision and can contribute to reducing the rate of postoperative atelectasis.[101]

Hemodynamic instability is common during open radical nephrectomy. The lateral kidney rest position can cause hypotension due to vena cava stretching and reduced venous return. This requires reduced flexion of the operating table and treatment with fluid loading. Compression of the vena cava by retractors can cause the same phenomenon. More importantly, nephrectomy patients are prone to significant blood loss, particularly if the mass is large or very vascular, a common finding in renal cell carcinoma. Large-bore intravenous access is mandatory, and central venous cannulation with a large-bore catheter may be helpful. Pulmonary arterial catheterization should not be used routinely but should be reserved for patients with significant cardiovascular comorbidities, or it should be used with the intent to reach and maintain specific hemodynamic goals, as discussed in the sections on surgery for prostate cancer or bladder cancer. Arterial cannulation also can be helpful for blood pressure monitoring and blood sampling. Hemodynamic monitoring and fluid management are particularly important in patients at significant risk for postoperative renal dysfunction, to prevent or treat renal hypoperfusion. Controlled hypotension may limit intraoperative blood loss but may not be

suitable for patients with preexisting chronic kidney disease. No evidence indicates that any pharmacologic strategy effectively provides perioperative renal protection. In particular, loop diuretics, mannitol, and renal vasodilators are not protective in patients undergoing vascular and cardiothoracic surgery. Currently no evidence supports the use of these agents in patients undergoing nephrectomy and other high-risk urologic procedures.

When minimally invasive nephrectomy is performed, the anesthetic management is similar to that for other types of laparoscopic procedures, as described in the next section. With a multimodal approach including local anesthetic injection at the port site and in the renal fossa, administration of nonopioid analgesics, and an early mobilization and nutrition schedule, Recart et al.[102] were able to discharge patients from the hospital at an average of 41 hours following surgery.

Nephrectomy is a very high-risk procedure in patients with vena cava invasion. However, this operation is frequently undertaken because patients have very poor life expectancy without surgery. The complexity of the procedure increases with the degree of tumor invasion. Patients at highest risk for mortality are those with tumor invasion above the diaphragm and into the right atrium. The procedure must be performed with cardiopulmonary bypass in these cases or when surgical control of the vena cave above the level of tumor invasion is not possible. Detachment of tumor fragments with pulmonary embolization is possible during the operation. These patients require large-bore intravenous access because massive blood loss is a possibility. Additionally, tumors partially or totally occluding the vena cava lumen cause distal elevation of venous pressures and formation of venous collaterals that, together, increase the extent of blood loss. Invasive hemodynamic monitoring is desirable, but central access is complicated by the risk of detaching tumor emboli when tumor extends to the right atrium, particularly for pulmonary arterial catheterization. Alternatively, TEE for hemodynamic monitoring may be useful. TEE allows intraoperative confirmation of the extent of tumor invasion and diagnosis of pulmonary embolization.[103]

Patients undergoing nephrectomy should always receive perioperative thromboembolic prophylaxis. This and other major urologic procedures are associated with a high risk for venous thromboembolic complications, and this risk probably is not reduced with laparoscopic techniques.

Minimally Invasive Urologic Surgery

Techniques

The last 10 years have seen increasing interest in minimally invasive and laparoscopic urologic procedures. The first procedures accomplished through laparoscopy were procedures for undescended testis and varix ligation, followed by retroperitoneal node dissection for testicular, prostate, and bladder cancer.[21] Laparoscopic nephrectomy, prostatectomy, and cystectomy are currently performed in certain centers. Laparoscopic urologic surgery offers the obvious advantages of decreased postoperative pain and reduced postoperative hospitalization. Whether laparoscopic cancer surgery achieves the same degree of eradication as standard procedures such as retroperitoneal node dissection and radical nephrectomy is not entirely clear.[21] Therefore, the long-term outcome of these laparoscopic procedures is still being evaluated, and they are not yet recommended as the standard approach.

More recently, minimally invasive surgery has been enhanced by the introduction of robotic techniques (Fig. 60–9). These techniques allow operators to perform complex procedures in less time and with more reliability compared to nonrobotic laparoscopy, improving the learning curve of the surgeon. Use of robotic techniques likely will become increasingly more common in urology.[104] Based on early reports, robot-assisted radical cystectomy with neobladder construction seems to be associated with a lower rate of complications and faster postoperative recovery.[105] This technique still requires prolonged operating time but likely will improve as experience accumulates.[106]

Laparoscopic radical prostatectomy, with and without the use of robots, has recently been introduced. Whether this surgical approach has improved outcome is not clear, and larger series are required. In a study that compared pain scores and narcotic use in patients undergoing robot-assisted radical prostatectomy versus standard RRP, no difference was observed between the two groups.[107]

Laparoscopic nephrectomy can be performed through a transperitoneal or retroperitoneal approach. With the latter, the patient is placed in a lateral or semilateral flexed position, and a working space is created in the retroperitoneum by inflating a balloon inserted through a small incision. This space is then distended by carbon dioxide (CO_2) insufflation. Laparoscopic surgery for nephrectomy is particularly appealing for live kidney donor surgery because of reduced pain and disability. Laparoscopic partial and total nephrectomy also are possible.[100,108] Laparoscopic partial nephrectomy allows early discharge from the hospital when coupled with a multimodal pain management approach that includes narcotics, nonsteroidal

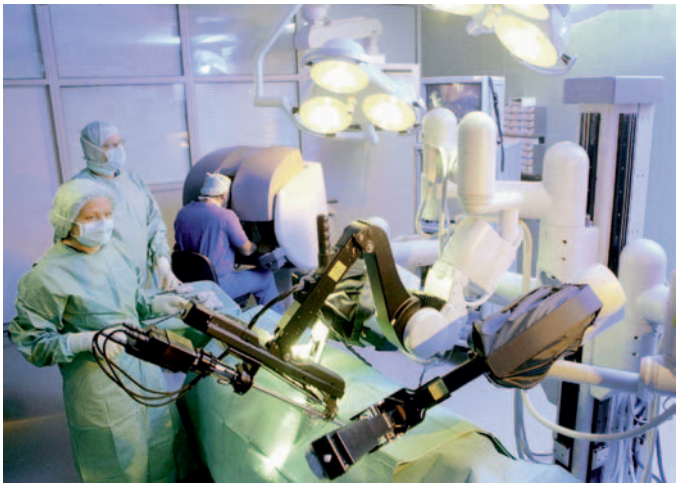

FIGURE 60–9. Typical operating room setup for robotic surgery. (Courtesy of 2006 Intuitive Surgical Inc.)

antiinflammatory drugs (NSAIDs), and local anesthesia to the port sites.[102]

Anesthetic Management

There is no standard anesthetic management of patients undergoing minimally invasive urologic procedures. The physiologic changes and problems encountered by patients undergoing laparoscopic operations are well known from the experience acquired in other surgical specialties. In particular, the effects of pneumoperitoneum and CO_2 insufflation on the cardiovascular, respiratory, and central nervous systems are well characterized. Laparoscopy in urologic surgery poses additional challenges, such as those related to particular positions adopted in this specialty. Pneumoperitoneum causes an upward shift of the diaphragm and decreased chest wall compliance that result in reduced lung volumes and increased airway pressures.[109] In the head-down position, the diaphragmatic shift is exaggerated, further decreasing lung volume. Atelectasis may result but can be prevented by application of positive end-expiratory pressure or treated by inflation maneuvers. The increased airway pressure observed during pneumoperitoneum is the result of decreased chest wall compliance and not of lung hyperinflation, and it should not be considered as a factor predisposing to barotrauma. Transperitoneal absorption of CO_2 causes parallel increases in arterial and end-tidal PCO_2 that must be compensated by increased ventilation to avoid acidemia. This can be accomplished by increasing respiratory rate, tidal volume, or both. Pneumoperitoneum combined with head-down position causes increased systemic arterial resistance, systolic heart volumes, and ventricular systolic work.[110] These changes may lead to myocardial ischemia in patients at risk. Laparoscopy in the lateral flexed position may significantly decrease venous return, causing low cardiac output and hypotension. This condition can be promptly reversed by deflation and table deflection and prevented by fluid loading. During pneumoperitoneum in the head-down position, the resulting changes in venous pressures, together with hypercapnia, can lead to significant increases in intracranial pressure and, potentially, brain injury in selected patients.[111] Laparoscopic procedures in this position are best avoided in patients with space-occupying intracranial lesions. In nephrectomy patients with preexisting renal disease, laparoscopy may create additional kidney injury as a result of elevated intraabdominal pressure and kidney manipulation. Kidney injury may be limited by maintaining adequate blood volume and hemodynamic stability. To date, none of the existing "renal protection" pharmacologic strategies has proven effective.

Depending on the surgeon's experience with these procedures, the anesthetic plan should anticipate the possibilities of conversion to open procedure and significant bleeding. Laparoscopy patients should undergo a preoperative evaluation identical to that for patients undergoing the equivalent open procedure. Cardiovascular monitoring should be appropriate for the planned procedure, based on the patient's clinical status. Central venous and pulmonary arterial wedge pressure measurements are biased during laparoscopy because of transmission of intraabdominal pressure to the mediastinal space. Use of TEE in high-risk patients allows more accurate assessment of cardiac volumes.[112] Bladder catheterization and nasogastric intubation usually are performed for laparoscopic procedures.

When laparoscopic procedures are performed in an ambulatory setting, the choice of induction and maintenance anesthetic agents reflects the need for prompt awakening and rapid recovery. In laparoscopic surgery, N_2O is often avoided, to prevent bowel distension should the procedure become prolonged. Intraoperative and postoperative analgesia usually is performed with a combination of opioids and NSAIDs.[102] Epidural analgesia is not routinely offered.

Among the complications of laparoscopic procedures are bleeding, subcutaneous emphysema, pneumothorax, diaphragmatic tears, and gas embolism.[113] Although the use of CO_2 for pneumoperitoneum reduces the probability of massive embolism, it is a potentially fatal complication and should be considered in case of intraoperative hemodynamic deterioration.

SUMMARY

Urologic surgery often is challenging for the anesthesiologist because of the complexity of the procedures performed and the increased frequency of comorbidities encountered in this patient population. However, this is also a rewarding field because the outcomes often are good and because it offers the opportunity to choose from among a relatively broad variety of anesthetic strategies. Ongoing progress in surgical techniques and particularly the recent interest for minimally invasive and robotic surgery likely will introduce more challenges and rewards in the future. An increasing number of patients with compromised health will present to the attention of the anesthesiologist. At the same time, the pressure for rapid anesthetic recovery times and high levels of patient comfort and satisfaction likely will increase.

CHAPTER 61

Anesthesia for Obstetric Care and Gynecologic Surgery

Lawrence C. Tsen, MD

Just a few months separated the introduction of anesthetics for general surgical procedures and obstetric care. Ether, then believed to be the panacea to "cure all ills," was found to be efficacious, but not optimal, in both environments. Today, although the use of general volatile anesthetics remains popular, the advent of regional anesthetic techniques has greatly expanded the ability to provide analgesia and anesthesia for a wide spectrum of procedures and conditions. Selection of the optimal anesthetic technique for the obstetric or gynecologic patient should consider the significant anatomic, hormonal, and physiologic adaptations that ultimately allow a female to conceive and carry a pregnancy. This chapter discusses the provision of analgesia and anesthesia for obstetric care and/or gynecologic surgery. Emphasis is placed on the three primary settings of care: provision of analgesia for labor and delivery, anesthesia for obstetric and nonobstetric surgery

KEY POINTS

1. The use of epidural, spinal, and combined spinal–epidural techniques for obstetric care has increased dramatically because of the quality and safety of the analgesia and anesthesia produced, the ability to titrate the degree and duration of pain relief, and the expanding number of situations for which their use is appropriate. Labor analgesia and obstetric anesthesia can have beneficial effects on the outcomes of external cephalic version, in utero fetal and placental surgery, and parturients with significant comorbid conditions.
2. Teratogenicity, defined as any significant postnatal change in function or form in an offspring after prenatal treatment, is difficult to evaluate in prospective clinical trials given the low incidence of occurrence and the number of confounding factors. The list of agents or factors proven to be human teratogens does not include anesthetic agents used routinely in clinical practice.
3. Clinically used estimates of gestational age originate from the first day of the last menstrual period. However, fertilization does not occur until 2 weeks after this time, so 14 days are added to actual fetal development in order to fit within the clinical schemas. Thus, although the period of major fetal organogenesis is considered to occur between 5 and 55 days, within the clinically used schemas this period occurs in weeks 3–10 of gestation.
4. Although important reductions in anesthesia-related maternal mortality have occurred in the past 5 decades, a significantly greater risk (16.7 times) of maternal death is still witnessed with the use of general versus regional anesthesia. This finding can be partially explained by changes in the airway that occur over the course of pregnancy. Promotion of regional techniques, familiarity with alternate airway devices, and review of difficult airway algorithms are strongly encouraged.
5. Antenatal and postpartum maternal hemorrhage can be masked until significant blood loss has occurred. With the recognition that blood loss and physiologic deterioration can occur rapidly, a cogent plan of investigation and response can significantly affect the outcome. Interventional radiologists may place transcatheter occlusion balloons within the uterine or hypogastric arteries in high-risk parturients to allow for timely control of bleeding.
6. Preeclampsia is a multisystem disease characterized by hypertension, proteinuria, and generalized edema. The presence of systemic vasoconstriction, intravascular volume and protein depletion, organ dysfunction, abnormalities in coagulation, and edema of the brain, larynx, and lungs make this disease of particular concern prior to any anesthetic technique. Of interest, the incidence of spinal-induced hypotension may not be greater than with epidural techniques.
7. Although many procedures in gynecologic surgery are approached using standard surgical techniques, the care and anesthetic management should be provided with an understanding of gender-related differences, including sensitivity to pain and anesthetic agents, which ultimately may affect patient outcomes and satisfaction.
8. A basic understanding of the anatomy and specific procedures within gynecologic surgery, coupled with discussions with the surgeon, is helpful in planning the optimal anesthetic technique. This is particularly true given the variety of approaches and positioning requirements for certain procedures.
9. The uterus and other female visceral structures are highly vascular. Blood loss can be sudden and profuse, air emboli can occur unexpectedly, and, in pregnancy-related procedures, amniotic fluid emboli can occur without provocation.
10. Hysteroscopic and laparoscopic procedures can result in significant adverse outcomes from absorption of distending medium and carbon dioxide (CO_2), respectively. CO_2 insufflation of the abdomen or pelvis may cause a number of disturbances in cardiac and respiratory physiology, which can be minimized if anticipated.
11. The Trendelenburg lithotomy position is commonly used for gynecologic procedures and may lead to a number of peripheral nerve injuries. Excessive hip flexion, abduction, and external rotation may cause femoral nerve, obturator, lateral femoral cutaneous, sciatic, and peroneal nerve injuries. Attention to positioning throughout the procedure, use of protective padding, and avoidance of contact with hard surfaces or supports are important elements of optimal care.

during pregnancy, and anesthesia for gynecologic surgery.

ANALGESIA AND ANESTHESIA ASSOCIATED WITH PREGNANCY

With the application of diethyl ether to aid in a vaginal delivery in 1847, James Young Simpson, an obstetrician, ushered in the use of anesthetics for obstetrics. The next half-century was associated with increased acceptance and evolution of anesthetics and techniques for both labor and delivery. Regional anesthetic techniques, which deliver pain relief to a discrete region of the body, were introduced to obstetrics in 1900, when Oskar Kreis described the use of spinal anesthesia. Since that time, central neuraxial techniques have evolved from single, limited duration injections into the intrathecal (subarachnoid) space to titratable, controlled infusions through flexible catheters most commonly placed into the epidural space. These techniques are often the optimal method for providing analgesia for labor, anesthesia for obstetric or nonobstetric surgery during pregnancy, and analgesia for postoperative care. Because these techniques are so fundamental to the practice of anesthesia for the parturient, they are discussed initially, and then the rationale and details for their use are expanded throughout the chapter.

Neuraxial Techniques

Regardless of which neuraxial technique is used for labor, delivery, or nonobstetric operations, a standardized approach is warranted. A preprocedure history and physical examination with notation of allergies, baseline vital signs, and assessment of the airway, body habitus, and hematologic system (e.g., preeclampsia-induced thrombocytopenia; see Hypertensive Disorders of Pregnancy below and Chapter 21) are mandatory, even if the situation is urgent. An intravenous (IV) catheter and fluid administration should be started, especially because hypotension can abruptly follow neuraxial technique placement and affect both maternal and fetal welfare. Whether crystalloid or colloid solutions are administered to minimize hypotension is controversial. Colloids have been observed to minimize, but not eliminate, hypotension, but they are associated with increased costs and risk of allergies, and they can affect coagulation when given in large doses (hetastarch in doses >20 mL/kg). IV fluids, regardless of the amount administered, do not reliably minimize hypotension. Thus, in urgent situations, waiting for an arbitrary amount of fluid to be infused prior to the neuraxial anesthesia or analgesia is not necessary. The seated position is often selected for the purportedly enhanced ability to palpate the vertebral spinous processes and identify the midline plane. However, these landmarks can also be achieved in the lateral recumbent position. In addition, in the pregnant patient the lateral recumbent position has the particular advantage of minimizing venous plexus engorgement, resulting in reductions in vessel trauma, vessel cannulation, and placement attempts.[1] In certain emergent situations, such as cord prolapse or fetal head entrapment, the seated position is not a viable option. As such, a general anesthetic would be the only available method for delivering anesthesia if the anesthesiologist is not comfortable instrumenting the back in the lateral position.

Selection of the optimal neuraxial technique depends principally on the desired onset, reliability and titratability of the resulting analgesia or anesthesia, with catheter-based techniques offering the greatest flexibility. The spinal technique offers confirmation of the space via cerebrospinal fluid (CSF) flow, fast onset, and very reliable sensory and motor blockade; however, the duration of blockade is time limited and may be associated with abrupt hemodynamic alterations. By contrast, the epidural technique has a slower onset, does not intentionally create a dural puncture, and, when used with a catheter, offers an almost unlimited duration of blockade; however, the resulting block may be patchy or one sided, and a large dural puncture may occur inadvertently. The dose, onset, and duration of various local anesthetics for epidural labor analgesia and anesthesia are well characterized (Table 61–1). The epidural technique may enable a lesser incidence and extent of maternal hypotension because of the ability to administer the dose of local anesthetic in a fractionated manner and allow compensatory cardiovascular mechanisms to respond to the more slowly developing sympathetic blockade. The combined spinal–epidural (CSE) technique, which consists of epidural needle placement, administration of subarachnoid medications via a spinal needle placed through the shaft of the epidural needle, and placement of an epidural catheter (Fig. 61–1),[2] appears to combine the best of both techniques with a blockade that is rapid in onset, is reliable, and can be prolonged. Because the spinal needle emerges 10–15 mm beyond the tip of the epidural needle,[3] the presence of CSF can confirm that the epidural needle is proximal to, or in, the epidural space. This information can be of value when multiple "losses of resistance" are encountered during epidural needle placement.

TABLE 61–1.

Local Anesthetics for Epidural Analgesia and Anesthesia

Anesthetic	Usual Concentration (%)	Onset	Duration
Analgesia			
Lidocaine	1–1.5	Moderate	Intermediate
Bupivacaine	0.0625–0.25	Slow	Slow
L-Bupivacaine	0.0625–0.25	Slow	Slow
Ropivacaine	0.1–0.2	Slow	Long
Anesthesia			
2-Chloroprocaine	2–3	Fast	Short
Lidocaine	2–5	Moderate	Intermediate
Mepivacaine	2	Moderate	Intermediate
Bupivacaine	0.5	Slow	Long
L-Bupivacaine	0.5	Slow	Long
Ropivacaine	0.5–1	Slow	Long
Tetracaine	1	Slow	Long

Intentional puncture of the dural ligament with an epidural needle and placement of a catheter into the subarachnoid space, called a "spinal catheter technique," is a viable option. Spinal catheter techniques have the benefit of CSF confirmation and the ability to provide a highly reliable and titratable blockade.[4] Such techniques are often used in parturients who are morbidly obese, in those with significant cardiac disease, or following an unintentional dural puncture with an attempted epidural catheter placement. Because placement of a spinal catheter depends on use of epidural equipment (e.g., 17-gauge Tuohy needle and 20-gauge catheter), a significant postdural puncture headache (PDPH) risk exists. Smaller needles and catheters for labor and delivery are currently being used or evaluated in Europe and the United States, respectively, with the hope of avoiding the cauda equina syndrome observed during the earlier microcatheter trials. This complication most likely resulted from pooling of excessive amounts of local anesthetics.[5,6]

Use of epidural, spinal, and CSE techniques has increased dramatically, particularly for obstetric indications (Fig. 61–2). This increase has been driven in large part by the quality and safety of the analgesia and anesthesia produced, the ability to dictate the intensity and duration of pain relief as required by the circumstances, and an expanding number of situations in which their use is appropriate. Use of neuraxial opioids results in improved analgesia compared with IV opioid administration, likely due to actions on both supraspinal and spinal opioid receptors (Table 61–2).[7] Currently, in developed countries, central neuraxial techniques provide labor analgesia for 30–50% of all parturients and the anesthesia for the majority of instrumental and operative deliveries.[8,9]

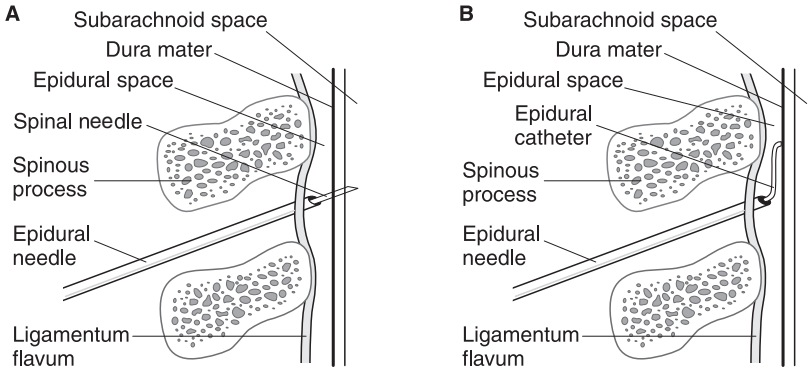

FIGURE 61–1. Combined spinal-epidural technique.

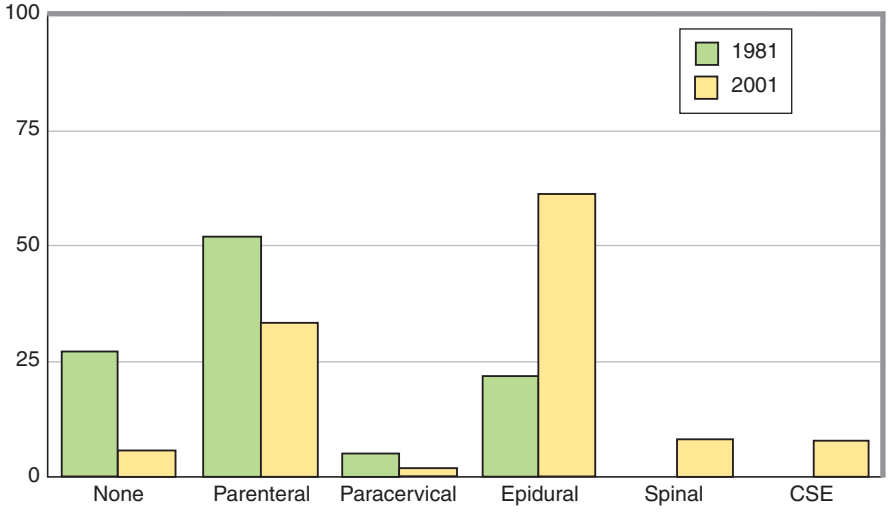

FIGURE 61–2. Types of analgesia provided for labor. Reported as percent of total cases in hospitals with more than 1500 births annually. (Based on data from Bucklin et al.[45])

Considerations on Maternally Administered Anesthetics

Although only a limited percentage of systemically or neuraxially administered anesthetics eventually reaches the fetus (see Chapter 21), an overlying concern during assisted reproductive technologies and pregnancy is the effect on fertilization and embryonic and fetal development. Teratogenicity, defined as any significant postnatal change in function or form in an offspring after prenatal treatment, is difficult to evaluate in prospective clinical trials given the low incidence of occurrence and the number of confounding factors; species susceptibility,

TABLE 61–2.

Opioids for Neuraxial Use in Obstetrics

Opioid	Epidural Dose	Spinal Dose	Duration (h)	Comments
Morphine	2.5–5 mg	0.1–0.2 mg	18–24	Useful primarily for postcesarean section analgesia
Fentanyl	50–100 μg	10–20 μg	3–4	Useful as labor and operative adjuvant
Sufentanil	10–20 μg	5–10 μg	3–4	Useful as labor and operative adjuvant
Meperidine	25 mg		2–3	
Hydromorphone	1 mg		12	
Methadone	4–5 mg		5–6	
Diamorphine	2.5–5 mg		5–15	Not available in the United States

genetic predisposition, and amount, timing, and duration of exposure all can affect reproductive outcome. The criteria for identifying an agent as a human teratogen requires (1) proven exposure to the agent at the critical time of development, (2) consistent findings in two or more high-quality epidemiologic studies, (3) careful delineation of the clinical cases, ideally with identification of a specific defect or syndrome, and (4) an association that makes "biologic sense."[10] Of note, the list of agents or factors proven to be human teratogens does not include anesthetic agents used routinely in clinical practice (Box 61–1); however, the reader is encouraged to refer to package inserts provided by drug manufacturers and standard teratology reference sources for more specific information.[10,11] The effect of anesthetics on early cellular division has been reviewed extensively.[12]

Early studies of neurotropic agents (e.g., opioids, tricyclic antidepressants, phenothiazines, benzodiazepines, butyrophenones) demonstrated significant teratogenicity in rodents. Subsequent studies, however, questioned the relationship given the high doses of drugs administered and the resulting respiratory depression and impaired feeding. Using more elegant study designs at clinically relevant doses, often provided with chronically implanted osmotic minipumps, the absence of teratogenicity in the agents commonly used for induction (barbiturates, propofol, ketamine, benzodiazepines), analgesia (opioids), and muscle relaxation has been confirmed.[10,13–15] With the exception of the association of chronic cocaine exposure with congenital defects and adverse reproductive outcomes, local anesthetics per se are devoid of teratogenic effects in clinically used doses.[10,16] As described under Considerations on Maternal Physiology, however, uncorrected maternal hypotension that may result from local anesthetics provided via neuraxial techniques may lead to decreased fetal perfusion, fetal acidosis, and fetal death. The effects of volatiles demonstrate the importance of timing; exposure to nitrous oxide and halogenated agents during in vitro oocyte fertilization causes delays in division from the one- to two-cell stage and impaired spindle cell function during meiosis, respectively. In vivo, mice or rats exposed during pregnancy to 50% or 0.75 minimum alveolar concentration (MAC) halothane, isoflurane, or enflurane at various stages of pregnancy have resulted in increased fetal resorptions and altered body laterality with nitrous oxide, but no teratogenic effects with the halogenated agents.[17] The teratogenicity with nitrous oxide initially was believed to result from rapid inhibition of methionine synthase in both animals and humans. However, this likely is not the only route of activity for several reasons: maximal methionine synthase inhibition occurs at concentrations much lower than those required to produced teratogenic effects, use of folinic acid to bypass methionine synthase partially prevents minor skeletal defects, coadministration of isoflurane or halothane prevents almost all teratogenic effects without affecting methionine synthase activity, and replacement of methionine prevents malformations except for situs inversus defects.[18] As such, the weak teratogenic effects of nitrous oxide are multifactorial. Regardless, the threshold requirements for adverse effects with nitrous oxide (i.e., >50% concentrations for 24 hours) are not likely to be encountered clinically.

The animal and human experience with all drugs suggests critical periods of susceptibility to teratogens. In general, exposure to known teratogens during the first 2 weeks of embryonic development are marked by either death or minor cellular damage and ongoing survival; highly sensitive periods for developmental effects are during fetal organogenesis when major morphologic changes are occurring. Of note, clinical estimates of gestational age originate from the first day of the last menstrual period; however, because fertilization does not occur until 2 weeks after this time, 14 days are added to actual fetal development to correct for the discrepancy. Thus, whereas the period of major fetal organogenesis is considered to occur between 5 and 55 days of gestation, within the clinically used schemas this period occurs in weeks 3–10 of pregnancy. Overall, anesthetic agents have limited effects from their earliest applications in assisted reproduction throughout pregnancy. Despite their limited effects, it seems prudent to limit the dose of anesthetics by using drug combinations or regional techniques.

Considerations on Maternal Physiology

The maternal and fetal consequences of anesthesia and surgery may be altered by pregnancy or pregnancy-related comorbid conditions (see Chapter 21). Even transient hypoxia, hypercapnia, stress, hypotension, and abnormalities in temperature and metabolism may adversely affect maternal and fetal outcomes. Alterations such as engorgement of the respiratory mucosa, increased consumption of oxygen, and hemodynamic effects of the gravid uterus represent important sources of concern in the provision of anesthesia during pregnancy.

Anesthesia-related maternal mortality has been declining over the last few decades but still accounts for 3–12% of maternal deaths; the majority occur as a result of failed intubation, ventilation and oxygenation, or pulmonary aspiration with general anesthesia. These statistics rank anesthesia as the sixth leading cause of peripartum maternal mortality in the United States, with a risk of maternal death 16.7 times greater with general versus regional anesthesia.[19] A comparison of maternal deaths due to anesthesia in

the Confidential Enquiries data of 2000–2002 with the data from 1964–66 yields a 30-fold improvement associated with a reduction in general anesthesia use.[20] Maternal deaths associated with general anesthesia can be partially explained by the significant airway changes that occur over the course of pregnancy and even during labor.[21] The ability to secure the airway emergently has been associated with even greater difficulty,[22] often requiring the use of alternative airway devices and techniques.[23] These maternal outcome data strongly support the use of regional techniques in both elective and emergent delivery situations when no contraindications exist for their use (Box 61–2).

The gravid uterus leads to progressively increasing cardiac demand and compromise of venous return during gestation. The growing uterus ultimately receives 600–700 mL/min of blood flow, which is of major importance when uterine trauma, including surgery, occurs. Moreover, the association between hypotension and the supine position in pregnant women, particularly in the late gestational state, is well demonstrated.[24] Upon assuming the supine position, acute hypotension, with increased pulse rate, increased femoral venous pressure, pallor, and sweating, can occur within minutes, so use of left lateral displacement, even as little as 15°, can reduce the incidence of hypotension and ultimately improve uterine blood flow and fetal health, as evidenced by improved blood gas values.

BOX 61–2.

Contraindications to Central Neuraxial Anesthesia

- Absolute
  - Patient refusal or inability to cooperate
  - Localized infection at insertion site
  - Sepsis
  - Severe coagulopathy
  - Uncorrected hypovolemia
- Relative
  - Mild coagulopathy
  - Severe maternal cardiac disease (including congenital and acquired disorders)
  - Neurologic disease (including intracranial and spinal cord pathologies)
  - Severe fetal depression

This syndrome most likely is a manifestation of hormonal as well as mechanical changes. Hormonally, pregnancy-related alterations in renin, angiotensin II, cardiac natriuretic peptide, prostaglandins, progesterone, estrogen, and endothelin cause a relaxation in vascular tone, reduction in stroke volume, decrease in left ventricular compliance, and overall reduction in cardiovascular reserve. These changes ultimately make the cardiovascular system less able to compensate for any mechanical reductions in venous return by the gravid uterus, particularly when the patient is in the supine position. This difficulty in compensation is also observed following spinal anesthesia-induced hypotension.

Additional concerns witnessed only during pregnancy stem from the presence of trophoblastic tissue (i.e., outermost layer of cells of the developing embryo that attaches to the uterine wall) and amniotic fluid. Intravascular systemic distribution of amniotic fluid may accompany uterine rupture or placental separation, leading to sudden cardiovascular collapse accompanied by coagulation disorders. More commonly, however, trophoblastic tissue from the maternal–fetal interface is implicated in the complications associated with preeclampsia, an entity for which delivery of the fetus or fetal tissues remains the only definitive therapy. Hypertensive crises, potential for seizures, intravascular depletion, and thrombocytopenia witnessed with preeclampsia are concerns relevant to anesthetic care (see Hypertensive Disorders of Pregnancy below).[25]

Considerations for Specific Situations

Concerns regarding the provision of analgesia and anesthesia for the obstetric patient begin prior to pregnancy and continue through pregnancy, the delivery, and the postpartum period. Throughout, anesthesia providers have the responsibility to consider the effects of their interventions during a variety of procedures, including assisted reproductive technologies, cerclage placement and removal, external cephalic version attempts, nonobstetric surgery during pregnancy, in utero fetal surgery, labor and vaginal delivery, cesarean delivery, and tubal ligation. Anesthesia care during dilatation and evacuation procedures, which are performed for pregnancy termination, pregnancy loss and retained products, and procedures involving ectopic pregnancies, are discussed in Considerations for Specific Situations under gynecologic surgery.

Assisted Reproductive Technologies

Whereas most patients undergoing procedures related to assisted reproductive technologies are young and otherwise healthy, a growing percentage have significant comorbid states that are responsible for either infertility or the inability to carry a pregnancy. For these individuals, assisted reproduction represents a mechanism to preserve fertility or to obtain oocytes for later use or transfer to gestational carriers. Almost all interventions that require anesthesia are for the purposes of oocyte retrieval and gamete (i.e., sperm or oocyte) or embryo transfer. Most of these procedures are performed transvaginally with ultrasound guidance; on occasion, a transabdominal approach is used.

The anesthetic options for these procedures include paracervical, conscious sedation, spinal, epidural, and general anesthetic techniques.[12] Paracervical anesthesia, which blocks sensation from vaginal but not ovarian pain fibers, often requires additional analgesia (Fig. 61–3). Conscious sedation techniques are the most commonly used mode of analgesia for oocyte retrievals; however, loss of consciousness, patient movement at critical times, and prolonged recovery room stays may result.[12] Total IV general anesthesia provided with IV propofol (titrated) and fentanyl (50–100 μg) offers an optimal approach. Midazolam (1–2 mg) can be added if needed to allay patient anxiety. Most patients can be managed with spontaneous ventilation via a high-flow oxygen mask and continuous carbon dioxide (CO_2) analysis to monitor the adequacy of ventilation. On rare occasion, as in individuals with multiple risk factors for aspiration or the need for laparoscopy, an endotracheal tube is placed. Inhalational anesthesia with enflurane and 70% nitrous oxide has been shown to produce significantly greater rates of nausea and emesis and more unplanned admissions compared to an IV technique of propofol and alfentanil combined with an inhaled air/O_2 mixture.[12]

Neuraxial techniques provide excellent pain relief with minimal oocyte

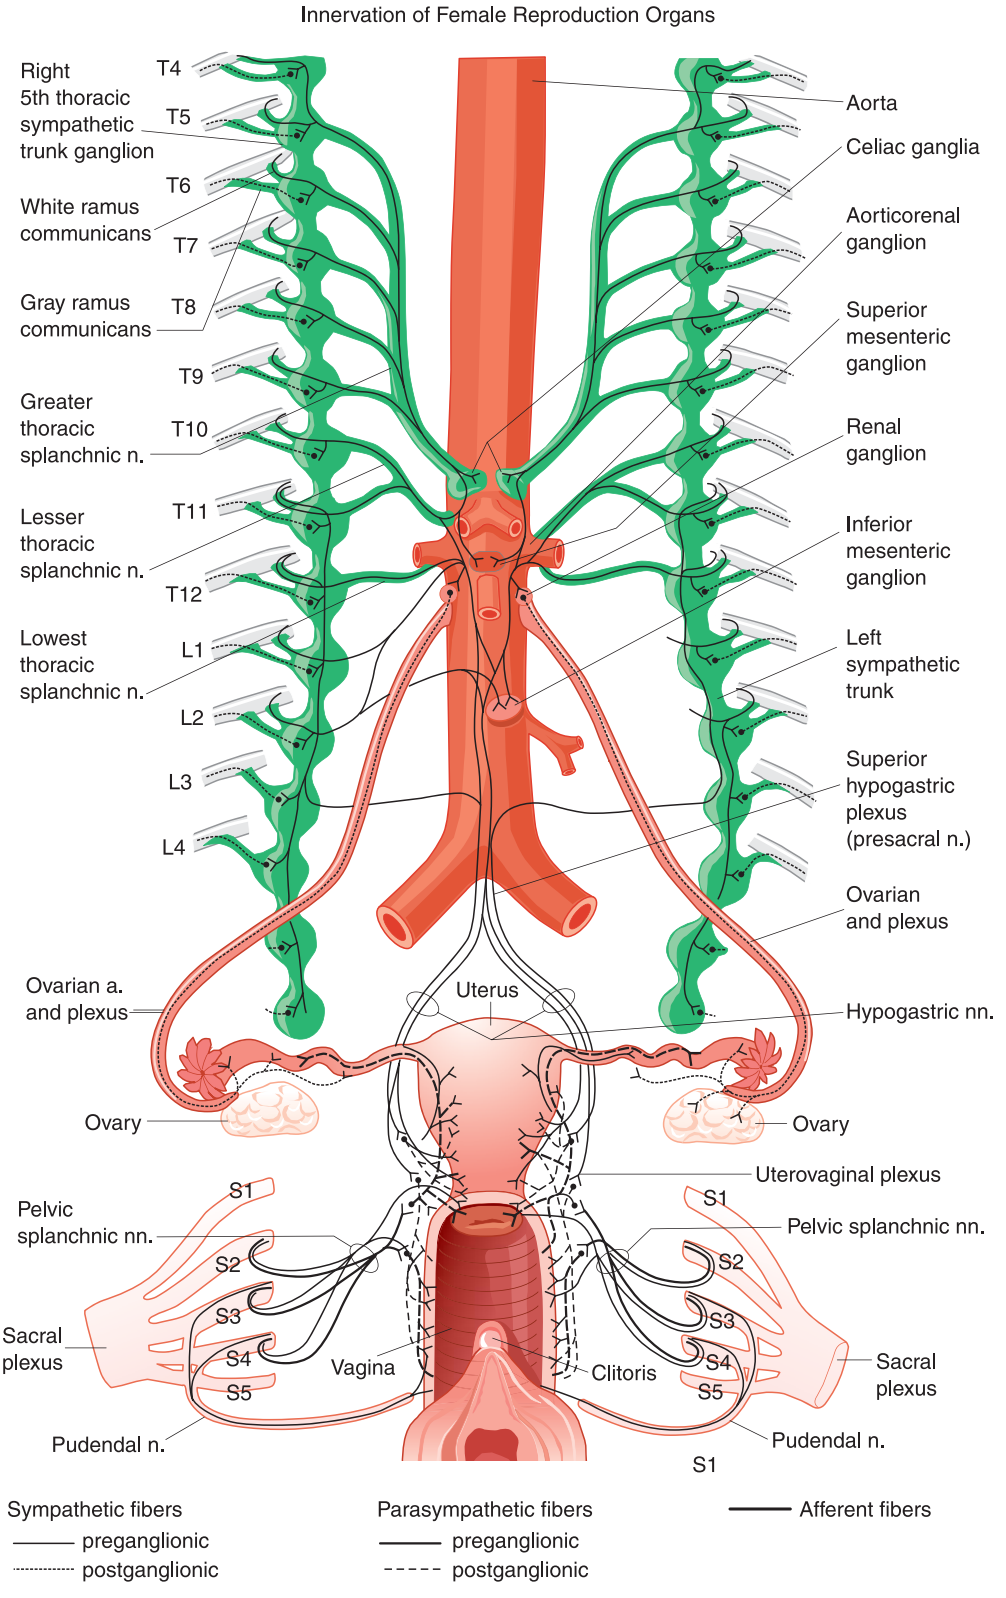

FIGURE 61–3. Innervation of female reproductive organs.

exposure to anesthetic agents. Compared to sedation with propofol and mask assisted ventilation with nitrous oxide, neuraxial techniques have been associated with fewer complications, especially nausea and emesis. Spinal anesthesia may be preferable to epidural anesthesia because of the reduced failure rate, lower systemic and follicular levels of anesthesia, and faster recovery profile.[26] Short-acting local anesthetics (1.5% concentrations of lidocaine or mepivacaine 45 mg) or low-dose longer-acting agents (0.75% bupivacaine 3.75 mg) can be used intrathe-

cally for these procedures, with good results. Use of low-dose bupivacaine may appeal to anesthesia providers hoping to reduce the incidence of transient radicular irritation associated with lidocaine or mepivacaine; however, a longer time to urination is witnessed and greater amounts of intrathecal opioids (25 μg) must be added.[26] The addition of small doses of intrathecal opioids (fentanyl 10 μg) to local anesthetics for spinal anesthesia improves postoperative analgesia for oocyte retrieval for the first 24 hours, with no increase in time to urination, ambulation, or discharge compared to local anesthetic alone.[27]

Pronuclear stage tubal transfer, zygote intrafallopian transfer, tubal embryo transfer, and gamete intrafallopian transfer are procedures that involve the transfer of gametes (sperm and oocytes) or embryos into the fallopian tubes during laparoscopy and local, regional, or general anesthesia. A general anesthetic with propofol and succinylcholine induction, intubation, and maintenance with isoflurane/oxygen and a short-acting muscle relaxant (e.g., atracurium or vecuronium) or a succinylcholine infusion can be used. A propofol with nitrous technique also can be used and has been observed to cause less postoperative sedation, lower pain scores, and less emesis compared to an isoflurane with nitrous technique.[12] Most embryo transfers occur 3–5 days after oocyte retrieval through a transcervical catheter technique that does not require sedation, analgesia, or anesthesia.

Postoperatively, especially following laparoscopic techniques, patients experience abdominal pain, uterine cramping, shoulder pain, nausea, and emesis. Pain is best treated with small doses of fentanyl (50–100 μg IV), as use of nonsteroidal antiinflammatory drugs may affect the prostaglandin milieu associated with embryo implantation.[12] Droperidol and metoclopramide for treatment of nausea and emesis should be avoided when possible because of the associated high prolactin levels and the potential for adverse fertility affects.[28] As with other outpatient procedures, patients should be able to drink and retain oral liquids, ambulate, and void before being discharged from the ambulatory procedure facility.

Special Concerns Based on the presence of preexisting disease states, preoperative evaluations for patients requiring assisted reproductive technologies may range from simple, immediate preprocedural discussions to more complex investigations that require time to collect consultant reports, laboratory studies, electrocardiograms, chest radiographs, and other testing results. All patients should be required to remain nil per os (nothing by mouth [NPO]) from solid foods from the midnight prior to the time of retrieval, and, if they have risk factors for aspiration (e.g., obesity, history of reflux), a nonparticulate antacid should be administered orally prior to the procedure. Use of IV metoclopramide, as a gastric prokinetic agent or as prophylaxis for nausea, should be used sparingly because of its relationship to hyperprolactinemia and adverse fertility effects.[28] Occasionally, a patient may not adhere to NPO policies, and, although delaying or cancelling the case is a viable option, the decision should consider the risks of not proceeding, particularly with an oocyte retrieval. If the window for maximal oocyte retrieval (34–36 hours following human chorionic gonadotropin [hCG] administration) is missed, spontaneous ovulation and loss of oocytes can occur, invalidating the considerable effort and expense leading to the retrieval procedure. More importantly, if follicle aspiration is not performed, the patient is at increased risk for ovarian hyperstimulation syndrome, with its potential for tension ascites, thromboembolic phenomena, renal and hepatic dysfunction, and mortality.[29] By contrast, the reduction in aspiration risk produced by delay or cancellation of the procedure is difficult to quantify, and a spinal anesthetic, instead of a technique that impairs airway reflexes, has an exceptional safety profile. As with all ambulatory surgical procedures, the ideal anesthetic results in effective pain relief with minimal postoperative nausea, sedation, pain, and psychomotor impairment.

Cerclage

A cervical cerclage is a circumferential suture placed around the cervical os to prevent pregnancy loss due to an incompetent cervix. It can be placed transvaginally or transabdominally with a laparoscopic technique. The clinical management guidelines from the American College of Obstetricians and Gynecologists acknowledge the limited data available on the efficacy of cerclages, yet the College suggests that an elective cerclage should be performed at weeks 13–16 of gestation in patients with a viable fetus and a history of three or more otherwise unexplained second-trimester pregnancy losses or preterm deliveries.[30] Urgent, or therapeutic, cerclages are often recommended for women with ultrasonographic changes consistent with a short cervix or evidence of funneling (i.e., internal cervical os dilation).[30]

When the cerclage procedure is performed transvaginally, a hyperbaric subarachnoid anesthetic with a local anesthetic that produces approximately 30–45 minutes of anesthesia is a good option in order to avoid maternal airway manipulation and minimize fetal anesthetic exposure. By contrast, if the cerclage is performed transabdominally, a general anesthetic with endotracheal intubation is recommended.

Special Concerns Although cerclage procedures are performed before week 20 of gestation, when the uterus transitions from a pelvic to an abdominal organ, the implications of NPO status and aspiration prophylaxis should be considered. The risk of aspiration during pregnancy, particularly early pregnancy, is controversial (see Chapter 21). However, in most situations requiring a cerclage placement, time exists to allow for gastric clearance and/or administration of aspiration prophylaxis.

External Cephalic Version

Use of external abdominal pressure to turn a fetus from a breech to cephalic presentation is called external cephalic version (ECV). Although the procedure is often performed in obstetric clinics without anesthetic intervention, improved maternal comfort, fetal safety, ECV success, and favorable cost-to-benefit analyses have been observed with neuraxial techniques.[31] Neuraxial techniques most likely improve ECV efficacy by relaxing the abdominal wall muscles, improving patient comfort during the attempt, and allowing the obstetrician to make a more concerted effort.[31,32]

Whereas most ECV attempts with epidural techniques are associated with significant increases in success and ultimate vaginal delivery with fewer total attempts,[33] spinal techniques have resulted in conflicting

outcomes. No improvement was observed with intrathecal bupivacaine 2.5 mg and sufentanil 10 μg (44% vs. 42%),[34] but significant improvement was found with use of intrathecal sufentanil 10 μg alone (80% vs. 33%).[32] The dichotomous outcomes most likely reflect obstetric provider or patient factors, including the amount of force applied and the extent of maternal discomfort tolerated for a given level of analgesia. In the more difficult setting of a repeat ECV after a previously failed attempt, a high success rate (83%) was reported with a spinal technique using lidocaine 45 mg with fentanyl 10 μg.[35] A CSE technique with a short-acting local anesthetic (1.5% lidocaine 45 mg) is the optimal technique for an ECV attempt because it allows for timely discharge from the hospital in the event of a successful version without labor, and, if a trial of labor or an operative delivery is warranted or precipitated, the epidural catheter can be used for additional analgesia or anesthesia.[35]

Special Concerns ECV attempts may lead to maternal and fetal complications, including fetal heart decelerations, placental abruption, preterm labor, uterine rupture, amniotic fluid embolism, nausea, emesis, and fetal demise. These adverse outcomes should encourage an ECV attempt in the operating room with maternal and fetal monitoring and with anesthesia providers readily available. Even if neuraxial techniques are not used for the ECV attempt, rapid administration of anesthesia may be necessary for maternal or fetal intolerance. Moreover, although tocolytics (terbutaline, ritodrine) are frequently used to relax the uterus prior to ECV attempts, IV nitroglycerin (50-μg bolus, wait 45 seconds prior to reattempt) has been reported to provide additional uterine relaxation.[35] Because nitroglycerin administration is often accompanied by hypotension, the anesthesia provider should encourage its use only with maternal and fetal monitoring and anesthesia provider presence.

In Utero Fetal and Placental Surgery

A growing number of interventions are being used to correct placental abnormalities and fetal defects in utero. Laser photocoagulation of placental vessels responsible for twin-to-twin transfusion syndrome, percutaneous catheter dilation of fetal cardiac valvular defects, and open hysterotomy with fetal repair of diaphragmatic hernias or resection of tumors are a few currently available procedures.[36] Ex utero intrapartum therapy, most commonly performed for large fetal head and neck tumors or severe heart and lung disorders immediately before cesarean delivery, allows partial fetal surgical exposure while maintaining placental circulation until an airway or alternate circulatory arrangement, such as extracorporeal membrane oxygenation, is secured.

Minimally invasive approaches with laparoscopic or percutaneous catheter techniques can be performed under local field blocks or neuraxial techniques. By contrast, operations that involve partial fetal exteriorization are best performed under general anesthesia for uterine quiescence and fetal anesthesia.[37] Fetal anesthesia and immobility can be augmented through intramuscular administration of opioids, muscular relaxants, and atropine to the fetus. Maternal postoperative analgesia can be improved with neuraxial preservative-free morphine (3 mg epidural, 0.2 mg subarachnoid), even if a general anesthetic is planned. Occasionally, more invasive monitoring, as with an arterial or central venous catheter, is warranted to allow for more immediate blood pressure and central venous pressure (CVP) monitoring and vascular access for laboratory studies during the perioperative and intraoperative periods.

Special Concerns The ability and timing of sentience, the capacity to experience painful or unpleasant sensations, in the fetus is a subject of growing interest and controversy.[38] Because structural and behavioral maturation ultimately determine the capacity to feel pain, the presence of reflex responses and cortical connections may not necessarily represent the ability to experience nociception. Although synapses to and from the cortex are present as early as 8.5 weeks of gestation, structures believed necessary for conscious pain perception, such as thalamic projections, intracortex connections, and synchronous electroencephalographic activity, have not been observed until 20 to 30 weeks.[38] Fetal analgesia or anesthesia, however, should be considered to prevent hormonal stress responses that may be associated with poor neonatal surgical outcomes or long-term neurodevelopmental and behavioral responses to pain and to inhibit fetal movement during procedures.[39] Fetal analgesia and anesthesia can be achieved by passive analgesic administration via maternal general anesthesia or by direct intramuscular injection into the fetus. Injection of narcotics directly into the amniotic fluid, which results in greater fetal than maternal concentrations in animal models, is a modality that may have application in the future.[40]

Labor and Vaginal Delivery

The pain of labor and vaginal delivery evolves through the first and second stages of labor (Fig. 61–3). The first stage of labor, defined as the onset of regular uterine contractions that result in progressive uterine cervical dilation, produces pain originating from both uterine and cervical stretching. Described as dull, aching, crampy, and poorly localized, the pain sensations are carried by visceral afferents entering the spinal cord at the T10 to L1 level. By contrast, the second stage of labor, defined as the time from complete cervical dilation to the delivery of the fetus, produces pain originating from vaginal and perineal stretching. More somatic in origin, the pain is sharp, discrete in location, and is carried by the lower lumbar and sacral fibers. Of interest, the contemporary pattern and progress of labor appear slower than previously described a half a century earlier.[41] Attributed to the greater maternal age and weight, increased fetal size, and significantly higher use of induction of labor, these factors may contribute to labor pain of longer duration.

A variety of techniques are used to provide analgesia during labor and delivery (Box 61–3). Neuraxial techniques have been demonstrated to be the most effective form for labor analgesia,[42] but there are some contraindications to their use (Box 61–2). Moreover, other techniques have been found to be useful or comforting for parturients and may add to overall maternal satisfaction with the birth experience. Various techniques are often used sequentially as labor progresses; however, their simultaneous use may not offer advantages greater than an epidural technique.

BOX 61–3.

Analgesic Techniques during Labor and Delivery

- Nonpharmacologic Techniques
  - Psychologic preparation
  - Emotional support
  - Touch and massage
  - Therapeutic heat and cold applications
  - Hydrotherapy
  - Biofeedback
  - Vertical or alternative positioning
  - Transcutaneous electrical nerve stimulation
  - Acupuncture/acupressure
  - Hypnosis
- Pharmacologic Techniques
  - Parenteral Agents
    - Opioids, opioids antagonist/agonists
    - Nonsteroidal antiinflammatory drugs
    - Barbiturates
    - Phenothiazines
    - Hydroxyzine
    - Scopolamine
    - Benzodiazepines
    - Ketamine
  - Inhalation Agents
    - Nitrous oxide
    - Volatile halogenated agents
  - Neuraxial Agents
    - Opioids
    - Local anesthetics
    - α_2-Agonists

Transcutaneous nerve stimulation, for example, does not appear to augment either epidural or CSE techniques.[43,44] Clear communication between the patient and all members of the healthcare team is essential for the proper timing of anesthetic care. In some cases, such as morbid obesity or preexisting back pathology, early placement of an epidural catheter with activation later during labor may be an optimal approach for maternal and fetal outcomes. The concern that neuraxial analgesia techniques could mask the pain of a uterine rupture in women with previous cesarean deliveries or uterine scars appears unfounded. Indeed, the presence of an epidural catheter in women undergoing vaginal birth after cesarean delivery may improve maternal and fetal outcomes by allowing for expedient cesarean delivery anesthesia if uterine rupture or fetal distress occurs. Overall, the use of epidural, spinal, and CSE techniques should be evaluated for each parturient because the duration of labor and the mode of delivery are not known a priori in most cases. Should the patient desire or require analgesia or anesthesia, a catheter-based technique allows for the most flexibility.

Epidural Analgesia The epidural technique is the most common neuraxial technique used for labor analgesia because of relatively rapid sensory analgesia with minimal motor blockade, uterine effects, and maternal or fetal toxicity (Fig. 61–2).[45] Almost all local anesthetics can be used in low concentrations; however, the longer-acting agents allow for less variation in the quality of analgesia (Table 61–1). Bupivacaine, which provides a high ratio of sensory to motor block, is the most commonly used agent for labor epidural analgesia worldwide. Ropivacaine and levobupivacaine are newer long-acting agents that, when given in equipotent concentrations to bupivacaine, may result in slightly less motor blockade and fewer cardiotoxic effects should intravascular absorption occur.[46,47] Epidural narcotics alone provide sufficient analgesia for the first stage of labor (Table 61–2),[48] but the combination of small doses of sufentanil (0.2–0.3 μg/mL) or fentanyl (0.2 μg/mL) with low doses of bupivacaine (0.0625–0.125%) is necessary for second-stage labor and vaginal delivery. An epidural bolus of fentanyl 100 μg with or without local anesthetic can improve maternal comfort during the second stage of labor when patchy analgesia or perineal sparing cannot be remedied with local anesthetics alone.[49]

Once the initial sensory blockade has been established, epidural analgesia can be maintained by intermittent bolus injections, continuous infusion, or both techniques simultaneously. The development of inexpensive infusion pumps has offered perhaps the optimal method: continuous infusion coupled with patient-controlled intermittent bolus injections through the epidural catheter. This combined method reduces the total amount of medication used, decreases the amount of motor blockade, and increases patient satisfaction compared to continuous infusions or intermittent bolus methods alone.[50]

Should an instrumental or operative delivery, laceration repair, or postpartum tubal ligation occur, labor epidural analgesia can be transitioned to anesthesia with a change in the concentration or type of local anesthetic used through the catheter (Table 61–1). Vacuum or forceps deliveries often require denser perineal sensory anesthesia for placement of instruments than offered by contemporary labor analgesia infusion concentrations as noted earlier in this section. This can be accomplished using 6–7 mL of 1% lidocaine solution with 8.4% bicarbonate in a 10:1 ratio. Increasing the sensory level from the tenth to the seventh or eighth thoracic dermatome also will allow for more rapid anesthetic extension to a fourth thoracic dermatome should the need for an emergent cesarean delivery develop.

Spinal Analgesia The limited duration of action of a single injection and the increased risk of PDPH with multiple injections limit the utility of spinal anesthesia for the management of labor. Spinal techniques, however, can be used successfully in the immediate peripartum period, especially in the event of a precipitous vaginal delivery, use of outlet forceps or vacuum extractions, or repair of extensive perineal lacerations. Short-acting, low-level spinal anesthesia can be used for many of these procedures; however, the range of likely obstetric outcomes should be evaluated carefully. A delivery by "trial of forceps," for example, can quickly transition to an urgent cesarean delivery. Spinal techniques that offer more flexibility include the CSE technique and a spinal catheter technique.

Combined CSE Analgesia The CSE technique for labor analgesia has increased in popularity.[45] When placed early in labor and compared to parenteral opioid or standard epidural techniques, a CSE technique with narcotics alone or in combination with local anesthetics may have beneficial effects on motor ability and the progress of labor.[51,52] Used later in labor, the CSE technique can provide quick onset of analgesia and the ability to extend the duration or level of the blockade should delivery methods mandate such augmentation.

Special Concerns ***Progress of Labor*** Whether central neuraxial analgesia affects the progress and out-

come of labor remains a controversial topic. The myriad of maternal and fetal variables and the differences in anesthetic and obstetric practices are confounding factors in such studies. Moreover, methodologic problems, such as difficulties in randomization and blinding, make an association difficult to evaluate. Overall, however, the use of epidural analgesia appears to have little affect on the progress and outcome of labor. A meta-analysis of 10 trials comparing parturients of mixed parity randomized to epidural analgesia or parenteral opioids noted a prolongation of the first and second stages of labor by 42 and 14 minutes, respectively, in association with the use of epidurals.[53] Despite the belief that an arbitrary threshold of 5 cm of cervical dilation should be achieved prior to epidural analgesia administration to prevent cesarean delivery,[54] early (<4 cm) placement of CSE labor analgesia versus parenteral opioids[51] or standard epidural techniques[52] has resulted in shorter times to achieve full cervical dilation with no alterations in the cesarean delivery rate. Overall, the risk of cesarean delivery does not appear to be increased with the use of neuraxial labor analgesia.[55]

Anesthetic Complications A number of complications may occur following neuraxial techniques (Table 61–3). Hypotension, defined as a 20–30% decrease in systolic blood pressure from baseline, can be observed in 20–100% of pregnant women as a result of the sympathetic vasomotor blockade associated with neuraxial analgesia and anesthesia.[56] Left uncorrected, hypotension may result in decreased uteroplacental perfusion, fetal hypoxia, and acidosis.[57] Preventive measures include maternal intravascular volume expansion with 500 mL of colloid (e.g., hetastarch) or 1000 mL of crystalloid (e.g., lactated Ringer solution) within 15 minutes of the neuraxial technique and positioning with a 15° left lateral tilt to avoid uterine aortocaval compression. Although IV titrated doses of vasopressors, such as ephedrine 5–10 mg or phenylephrine 40–100 μg, can be used prophylactically, the occurrence and extent of hypotension are unpredictable; thus, many regimens have focused on using these agents as treatments rather than prophylaxis. The nausea and vomiting following neuraxial techniques may be associated with reductions in sympathetic tone, blood pressure, and cerebral blood flow and can be reduced significantly with vasopressor use.[58] PDPH occurs in approximately 1–3% of the obstetric population following dural puncture and is related to needle size and tip design, with larger, cutting (beveled) needles associated with a greater incidence.[59] Typically, PDPH presents as a positional headache that worsens and improves in the upright and recumbent positions, respectively. The differential diagnosis should include other types of headaches, hypertensive disorders, infectious diseases, dural venous sinus thromboses, and other intracranial pathologies. If the diagnosis of PDPH is made, bed rest may aid in pain relief,[60] and conservative measures of hydration and oral intake of caffeinated and analgesic products (including Fioricet or Fiorinal) can be used for 24–48 hours. An epidural blood patch, with 10–20 mL of autologous blood placed in the epidural space, has been associated with a >80% incidence of success in most trials.[59,61] Although significant complications (e.g., cauda equina syndrome, transverse myelitis, arachnoiditis, spinal–epidural abscesses, and vascular trauma) following neuraxial analgesia and anesthesia in the obstetric population are extremely rare,[61] when signs and symptoms are unclear or rapidly progressing, consultation with a neurologist may assist in diagnosis and treatment. Finally, an unexpected high level of anesthesia can result in hypotension, dyspnea, inability to speak, and loss of consciousness. Ventilatory and circulatory support should always be readily available when these techniques are provided.

Of interest, relatively few complications are inherent to CSE technique per se. The risks of a dural puncture with an epidural needle may actually be reduced, as CSF within the spinal needle can be used to confirm proximity to the epidural space. The likelihood of the epidural catheter passing through the spinal needle dural puncture site is low in laboratory and clinical studies.[62] Epidural analgesia following a dural puncture has been observed to have a faster onset and improved sacral spread, especially when epidural dosing is performed immediately after the dural puncture with surgical local anesthetic concentrations.[63] The timing and dose of the epidural bolus and the size of the dural puncture may have relevance. Labor analgesia medications placed in the epidural space appear to have limited passage through a 27-gauge dural puncture.[64] The risk of a high spinal blockade as a result of a CSE technique appears negligible. The failure of an "untested" epidural catheter following the spinal portion of a CSE technique is a potential concern, but epidemiologic evidence suggests that CSE epidural catheters have a lower failure rate than does the epidural technique alone.[65] In parturients with difficult airway access or those with a high probability of an instrumental or operative delivery, a standard epidural technique, which tests the function of the catheter at the time of placement, may be a safer alternative.

Cesarean Delivery

With the advent of fetal heart rate and tocodynamometric monitoring, a reduction in breech and forceps-assisted deliveries, and the changing social and medicolegal environment, cesarean deliveries now account for 25–30% of deliveries nationally and internationally.[66] Although anesthesia-related maternal mortality has been declining during the last few decades, it still accounts for 3–12% of maternal deaths, with the majority associated with general anesthesia secondary to failures in intubation, ventilation, and oxygenation. As such, the use of regional neuraxial techniques has been strongly preferred. However, the urgency of the procedure, the health and comorbidities of the mother and fetus, and the desires of the mother and healthcare providers must be considered when deciding on the optimal anesthetic technique.

Cesarean delivery is performed most commonly through a low transverse abdominal incision (Pfannenstiel) above the pubic crest, with dissection of the fascia and separation of the rectus muscles. Following opening of the peritoneum, a transverse uterine incision (hysterotomy) typically is used for delivery of the fetus. Advantages of the transverse incision include better cosmetic results, less pain, and low incidence of hernia formation. Disadvantages include limited access to the upper abdomen, a greater incidence of subfascial hematomas from small perforating vessels through the rectus muscle, and increased nerve injury resulting in overlying skin paresthesias. In the setting of a

TABLE 61–3.

Major Complications of Neuraxial Analgesia and Anesthesia

	Transient Neurologic Syndrome	Cauda Equina Syndrome	Traverse Myelitis	Anterior Spinal Artery Syndrome	Arachnoiditis	Epidural Hematoma	Epidural Abscess
Signs and symptoms	Pain in lower back and/or buttocks	Pain in low back with variable motor and sensory deficits	Pain in low back with motor weakness and sensory alterations	Painless loss of motor and sensory function	Pain in low back with variable motor and sensory deficits	Pain or pressure in low back with progressive motor or sensory blockade	Pain in low back that is tender on palpitation and accompanied by sensory or motor deficits and fever; may progress
	With/without unilateral or bilateral radicular pain described as aching, burning, or cramping	Unilateral or bilateral radicular pain, sensory loss particularly in the saddle region	Allodynia (heightened sensitivity to touch)	Preservation of vibration and joint position	Unilateral or bilateral pain that increases with activity	Unilateral or bilateral radicular pain	Unilateral or bilateral radicular pain
		Bladder and bowel dysfunction	Bladder and bowel dysfunction			Bladder and bowel dysfunction	Bladder and bowel dysfunction
Cause	All contemporary local anesthetics	Ischemic compression by hematoma or abscess, or direct neurotoxicity, possibly due to prolong nerve exposure to high doses or concentrations of local anesthetics	Exact cause unknown; however, infections, abnormal immune reactions (e.g., lupus), ischemia, and multifocal neurologic disease (e.g., multiple sclerosis), and neuraxial techniques have been suggested	Hypotension, disruption of blood supply, vasoconstrictors or vasospasm	Disinfectants, local anesthetics, contrast media, blood, infections, vasoconstrictors, hemorrhage, multiple spinal surgeries	May occur spontaneously, after trauma, or after instrumentation; higher risk if abnormal coagulation status at time of instrumentation or catheter removal	Bacterial, immunocompromised patients are at higher risk; nonsterile techniques involving neuraxial technique
Testing	None	MRI	MRI or myelogram	MRI and angiogram	MRI or myelogram	MRI	MRI
Consults	Anesthesiologist	Neurologist and/or neurosurgeon	Neurologist	Neurologist	Neurologist	Neurologist and/or neurosurgeon	Neurologist and/or neurosurgeon
Onset	12–24 h after surgery		Acutely (hours to days) or subacutely (1–2 wk).	Following insult whether surgical or traumatic	May occur years after the precipitating cause	Spontaneously, or 0–2 days after insult,	2–7 days after instrumentation

TABLE 61–3.

Major Complications of Neuraxial Analgesia and Anesthesia (Continued)

	Transient Neurologic Syndrome	Cauda Equina Syndrome	Traverse Myelitis	Anterior Spinal Artery Syndrome	Arachnoiditis	Epidural Hematoma	Epidural Abscess
Treatment	Nonsteroidal anti-inflammatory drugs Opioids Heat Muscle relaxants Leg elevation	Corticosteroids (limited data)	Corticosteroids (no clinical data), pain management, physiotherapy, exercise, psychotherapy	Correction of any existing hypotension, correction of vasospasm, physiotherapy, exercise	Pain management, physiotherapy, exercise, psychotherapy Steroid injections and electrical stimulation may be helpful Surgical intervention usually not helpful	Surgical decompression usually is indicated within 6–12 hours of symptom onset	Intravenous antibiotics, percutaneous drainage, laminotomy with washout of epidural space, laminectomy
Recovery	Full	Limited clinical data	Within 2–12 wks of symptom onset and continue for up to 2 y; if no improvement within 3–6 mo, significant recovery unlikely	Variable, may have full, partial, or no recovery	No significant improvement with treatment; usually a chronic pain disorder that is not progressive	Variable and dependent on extent of neurologic involvement and treatment	Variable, dependent on extent of neurologic involvement and treatment
Duration	Symptoms last for 6 h to 7 days	Variable	Variable	Variable	Incurable	Variable	Variable

MRI, Magnetic resonance imaging.

TABLE 61–4.

Medications Used to Augment Uterine Tone in Obstetric and Gynecologic Surgery

Medication	Uses	Route of Administration	Risks
Oxytocin	Induces labor, increases uterine tone	IV infusion; no more than 20 units/1000 mL solution	Uterine hyperactivity; hypotension; reflex tachycardia; ADH-like response if given in high doses with risk of water intoxication; should be given in electrolyte-containing solutions, not dextrose in water
Ergonovine	Increases uterine tone	IM/oral	Peripheral vasoconstriction
Methylergonovine	Increases uterine tone	IM 0.2 mg	Acute hypertension, seizures, cerebrovascular accidents, retinal detachment if given IV; use with caution in patients with coronary artery disease, essential hypertension, preeclampsia, atherosclerotic disease; nausea and vomiting may reflect direct central nervous system effect
Prostaglandin E_2	Increases uterine tone	Oral, rectal, or vaginal; dose depends on desired effect	Nausea, vomiting, diarrhea, fever, tetanic uterine contractions, hypotension; hypertension
Prostaglandin $F_{2\alpha}$	Increases uterine tone	IM 0.25 mg	Nausea, vomiting, bronchospasm; tetanic uterine contractions; hypotension; hypertension

ADH, Antidiuretic hormone; IM, intramuscular; IV, intravenous.

preterm cesarean delivery, especially prior to elongation of the lower uterine segment in the week 34 of gestation, the hysterotomy is sometimes performed with a vertical incision for greater surgical exposure. Because a vertical uterine incision is more prone to dehiscence or rupture with uterine contractions, all subsequent pregnancies must undergo a cesarean delivery.

Regardless of the type of incision, uterine tone may be compromised in preterm deliveries as the number of oxytocin receptors increases closer to term. Uterine tone may be further limited in conditions that augment the size of the uterus, such as polyhydramnios, multiple gestation, and fibroids. Uterine atony accounts for 75–90% of postpartum hemorrhage and remains a leading cause of postpartum hysterectomy and blood transfusion. In an attempt to reduce the incidence of uterine atony and its sequelae, initial efforts at time of cesarean delivery include uterine massage and IV oxytocin, a uterotonic medication (Table 61–4).[67] Doses of oxytocin range from 5–20 IU in 500 or 1000 mL of lactated Ringer solution at a rate of 10 mL/min until the uterus remains firmly contracted. The infusion rate is then reduced to 1–2 mL/min. Oxytocin, particularly when given as an IV bolus, has been associated with morbidity, including hypotension, nausea and vomiting, antidiuretic effects leading to fluid retention and pulmonary edema, and even death from cardiovascular collapse.[68,69] Other more powerful uterotonic agents, including prostaglandins (15-methyl-prostaglandin 250 μg) and ergot preparations (methylergotamine 200 μg) can be administered intramuscularly or directly into the myometrium at intervals of 15–20 minutes to a total dose of 1 mg. These agents, however, are associated with significant side effects, including nausea, bronchospasm (especially with prostaglandins), hypertension, pulmonary edema, and cerebral hemorrhage.[70] Should these medical therapies fail, uterine or hypogastric artery ligation, interventional arterial balloon catheterization, or hysterectomy may be necessary.

Spinal Anesthesia A simple and reliable technique with rapid onset, spinal (subarachnoid) anesthesia provides an awake and comfortable patient with minimal risks for pulmonary aspiration of gastric contents. Despite the lower abdominal incision, a T4 sensory dermatome level is required to prevent referred pain from traction on the peritoneum and uterus. The type and dose of local anesthetic used to provide the spinal anesthetic must include consideration of the level of anesthesia desired, duration of surgery, postoperative analgesia plan, and preferences of the anesthesiologist. Spinal administration of hyperbaric 0.75% bupivacaine with fentanyl and preservative-free morphine may be the optimal combination (Box 61–4). The almost immediate onset of fentanyl reduces visceral discomfort and even nausea during the procedure, whereas the delayed onset and 18 to 20-hour duration of morphine provides prolonged relief following the procedure. Although ropivacaine and levobupivacaine can be used in similar concentrations and doses, the potential for reduced toxic-

BOX 61–4.

Optimal Neuraxial Medication Combinations for Cesarean Delivery

Medication	Spinal	Epidural
Local anesthetic	Bupivacaine 12 mg (range 9–15)	Lidocaine 2%; chloroprocaine 3% if urgent. Both added in 10:1 volume ratio to 8.4% bicarbonate
Fentanyl	15–35 μg	50–100 μg
Morphine	0.1 mg	3.75 mg

ity should intravascular absorption occur seems limited given the extremely small doses of agents used. Adjuvant spinal medications, including epinephrine, may augment the quality and duration of the anesthesia and analgesia.[71,72]

Following administration of a subarachnoid technique, the patient may complain of dyspnea. This can occur because of several factors, including blunting of thoracic proprioception, partial blockade of abdominal and intercostal muscles, and increased pressure of the abdominal contents against the diaphragm in the recumbent position. Despite these changes, significant respiratory compromise is unlikely as the blockade rarely affects the cervical nerves that control the diaphragm. Should the patient lose the ability to vocalize, give a strong hand grip, or demonstrate oxygen desaturation by pulse oximetry, a rapid sequence induction of general anesthesia, with cricoid pressure and placement of an endotracheal tube, can be performed to maintain ventilation and prevent pulmonary soiling with gastrointestinal contents.

The most common complications of spinal anesthesia have been described earlier under Anesthetic Complications and include hypotension, nausea and vomiting, and risk of PDPH.

Epidural Anesthesia Use of epidural anesthesia for cesarean delivery has increased during the past 2 decades, primarily as a result of its use for labor analgesia. Although medications used in the spinal and epidural space are identical, epidural doses are 5–10 times greater and given in much larger volumes to encourage adequate blockade and spread of the drug. Overall, a greater sensitivity of nerves to local anesthetics during pregnancy has been observed clinically through decreased anesthetic requirements for epidural blockade,[73,74] For cesarean delivery, the most commonly used agents are 2% lidocaine with epinephrine 1:200,000 or 3% 2-chloroprocaine. Chloroprocaine is the agent of choice for emergency cesarean deliveries because of its rapid onset and rapid maternal and fetal metabolism; fetal accumulation, especially when acidosis is present, is minimized.[75] By contrast, chloroprocaine is avoided for routine nonurgent deliveries because the short duration requires multiple doses, and its use can adversely affect the efficacy of subsequent epidural opioid analgesia.[76] In addition, chloroprocaine used in higher total volumes (>40 mL) can increase the incidence of back pain.[77] Alkalinization with sodium bicarbonate hastens the onset time of local anesthetics significantly and is recommended for use in urgent cesarean deliveries with 1 mL of 8.4% bicarbonate for every 10 mL of lidocaine or chloroprocaine (Fig. 61–4).[78] By contrast, 10 mL of bupivacaine, levobupivacaine, or ropivacaine precipitates out of solution with <0.5 mL of bicarbonate, leading to an inability to inject the local anesthetic through a needle or catheter; therefore, bicarbonate should not be added to these longer-acting local anesthetics.[79]

The complications of epidural anesthesia have been described previously under Anesthetic Complications and include hypotension, risk of PDPH, systemic toxic reactions, and, rarely, neurologic complications. Epidural techniques can provide patchy or inadequate blockade due to anatomic or technical reasons.[80] Often, these failures can be identified a priori through observation of the quality of labor epidural analgesia or quickly after partial augmentation of the blockade. Alternative techniques, such as supplementation with IV or inhalational agents, spinal anesthesia, or general anesthesia, must always be considered as options when analgesia is clearly inadequate.

CSE Anesthesia The principal advantage of the CSE technique for cesarean delivery is the ability to augment the density or duration of the anesthesia administered via the epidural catheter. This is particularly useful in obstetrics where a trial of labor may be attempted prior to an operative delivery, or the duration of the surgery may be prolonged (e.g., possible placenta accreta, history of multiple abdominal surgeries, high index of suspicion for gravid hysterectomy). A guiding principle in the selection of the CSE technique is whether the parturient appears to have an airway that would be difficult to intubate. A patient who presents as an intubation risk perhaps would be better served by avoiding the CSE technique, as the epidural catheter is "untested" and may not provide optimal anesthesia. In such cases, an epidural technique is often used to initiate and maintain anesthesia.

Special Concerns during Cesarean Delivery Although regional anesthesia is used whenever possible to avoid the potential airway complications associated with general anesthesia, certain conditions or time constraints may contraindicate its use (Box 61–2).[81] Such comorbidities include localized infection or generalized sepsis, coagulation disorders, severe hypovolemia, and cardiac pathologies where hypotension may be especially

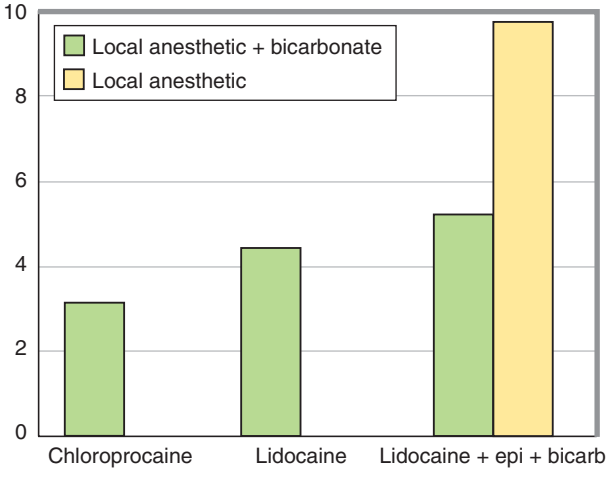

FIGURE 61–4. Extension of labor epidural analgesia for cesarean delivery. Onset (in minutes) for extension of T10 labor analgesia to T4 cesarean anesthesia. Note the values for chloroprocaine and bicarbonate. (Based on data from Gaiser RR, Cheek TG, Adams HK, et al. Epidural lidocaine for cesarean delivery of the distressed fetus. Int J Obstet Anesth 1998;7:27–31; Lam DT, Ngan Kee WD, Khaw KS. Extension of epidural blockade in labour for emergency Caesarean section using 2% lidocaine with epinephrine and fentanyl, with or without alkalinisation. Anaesthesia 2001;56: 790–794.)

detrimental. Severe obstetric hemorrhage in the antepartum period, including uterine rupture and acute and severe fetal distress also may contraindicate the use of regional anesthesia procedures because of the time necessary to establish a surgical anesthetic.

Patients with severe preeclampsia or hypertension may undergo rapid hemodynamic changes with regional techniques; however, both epidural and spinal techniques can be used successfully in this setting.[82,83] In addition, gravid hysterectomies can be performed safely with regional techniques.[84] Overall, however, general anesthesia should be considered if questions exist regarding the ability of maternal compensatory mechanisms to react to the regional anesthetic or surgery.

Hypotension presents the greatest risk to maternal and fetal comfort and health.[56] Prevention and prompt treatment with IV fluids and administration of vasopressors have been beneficial but may not be completely successful.[85,86] In terms of volume expansion, spinal anesthesia in the urgent setting should not be delayed until a fixed arbitrary volume has been infused. In addition, aggressive hydration with large fluid volumes (>20 mL/kg crystalloid) may increase the risk of edema with only limited reductions in hypotension.[85] Colloid solutions appear to be more effective than crystalloids in preventing the hemodynamic consequences of spinal anesthesia.[87] However, in most cases the allergic, cost, and coagulation implications offset their benefit. Current investigations into the use of vasopressors for prevention and treatment of hypotension in this setting include use of phenylephrine, sometimes in combination with ephedrine, administered via bolus and infusion pump techniques.[88,89] Although most animal studies indicate combined α- and β-adrenergic agonists (e.g., ephedrine) are more effective than α-adrenergic agonists (e.g., metaraminol, phenylephrine) in terms of restoration of maternal blood pressure and fetal acid–base status, clinical investigations appear to favor the use of α-adrenergic agonists.[90] Because clinical and animal data do not support a single agent in all circumstances, a rational strategy is vigilance and a proactive response with both ephedrine and phenylephrine as guided by maternal blood pressure and heart rate.

Nausea and emesis during and after cesarean delivery can have a number of causes but are best prevented by controlling hypotension, optimizing the use of neuraxial and IV opioids, improving the quality of surgical blockade, minimizing surgical stimuli, and judiciously administering uterotonic agents.[91]

Although pruritus following neuraxial blockade is attributed to a number of postulated mechanisms and has several treatments,[92] a narcotic antagonist or partial antagonist (e.g., nalbuphine 4 mg IV) appears more effective than some other modalities. Postoperative shivering also may have several etiologies and treatments. IV meperidine 25 mg, clonidine 150 μg, doxapram 100 mg, ketanserin 10 mg, and alfentanil 250 μg all have been used with success, although meperidine appears to be the most consistently effective.[93]

General Anesthesia There are few, if any, absolute contraindications to general anesthesia. However, regional anesthesia remains a preferred method to avoid the risks of airway management and allow the patient the ability to witness delivery of the fetus. General anesthesia, however, may offer advantages in cases where uterine relaxation would be beneficial, such as extracting difficult breech presentations, removing retained placentas, restoring uterine inversions, and performing in utero fetal operations.

The importance of proper airway evaluation during the antenatal period or in early labor, if possible, cannot be overemphasized, as failed intubation, failed ventilation and oxygenation, and/or pulmonary aspiration of gastric contents are the leading anesthetic causes of maternal death.[94,95] If the airway evaluation suggests a difficult intubation or risk factors for a difficult neuraxial placement (e.g., morbid obesity, scoliosis, dropping platelet count), the establishment of a continuous neuraxial technique early in labor should be strongly encouraged.[96] If the parturient does not desire epidural analgesia during labor, the epidural catheter still can be placed, tested for a bilateral sensory distribution with 6–7 mL of 1–2% lidocaine with bicarbonate, and then allowed to wear off until such time that analgesia or anesthesia is desired. If a difficult airway is discovered during a rapid sequence intubation attempt, options include allowing the patient to awaken, using alternate techniques (e.g., fiberoptic- or light-guided intubation) to place an endotracheal tube, or using alternative airway devices (for a detailed review of airway management, see Chapter 35). Although the laryngeal mask airway (LMA) cannot prevent pulmonary soiling with gastric contents, it can be a lifesaving measure in failed intubation situations.[97] It has been used without adverse sequelae with continuous cricoid pressure held for the duration of cesarean delivery.[98] Emergency airway equipment should be readily available in all obstetric operating rooms.

Attempts should be made to minimize the risk of maternal aspiration, even when the need for intubation is not anticipated. With an elective cesarean delivery, adherence to an NPO policy for 8 hours prior to surgery is advised. A nonparticulate antacid is believed to decrease damage to the respiratory epithelium if aspiration occurs,[99] and H_2 antagonists (cimetidine, ranitidine) and promotility agents (metoclopramide) can reduce gastric acid secretion and facilitate emptying, respectively.[100,101]

The patient should be placed supine with left uterine displacement and optimal airway positioning. Following the placement of routine monitors, including electrocardiography, pulse oximetry, blood pressure, and capnography, preoxygenation and denitrogenation with 100% oxygen should be performed to delay the onset of hypoxemia stemming from the parturient's decreased functional residual capacity and increased oxygen consumption. In urgent situations, four maximal (i.e., approaching vital capacity) breaths of 100% oxygen will provide adequate preoxygenation.[102] After the surgical drapes have been applied and the operating personnel are ready at the bedside, the surgeon should be instructed to delay the initial incision until the anesthesia provider confirms correct placement of the endotracheal tube and gives verbal confirmation to proceed with the operation. A rapid sequence induction with full cricoid pressure after induction with thiopental 4–5 mg/kg and succinylcholine 1–1.5 mg/kg is performed. Ketamine 1–1.5 mg/kg should be substituted for thiopental if hemodynamic instability is present prior to induction. Cricoid pressure should be continued until correct positioning of the endotracheal

tube is validated with auscultation and confirmation of carbon dioxide. A short-acting nondepolarizing agent or succinylcholine infusion can be used to maintain muscle relaxation. In most instances, <50% FiO_2 is sufficient, but 100% FiO_2 oxygen should be used If fetal compromise exists. Some evidence suggests that >60% FiO_2 may result in detrimental fetal oxygen free radical formation in the fetus.[103] Maintenance of anesthesia can be provided with volatile anesthetics titrated as necessary; however, upon delivery, concentrations should be reduced to <1–1.5 MAC, the threshold above which relaxation of uterine tone cannot be attenuated with oxytocin. No advantage in minimizing uterine tone relaxation or fetal effects has been found with the selection of specific volatile anesthetic agents (isoflurane, sevoflurane, or desflurane). Overall, a 25–40% reduction in halogenated agent requirements is witnessed during pregnancy.[104] Comparison of neonatal outcomes following general versus epidural anesthesia for cesarean delivery suggests small, transient differences.[105] However, with both techniques, a uterine incision to delivery time >180 seconds can result in lower Apgar scores and greater fetal acidosis (most likely reflecting the difficulty in delivering the baby rather than direct effects of the anesthetic agents).[106] General anesthetic agents can redistribute from the fetal fat to the fetal circulation and result in secondary depression of neonatal ventilatory effort. Thus, the presence of a pediatrician in such cases is advisable until a normal ventilatory pattern is observed.

Postoperative Pain Management

By directly activating spinal and supraspinal opioid receptors, epidural and spinal opioids blunt nociceptive input and produce analgesia of greater intensity than doses administered parenterally or intramuscularly (see Chapter 74).[7] Morphine has emerged as the leading agent for postcesarean section analgesia because of its long duration of action and low cost (Table 61–2); optimal doses are 0.1 and 3.75 mg in the intrathecal and epidural spaces, respectively.[71,107] Because of its low lipid solubility, the peak analgesic effects of morphine are delayed 60–90 minutes but persist to provide reliable analgesia for up to 24 hours.[107] A sustained-release epidural morphine preparation that can provide up to 48 hours of postcesarean section analgesia has been developed[108]; however, its use is limited by its immediate release when mixed with local anesthetics and the inability for its use in the intrathecal space. Thus, it is being used as a part of a CSE technique, where the local anesthetic is placed in the intrathecal space, followed by administration of morphine in the epidural space.

The choice of local anesthetic for epidural anesthesia may influence the efficacy of epidural morphine. In parturients who received 2-chloroprocaine (a short-acting, rapid-onset local anesthetic used primarily for emergent cesarean deliveries) versus other local anesthetics, postcesarean section analgesia was significantly reduced to <3 hours.[109] The mechanism by which chloroprocaine affects the duration of opioids, as well as other local anesthetics, is unknown. These interactions, coupled with the potential for neurotoxicity, especially when preserved with metabisulfite, limit the use of chloroprocaine to emergent situations where rapid augmentation is desired.[110] Patient-controlled epidural infusions of low-concentration local anesthetics with opioids (e.g., bupivacaine 01.25% with hydromorphone 0.2 mg/mL or fentanyl 2 μg/mL at 6 mL/h) may offer an analgesic option in patients in whom a prolonged analgesia is desired.[111]

Postoperative analgesia has been greatly improved through the use of central neuraxial techniques, most commonly provided through a single-dose administration of morphine. Given in the spinal and epidural compartments, opioids provide enhanced quality and duration, with a very acceptable side effect profile compared to oral or IV analgesics.

Considerations for the High-Risk Parturient

Antenatal and Postpartum Hemorrhage

Vaginal bleeding occurs in up to 24% of clinically diagnosed pregnancies and most often is associated with minimal blood loss and limited pathology. Major antepartum and postpartum bleeding may occur at any time and is a leading cause of maternal and perinatal morbidity and mortality. What constitutes "bleeding" versus "hemorrhage" is an issue of semantics. More important is recognizing that blood loss and physiologic deterioration can occur rapidly and that a cogent plan of investigation and response can significantly affect the outcome.

Divided by week 20 of gestation into early and late time periods, antepartum hemorrhage is associated with a number of etiologies. Early-pregnancy bleeding can result from implantation or miscarriage of the embryo, an ectopic pregnancy, gestational trophoblastic disease, dysfunctional uterine bleeding, and reproductive tract tumors. In first-trimester pregnancies complicated by bleeding, <50% will progress normally beyond 20 weeks of gestation, 10–15% will be an ectopic pregnancy, 0.2% will be a hydatidiform mole, and >30% will result in a miscarriage.[112] Bleeding during late pregnancy complicates 2–5% of pregnancies, with the most common causes being placental abruption (31%) and placenta previa (22%; Table 61–5).

Although obstetric hemorrhage can be masked by physiologic adaptations in blood volume and cardiac output (see Chapter 21), ultimately, the 600–700 mL of blood flow through the placental intervillous spaces each minute can result in signs of shock (Table 61–6).[113] Coagulopathy, initially dilutional from the ongoing loss of blood components and rapid volume replacement, may be accompanied by disseminated intravascular coagulation (DIC). Laboratory analysis of DIC includes a prolonged prothrombin time (PT), prolonged partial prothrombin time (PTT), hypofibrinogenemia, thrombocytopenia, and elevated fibrin degradation products (FDPs).

Underestimation of blood loss and inadequate resuscitation are common problems in cases of antepartum hemorrhage resulting in maternal mortality. In a report on maternal deaths in the United Kingdom, substandard responses were noted to be a contributing factor in 79% of maternal deaths resulting from hemorrhage.[114] Rapid volume replacement is more important for tissue perfusion and oxygenation than is the type of fluid given. Large-bore IV access with pressurized transfusion equipment is essential during severe hypovolemia. Intravascular expansion with colloids versus crystalloid preparations during pregnancy has been observed to be longer in duration and more effective in augmenting cardiac output. These qualities are helpful in cases of peripartum hemorrhage and may be an effective

TABLE 61–5.

Characteristics of Early and Late Antepartum Hemorrhage Diagnoses

Early Pregnancy	
Miscarriage	Vaginal bleeding (+/– pain) >8 wks after last menstrual period
	Slight tenderness to uterine examination
	No adnexal mass
Ectopic pregnancy	May not have vaginal bleeding
	Pain <8 wk after last menstrual period
	Unilateral tenderness
	May present as shock with normal-sized uterus
Late Pregnancy	
Placenta previa	Painless vaginal bleeding (although 10% may have coexisting, painful abruption)
	Malpresentation of fetus (35%)
	Difficulty palpating presenting part
Placenta abruption	Painful vaginal bleeding
	Uterine irritability or tetany
	Coagulopathy
	Fetal distress/death
Uterine rupture	Vaginal bleeding (+/– pain)
	Hypotension
	Cessation of labor
	Fetal distress
Vasa previa	Painless vaginal bleeding
	Presence of fetal hemoglobin in shed blood
Unclassified bleeding	Painless vaginal bleeding
	Mild bleeding that often resolves spontaneously
	Often >37 wk of gestation

bridge until blood products are available.[87] Although many institutions require a type and screen for parturients who are at high risk for hemorrhage and undergoing vaginal delivery or for all parturients undergoing cesarean delivery, a cross-match for 2–4 U of packed red blood cells should be considered when the potential for significant blood loss appears eminent. Such cases often involve abnormalities with placentation, including low implantation (previa), partial abruption, or adherence without a decidual layer, invasion into the myometrium, or penetration through the myometrium (placenta accreta, increta or percreta, respectively). Imaging tests, especially ultrasound and magnetic resonance imaging (MRI), have dramatically altered the evaluation and outcome of these placental abnormalities. More recently, the use of interventional radiologic techniques for placement of prophylactic or treatment transcatheter occlusion balloons within the uterine or hypogastric arteries has allowed for timely control of bleeding.[115] When uterine bleeding occurs postpartum, use of an inflated Sengstaken-Blakemore esophageal balloon catheter placed in the uterine cavity and filled with 70–300 mL of warm saline has been demonstrated to tamponade and potentially treat intrauterine sources of bleeding and allow time to correct coagulopathies.[116]

TABLE 61–6.

Assessment of Obstetric Hemorrhage

Severity of Shock	Findings	Blood Loss (%)
None	None	15–20
Mild	Tachycardia (<100 beats/min)	20–25
	Mild hypotension	
	Peripheral vasoconstriction	
Moderate	Tachycardia (100–120 beats/min)	25–35
	Hypotension (SBP 80–100 mm Hg)	
	Restlessness	
	Oliguria	
Severe	Tachycardia (>120 beats/min)	>35
	Hypotension (SBP < 60 mm Hg)	
	Altered consciousness	
	Anuria	

SBP, Systolic blood pressure.

In situations where the need for emergent blood transfusion precedes the availability of cross-matched blood, then uncross-matched, type O, Rh-negative blood should be used. Continued blood loss and hemodynamic instability despite transfusion of packed red blood cells often is an indication for an arterial line and more invasive monitoring. However, restoration of circulating volume takes precedence. Urine output, heart rate, and blood pressure assessments can assist in rapid assessment of volume resuscitation. The need for blood component therapy other than red cells may be more limited than previously thought. Following the delivery of the fetus when uterine perfusion and oxygenation become less relevant, parturients usually are able to tolerate low hemoglobin, coagulation proteins, and platelets. The task force on blood component therapy of the American Society of Anesthesiologists has stated that transfusion of packed red blood cells, platelets, and fibrinogen component therapy is rarely indicated unless the hemoglobin concentration is < 6 g/dL, platelet count is $< 50 \times 10^9$/L (unless platelet dysfunction and microvascular bleeding is present), and fibrinogen concentration is < 80–100 mg/dL in the presence of microvascular bleeding (for details of transfusion therapy, see Chapter 85).[117]

Simultaneously with fluid resuscitation, a hemorrhaging parturient should be prepared for an operative delivery, if not already accomplished, and a pos-

sible hysterectomy. Complete replacement of blood loss before or during surgery is frequently an unrealistic goal because bleeding often continues until the offending pathology is corrected or removed. Although a regional anesthetic approach can be continued if the bleeding is modest and controllable, the case of a briskly bleeding, hemodynamically unstable patient requires induction of general anesthesia, controlled ventilation, and aggressive fluid resuscitation.

Hypertensive Disorders of Pregnancy

Whether preexisting, gestational, or related to preeclampsia or eclampsia, hypertension is associated with a higher incidence of maternal, fetal, and neonatal mortality and morbidity. Preeclampsia, with its systemic vasoconstriction, intravascular volume and protein depletion, and simultaneous retention of extravascular sodium and water, is of particular concern to anesthesiologists. In addition to individual organ dysfunction, abnormalities in coagulation and edema of the brain, larynx, and lungs may occur. Medical management of blood pressure should be achieved prior to obstetric or anesthetic interventions if possible. Control of blood pressure with labetalol, hydralazine, or infusions of nitroglycerin or nitroprusside should be commenced with arterial and central venous monitoring in severe cases. Of note, use of magnesium for prevention of seizures and use of antihypertensive medications for control of severe hypertension (systolic pressure >160 mm Hg and/or diastolic pressure at least 110 mm Hg) may affect the duration of muscle relaxants and the response to induction medications, respectively.[118] Overall, the suggested goal of antihypertensive therapy is systolic pressure between 140 and 155 mm Hg and diastolic pressure between 90 and 105 mm Hg.[118]

Fluid management guided by CVP in severe cases has been demonstrated to improve urine output, maintain mean arterial pressure, and decrease diastolic pressure.[119] If oliguria persists after normalization of CVP (usually between 2 and 3 cm H_2O) or the physiologic state is complicated by pulmonary edema or cardiovascular decompensation, a pulmonary arterial (PA) catheter may be helpful. A cardiology consultation and an assessment of cardiopulmonary function with a transthoracic echocardiogram may assist with the diagnosis and management. The course of preeclampsia can be complicated by mild to severe coagulopathy even in the presence of a normal platelet count.[120,121] For the benefit of both obstetric and anesthetic management, if the initial platelet count is less than an arbitrary 70–75/L^{-9}, the clinical history and the results of additional studies, such as PT/PTT or thromboelastography, should be reviewed. If the low (>70–75/L^{-9}) platelet count has been stable or trending slowly downward for 2–3 weeks and the patient has no clinical history of bleeding gums, prolonged bleeding, or significant bruising with trauma, a neuraxial approach to analgesia or anesthesia appears reasonable. However, if the platelet count has rapidly fallen within the 2–3 weeks or the clinical signs noted are present, a few options exist. In patients who will undergo labor, the analgesia can be managed with a patient-controlled IV pump; fentanyl 13 μg q6min with a lockout of 300 mg per 4 hours has been used with some success. Of note, intramuscular administration of narcotics, a common method of analgesia used for labor, is not recommended because of the possibility of hematoma formation. If an instrumented or operative delivery is planned, additional laboratory testing, such PT/PTT and thromboelastography, may provide information on the extent of coagulation dysfunction. If thrombocytopenia or prolonged PT/PTT indicates that pooled platelets or fresh-frozen plasma may reduce the risk of maternal hemorrhage with delivery, placement of neuraxial techniques should await the administration of these products.

During labor, epidural analgesia offers the advantage of limiting pain or stress, thus reducing catecholamine release, decreasing maternal blood pressure, and indirectly increasing placental perfusion.[119] Epidural anesthesia can also be a preferred technique for cesarean delivery because the dose of medications can be slowly titrated, resulting in more gradual blood pressure changes. Spinal anesthesia should not be avoided, particularly in urgent or emergent cases where rapid onset of anesthesia is important. Limited studies suggest that the incidence of hypotension is not significantly different compared to epidural anesthesia for cesarean delivery.[82,122] A CSE technique with a small initial spinal dose (bupivacaine 7.5 mg) followed by sequential epidural catheter dosing is another method that may produce rapid anesthetic onset with less profound hypotension; however, the value of this technique in limiting hypotension has not been validated in randomized controlled trials. Overall, neuraxial techniques represent an optimal approach to analgesia and anesthesia in the preeclamptic patient. This is particularly true when assessing awake, nonsedated patients during labor and delivery for the severity of disease and avoiding the risks of general anesthesia associated with airway narrowing that accompanies pregnancy, labor, and preeclampsia[123] and the increases in systemic and intracranial pressures that can occur during intubation and extubation.

Intravascular hypovolemia associated with preeclampsia, use of antihypertensive medications, and administration of magnesium for seizure prophylaxis may augment the hypotension produced by neuraxial techniques. When responding pharmacologically to hypotension, restraint is advocated because patients with hypertensive disorders may be have an exuberant response. Small doses of vasopressors (i.e., ephedrine 5 mg or phenylephrine 20–40 μg) should be given initially. Similarly, the response to hypertension associated with the disease or reactive hypertension from labor pain, intubation, or emergence from general anesthesia should be treated judiciously. Labetalol 5–10 mg IV is a popular first-line agent that has a relatively wide margin of safety and can be doubled every 20 minutes until an effect is observed or 150–200 mg has been reached. At these thresholds, other agents such as hydralazine or calcium channel blockers can be used. Infusions of nitroglycerine, nitroprusside, and trimethaphan can be initiated, but arterial monitoring should be used to more carefully titrate the effect (see Invasive Monitoring in the Parturient).

Invasive Monitoring in the Parturient

Whereas noninvasive measurement of blood pressure, heart rate, oxygen saturation, urinary output, and fetal cardiotocography is standard practice in most labor and delivery facilities, the use of invasive monitors is vari-

able and controversial. Despite practice guidelines written by a number of professional organizations, including the joint task force of the American College of Physicians, the American College of Cardiology, and the American Heart Association,[124] poor collection and incorrect interpretation of hemodynamic data from invasive monitors remain the key problems with their use.[125,126]

In addition to correctly interpreting the data produced, knowing when to use invasive monitoring is a vital clinical skill. The indications for invasive arterial blood pressure monitoring during pregnancy include the desire to more carefully manage blood pressure, lack of reliable noninvasive cuff measurements, need for vascular access for blood studies, and planned use of certain hemodynamic agents (particularly drugs given by infusion, such as nitroglycerin and nitroprusside). By contrast, the indications for invasive central monitoring are not as clear or uniformly accepted. A CVP catheter is often placed to yield an approximation of volume status (or to follow a trend in blood loss or replacement therapy) and to give a greater understanding of the mechanical phases of the cardiac cycle. Management of oliguria unresponsive to a fluid challenge, pulmonary edema, and refractory hypertension are clinical situations where some clinicians desire CVP monitoring.

Although a PA catheter can assist in determining the etiology of pulmonary edema, oliguria with normal CVP, or cardiovascular failure, its use is the most controversial. Advocates of PA catheter use suggest that it can provide information on left and right ventricular function, systemic vascular resistance, and cardiac output. Detractors question the validity of the data, noting that in the setting of preeclampsia, for example, the correlation between CVP and pulmonary capillary wedge pressure is unreliable for CVP readings >6 cm H_2O.[127] In deciding between a PA versus CVP catheter, the clinician should recognize that although the insertion-related complications are similar,[128] the PA catheter is associated with more use-related complications, including balloon rupture, pulmonary infarction, valvular damage, and erosion of the PA. Thus, the benefits of PA catheter use should clearly outweigh its inherent risks before its use can be recommended. The 1999 practice guidelines of the American Society of Anesthesiologists Task Force on Obstetrical Anesthesia state that "the decision to perform invasive hemodynamic monitoring should be individualized and based on clinical indications that include the patient's medical history and cardiovascular risk factors."[129] To date, although PA catheter use has been reported in parturients (primarily with cardiac pathology), no controlled trials are available that confirm the benefit of PA catheter monitoring on maternal or fetal outcome. PA pressures are observed with different etiologies of pulmonary edema and oliguria (Boxes 61–5 and 61–6).[130,131] Renal and postrenal etiologies of oliguria, such as renal artery vasospasm, acute tubular necrosis, and postrenal obstruction, are less commonly encountered in the obstetric population. Future modalities for hemodynamic monitoring, such as Doppler ultrasound and three- and even four-dimensional echocardiography, are able to provide detailed, dynamic information on cardiac structures and function and in the future may offer significant clinical advantages.[132]

ANESTHESIA FOR GYNECOLOGIC SURGERY

Although many of the procedures in gynecologic surgery are approached using standard surgical techniques, the care and anesthetic management should be provided with an understanding of gender-related differences that ultimately may affect patient outcomes and satisfaction. In addition to the many alterations discussed in the obstetric section of this chapter, gender-related changes in the sensitivity to pain and anesthetic agents is relevant to each case. Full appreciation should be given to the highly vascular uterus and other visceral structures found in women, which can result in sudden and profound blood loss, air emboli, and, in pregnancy-related procedures, amniotic fluid emboli.

Preoperative Assessment and Evaluation

A few elements in taking a gynecologic history deserve emphasis, particularly because a few weeks may have lapsed between the gynecologic surgeon's assessment and the surgical date. The menstrual cycle can serve as a guide to other pathology and rule out the possibility of pregnancy. Abnormal or prolonged uterine bleeding can be produced by a variety of endocrine and metabolic disorders, including hypothyroidism, hyperprolactemia, coagulopathies, and insulin metabolism disorders, which in turn may impact anesthetic care. Because pregnancy

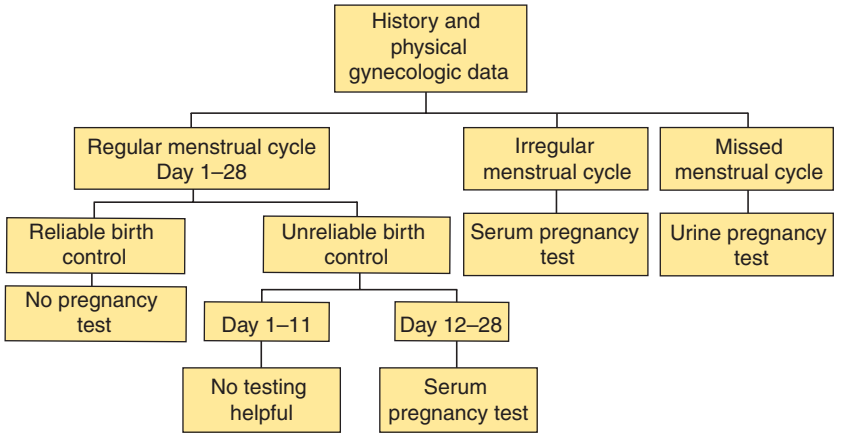

FIGURE 61–5. Preoperative pregnancy testing algorithm.

has implications on surgical interventions and anesthetic care, testing should be used in individuals with absent or irregular menses, unreliable knowledge of menstrual cycle or contraceptive use, noncompliance with hormonal birth control regimens, or if the report is desired. Algorithms for the use of serum and urine beta hCG pregnancy tests are helpful if applied appropriately (Fig. 61–5). The serum test uses a radioimmunoassay that can detect a pregnancy within 24–72 hours following conception at levels as low as 1–3 mIU/L.[133] By contrast, the urine test uses an antibody agglutination methodology that detects a level >25 mIU/L, which is achieved only after 10–12 days.[133] A positive serum hCG combined with a positive uterine ultrasound (demonstrating decidual thickening of the uterus) can diagnose pregnancy with 100% clinical accuracy.

The psychological impact of the surgical condition should be considered and managed with sensitivity. Fear, anxiety, embarrassment, and even guilt may be associated with some procedures. Infertility patients may exhibit a number of emotions as they undergo an escalating series of tests, medications and procedures, including tubograms, laparoscopies, laparotomies, tubal reconstructions, and in vitro fertilization. Patients who have spontaneous, missed, or therapeutic abortions may have feelings of guilt or mourning. Patients with chronic pelvic pain may have concerns regarding complicated, multimodal pain therapies; such individuals often benefit from preoperative pain and psychiatric consultations. Patients with urinary or fecal incontinence may be acutely embarrassed by their condition. Patients with malignant breast or pelvic masses may have anxiety or fear of disfigurement and concern over loss of sexual function and desirability.

Patients who present for surgical management of gynecologic malignancies require additional considerations. The tumor mass may create anatomic and physiologic alterations, including aortocaval compression, respiratory embarrassment, changes in renal or hepatic function, and the potential for adhesions and scarring. The additional comorbidity of prior surgeries, chemotherapy, or radiation therapy must be considered as well. Chemotherapy may be associated with disruptions in hematopoiesis, infection resistance, nausea and emesis, and myocardial, renal, and hepatic function (Table 61–7). Anemia, coagulation disorders, and platelet dysfunction also may be present. Alternatively, malignancies may result in hypercoagulable states, and the impact of various regimens for prophylaxis and treatment should be considered in the perioperative period.[134,135]

Intraoperative Considerations and Management

Gender Differences in Sensitivity to Pain

Gender differences in biologic, psychological, and sociocultural factors are believed to be responsible for women reporting pain that is more severe, frequent, and of longer duration than that experienced by men.[136] Although gender role expectations may be partially responsible for these observations, female gonadal hormones have been associated with pain sensitivity, albeit contradictory to most expectations. Female hormonal increases, as occur during pregnancy, have been associated with decreases in response to noxious stimuli. By contrast, hormonal decreases, such as those witnessed in menopause, have been associated with increases in pain sensitivity.[137] Although progesterone previously was demonstrated in animal and human studies to be the female gonadal hormone most responsible for modulating pain,[138] the demonstration of an inverse relationship between estrogen and β-endorphins and estrogen receptors in the noxious stimuli processing areas of the brain

TABLE 61–7.

Chemotherapeutic Agents with Unique Toxicities Affecting Anesthetic Management

Agent	Gynecologic Malignancy	Usual Dose	System Affected	Toxic Manifestation	Diagnostic Tests
Adriamycin (doxorubicin)	Endometrial carcinoma, ovarian carcinoma	500 mg/M²	Heart	Myocardial fibrosis, congestive heart failure	Echocardiogram, ejection fraction
Bleomycin (Blenoxane)	Cervical carcinoma, germ cell tumors of the ovary	400 U	Lung	Pulmonary fibrosis	Spirometry, diffusing capacity
cis-Platinum	Endometrial carcinoma, cervical carcinoma	50–75 mg/M²	Kidney	Renal tubular dysfunction	Creatinine clearance (dose-related)

and spinal cord suggests a greater role for estrogen. Acute estradiol exposure decreases the number of opioid binding sites, reduces the antinociception effect produced by morphine in ovariectomized rats, and diminishes the plasma, pituitary, and hypothalamic levels of β-endorphin.[138,139] In human clinical models, high estrogen levels alter noxious stimuli processing,[140] a finding that may be relevant to therapies that involve estrogen replacement or manipulation.

Gender-related differences in pain from the surgical exploration of abdominal and pelvic organs also may stem from the more complex anatomy and function of the female reproductive organs. The relative contributions of somatic and visceral sensory fibers to pain originating from the pelvic, uterine, cervical, and perineal structures have not been completely characterized. Investigations into visceral afferent contributions to pain have been particularly abbreviated because of the lack of suitable experimental models and noninvasive neurophysiologic techniques. Recent and future work, however, promises to more fully elucidate the contribution of female reproductive organs to gender-related pain.[141]

Gender Differences in Sensitivity to Anesthetic Agents

Gender-related pharmacokinetic and pharmacodynamic alterations are produced by the greater percentage of body fat and the smaller body water content in females. In general, this results in a greater distribution per kilogram of body weight for lipophilic drugs, such as opioids and benzodiazepines, and a smaller distribution for water-soluble drugs, such as muscle relaxants.[142] Because the volume of distribution is the most important pharmacokinetic factor responsible for initial drug concentrations, the response to induction and bolus administration agents may be altered. Drug clearance, which is dependent on metabolism and excretion and is related to steady-state concentrations, also is affected by gender. Hepatic metabolism, which accounts for a major route of elimination of most IV anesthetic drugs, has gender-related alterations within the cytochrome P450 (CYP) and uridine diphosphate (UDP)-glucuronosyltransferase systems (Table 61–8). Glomerular filtration rate, the most important renal parameter for excretion of nonactively secreted or reabsorbed drugs, is lower in females, but the impact of this change is not well characterized.[142]

Adapted from Pleym et al.[142]

Hormonal alterations from the use of contraceptive pills, in vitro stimulation regimens, pregnancy, menstrual cycles, and menopause may modify CYP enzyme activity. Although clearance of drugs may be higher in the middle of the menstrual cycle,[143] minimal to no menstrual phase variations have been noted with the disposition of certain anesthetic drugs, including alfentanil, alprazolam, and midazolam.[144,145] Menopause has been associated with decreases in midazolam and alfentanil clearance; however, this phenomenon is not entirely hormonally mediated, as hormonal replacement does not return clearance to premenopausal levels.[146] Faster emergence from propofol anesthesia in women likely is related to a rapid decline in plasma levels[147]; whether this condition is due to elimination or intercompartmental distribution remains unclear. The analysis is further complicated by the greater sensitivity of women to given plasma concentrations of propofol.[147] These changes demonstrate that the effect of gender on pharmacokinetics and pharmacodynamics is a multimodal issue for which more information is needed.

Anesthetic Selection and Care

Performing a history and physical examination, reviewing the chart, previ-

ous anesthetic records, and relevant testing, and discussing the overall plan with the surgeon are essential steps in selecting an appropriate anesthetic plan. This is particularly true given the variety of positioning requirements and surgical approaches for certain gynecologic procedures (e.g., abdominal, laparoscopic, vaginal hysterectomy).

All patients, including those who received local anesthesia, should be monitored with an electrocardiogram, blood pressure cuff, and pulse oximeter. Additional monitors include a capnography sampler, temperature probe, peripheral nerve stimulator, and Foley catheter as appropriate. Invasive monitors, such as an arterial catheter, central venous catheter, PA catheter, or transesophageal echocardiography probe, may be indicated in patients with serious medical problems or who are undergoing radical, prolonged procedures accompanied by extensive fluid shifts and volume replacement.

Monitored IV sedation, often used with a local anesthetic field block, is often appropriate for certain procedures, such as dilation and curettage (D&C), hymenotomy, and breast biopsy. IV sedative and analgesic medications may be beneficial prior to placement of the field block, particularly when the block is administered to the paracervical or perineal region. Because the cervix is highly vascular, field blocks in this region can result in high plasma local anesthetic concentrations, so vigilance should be given to signs of toxicity.

Neuraxial regional techniques are suitable for many operations, including conservative abdominal and pelvic procedures. However, the duration of the case, requirements for Trendelenburg position, and unanticipated need for extensive exploration may limit the use of spinal and epidural anesthesia. The selection of local anesthetics and the specific neuraxial technique depends on the magnitude and duration of the operation; however, a T4 to T6 level is advised for intraabdominal surgery. Prophylactic antiemetic and supplementary opioid use may prevent the nausea and discomfort that result from peritoneal stimulation. Catheter-based techniques, as opposed to single-dose techniques, offer the most control and flexibility. When provided as part of a combined spinal technique, a short-acting spinal anesthetic can be given for procedures of potentially short, but unknown, duration. The catheter then can be used if the duration of the operative event is longer than anticipated or postoperatively for analgesia is appropriate. Whether these catheters should be placed intrathecally or epidurally is controversial. Microcatheters, which historically were passed through standard 25- to 32-gauge needles into the intrathecal space, were associated with cauda equina syndrome when used with 5% lidocaine in 7.5% dextrose. Speculation for this outcome has been placed on drug "pooling" by the nerve roots within the subarachnoid space. These outcomes were associated with clinical abandonment of these catheters in the United States but not in Europe. Since that time, slightly larger microcatheters, which pass through a 22- to 26-gauge spinal needle, have been evaluated. Microcatheters are believed to contribute to lesser risk for PDPH than standard macrocatheters (20-gauge) placed through a 17-gauge Tuohy or Weiss needle used in similar fashion. The combination of general anesthesia and an epidural catheter, whether used for intraoperative anesthesia or postoperative analgesia, can be advantageous for particularly large or painful procedures.

General anesthesia is best suited for procedures that require extensive abdominal dissection, steep Trendelenburg positioning, extended CO_2 insufflation for laparoscopy and pelviscopy, or deep levels of anesthesia for a short period of time. Although mask and LMA devices are often used, endotracheal intubation remains the conduit of choice for ventilation and anesthesia when pulmonary soiling is a risk. These cases include patients with suspected gastric contents ("full stomach"), obesity, severe anxiety, nausea, or vomiting, surgical cases that will result in aggressive Trendelenburg position or massive fluid shifts, or cases where emergent exploration is required. Overweight or obese patients are increasingly prevalent, even within younger age groups. The National Health and Nutrition Examination Survey (NHANES) found that obesity is becoming more common at younger ages and more prevalent with age.[148] Among women in their second, third, and fourth decades, the prevalence of obesity is 23.3%, 32.5% and 35.4%, respectively.[148] Should instrumentation of the airway present a concern, alternative anesthetic options and the difficult airway algorithm should be invoked. An elective, awake fiberoptic intubation in a controlled environment with adequate assistance is often the optimal approach.

Considerations for Specific Situations

In general, gynecologic surgery can be divided into four major categories: perineal, transvaginal, intraabdominal, and transabdominal (Box 61–7). Anesthetic management for these procedures depends on a number of factors specific to the procedure, patient, and healthcare providers.

Perineal and Urologic Surgery

Anatomy The vulva includes all the structures visible externally from the pubis to the perineum, including the mons pubis, labia, clitoris, vestibule, urethra, and Skene and Bartholin glands. The primary blood supply to the vulva is via the internal pudendal artery, a branch of the internal iliac artery. The nerve supply is via the pudendal nerve that arises from the

BOX 61–7.

Common Gynecologic Procedures

- Transvaginal
  - Dilation and curettage
  - Dilation and evacuation
  - Cervical
    - Cone biopsy
    - Cerclage
  - Hysteroscopy
  - Vaginal reconstruction
- Perineal
  - Laser fulguration of condylomata
  - Hymenotomy
  - Marsupialization of Bartholin cyst
  - Anteroposterior repair
  - Vulvectomy
  - Stamey urethropexy (urologic)
- Intraabdominal
  - Oophorectomy
  - Cystectomy
  - Salpingectomy
  - Salpingostomy
  - Myomectomy
  - Hysterectomy
  - Radical hysterectomy
  - Ruptured ectopic pregnancy
- Transabdominal
  - Laparoscopy
  - Pelviscopy

sacral nerve roots (S2, S3, and S4; Fig. 61–3). The pudendal nerve, artery, and accompanying veins pass from the pelvis via the lesser sciatic foramen and along the lateral wall of the ischiorectal fossa. The pudendal nerve, sometimes used in obstetrics for a vaginal delivery or perineal repair, can be readily blocked through a transperineal or transvaginal approach with local anesthetic placed posterior and medial to the ischial tuberosity.[149] The lymphatic drainage of the vulva is principally through the superficial inguinal lymph nodes to the deep inguinal and pelvic nodal systems.

Specific Procedures Although a number of minor vulvar procedures are routinely performed under local anesthesia, the majority of procedures performed in the operating room require regional or general anesthesia. Such procedures include biopsies, hymenectomies, drainage of Bartholin glands, and laser fulguration of intraepithelial neoplasia.

Surgical interventions to treat stress urinary incontinence in women include procedures to reestablish the posterior urethrovesical angle and resuspend the urethra. Traditional approaches include retropubic (e.g., Marshall-Marchetti-Krantz or Burch procedures) and transvaginal approaches (e.g., Kelly plication or Pereyra and Stamey urethropexy). Most of these procedures involve suturing the vaginal epithelium to the rectus fascia above the pubis. During placement of the paraurethral suture, the patient must not cough or strain. Regional anesthesia, usually in the form of a spinal technique, provides a quiescent surgical field and good postoperative conditions. Prophylactic use of antiemetics (metoclopramide 10 mg IV, ondansetron 4 mg IV, and dexamethasone 8 mg IV) is recommended.

Major vulvar procedures, including operations for trauma or invasive carcinomas, often require extensive dissection into the tissues of the inferior fascia of the urogenital diaphragm, pelvis, and abdomen. These procedures frequently result in major blood loss from the vestibular bulbs, pudendal artery, and retropubic space of Retzius. Preparation for these cases should include use of large-bore IV catheters, immediate availability of resuscitation equipment and fluids, and use of invasive monitoring and blood products where appropriate. Anesthetic management that includes epidural catheter-based techniques allows for minimization of intraoperative general anesthetic agents and provision of superior postoperative analgesia. Patients with significant cardiac or pulmonary comorbid conditions, obesity, a potentially difficult airway, or an expectation for significant blood loss may benefit from induction of general anesthesia at the beginning of the case, when the intubation can be achieved in a controlled, stable environment.

Special Considerations Use of operative lasers entails risks to the patient and the operating room staff through thermal and retinal injury from reflected light, ignition of operative drapes, and possible viral inoculation from inhalation of laser plume particulates. Human papilloma viral DNA has been found in laser plumes, but whether this represents an infectious risk is unclear.[150] Regardless, the smoke contains bioaerosols that can cause lung irritation and other potentially adverse effects.[150] Therefore, appropriate eye protection, occlusive laser masks, and properly functioning smoke evacuators are necessary. For patient safety, surgical site immobilization is of great importance. Dense regional anesthesia or general anesthesia with ventilation by mask, LMA, or endotracheal intubation are reasonable approaches.

Transvaginal Surgery

Anatomy The vagina is an 8- to 10-cm compliant musculomembranous canal that extends from the external genitalia to the uterine cervix. Anteriorly and posteriorly related to the urethra and bladder, respectively, the vagina is in close proximity to the rectal ampulla, perineum, and cul-de-sac of Douglas. The primary blood supply to the vagina is derived from branches of the uterine and pudendal arteries. Lymphatic drainage of the upper third of the vagina is predominately to the parametrial and pelvic lymph nodes, whereas the lower two thirds share the superficial inguinal lymph nodes with the vulva. The sensory nerve supply to the vagina arises from S2, S3, and S4 via the pudendal nerve. The sympathetic and parasympathetic nerve supplies originate from the hypogastric plexus (L1 to L3) and sacral nerves, respectively (Fig. 61–3).

The cervix enters the vagina at a variable angle through the anterosuperior wall and is composed of myometrial muscle and dense stroma. The blood supply is derived from the descending branch of the uterine artery, and lymphatic drainage is through the paracervical nodes. Innervated by the nerves arising in the hypogastric plexus, the exocervix is poorly supplied by sensory nerves and thus are relatively insensate. By contrast, the endocervix has an abundant nerve supply and is very sensitive to surgical manipulation.

Specific Procedures D&C requires dilating the cervix and mechanically scraping or suctioning the uterine walls to obtain tissue for evaluation, perform an abortion, or investigate abnormal uterine bleeding. Frequently performed in an office setting, D&C procedures should be performed in an operative setting in patients with significant comorbid conditions, distorted anatomy, or inability to tolerate an office procedure. The major surgical risk of the procedure is uterine perforation and subsequent hemorrhage, particularly when the perforation occurs through the lateral wall and involves the uterine artery. Preexisting acute or chronic anemia may exacerbate the patient's condition. If a perforation is suspected, gentle probing to localize the defect, observation, and laparoscopy or laparotomy may be needed for surgical repair.

Dilation and evacuation (D&E) and dilation and extraction (D&X) are similar to D&C but usually are performed to interrupt pregnancy. From gestational week 16, fetal size and structure dictate the mechanical disruption and then evacuation of fetal tissue. Extraction involves evacuation of intracranial contents after delivery of the fetal body through the dilated cervix to minimize uterine or cervical injury. Because these procedures disrupt fetal and placental tissue, amniotic fluid emboli, disseminated intravascular coagulation, and uterine atony accompanied by maternal hemorrhage can follow.[151] Procedures being performed for an in utero fetal demise warrant coagulation studies, particularly if associated with an abruption or uterine dehiscence; however, a dead fetus per se does not result in coagulopathies for a period of days to weeks.[152,153] Complication rates correlate with the gestational age of the fetus and the experience of the surgeon. D&E procedures are also performed in patients with hydatidiform moles or persistent ges-

tational trophoblastic tissues, which are neoplastic conditions resulting from deranged placental growth. Such pregnancies are associated with vaginal bleeding, anemia, and the need for subsequent chemotherapy.[154]

D&C, D&E, and D&X procedures often are performed with a paracervical block, with the assumption that a uterine perforation would be accompanied by sudden, acute report of abdominal pain, but this has not been validated. Spinal and general anesthesia are viable options, with the notation that volatile halogenated anesthetics, including sevoflurane and desflurane, have a dose-dependent association with uterine atony in in vitro experiments.[155] No clinical differences in blood loss with volatile agent administration in doses up to 1 MAC have been observed. Moreover, oxytocin appears to successfully diminish these volatile effects up to 1.5 MAC.[155] A number of uterotonic agents, such as methylergonovine and prostaglandin $F_2\alpha$, also can be used to augment uterine tone (Table 61–4).

Diagnosis and therapy for preinvasive or invasive cervical lesions is often achieved with a cone biopsy, which provides concentric excision of both exocervical and endocervical stroma. Because the cervix is well vascularized, bleeding is common, especially in pregnant patients. Hemostatic sutures can be placed laterally in the descending cervical branches of the uterine artery. Dilute solutions of vasopressin (20 U in 20 mL of normal saline) or epinephrine (1:200,000) can be injected locally into the cervix to induce vasospasm; both of these agents may induce hypertension. Resulting hypertension that is severe and sustained may require a direct-acting vasodilator such as hydralazine; β-adrenergic blocking agents are less effective. Most cone biopsies are performed as day surgery procedures under spinal or general anesthesia. A mask or LMA technique can also be used with spontaneous or assisted ventilation.

Rigid or flexible hysteroscopic procedures are performed to evaluate the endocervix or endometrial cavity. The scope is inserted through the cervix into the uterine cavity. CO_2 or liquid then is used to distend the uterus for improved visibility and surgical access. Isoosmolar, nontoxic, nonconducting distending mediums, such as glycine, dextrose, sorbitol/mannitol, and saline, are used, and accurate accounting of the volume used and returned are essential to minimize water intoxication, hyponatremia, and ammonia toxicity. Diagnostic examinations for evaluation of unexplained fertility or abnormal uterine bleeding are performed with minimal cervical dilation using small-caliber devices that are placed under a paracervical block. By contrast, operative procedures, such as ablation or resection of intracavity uterine lesions, septae, or adhesions, are performed with larger-caliber devices capable of electrocautery, wire loop cutting, or lasering and necessitate a neuraxial or general anesthetic.

Vaginal hysterectomies are performed for benign conditions or early-stage malignancies of the uterus and cervix. They also are used in patients with loss of pelvic support associated with uterine prolapse. Excessive uterine size, prior abdominal surgery, and suspicion of intrapelvic malignancies all are contraindications to a vaginal approach. The procedure requires entry into the anterior and posterior culs-de-sac to expose the broad ligament containing the uterine artery and can be performed in association with cystocele or rectocele (bladder or rectal prolapse, respectively) repair or an urethropexy (see Perineal and Urologic Surgery, Specific Procedures above). The ovaries may be conserved or removed vaginally. These procedures can be performed under a hyperbaric spinal anesthetic at a T6 to T8 level to block the peritoneal sensation of uterine traction (Fig. 61–3). If significant Trendelenburg positioning and laparoscopy-assisted techniques will be used, a general anesthetic with endotracheal intubation is recommended.[156]

Special Concerns The majority of transvaginal procedures are performed in the lithotomy position. Excessive hip flexion, abduction, and external rotation may allow the inguinal ligament to apply continuous pressure on the femoral nerve[157] or place the obturator and lateral femoral cutaneous nerves in a position where they are prone to stretch injury.[158] Extensive rotation of the thighs at the hip or extension of the legs without knee flexion may result in sciatic and peroneal nerves injury.[157] Compression of the lateral fibular head results in common peroneal nerve injury, which can result in foot drop and lateral lower extremity paresthesias.[157] Protective padding, avoidance of contact with hard surfaces or supports, and attention to positioning are important elements of optimal care.[159]

The Trendelenburg position is often used in transvaginal procedures to assist with surgical visualization. This position is associated with potentially severe consequences, including venous air emboli, alterations in circulation and respiration, and upper extremity peripheral nerve injuries.[156,159] When combined with laparoscopy, further hemodynamic and respiratory encroachment may occur.[156]

Use of distending mediums for hysteroscopy may result in absorption of large volumes of irrigating fluid, leading to hypervolemia, hyponatremia, and decreased osmolarity. Together, these alterations may produce hypertension, bradycardia, altered mental status, nausea, vomiting, headache, agitation, and lethargy. These symptoms are masked if general anesthesia is used. If the resulting "hypoosmolar hyponatremia" is not recognized, seizures, coma and death may occur. Treatment includes halting or rapidly completing the surgery, sending blood for a complete blood count, electrolytes, and osmolality, and administering normal saline and furosemide. Although severe hyponatremia (<120 mEq/L) has a significant association with mortality, correction with hypertonic saline (3% NaCl) should occur no faster than 1–2 mEq/L/h with a goal of 125–130 mEq/L. Overly rapid correction can lead to central pontine myelinolysis, with paresis, mutism, pseudobulbar palsy, and other neurologic disorders.[160,161]

Intraabdominal Operations

Anatomy Intraabdominal operations relate mostly to the vagina, uterine cervix, uterus, fallopian tubes, and ovaries. On occasion, especially when associated with sepsis and/or tumor invasion, the rectum and bladder are involved through fistulous communications. The blood supply to the pelvis is largely derived from the internal iliac (hypogastric) artery, which in turn gives rise to the uterine arteries, the superior, middle, and inferior vesical arteries, the middle and inferior hemorrhoidal arteries, and the vaginal arteries. The extensive collateral circulation network to organs within the pelvic viscera alternatively allows extensive bleeding during pelvic dissec-

tion or obstetric hemorrhage as well as the possibility of ligating major arteries, including the internal iliac, with few untoward effects.

The pelvic organs are innervated by sympathetic fibers derived predominately from the first through fourth lumbar nerves (L1 to L4) and enter the hypogastric or presacral plexus (Fig. 61–3). The presacral sympathetic plexus serves the uterine fundus, cervix, vagina, and excretory organs, including the rectosigmoid region of the colon, anus, bladder, and urethra. Parasympathetic preganglionic fibers arise from the second through fourth sacral nerves (S2 to S4). Sensory nerves from the pelvic viscera, including the uterus, arise from the T10 to L4 spinal cord segments. By contrast, the cervix is served by nerve fibers from the S2 to S4 spinal cord segments. Lymphatic drainage of the female reproductive organs is predominately through the pelvic and paraaortic lymph nodes in the retroperitoneum, although the superficial and deep inguinal lymph nodes may be involved as well.

Specific Procedures Ovarian surgery is performed for a variety of conditions, including removal of cystic masses, endometrial lesions, and neoplastic tissues. Ovarian carcinomas are the most lethal of all gynecologic malignancies because of their ability to grow silently until the disease is advanced and widespread.[162] With extensive ovarian cancer, subdiaphragmatic lymphatic obstruction often results in profound ascites that may impair diaphragmatic excursion, impede venous return, and delay gastric emptying. Cytoreductive procedures, which remove all visible tumor masses to improve the response to chemotherapy, can include extensive retroperitoneal dissections with bowel resections and bypasses.

Surgery of the fallopian tubes is performed most often for nonneoplastic processes; both benign and malignant neoplasias are rare. Salpingoscopies are becoming more common because of their association with infertility evaluations.[163] Tubal ectopic pregnancies, which occur in approximately 1:100 pregnancies, are associated with pelvic inflammatory disease, intrauterine device use, diethylstilbestrol exposure, and prior tubal procedures or pathology.[164] Ectopic pregnancies may be located throughout the fallopian tube, including the uterine anastomosis; the pregnancy is surrounded by myometrial uterine tissue at this site and may grow significantly prior to becoming symptomatic. Ectopic pregnancies may rupture without warning, leading to acute hemoperitoneum and massive exsanguination. Management should center on providing rapid fluid resuscitation, securing the airway, and preparing for massive blood transfusion and immediate surgery. Procedures for removing ectopic gestations are time consuming because hemostasis may be difficult to obtain. On occasion, particularly if the ectopic gestation is implanted near the uterus, a salpingectomy and hysterectomy may be required.

Tuboovarian abscesses are managed surgically when they are >8 cm, nonresponsive to antibiotic therapy, or potentially ruptured. Ruptured tuboovarian abscesses may be accompanied by peritonitis, septic shock, respiratory distress, and coagulopathies. Surgical management of intact abscesses includes percutaneous or laparoscopic drainage. However, a laparotomy with a salpingo-oophorectomy and hysterectomy may be necessary, particularly when associated with a rupture or extensive pelvic inflammatory disease.

Uterine leiomyomas (fibroids) are the most common benign tumor in women and may be associated with menometrorrhagia, ureteral obstruction, pain, infertility, and, rarely, pregnancy loss. Usually well-circumscribed but nonencapsulated, fibroids occur in the submucosal, intramural, or subserosal layers (innermost to outermost layers, respectively) of the uterus. Patients often are placed preoperatively on leuprolide, a gonadotropin-releasing hormone agonist, in an attempt to reduce the size of the fibroids. Myomectomies can range from straightforward hysteroscopic procedures of pedunculated subserosal fibroids to prolonged dissections of intramural fibroids accompanied by extensive bleeding. Vasospastic solutions of vasopressin or epinephrine are sometimes injected directly into the myometrium to reduce blood loss. Myomectomies can be performed under regional or general anesthesia.

Uterine reconstructive surgeries are performed for congenital malformations of the uterus and include removal of uterine septa or reunification of duplicate uterine horns. Most are performed to enable fertility or gestation.

Abdominal hysterectomies, which include subtotal (supracervical), total, and radical types, are performed for a variety of benign and malignant diseases. Common indications include symptomatic uterine fibroids, pelvic pain, and endometriosis. Acute inflammatory disease, endometriosis, and malignancies may result in extensive adhesions, increased vascularity, and destruction of normal tissue planes. These alterations prolong surgery and increase blood loss. Because a steep Trendelenburg position is often required for these operations, general anesthesia with endotracheal intubation is used.

Special Considerations Although vertical and transverse approaches can be used for intraabdominal surgeries, the low transverse incision is selected when possible for its cosmetic acceptability and strength of repair. The Pfannenstiel incision, the most common approach for cesarean delivery, often is modified to include dissection of the rectus abdominis (Maylard or Cherney incisions) for improved access to the lateral margins of the pelvis. When access to the upper abdomen is required, vertical midline or paramedian incisions are used. Such incisions are avoided, when possible, because the intrinsic strength and structural integrity of the repair are less robust, and respiratory splinting may occur.

Blood loss in gynecologic surgery may be precipitous and unexpected, although such cases often can be anticipated. Additional vascular access, invasive monitoring, and blood conservation techniques, such as erythropoietin-induced red cell production, autologous donation, and acute normovolemic hemodilution, should be considered in advance.[165,166] Because preoperative autologous donation is limited by the maximum life span of stored blood, collection must occur within 6 weeks of the planned operation, with an average unit collection interval of 3–7 days.[166] Although the use of blood cell salvage technologies remains controversial, particularly in the presence of malignancies, recovery of 2–3 U of blood has been deemed to be cost effective.[166] Moreover, the irradiation of blood cells retrieved intraoperatively has been demonstrated to eliminate cancer cells. [167] Most recently, the placement of prophylactic bal-

loon catheters in major vessels by interventional radiologists may allow for timely control or embolization of intraoperative bleeding, particularly from the uterus.

The extent of surgery for gynecologic malignancies often depends on the clinical staging of the disease, the presence or absence of lymph node metastases, and an examination of involved tissues by a surgical pathologist. The gynecologic surgeon and the anesthesia provider should discuss the likelihood of progression to a more radical surgery prior to and during an operation. Such discussions help guide decisions about placement of invasive monitoring catheters, use of large doses of narcotics and neuromuscular blocking agents, and selection of an anesthetic technique that is inappropriate for the duration and surgical exposure necessary for the case. On occasion, if the malignancy is confined to the pelvis without fixation to the pelvic sidewall, a pelvic exenteration is performed. This massive procedure involves radical hysterectomy, cystectomy with urinary diversion, and proctocolectomy with a permanent colostomy. Major fluid and electrolyte shifts, blood and heat loss, and coagulopathies can occur. Low-flow or closed-circuit volatile agent techniques and use of passive humidifiers, heating blankets, and fluid warmers are encouraged. A combined epidural-general anesthetic technique offers the benefits of a sympathetic blockade during the surgery and optimal analgesia postoperatively. Epidural analgesia is a particularly effective technique for reducing pain following intraabdominal procedures. With the exception of a herniotomy, use of incisional local anesthesia is not consistently effective for reducing postoperative pain.[168]

Transabdominal Surgery

In distinction to open surgical procedures, transabdominal surgery occurs through small incisions with rigid or flexible scopes and instrumentation. Advantages of these procedures include smaller incisional sites, lower risks of wound complications, reduced postoperative pain and complications, and improved recovery.[169] Disadvantages include poor visualization, injury to viscera and blood vessels, and complications from CO_2 insufflation. In some cases, such as hysterectomies, vaginal approaches may be superior to laparoscopic approaches; however, both have benefits over open laparotomy.[170]

Although initially developed as a means for diagnosis, laparoscopy and pelviscopy are used routinely for a variety of operative procedures, including tubal ligation and repair, endometriosis fulguration, ovarian cyst aspiration and resection, ectopic pregnancy removal, and fibroid excision. Laparoscopic-guided carcinoma staging and resection procedures have been demonstrated to result in improved short-term and long-term outcomes compared to open laparotomies.[171] Most recently, "hand-assisted laparoscopy," which uses laparoscopy combined with a small incision for insertion of a hand, has shown increased utility and benefit over open laparotomy.[172]

Laparoscopy and pelviscopies are performed, often after catheterization of the bladder, with the surgeon placing a needle with a stopcock periumbilically through the fascial layers into the peritoneum. CO_2 is insufflated through this needle to a pressure of approximately 19 mm Hg. If the pressure increases rapidly, the needle may be inappropriately located between the fascial planes of the muscle layers and will need to be replaced. In the proper location and with the appropriate degree of abdominal distension achieved, the hollow needle is replaced with a trochar with a self-sealing opening for the laparoscope. The laparoscope then is placed and connected to an insufflator that provides gas (CO_2) flows at a rate of 200 mL/min to maintain pressure.

BOX 61–8.

Concerns and Complications from Laparoscopy and Pelviscopy

- Concerns
  - Cardiovascular Alterations
    - Low Pressure (14–20 mm Hg) Insufflation: Increased central venous pressure, stroke volume and blood pressure
    - High Pressure (40 mm Hg) Insufflation: Decreased venous return, hypotension
  - Ventilatory Alterations
    - Decreased functional residual capacity, increased airway pressures and closure, decreased lung compliance, right main stem intubation, hypoxemia
  - Other Alterations
    - Carbon dioxide absorption with possible increase in plasma catecholamines, tachycardia, arrhythmias, vasodilation
    - Increased intraabdominal pressure
- Complications
  - Carbon Dioxide Gas Embolism
  - Hemorrhage
  - Pneumothorax
  - Pneumomediastinum
  - Subcutaneous Emphysema
  - Perforated Viscus
  - Explosion
  - Retroperitoneal Emphysema
  - Cardiovascular Collapse
  - Carbon Monoxide Accumulation
  - Pulmonary Edema

Special Considerations Although CO_2 is a biologically produced gas and is nonflammable and rapidly absorbed, a number of consequences and complications may result from CO_2 insufflation. During the routine practice of laparoscopy and pelviscopy, distension of the abdomen may cause a number of disturbances that have implications for the anesthesiologist (Box 61–8). Pressure on the diaphragm, coupled with the use of anesthetic agents, tends to impede respiration. If patients are breathing spontaneously, minimal to moderate respiratory acidosis and oxygen desaturation may occur. Use of controlled ventilation with increased minute volumes can compensate for increased CO_2, however, higher inspiratory pressures are frequently observed, particularly in obese patients in the Trendelenburg position. Because sustained high plateau pressures can lead to bronchoalveolar damage, several changes may be necessary, such as modification of ventilatory settings to lower tidal volumes, release of some gas from the abdomen by the surgeon, and reduction of the degree of Trendelenburg positioning. Tension pneumothorax related to excessive inspiratory pressures can occur and must be ruled out if a sudden increase in inspiratory pressure is accompanied by decreasing oxygen saturations.

A massive CO_2 embolus, although rare, is rapidly fatal unless recognized and treated immediately. The usual sequence is the onset of sudden and severe hypotension, arterial desaturation, and cardiovascular collapse shortly after placement of the insufflation needle or laparoscope. A "mill wheel" murmur throughout the cardiac cycle from gas in the right heart and

pulmonary outflow tract has been reported; however, this is an unreliable sign. Capnography most likely will reveal a sudden decrease in expired CO_2 because an acute increase in "physiologic" dead space, and fulminant pulmonary edema may occur. Treatment is largely supportive, with immediate discontinuance of CO_2 insufflation, intubation (if not already part of the anesthetic technique), provision of 100% oxygen, and cardiovascular support. Placing the patient in a left lateral head-down position to trap the gas in the apex of the right ventricle rather than the pulmonary outflow tract (i.e., Durant maneuver) is controversial. Placement of a central venous catheter into the right atrium to remove gas or air acting as a mechanical obstruction is controversial. Fortunately, CO_2 is highly soluble and rapidly cleared, and more favorable outcomes have been observed than with massive air emboli. If pulmonary edema develops, 5–10 cm H_2O of positive end-expiratory pressure and use of IV furosemide may be helpful. If significant CO_2 sequelae occur, the procedure should be rapidly terminated and the patient brought to an intensive care environment for continued observation and therapy.

Postoperatively, laparoscopy and pelviscopy have been significantly associated with postoperative nausea and vomiting. Moreover, laparoscopy may be a risk factor for superficial thrombophlebitis, deep venous thrombosis, and pulmonary embolism.[173]

CONCLUSION

The care and management of women undergoing obstetric and gynecologic surgery involves an appreciation of the physiologic, pharmacologic, and anatomic differences. Because a growing amount of evidence-based research and clinical practice now indicates alterations in care and outcome based on gender, anesthesiologists should guide their practice with an appreciation of these differences for optimal patient safety, outcomes, and satisfaction.

CHAPTER 62

Anesthesia for Newborn Surgical Emergencies

Myron Yaster, MD, and
Mark I. Rossberg, MD

Except for extraordinary circumstances, all newborns require anesthesia for surgery.[1–3] In the past, it had been assumed that newborns neither experienced nor perceived painful stimuli to the same degree that adults do. Indeed, it was believed that the newborn did not have the neurologic substrate necessary for perception of pain because of lack of myelinization, incomplete pain pathways from the periphery to the cortex, or immaturity of the cerebral cortex. Absolutely no evidence indicates any of these conditions is true.[3–5] By week 24 of gestation, the newborn responds to noxious stimuli with behavioral, physiologic, metabolic, and hormonal responses suggestive of substantial stress.[6] The neurophysiologic pathways for nociception from the peripheral receptors to the cerebral cortex are developed, even in premature infants. Furthermore, the primary pathways of pain transmission involve unmyelinated C and A delta fibers, so postnatal myelination is not required for most pain perception.[7] Finally, failure to provide anesthesia is associated with an increased incidence of circulatory, respiratory, and metabolic complications in newborns.[8,9] Thus, the preponderance of evidence suggests not only that newborns respond to noxious stimuli, but that the failure to provide analgesia and anesthesia significantly increases perioperative morbidity and mortality.

The newborn differs from the adult and older child with regard to the uptake, distribution, metabolism, and excretion of all drugs. During the first month of life (the "neonatal" period), the newborn must function independently and adapt to extrauterine life. This involves anatomic, physiologic, and pharmacologic changes to maintain homeostasis and to ensure the infant's survival. Disease, congenital anomalies, surgery, and anesthesia may interfere with these adaptations and threaten survival. The important elements of the preoperative history and preanesthetic assessment, including a review of systems, developmental physiology, and the transition from intrauterine to extrauterine life, are discussed in Chapter 18. In this chapter, we discuss anesthetic pharmacology in the neonate, an approach to intraoperative management, and the specific management of commonly encountered surgical problems. The general principles of pharmacokinetics and pharmacodynamics are discussed in detail in Chapter 39. This chapter focuses on the unique aspects that apply specifically to the neonate.

ANESTHETIC PHARMACOLOGY IN THE NEONATE

When physicians administer drugs to patients of any age, they do so with the expectation that an anticipated therapeutic effect will occur. Unfortunately, other less desired results can occur, namely, the patient may derive inadequate or no therapeutic benefit from the administered drug, or, worse yet, they may develop a toxic reaction. The aim of modern clinical pharmacology is to take the guesswork out of this process and to establish the relationship between the dose of a drug given and the response elicited. To attain this goal, clinicians need a working knowledge of the principles of drug absorption, distribution, and elimination and how these processes are related to intensity and duration of drug action. Additionally, they need a thorough understanding of the history, chemical and physical properties, physiologic effects, disposition, mechanisms of action, and therapeutic uses of the drugs that are used to provide anesthesia in the newborn.

An understanding of the factors that determine drug concentrations within the body is crucial to rational drug use in patients and to achieving desirable plasma drug concentrations. *Pharmacokinetics* describes the study of drug disposition within the body. It includes absorption, distribution, metabolism, and elimination of drug molecules from the body. *Pharmacodynamics* describes the study of drug action within the body. It defines the relationship between the concentration of the drug

KEY POINTS

1. The preponderance of evidence suggests not only that newborns respond to noxious stimuli, but that the failure to provide analgesia and anesthesia significantly increases perioperative morbidity and mortality.
2. At equipotent doses, all of the potent inhalational anesthetics (e.g., halothane, sevoflurane, desflurane, and isoflurane) produce unacceptable hypotension in newborns, requiring emergency surgery. The risk of cardiovascular collapse during induction of general anesthesia is much greater in newborns than in older children and adults.
3. The newborn has a fixed stroke volume and can increase cardiac output only by increasing heart rate.
4. In our zeal to protect the eye, we must never compromise oxygen delivery to the neonate's brain!
5. In our experience, central venous pressure is very useful, particularly in surgery involving major blood or third space loss, shock, or when intraabdominal pressure is elevated.
6. Prior to induction of general anesthesia in neonates requiring emergency surgery, we routinely provide a fluid bolus of at least 20 mL/kg of lactated Ringer solution in an attempt to ensure an adequate preload.
7. Life-threatening hyperkalemia has occurred following large-volume blood transfusions in the newborn and may be prevented with washed red cells or fresh whole blood.
8. Infants younger than 6 months are obligate nose breathers.
9. Except for extraordinary circumstances, all newborns require anesthesia and analgesia for surgery.

at the site of action and the physiologic response. The relationship between pharmacokinetics and pharmacodynamics provides an understanding of the dose–response curves of the onset of action, magnitude of action, and duration of action of drugs used in treating patients.

Drug Distribution

How much drug reaches a receptor site depends on the degree of protein binding, tissue volume, tissue solubility coefficients, and blood flow. Anatomic and maturational changes involving body composition, distribution of water, metabolism, protein binding, and organ function in health and in disease contribute to the unique responses of newborns to various drugs. In the blood, opioids (e.g., fentanyl, morphine), amide local anesthetics (e.g., bupivacaine, lidocaine), and muscle relaxants (e.g., pancuronium, rocuronium) bind to albumin and other serum proteins, such as α_1-acid glycoprotein.[10,11] It is the unbound or "free" drug that is available to cross biologic membranes, bind to receptors, and initiate a pharmacologic effect. Concentrations of both albumin and α_1-acid glycoprotein are lower in the newborn period than at any other moment in life. Additionally, the number of binding sites on these proteins is fewer and the affinity of the binding sites is less than in later life. Thus, a greater proportion of active or free drug is available to penetrate the brain, heart, and other viscera. Further, the biologic membranes that separate target receptors from the blood (e.g., the "blood–brain barrier") may be immature at birth and thereby allow agonists with limited lipid solubility, such as morphine, greater access to the brain. Way et al[12,13] demonstrated that morphine concentrations were 2–4 times greater in the brains of younger rats than in older rats despite equal blood concentrations. On the other hand, decreased protein binding may contribute to the larger apparent volume of distribution of many drugs as well. A large apparent volume of distribution has the effect of diluting the plasma concentrations of parenterally administered drugs and explains, in part, why some drugs must be given in larger doses (on a milligram per kilogram basis) to achieve a therapeutic effect.[14]

Body composition changes with age. Eighty percent of the newborn's body mass is composed of water (Table 62–1).[15] In the very-low-birthweight premature infant (<1000 g), total body water can be estimated at 100% of body weight. This increase in total body water occurs primarily in the extracellular fluid space, mostly in interstitial water, and also explains the larger apparent volume of distribution of most parenterally administered drugs in the newborn. In the newborn, interstitial water makes up 40% of the body weight and declines to 10–15% in adults.

Blood flow determines how much drug reaches a target receptor. As in the adult, a high proportion of cardiac output perfuses vessel-rich organs, such as the brain, kidney, and intestinal viscera. Very high brain concentrations are achieved following the administration of any lipophilic or inhalational anesthetic agent because the infant's brain receives almost 30% of the cardiac output versus only approximately 15% in the adult. The very small muscle and fat mass of the infant provides less uptake of an administered drug and less of a reservoir to lower blood concentrations of drugs. Further, the potent vapors are less soluble in neonatal blood than in adult blood. This allows higher concentrations of an administered drug (e.g., halothane, sevoflurane) to be achieved more quickly than might be expected.[16,17] Finally, the perinatal adaptation to extrauterine life produces rapid changes in the circulation. This process may be inhibited by congenital heart disease or any condition that increases pulmonary vascular resistance more than systemic vascular resistance, such as hypoxia, hypercarbia, and acid–base problems. Uptake, distribution, metabolism, and excretion may be drastically affected when cardiovascular function is abnormal.

Biotransformation and Elimination

Following administration, the disposition of a drug depends on distribution ($t^1/_2\forall$) and elimination. The terminal half-life of elimination ($t^1/_2$) is directly proportional to the volume of distribution (Vd) and inversely proportional to the total body clearance (Cl) by the following formula:

$$t^1/_2 = 0.693 \times (Vd/Cl) \quad (1)$$

Thus, prolongation of $t^1/_2$ may be due to either an increase in a drug's volume of distribution or a decrease in its clearance.

Following redistribution, the major processes that lead to termination of a drug's effect are biotransformation, metabolism, and excretion. Many anesthetic drugs (e.g., opioids, muscle relaxants, hypnotics) are biotransformed in the liver prior to excretion. Many of these reactions are catalyzed in the liver by microsomal mixed-function oxidases that require the cytochrome P450 system, nicotinamide adenine dinucleotide phosphate (NADPH), and oxygen. The cytochrome P450 system is very immature at birth and does not reach adult levels until the first month or two of life. This immaturity of this hepatic enzyme system may explain the prolonged clearance or elimination of some drugs in the first few days to weeks of life and the inability of the liver to convert a precursor into its active form (e.g., codeine into morphine).[18,19] On the other hand, the cytochrome P450 system can be induced by various drugs (e.g., phenobarbital) and substrates, and this enzyme system matures regardless of gestational age. Thus, it is the age from birth, and not the duration of gestation, that determines how

TABLE 62–1.

Reference Values for Body Compartments by Age

Body Compartment	Premature (<2.5 kg)	Full term (>2.5 kg)	Adult
Total body water (% body weight)	90–100	70–85	60
Extracellular fluid (% body weight)	40–60	40	20
Intracellular fluid (% body weight)	40	40	40
Blood volume (mL/kg)	90–105	80–95	50–65
Muscle mass (% body weight)	15	20	50
Fat (% body weight)	3	10	15–30

premature or full-term infants metabolize many drugs. Greeley et al.[20] demonstrated that sufentanil is more rapidly metabolized and eliminated in 2- to 3-week-old infants than in newborns younger than 1 week. Elimination may be further prolonged by abnormal or decreased hepatic blood flow, which may occur following an acute illness or abdominal surgery. Certain conditions that may raise intraabdominal pressure (e.g., closure of abdominal wall defect, such as omphalocele or gastroschisis) may further decrease hepatic blood flow by shunting blood away from the liver via the still patent ductus venosus.[21,22] Finally, in all newborns, excretion may be reduced compared to the older child and adult because both glomerular and tubular renal function, which are responsible for active secretion and passive resorption, are reduced in the newborn.[23]

CHOICE OF ANESTHETIC AGENTS

Inhalational Agents

At equipotent doses, all of the potent inhalational anesthetics (e.g., halothane, sevoflurane, desflurane, and isoflurane) produce unacceptable hypotension in newborns requiring emergency surgery.[24–32] The risk of cardiovascular collapse during induction of general anesthesia is much greater in newborns than in older children and adults. This greater decrease in blood pressure is due to differences in uptake and distribution of the anesthetic agents, anesthetic dose requirements, the intrinsic properties of anesthetic agents, and the sensitivity of the newborn's myocardium to these agents.[33–35] The newborn attains a greater absolute concentration of halothane (or any of the potent vapors) in the brain and heart and at a faster rate than does an adult at the same inspired concentration. If the inspired concentration of an inhaled agent is kept constant, the ratio of the inspired agent concentration to its alveolar end-tidal concentration (FA/FI) is significantly greater in the newborn compared to the adult because of differences in ventilation and anesthetic uptake. The infant has 3–4 times the minute ventilation of an older child and adult but the same functional residual capacity on a milliliter per kilogram basis (Table 62–2). Thus, inhalational anesthetics wash in (and wash out) rapidly because the time constant of the lung is so markedly reduced compared to that in the adult (0.19 minutes in the infant vs. 0.73 minutes in the adult). Controlled ventilation further exacerbates this phenomenon.

TABLE 62–2.

Pulmonary Function Variables by Age

Respiratory Variable	Newborn (mL/kg)	Adult (mL/kg)
Tidal volume	7	7
Respiratory rate	30–40	10–15
V_D/V_T	0.3	0.3
Functional residual capacity	20–30	20–30
Vital capacity	50–70	50–70
Alveolar ventilation: Functional residual capacity	5:1	1.5:1

Uptake of a potent vapor is very rapid in the newborn as well. Because the mass of vessel-rich organs is so small, uptake of inhalational agents by the tissues is rapid, and tissue concentrations saturate quickly. Venous blood returning to the lung arrives at a relatively high anesthetic partial pressure compared to the adult, which further reduces FA/FI and increases the amount of potent agent in the alveolus. This allows a higher concentration of inhalational agent to be taken up by the blood for delivery to the major organs. End-tidal gas monitoring may help prevent inadvertent overdosage. Finally, both left-to-right and right-to-left shunting occurs in infants. A left-to-right shunt has little to no effect on anesthetic uptake. A right-to-left shunt may slow the rate of rise of the arterial concentration of an inhaled anesthetic.

The minimum alveolar concentration (MAC) of halothane or isoflurane is significantly lower in newborns than in infants 1–6 months old.[24–32] Further, premature infants have lower MAC requirements than do full-term infants. Thus, some of the hypotension associated with inhalational agents may have occurred because of anesthetic overdose. Nevertheless, even at "true" MAC concentrations, heart rate and blood pressure decrease by 12% and 30%, respectively, in the newborn for all vapor anesthetics. This can be partially attenuated by pretreating the infant with an intravenous anticholinergic such as atropine immediately prior to induction of anesthesia.[36] Atropine requirements in the newborn are higher than in the adult (0.03–0.05 mg/kg vs. 0.01–0.02 mg/kg, respectively). Additionally, intravenous doses of atropine < 0.1–0.15 mg may produce paradoxical bradycardia.

The other cause of the profound hypotension associated with inhalational agents relates to intrinsic properties of the newborn's myocardium.[37] The newborn's myocardium is less compliant than that of the older child and adult.[37] The newborn has a fixed stroke volume and can increase cardiac output only by increasing heart rate. The newborn's myocardium has decreased contractile mass and a decreased velocity of shortening. Therefore, the negative inotropic and chronotropic effects associated with inhaled anesthetics are poorly tolerated.[38–40] Furthermore, the baroreceptor reflexes are blunted or obliterated by these agents.[25,41] Reflex tachycardia, which is vital to supporting blood pressure and cardiac output, may not occur.

Fentanyl(s)

Fentanyl and its structurally related relatives sufentanil, alfentanil, and remifentanil are highly lipophilic drugs that rapidly penetrate all membranes, including the blood–brain barrier. Following an intravenous bolus, fentanyl is rapidly eliminated from plasma as a result of its extensive uptake by body tissues. The fentanyls are highly bound to α_1-acid glycoproteins in the plasma, which are reduced in the newborn.[42,43] The fraction of free unbound sufentanil is significantly increased in neonates and children younger than 1 year (19.5% ± 2.7% and 11.5% ± 3.2%, respectively) compared to older children and adults (8.1% ± 1.4% and 7.8% ± 1.5%, respectively), and this correlates to levels of α_1-acid glycoproteins in the blood.[42–44]

Fentanyl pharmacokinetics differ among newborn infants, children, and adults. The total body clearance of fentanyl is greater in infants 3–12 months old than in children older than 1 year and in adults (18.1 ± 1.4 mL/kg/min, 11.5 ± 4.2 mL/kg/min, and 10.0 ± 1.7 mL/kg/min, respectively), and the half-life of elimination is longer (233 ± 137 minutes, 244 ± 79 minutes, and 129 ± 42 minutes, respectively).[42–44] The prolonged elimination half-life of fentanyl from plasma has important clinical implications. Repeated doses of fentanyl for maintenance of analgesia will lead to accumulation of fentanyl and its ventilatory depressant effects. Very large doses (0.05–0.10 mg/kg) may be expected to induce long-lasting respiratory depression because plasma fentanyl levels will not fall below the threshold level at which spontaneous ventilation occurs during the distribution phases.[45]

Robinson and Gregory[46] reported the first use of fentanyl (30–50 μg/kg) as the principal anesthetic in neonates undergoing ductus ligation surgery. Using heart rate and blood pressure responses as indices of adequate anesthesia, these investigators demonstrated that the combination of fentanyl, oxygen, and pancuronium could provide anesthesia with minimal hemodynamic consequences. The hemodynamic stability associated with fentanyl (or sufentanil) administration in the newborn has been confirmed by several other investigators.[8,9,47] In all reported studies, both hypotension and bradycardia are rare, as long as a vagolytic agent (either pancuronium or atropine) is administered concomitantly. Furthermore, in the newborn lamb, fentanyl does not significantly affect heart rate, blood pressure, cardiac output, or regional distribution of blood flow to the major organs (e.g., brain and gastrointestinal tract) when it was administered in doses ranging between 30 and 3000 μg/kg.[48] On the other hand, the safety of "fentanyl" anesthesia may be diminished when other anesthetics (e.g., nitrous oxide, barbiturates, or benzodiazepines) are administered concomitantly.[49]

Yaster[47] extended the observations of Robinson and Gregory[46] in a prospective study of premature and full-term infants younger than 7 days undergoing a variety of thoracic, abdominal, and genitourinary emergency operations. In his study, fentanyl in doses from 10–12.5 μg/kg produced insignificant hemodynamic changes and provided reliable anesthesia for at least 75 minutes. There are several reasons for the discrepancies in fentanyl requirements in these studies. Robinson and Gregory studied premature infants varying in age from 1 day to 6 weeks undergoing thoracic surgery. Yaster's patients were younger (majority younger than 24 hours). Analgesic requirements are known to be reduced in the first few days of life. This may be caused by the release of endogenous opioids in response to birth or to fetal and neonatal distress. The blood–brain barrier is immature in the first few days of life, and this may allow more fentanyl to reach the μ-opioid receptors within the central nervous system. However, this is more important for less lipid soluble agonists such as morphine. Alternatively, the increased fraction of free unbound fentanyl in the newborn may allow more drug to penetrate into the brain. Additionally, fentanyl clearance increases markedly in the first weeks of life, probably as a result of increasing activity of the cytochrome P450 system and increasing hepatic blood flow following closure of the ductus venosus. Thus, the increased fentanyl metabolism that occurs in older newborns may increase their anesthetic (fentanyl) requirements. Finally, many of the patients in Yaster's study underwent abdominal surgery and/or had significant abdominal pathology, such as necrotizing enterocolitis. Fentanyl clearance as well as analgesic requirements may be significantly decreased in these situations, particularly if intraabdominal pressure increases. Increased intraabdominal pressure (>15–20 mm Hg) markedly reduces hepatic and splanchnic blood flow and has been documented to occur following closure of abdominal wall defects, such as omphalocele or gastroschisis.[21,22] This decreased hepatic blood flow reduces fentanyl biotransformation and thereby anesthetic requirements. Therefore, fentanyl dose may be dependent on the neonate's postnatal age, type of surgery being performed, as well as patient "risk" factors such as acidosis, hypoxia, and circulatory stability.

Use of fentanyl in newborns may result in the need for postoperative intubation and ventilation, independent of the infant's medical or surgical condition. All opioids produce profound respiratory depression in the newborn. A number of studies suggest that the respiratory depression and analgesia produced by μ-opioid agonists involve different receptor subtypes. These receptors change in number in an age-related fashion and can be blocked by naloxone. Working with newborn rats, Pasternak et al.[50,51] showed that 14-day-old rats are 40 times more sensitive to morphine analgesia than are 2-day-old rats. Nevertheless, morphine depresses the respiratory rate in 2-day-old rats to a greater degree than in 14-day-old rats. Thus, the newborn may be particularly sensitive to the respiratory depressant effects of the commonly administered opioids in what may be an age-related receptor phenomenon.

The need for early extubation and minimal residual respiratory depression has led to the increased use of remifentanil in newborn anesthesia practice.[52,53] Remifentanil is primarily metabolized by plasma esterases. The pharmacokinetics of remifentanil are characterized by small distribution volumes, rapid clearances, and low variability compared to other intravenous anesthetic drugs.[54,55] The drug has a rapid onset of action (half-time for equilibration between blood and the effect compartment = 1.3 minutes) and a short context-sensitive half-life (3–5 minutes). The latter property is attributable to hydrolytic metabolism of the compound by nonspecific tissue and plasma esterases. Virtually all (99.8%) of an administered remifentanil dose is eliminated during the α half-life (0.9 minutes) and β half-life (6.3 minutes). The pharmacokinetics of remifentanil suggest that, within 10 minutes of starting an infusion, remifentanil will reach nearly steady state. Thus, changing the infusion rate of remifentanil will produce rapid changes in drug effect. The rapid metabolism of remifentanil and its small volume of distribution mean that remifentanil will not accumulate. Discontinuing the drug rapidly terminates its effects regardless of the duration of administration.[45,56] Finally, the primary metabolite has little biologic activity, making it safe even in patients with renal disease.

Muscle Relaxants

Structural and functional development of the neuromuscular system is incom-

plete at birth.[57] The newborn has decreased neuromuscular reserve compared to the older child and adult. At a stimulation rate of 20 Hz, many neonates demonstrate tetanic fade, and premature infants demonstrate posttetanic exhaustion.[58,59] At a higher stimulation rate (50 Hz), all newborns demonstrate posttetanic exhaustion. The train-of-four ratio and the magnitude of posttetanic facilitation all increase with age. Based on these findings and on clinical criteria, it has been suggested that the newborn is more "sensitive" to nondepolarizing muscle relaxants than are older patients.[57]

Several investigators have documented the sensitivity of infants to D-tubocurarine, even if one compensates for the newborn's increased extracellular fluid space and apparent volume of distribution.[14] However, a single dose of curare does not appear to have a longer duration of action in the newborn compared to the adult because, in neonates, the steady-state plasma concentration associated with 50% neuromuscular block is only one third of adult values.[14] This also means that subsequent doses of curare may lead to a prolonged duration of paralysis.

At appropriate doses, all of the nondepolarizing muscle relaxants are effective paralytics in newborns; thus, the choice is more often based on other properties of these drugs. Because pancuronium is a potent vagolytic, it remains one of the agents most commonly used in the newborn.[60] Unlike the adult, tachycardia is often a *desired* side effect because the infant responds to a variety of stimuli, such as hypoxia, intubation, and halothane and fentanyl administration, with bradycardia. Because the newborn's cardiac output is heart rate dependent, bradycardia has the potential to be catastrophic. Occasionally, other relaxants (e.g., atracurium and mivacurium) are selected because end-organ pathology (liver or kidney) may interfere with drug elimination or because the duration of paralysis or onset time of paralysis is inappropriate for the surgery being performed.

Interestingly, newborns are relatively resistant to succinylcholine even though plasma cholinesterase levels are reduced following birth.[61] Intravenous doses of 1–2 mg/kg, rather than 0.5 mg/kg, are required for complete paralysis. Intravenous succinylcholine produces myriad arrhythmias, including sinus bradycardia, sinus arrest, nodal rhythms, and ventricular ectopy. Several neonates have developed pulmonary edema and hemorrhage in the absence of upper airway obstruction following intravenous use succinylcholine.[62] Other well-known complications of succinylcholine administration include malignant hyperthermia, hyperkalemia, myoglobinemia, and increased intraocular (and perhaps intracranial) pressure. Because of these effects, increasing numbers of pediatric anesthesiologists are discouraging the routine use of succinylcholine. Nevertheless, succinylcholine remains one of the most rapidly acting neuromuscular blocking agents available. Despite the problems associated with its use, there is no substitute for succinylcholine when "full stomach" precautions are required or laryngospasm occurs.[63] Thus, our practice is to "always have it, rarely use it."

Ketamine, General Anesthetics, Sedatives, and the Developing Brain

Ketamine produces tachycardia, hypertension, relative hemodynamic stability, analgesia, and an altered "dissociative" level of consciousness. It increases both systemic and pulmonary vascular resistance and is often used in infants with congenital heart disease, cardiovascular instability, or both. It is an *N*-methyl-D-aspartate (NMDA) receptor antagonist. In a series of major publications, Ikonomidou, Olney, and colleagues showed in rat pups that even brief exposure to NMDA antagonists, such as ketamine, causes apoptotic neurodegeneration during vulnerable developmental ages.[64–67] They have extended their findings to γ-aminobutyric acid ($GABA_A$) agonists such as the vapor anesthetics and the benzodiazepines.[65,68] *If* these results are applicable in human newborns, and this is a very big "if," the consequences may be enormous. Although others have disputed these findings, we are left with the dilemma: "Are these and other drugs that we routinely use in the newborn to provide anesthesia safe"?[69] Equally compelling is the alternative: "What are the consequences to the developing brain of not providing analgesia and anesthesia for surgery"?

Local Anesthetics

Local anesthetics work by blocking initiation and propagation of action potentials in axons. All currently available local anesthetics work by blocking sodium ion flux through open, voltage-gated sodium channels and are of two classes: amino amides and amino esters.[70,71] The amino amides lidocaine, bupivacaine, and ropivacaine are metabolized in the liver by the cytochrome P450 (CYP-linked) isoenzymes. Details of local anesthetic pharmacology are provided in Chapter 44. These metabolic pathways have markedly diminished in function in the neonatal period; therefore, clearance of these drugs is greatly reduced.[72,73] When combined with fewer plasma proteins and more free drug, the potential for severe toxicity is obvious. The amino esters, on the other hand, are metabolized by plasma esterases. Although these enzymes are reduced in quantity and function in the newborn period as well, the clearance of amino esters is much less impaired than that of amino amides.[74]

Monitoring

Critically ill neonates undergoing emergency surgery require as much, if not more, monitoring during anesthesia and surgery than do critically ill adults because the margin of error is so small and because disaster can strike so quickly. Unfortunately, compromises are often made because of the technical difficulty in monitoring small children and because, once positioned and draped on the operating room table, observation, palpation, and even auscultation often are difficult, if not impossible. Meticulous attention to detail is absolutely necessary. It must be emphasized that no machine can replace a vigilant anesthesiologist who will evaluate, interpret, and analyze the patient's condition.

One of the simplest and most effective monitors in newborn anesthesia is the precordial or esophageal stethoscope. Stethoscopy provides beat-to-beat, breath-by-breath information on the patient's condition. For example, the first indication of cardiovascular deterioration in children may be a change in heart sounds, from brisk and close to muffled and distant. Loss of breath sounds may indicate a mechanical disconnection or an endobronchial intubation well before a mechanical alarm sounds. Despite its importance, this low-technology, inexpensive monitor is rapidly being discarded by anesthesiologists in favor of more glitzy and expensive monitors.

Only slightly less important than the precordial stethoscope is the pulse oximeter. This noninvasive, beat-to-beat monitor of oxygen saturation has revolutionized anesthesia monitoring and should be used not only in the operating room but in transport to and from the operating room as well.[75,76] In neonates, the probe is preferentially placed on the right hand, ear lobe, or on the buccal mucosa. It is used to maintain an oxygen saturation between 90% and 95% (PaO_2 50–70 mm Hg). Higher oxygen saturations have been associated with retinopathy of prematurity (ROP). Because of intracardiac shunting, many anesthesiologists use two pulse oximeters, one on the right hand and one on the lower extremity, to measure preductal and postductal flows. Preductal arterial oxygen saturation reflects coronary and cerebral oxygen saturation, and it is the cerebral oxygenation that affects the eye and is responsible for ROP. Nevertheless, in our zeal to protect the eye, we must never compromise oxygen delivery to the neonate's brain!

The next most important monitor is blood pressure. Newborns, particularly premature newborns weighing < 1.5 kg, may have normal systolic blood pressures of only 40 mm Hg. Blood pressure measurement and control become herculean tasks. This is the reason why many pediatric anesthesiologists prefer fentanyl-based anesthetics to inhalational agents when providing anesthesia for newborn surgery. In most cases, blood pressure can be adequately measured with an appropriately sized blood pressure cuff and commonly available noninvasive automatic blood pressure devices. Occasionally, a Doppler ultrasonic transducer or a strategically placed oxygen saturation probe can help in blood pressure measurement. However, for most major operations, continuous invasive intraarterial monitoring is indicated for the safe conduct of anesthesia. Catheterization, preferably of the radial artery, is accomplished either percutaneously or by surgical cutdown. In general the temporal arteries must be avoided as intraarterial cannulation sites because catastrophic brain injury, presumably from embolization of clot and debris, has been associated with its use. Alternative catheterization sites include the dorsalis pedis, posterior tibial, and umbilical artery. The arterial catheter provides beat-to-beat monitoring and a means for frequent sampling of blood gases, hematocrit, and glucose. It also is an extremely sensitive guide of the patient's intravascular volume status. Meticulous attention to detail and technique is needed when flushing these catheters. We recommend high-pressure, low-volume tubing and, following aspiration of blood for sampling, flushing the tubing with 0.5–1 mL of saline to minimize the risk of embolization into the cerebral circulation.

Judging intravascular volume clinically in the neonate is extremely difficult. During abdominal surgery (e.g., necrotizing enterocolitis), third space fluid losses may approach 100–200 mL/kg. The arterial waveform displayed on a monitor or recorder is one of the best signs of early intravascular volume losses (Fig. 62–1). One looks for either a change in the shape of the arterial waveform (decreased area under the curve) or the development of respiratory variation in the waveform. During positive-pressure ventilation, decreased venous return causes a dramatic decrease or drift in the arterial waveform with each breath. Typically, this decrease occurs when the intravascular volume has been depleted.

In adults, the more commonly used monitor for intravascular volume is either a central venous or pulmonary arterial catheter. Historically, central venous pressure measurements in newborns have been considered not

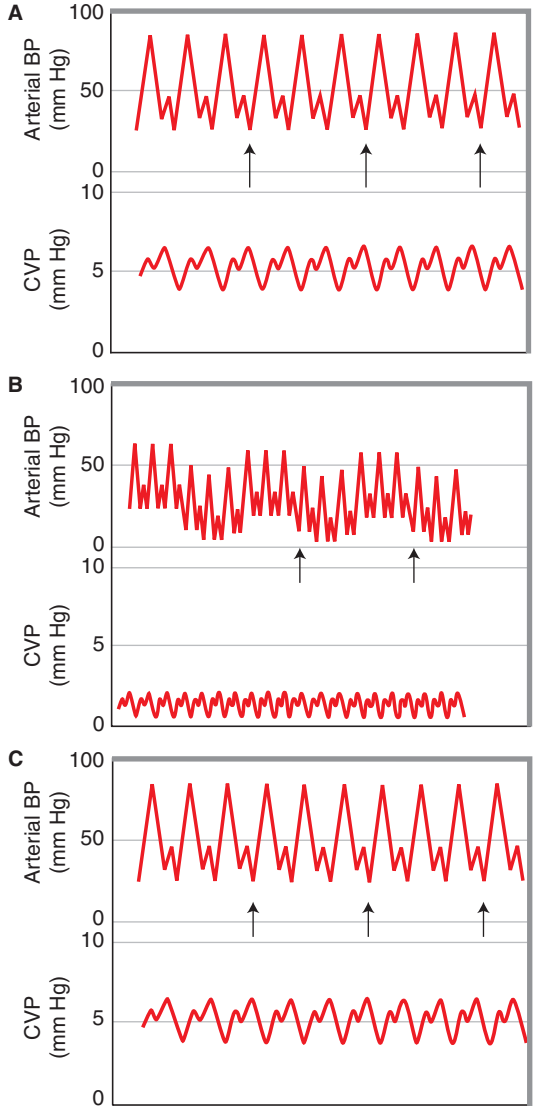

FIGURE 62–1. Hypovolemia is detected on both the arterial and central venous waveforms. Following a positive pressure breath (arrow), decreased venous return produces a pulsus paradoxus and a fall in central venous pressure. With volume resuscitation the tracing returns to normal.

only technically difficult to obtain but also insensitive to volume status. Experiments during exchange transfusions performed in the 1960s demonstrated little correlation between blood losses of as much as 20% of the estimated blood volume and central venous pressure as measured by umbilical central venous catheters.[77] These experiments have never been repeated with central venous catheters placed in the internal or external jugular vein and pressure transduced with modern equipment. In our experience, the central venous pressure is very useful, particularly in surgery involving major blood or third space loss, shock, or when intraabdominal pressure is elevated.[21,22] Because these are large-bore catheters, securely inserted within the vascular tree, usually the internal jugular vein, they supply a reliable means for administering fluids and vasoactive drugs.

One of the mainstays in the assessment of volume status of the newborn is the measurement of urine output (or lack thereof). Bladder catheterization is easily accomplished using a 5F feeding tube (not a balloon-tipped Foley catheter). The catheter is secured to the skin with tape and connected to a calibrated urinometer by low-volume tubing. Minimum acceptable urine outputs range between 0.5 and 1.0 mL/kg/h.[23,78] In very small children, this small volume of urine may take hours to travel the length of the operating room table to reach the urinometer. Additionally, the drainage tubing usually is under the surgical drapes and not easily accessible to the anesthesiologist, making identification of kinks and disconnects almost impossible. Because of these factors, measurement of urine output during surgery may be of marginal value.

Because neonatal anesthesia virtually always is performed with controlled mechanical ventilation, respiratory monitoring with capnography is essential. Despite the many technical problems involved in measuring end-tidal carbon dioxide concentrations through small uncuffed endotracheal tubes, it is a "standard of care" and is a mandatory monitor for the provision of safe anesthesia.[79,80]

Last, but not least, is temperature monitoring. All newborns are at extraordinarily high risk for becoming cold during transport and while in the operating room. To minimize this risk, we routinely wrap children in plastic bags, use forced-air heating mattresses, increase the ambient temperature of the operating room, warm up intravenous fluids, and use heated, humidified respiratory gases.[81,82] Temperature is routinely monitored with either a rectal or a nasopharyngeal temperature probe. We strive to maintain a core temperature at 36°C in order to avoid the consequences of hypothermia, which include hypoventilation or even apnea, relative anesthetic overdose (reduced MAC at lower temperatures), metabolic acidosis, norepinephrine secretion, and increased oxygen demand. Increased oxygen demand to maintain normal core temperature and increased norepinephrine secretion may cause pulmonary and peripheral vasoconstriction, right-to-left shunting, anaerobic metabolism, and increased acidosis and oxygen consumption, all of which may exacerbate preexisting cardiopulmonary insufficiency.

Fluids

Intraoperative intravenous fluid therapy provides the infant with maintenance requirements of water, electrolytes, and glucose to replace preoperative deficits and ongoing intraoperative "third space" and blood losses. Maintenance fluid requirements are calculated based on the assumption that 100 mL of water is required for every 100 calories consumed.[83–86] The newborn's energy (and fluid) requirements are 100 calories (mL) per 24 hours in the unanesthetized state or approximately 4 mL/kg/h. Although basal caloric requirements are significantly reduced under general anesthesia, we continue to provide maintenance fluid, usually with 5–10% (50–100 mg/mL) glucose at a rate of 4 mL/kg/h.

Because the majority of newborns who present for emergency surgery are in neonatal intensive care units and are receiving intravenous fluids prior to surgery, the logical presumption is that preoperative deficits are nonexistent. Unfortunately, this is rarely true. Most newborns are fluid restricted in the nursery despite the presence of a surgical emergency and third space fluid losses.[84,85] Furthermore, infants are rarely given solutions containing electrolytes, even though the newborn's kidney cannot tolerate a water load and will waste sodium even when water overloaded. The maximum urine osmolality achievable by the neonatal kidney is only 800 mOsm/L. Unsuspected hypovolemia when combined with anesthetic drugs can be catastrophic. Thus, prior to induction of general anesthesia in neonates requiring emergency surgery, we routinely provide a fluid bolus of at least 20 mL/kg of lactated Ringer solution in an attempt to ensure an adequate preload.

Surgical trauma and manipulation, or inflammation of the bowel, result in internal sequestration of functional extracellular fluids and often are referred to as "third space" losses. The fluid and salt within the third space acts as sequestered fluid and is nonfunctional in terms of the duties of the extracellular fluid. Replenishment of this interstitial water and salt loss with balanced salt solutions ("isotonic crystalloid solutions"), such as lactated Ringer solution or normal saline, is essential. The magnitude of the third space loss depends on the site and extent of injury. Abdominal surgery, particularly if extensive bowel pathology or manipulation is involved, may require third space replacement therapy of 10–20 mL/kg/h, whereas peripheral or thoracic surgery may require only 3–5 mL/kg/h.

All blood loss must be replaced with balanced salt solutions, 5% albumin, or blood. Normally, infants are born with high hematocrit (>50%), which fall to 30% over the first 3 months of life. Additionally, these red cells are made primarily of hemoglobin F (HgbF), which has a greater affinity for oxygen than does adult hemoglobin (HgbA). The partial pressure at which 50% of hemoglobin is saturated (P_{50}) is 19 for HgbF versus 27 for HgbA. Because the newborn has limited stores of iron and limited ability to replace lost red cells with new red cells, the hematocrit should not be allowed to fall below 35% during surgery. The allowable blood loss can be calculated by the following formula:

$$[\text{Weight (kg)}] \times [\text{EBV}^*] \times \left[\frac{\text{Hct}_{\text{start}} - 0.35}{\text{Hct}_{\text{average}}^{**}}\right]$$

$$\text{Hct}_{\text{average}} = \left[\frac{\text{Hct}_{\text{start}} + 0.35}{2}\right] \quad (2)$$

where EBV = estimated blood volume (Table 62–1), and $\text{Hct}_{\text{average}} = (\text{Hct}_{\text{start}} + 0.35)/2$.

Ideally, blood would be replaced with fresh whole blood because it contains

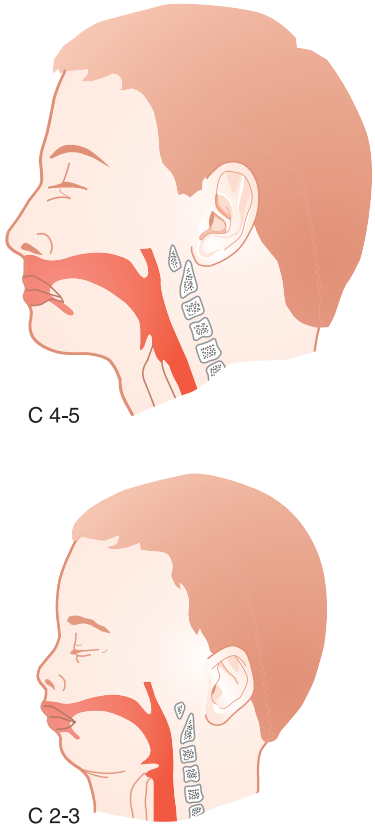

FIGURE 62–2. Comparative anatomy of the adult and infant airways.

platelets and clotting factors as well as red cells. Unfortunately, fresh whole blood is rarely, if ever, available. Packed red blood cells usually are used instead. This blood product typically has a hematocrit of 60–70%, high potassium concentration, and little, if any, factors V and VIII. Large blood losses and massive transfusion (2–3 times the estimated blood volume) often produce a secondary coagulopathy and hyperkalemia.[87] This bleeding often is caused by either dilutional or consumptive thrombocytopenia. Platelets can be transfused based on the following formula:

$$\text{Platelet increment/mm}^3 = \frac{30{,}000 \times (\text{Number of units})}{\text{EBV (L)}} \quad (3)$$

Fresh-frozen plasma is rarely necessary and should be given only for legitimate indications. All blood products, including fresh-frozen plasma, may be contaminated with viruses. The newborn should be considered an immunocompromised host. Therefore, consideration should be given to irradiating any blood product that may contain white blood cells prior to transfusion because of the possibility of producing a graft-versus-host reaction. Finally, all banked blood (especially older blood) contains significant amounts of potassium.[87,88] Life-threatening hyperkalemia has occurred following large-volume blood transfusions in the newborn and may be prevented with washed red cells.

Airway

Understanding the anatomic differences among infants, children, and adults is crucial for successful airway management in the normal child and the child with a congenital anomaly (Fig. 62–2). Infants younger than 6 months are obligate nose breathers. Anatomic (e.g., choanal atresia), physical (e.g., nasogastric tube), or infectious obstruction of the nasopharynx will rapidly cause respiratory distress and/or failure. The abundant and friable lymphoidal tissue of the nasopharynx also precludes the routine placement of nasopharyngeal airways in patients in this age group when treating upper airway obstruction.

The tongue is relatively large in relation to the mandible in children younger than 2 years, making visualization of the larynx difficult. It is the tongue that most commonly obstructs the upper airway when consciousness is lost following induction of anesthesia. The larynx is difficult to visualize because it is anterior and more cephalad in the newborn. It is located at the second to third cervical vertebrae in infants and at the fourth to fifth cervical vertebrae in adults. The vocal cords also differ in appearance. In infants they are 40% ligament and 60% arytenoid cartilage. This ratio is reversed in adults.

The infant's epiglottis is omega shaped, floppy, and has a 45° angle of entry into the pharyngeal wall. Visualization of the larynx requires lifting the epiglottis directly with an appropriately sized straight laryngoscope blade (no. 0 or 1 Miller blade). In contrast, the adult's epiglottis is stiff, flat, and parallel to the tracheal wall. Visualization of the larynx can be made indirectly by placing the laryngoscope blade in the vallecula (Fig. 62–3).

Finally, the trachea is different. The narrowest part of the airway in children younger than 10 years is the cricoid ring. Uncuffed endotracheal tubes, generally 2.5–3.5 mm in diameter, are used in neonates to prevent damage to the mucosa underlying this structure. Furthermore, the infant's trachea may be only 4–5 cm in total length. This makes inadvertent endo-

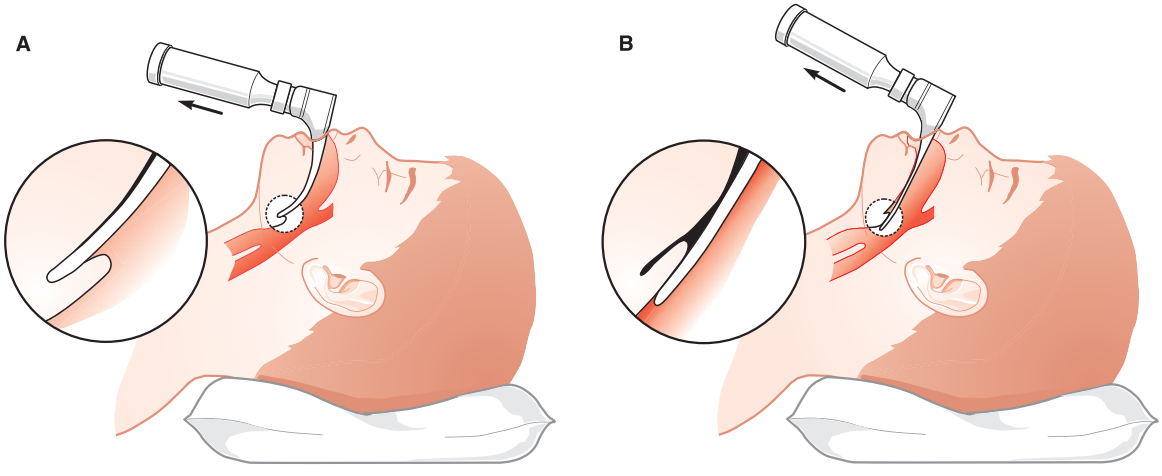

FIGURE 62–3. Laryngoscope blades. **A.** Curved (MacIntosh) inserted in the vallecula only. **B.** Straight (Miller) inserted either under the epiglottis or in the vallecula.

bronchial intubation extremely likely, even by highly experienced practitioners. To minimize this risk, we use the "1-2-3...7-8-9" rule to assist in correct endotracheal tube positioning. The "1-2-3" refers to the patient's weight in kilograms, and the "7-8-9" refers to the position of the endotracheal in centimeters at the patient's lip. Thus, a 1-kg infant would have the tip of his endotracheal tube taped at the 7-cm mark at the lip. Proper positioning of the endotracheal tube can be made by auscultation (return of breath sounds after a deliberate right mainstem intubation), palpation of the tip of the endotracheal tube in the sternal notch, inspection of the distal line marker at the level of the vocal cords, and chest x-ray film. Once positioned, the endotracheal tube must be secured in place with adhesive tape in a way that minimizes the likelihood of dislodgement or accidental extubation. The "fish-mouth" technique is our preferred method (Fig. 62–4).

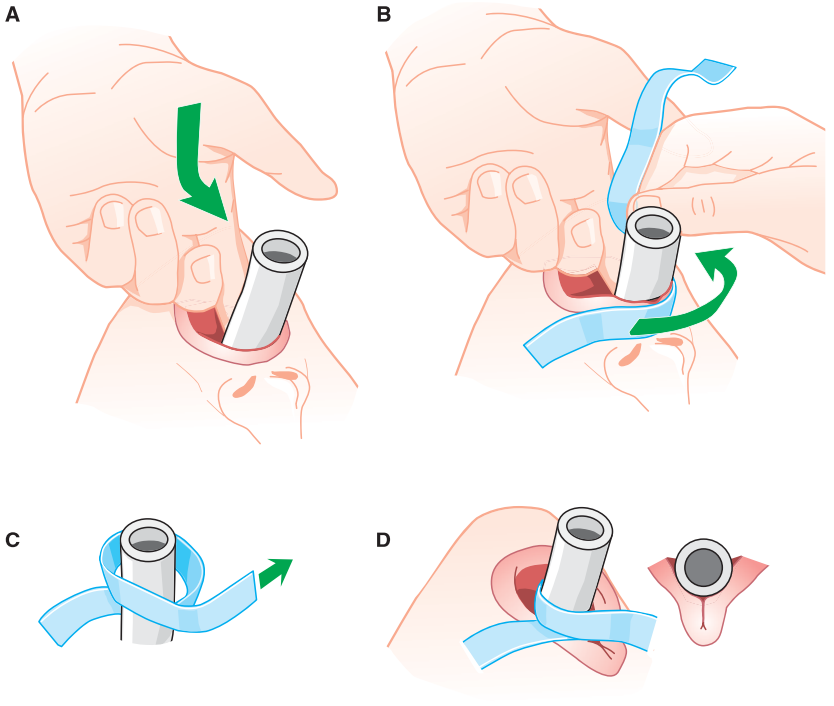

FIGURE 62–4. Using 1/2-inch adhesive tape, the endotracheal tube is secured with the "fish-mouth technique." Starting at one zygoma, the tape is pulled, wrapped around the endotracheal tube, and then pulled to the opposite zygoma.

How to intubate the trachea is controversial. Because of the anatomic considerations and because the newborn rapidly desaturates following only 15–20 seconds of apnea, in the past many anesthesiologists believed it was safer to intubate the newborn "awake." However, recent evidence that awake intubation may cause intraventricular hemorrhage in fragile, premature newborns has counterbalanced this sentiment.[89,90] Furthermore, awake intubations are technically more difficult to accomplish and often result in trauma to the vocal cords, hemorrhage, bradycardia, and desaturation secondary to breath holding. We prefer to use a "rapid sequence" induction in infants requiring "full stomach" precautions, that is, infants who are at risk for aspirating their gastric contents (e.g., intestinal obstruction, necrotizing enterocolitis) and who have a normal airway on physical examination. After fluid volume resuscitation (10–40 mL/kg of lactated Ringer solution), preoxygenation, and pretreatment with atropine (0.15 mg), gentle cricoid pressure is applied to occlude the esophagus.[91,92] If cricoid pressure is applied too vigorously, the position of the larynx may be distorted or the trachea itself occluded. In hemodynamically stable patients, a rapid sequence intravenous induction can be accomplished by bolus administration of thiopental 4–7 mg/kg, propofol 2–3 mg/kg, ketamine 2–4 mg/kg, or fentanyl 12.5 μg/kg (note: chest wall rigidity may occur with this dose of fentanyl!), immediately followed by succinylcholine 2 mg/kg or rocuronium 0.9–1.2 mg/kg.[93,94] Newborns not requiring full stomach precautions are in the minority (e.g., myelomeningocele or bladder exstrophy), and in these patients anesthesia can be induced by inhalational agents delivered by mask or intravenously without cricoid pressure.

SURGICAL EMERGENCIES IN THE NEWBORN

It is beyond the scope of this chapter to discuss the anesthetic management of every surgical emergency that occurs in the first few weeks of life. However, by concentrating on the most common, the basic principles provided can be applied to conditions that are not specifically discussed.

Congenital Diaphragmatic Hernia

Congenital diaphragmatic hernia is the most challenging and frustrating of all neonatal surgical emergencies. This malformation, which by definition involves herniation of the abdominal viscera into the thorax, has a high (20–50%) mortality regardless of the treatment method.[95,96] Even early prenatal ultrasound diagnosis and attempts at in utero, fetal surgical correction have done little, if anything, to affect outcome.[96–98] The incidence of this devastating problem, which has significant short- and long-term morbidity, is reported to be 1:2000–5000 live births.

In its most common presentation, the abdominal viscera, including the small bowel and colon, liver, and occasionally the kidney, herniate into the left hemithorax during the first or second trimester of affected pregnancies and interfere with the development of both the lung parenchyma and its blood supply. Infants born with this anomaly present with the classic triad of dyspnea, cyanosis, and apparent dextrocardia. Physical examination reveals a scaphoid abdomen, bowel sounds in the chest, distant or displaced heart sounds, and absent breath sounds in the affected chest. Chest radiography demonstrates loops of gas-filled bowel or a gastric tube in the affected chest, mediastinal shift, absent lung markings in the affected chest, and, most ominously, a contralateral pneumothorax. Pneumothorax is an iatrogenic compli-

cation that usually occurs as a result of vigorous attempts at oxygenation or resuscitation. The major differential diagnosis is a cystic adenomatoid malformation of the lung or congenital lobar emphysema. Approximately 20% of patients have associated congenital heart disease.

Surgical decompression of the herniated abdominal viscera (which may consist of midgut, stomach, colon, kidney, and/or liver) from the affected hemithorax and repair of the diaphragmatic defect, although essential in the management of this malformation, do not determine ultimate survival. Rather, outcome depends on the pulmonary vasculature and whether it will respond in an exaggerated, hyperreactive fashion to the stimuli that vasoconstrict and elevate pulmonary artery pressure.[99] Histologic studies of the lungs of children born with this anomaly reveal decreased number and size of bronchi, lung saccules, and alveoli, and abnormalities of the pulmonary vascular bed. The numbers of pulmonary blood vessels are reduced, and the arterial muscularis and media are hypertrophied. Hyperactive pulmonary arterial vasoconstriction caused by hypoxia, hypercarbia, acidosis, pain, or positive-pressure ventilation can set in motion a catastrophic cycle of events in which desaturated blood returning to the lung is preferentially shunted across the still patent ductus arteriosus and atrial septum into the systemic circulation. This shunting of blood across the ductus and atrial septum is a return of the circulation to the pattern that existed in utero and is referred to as *persistent fetal circulation* or persistent pulmonary hypertension of the newborn (PPHN).[37] The goal of anesthetic management is to prevent this catastrophic cascade from occurring by maximizing arterial oxygenation and preventing pain and metabolic or respiratory acidosis.

The most severely affected infants require immediate intubation and decompression of the stomach as soon as the diagnosis is suspected. This usually takes place in the delivery room or in the neonatal intensive care unit before surgery. Medical management is directed at improving oxygenation and increasing pulmonary blood flow. This is accomplished by the judicious use of muscle relaxants, analgesics, usually fentanyl (1–10 μg/kg as an initial bolus, followed by a continuous infusion of 3–10 μg/kg/h), hyperventilation, using rapid rates (> 100 breaths/min) and low inflating pressures, and correction of acidosis with intravenous bicarbonate therapy.[100] Interestingly, this is also the basis of intraoperative anesthetic management. Nevertheless, aggressive proactive management may be harmful; barotrauma and volume trauma from too vigorous ventilation may induce alveolar and capillary damage and induce a catastrophic inflammatory cascade. Inhalational anesthetic agents are mostly avoided because of their hypotensive and cardiac depressant effects. Nitrous oxide is contraindicated because it can diffuse into the bowel and further compromise lung function. The importance of inadequate cardiac output in persistent fetal circulation should not be overlooked. Decreased cardiac output leads to decreased pulmonary perfusion and further hypoxemia. Blood returning to the heart from poorly perfused organs arrives with a lower oxygen content, which potentiates the hypoxemia caused by right-to-left shunting.

Bohn et al.[101,102] advocate the avoidance of the "mad dash" to the operating room and recommend instead a 24- to 48-hour period of stabilization. Furthermore, they contend that infants who do not respond to this therapy will fail to survive with surgery or any other therapy, including extracorporeal membrane oxygenation (ECMO). Bohn et al.[102] also suggest a nomogram to predict the extent of pulmonary hypoplasia present in these infants and their chance of survival. They used the preoperative $PaCO_2$ and correlated it and an index of ventilation that is determined by the mean airway pressure times the respiratory rate. If $PaCO_2$ could be reduced to < 40 mm Hg and the ventilatory index was < 1000, survival was almost universal. On the other hand, if $PaCO_2$ was > 40 mm Hg and the ventilatory index was > 1000, death was virtually inevitable. Interestingly, these latter infants were found at autopsy to have < 10% of the normal number of alveoli bilaterally.

Others have approached the newborn with congenital diaphragmatic hernia with a different perioperative management strategy.[103,104] They work to stabilize these newborns preoperatively and bring them through their period of PPHN with a strategy of "gentle ventilation." Using low peak inflating pressures and permissive hypercapnia, they are careful to avoid iatrogenic damage from barotrauma to the already hypoplastic lungs of these newborns. After a period of stabilization, during which pulmonary arterial pressure falls, the patient is electively taken to the operating room for surgical repair.

Blood loss is minimal during surgical repair of this problem, and third space losses can be assumed to average 8–10 mL/kg/h. Aside from routine monitoring, these patients require intravascular arterial and central venous catheters for continuous blood pressure monitoring and for blood gas, hemoglobin, and blood chemistry sampling. Central venous access is obtained either via an umbilical vein or from the jugular or subclavian veins. If the latter approach is attempted, it is essential to avoid a pneumothorax or hemothorax in the normal lung. A precordial stethoscope placed in the unaffected right axilla may help alert the anesthesiologist to one of the most feared intraoperative catastrophes, namely, the development of a contralateral pneumothorax. This is heralded by sudden hypoxia and/or hypotension. Placement of a chest tube when this condition occurs may be lifesaving. Some authors have suggested the insertion of a prophylactic chest tube on the contralateral side because this complication is so catastrophic.

Vasodilator therapy also has been advocated for perioperative control of increased pulmonary arterial pressures. Suggested intravenous agents include isoproterenol, nitroglycerin, tolazoline, adenosine, and adenosine triphosphate. These agents rarely are effective because the pulmonary vasodilatation produced is matched by an equal fall in systemic vascular resistance. They have been largely replaced by inhaled nitric oxide (NO).[105,106] NO diffuses across alveolar capillary membranes and stimulates cyclic guanylate cyclase, which increases cyclic guanosine monophosphate (cGMP). cGMP is a potent dilator of vascular smooth muscle. Because NO is rapidly metabolized by red blood cells, it has a potent local effect and should preferentially dilate only the pulmonary vascular musculature. NO can be used anytime during the perioperative or intraoperative period, as needed. Finally, the anesthesiologist should anticipate the possibility of a cardiac arrest during this operation. Vasopressors, including

dopamine (4–10 μg/kg/min) and epinephrine (0.1–1.0 μg/kg/min), should always be available for emergency intraoperative administration.

The most recent innovation in the treatment of congenital diaphragmatic hernia is perioperative use of ECMO.[107–109] The use of ECMO is both controversial and confusing.[109–111] Infants who would not survive according to Bohn criteria or who develop a persistent fetal circulation pattern following a "honeymoon" period can be placed on ECMO in order to allow the infant's lungs time to develop and restructure. Unfortunately, the timing of when to initiate ECMO therapy (either before or after surgery), when to operate if a patient is on ECMO, and when to withdraw ECMO support constitute a very parochial decision that may differ among physicians, even those within the same institution. The utility (or lack thereof) of this therapeutic modality may remain unknown until controlled multicenter trials are performed in specialized centers of excellence.[111]

Omphalocele/Gastroschisis

Abdominal wall defects are rare. Although at first glance they appear to be similar, in fact they are quite different. An omphalocele is a central, midline defect and is always associated with other congenital anomalies. It occurs because of failure of the gut to return to the abdominal cavity at week 10 of gestation. The herniated bowel is covered by the amnion, which protects it from fluid loss, infection, and a chemical, amniotic fluid burn. The apex of the herniated sac is the umbilical cord. A gastroschisis, on the other hand, is not a midline defect and therefore is rarely associated with other defects. It results from an intrauterine vascular accident that results in interruption of the abdominal wall and musculature. The herniated bowel is not covered by any membrane, is "burned" by the amniotic fluid, and is covered by an inflammatory coating or peel. It is subject to tremendous postnatal evaporative fluid losses as well as infection. In gastroschisis, the umbilical cord is found to the side of the herniated bowel.

The optimal method for operative management of congenital abdominal wall defects is controversial. Two options are available: either primary fascial closure, with or without intraoperative and postoperative muscle paralysis, or a staged repair using either a silicone elastomer silo or a primary skin closure. Primary fascial closure of omphalocele or gastroschisis carries the risk of placing the abdominal contents under pressure, which may produce a reduction in cardiac output, hypotension, bowel ischemia, venous stasis, and postoperative respiratory and renal failure.[21,22,112] When primary fascial closure cannot be achieved, either because the defect is too large or because it critically compromises respiratory or cardiovascular function, the alternative approach is a staged repair using either a silicone elastomer silo or a skin closure with secondary fascial closure. When using the silo, the defect is reduced over several days until the stable infant with a small defect can be taken to the operating room for final repair. The staged silicone elastomer repair carries an increased risk of infection.

Traditional criteria for deciding on which course to use have been based on the size of the defect, the presence of associated congenital anomalies, or clinical observations of the infant's respiratory rate, pulmonary compliance, blood pressure, skin color, and peripheral perfusion during fascial approximation. Unfortunately, these clinical observations may not be reliable, particularly in paralyzed, anesthetized infants.

Anesthetic Management

Infants are transported to the operating room by placing the exposed bowel in a bag designed for this purpose. It helps to maintain normothermia and reduce evaporative fluid losses. Patients are fluid resuscitated with a balanced salt solution, preoxygenated, anesthetized with fentanyl (10–12.5 μg/kg), pancuronium, and oxygen, and intubated. In addition to routine monitoring, we place catheters in the right radial artery, an internal jugular vein, and the stomach. An oral or nasal gastric tube both decompresses the abdomen and allows measurement of intragastric pressure by fluid filling the tube. Yaster et al.[21,22] suggest that management of omphalocele or gastroschisis can be successfully and reliably determined by intraoperative measurement of intragastric and central venous pressures (Fig. 62–5). In this treatment algorithm, primary repair is always attempted. However, if the intragastric pressure rises above 20 mm Hg and/or central venous pressure increases by 4 mm Hg or more following closure of the abdominal fascia, the primary repair is abandoned and a staged repair with a silicone elastomer chimney is performed. This algorithm avoids the consequences of acutely elevating intraabdominal pressure. Following surgery, the patient is taken to the neonatal intensive care unit intubated and placed on controlled mechanical ventilation. In infants treated with a staged repair, the chimney is gradually reduced over 5–10 days. Central venous and intragastric pressure can be used to guide this therapy as well.

Newborn infants with abdominal wall defects have significantly increased fluid requirements because of the increase in insensible losses that occur when eviscerated bowel is exposed to the environment. Additionally, they have enormous "third space" losses due to the traumatized, inflamed bowel and adynamic ileus that develops perioperatively. Fluid requirements are even greater in gastroschisis patients because the herniated viscera lack a protective covering, resulting in a chemical burn preoperatively.

Intestinal Obstruction/ Necrotizing Enterocolitis

Intestinal obstruction is among the most common surgical emergencies encountered in the newborn and is characterized by feeding intolerance, bilious vomiting, and abdominal distension. Common sites of obstruction include the duodenum, the jejunum–ileum, particularly the terminal ileum, and the anus. Necrotizing enterocolitis, on the other hand, is caused by bacterial invasion of previously injured or ischemic bowel wall. It is characterized by intestinal obstruction, gangrene, perforation, intramural air ("pneumatosis intestinalis"), and peritonitis.[113,114] Patients usually are premature and often are septic, hypotensive, thrombocytopenic, and in respiratory failure. Metabolic and respiratory acidosis and electrolyte disturbances are common. Although the initial management is nonoperative and supportive (i.e., decompression, antibiotics, correction of hematologic abnormalities), evidence of intestinal gangrene (e.g., positive results of paracentesis), pneumoperitoneum, and clinical deterioration results in the need for emergency exploratory laparotomy.

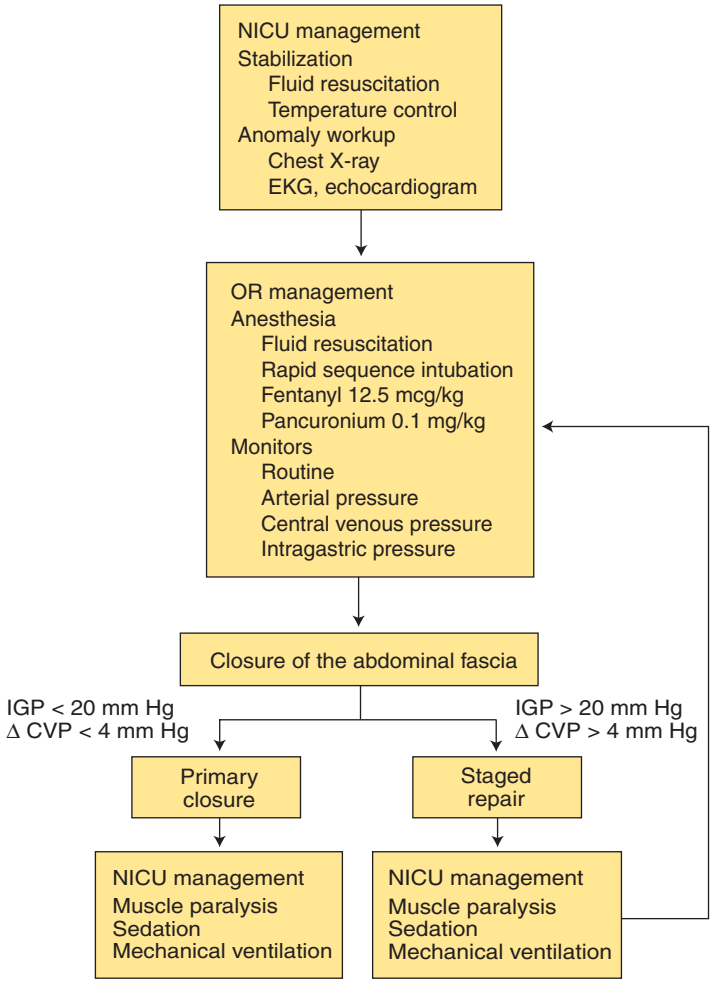

FIGURE 62–5. Algorithm for intraoperative and postoperative management of children with congenital abdominal wall defects. Note that intragastric pressures and changes in central venous pressure are measured.

Duodenal obstruction typically presents within the first hours of life and is extremely common in children with trisomy 21 (Down syndrome). An abdominal x-ray film will show the classic "double bubble" sign (i.e., dilated air-filled stomach and proximal duodenum). Because these children present so early in life, usually within the first 12 hours, they rarely are dehydrated or hypochloremic. Small and large bowel obstructions typically present later, usually 2–7 days after birth, and often are associated with hemodynamic compromise and metabolic disturbances. Jejunal or ileal atresias are thought to be caused by intrauterine vascular accidents. Meconium ileus is an obstruction of the small bowel caused by inspissated abnormal meconium and is pathognomic of cystic fibrosis. At the time of presentation, these infants do not have the lung disease associated with this devastating condition. Malrotations of the bowel also present with obstruction and are very common in patients with congenital diaphragmatic hernia and omphalocele/gastroschisis. Infants with Hirschsprung disease have a functional distal obstruction due to lack of ganglia in the rectum and distal colon. Imperforate anus, which should be readily obvious in the delivery room, requires special attention because of the many anomalies associated with it. At one time called the VATER (vertebral defects, anal atresia, tracheoesophageal fistula, esophageal atresia [see Esophageal Atresia and Tracheoesophageal Fistula below], renal anomalies) syndrome, this condition also has a 20% incidence of significant congenital heart disease. In patients diagnosed with the syndrome, an echocardiogram should be obtained prior to surgery.

Regardless of the underlying pathology, the major anesthetic challenge with this group of surgical patients is maintaining an adequate circulating blood volume and preventing pulmonary aspiration of gastric contents. Virtually all newborns presenting for emergency abdominal surgery are intravascularly depleted secondary to the enormous ongoing third space losses. Sepsis, bowel manipulation, peritonitis, use of contrast agents, and release of vasoactive peptides significantly deplete the circulating blood volume and extracellular fluid space of water and electrolytes. In necrotizing enterocolitis, third space fluid replacement therapy in the perioperative period may exceed 100–200 mL/kg/h! Fresh-frozen plasma, platelets, and packed red blood cells are often needed and should be used early in surgery in response to clinical and laboratory evidence of coagulopathy. Additionally, the critically ill, septic patient may not be able to tolerate these enormous fluid shifts, and dopamine 4–10 μg/kg/min should be infused to help maintain blood pressure and blood flow. Both arterial and central venous pressure monitors are required to monitor intravascular volume in these situations.

All newborns presenting for emergency abdominal surgery may aspirate their abdominal contents at the induction of anesthesia. Therefore, methods that minimize these risks, such as awake intubation or rapid sequence induction with cricoid pressure, must be used. This has been described in the section Airway. We prefer to maintain anesthesia with the fentanyl, pancuronium, and oxygen technique for this group of patients. Potent inhalational anesthetics are often poorly tolerated in this group of infants. Nitrous oxide is almost never used in these patients because it will further distend the bowel and complicate intestinal perfusion and fascial closure.

Esophageal Atresia and Tracheoesophageal Fistula

Ninety percent of infants born with a tracheoesophageal fistula have a blind esophageal pouch and a fistula connecting the distal esophagus and the distal trachea, usually within 1–2 cm of the carina (Fig. 62–6). From 30–50% of these infants have the associated anomalies of VATER syndrome (see Intestinal Obstruction/Necrotizing Enterocolitis above). The most common associated defect is cardiac and necessitates an echocardiogram

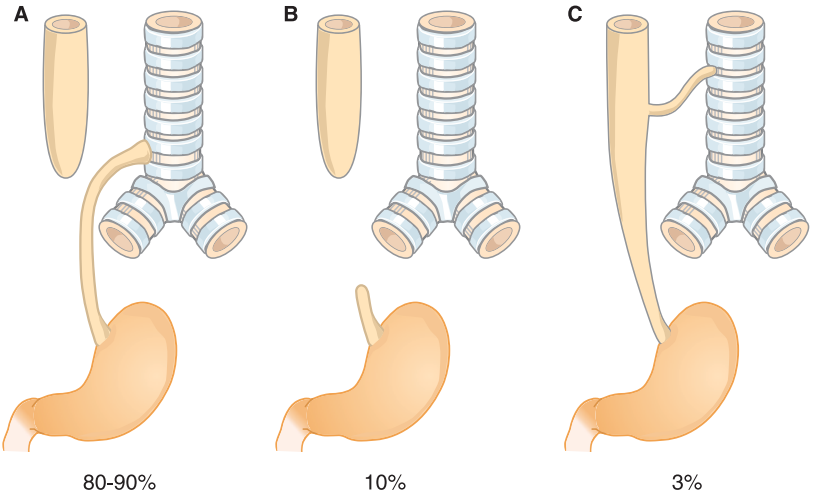

FIGURE 62–6. Three most common types of esophageal atresia and tracheoesophageal fistula (TEF). **A.** Proximal atresia and distal TEF account for 80–90% of cases. **B.** Pure esophageal atresia with no TEF accounts for 10% of cases. **C.** H-type TEF accounts for 3% of cases. Philadelphia: WB Saunders, 1993:318–336, with permission from Elsevier.)

prior to surgery.[115] Often suspected prenatally by polyhydramnios, infants present with excessive salivation ("mucousy mouth"), choking, coughing, aspiration pneumonia, and cyanosis. Attempts at feeding are met with explosive vomiting, and passing an oral (nasal) gastric tube is impossible. A chest radiograph of a coiled oral gastric tube in the cervical esophageal pouch is diagnostic of tracheoesophageal fistula. Because of the potential for aspiration, contrast media should not be instilled to confirm this diagnosis!

The tracheal to distal esophageal fistula aerates the gastrointestinal tract and allows for regurgitation of gastric juice up the fistula into the lung. Thus, pulmonary aspiration occurs by two methods. The first involves aspiration of saliva or attempted feedings from the blind esophageal pouch, and the second occurs by gastric juice contamination via the fistula tract. If significant aspiration pneumonia occurs, definitive corrective surgery is deferred, and a decompressing gastrostomy is placed under local or caudal anesthesia.[116,117]

As soon as the diagnosis is confirmed, the child is placed in a head-up position and the upper pouch is decompressed with a large-bore, sump (Replogle) tube. Following diagnostic workup, the child is transported to the operating room for corrective repair, which historically has been performed through a right-sided thoracotomy. Increasingly, thoracoscopic surgical repair is being performed with excellent results in the hands of experts.[118] Routine monitors are placed. The precordial stethoscope is placed in the left axilla and carefully secured in place, with both "double-stick" and clear plastic adhesive dressing. Adequate intravenous access and a radial artery catheterization complete the preinduction preparation.

Immediately before intubation, the infant is given atropine 0.15 mg intravenously, and the esophageal pouch is suctioned. Then, with the infant in a semisitting position, the trachea is intubated while the patient is awake. This allows appropriate positioning of the endotracheal tube without positive-pressure ventilation, which can cause gastric distension through the fistula. Then, using the classic technique, with the infant spontaneously breathing sevoflurane, the endotracheal tube is positioned below the fistula but above the carina, by deliberately intubating the right mainstem bronchus and then slowly pulling the tube back until breath sounds are heard in the left axilla and not in the stomach. Isolation of the fistula is possible because, in the majority of cases, the fistula is approximately 0.5–1.0 cm above the carina on the posterior surface of the trachea. If the endotracheal tube has a side ("Murphy eye") hole, it should be turned to the left, opposite its normal orientation, to maximize left lung ventilation. Even if the endotracheal tube does not have a side hole, it is helpful to turn the bevel of the tube 180° so that the curve of the tube faces forward. This will reduce ventilation into the fistula and stomach. Once positioned, the endotracheal tube is secured with the "fishmouth" technique to avoid displacement of the endotracheal tube down the right mainstem bronchus or, more ominously, into the fistula tract itself (Fig. 62–4). For this reason, the precordial stethoscope is placed securely in the left axilla.

Once the endotracheal tube is positioned, anesthetic management is based on the presence or absence of a decompressive gastrostomy and by the preferential flow of gases down the path of least resistance, namely, through the fistula tract into the stomach. Positive-pressure ventilation may allow oxygen and other gasses to bypass the lungs and acutely dilate the stomach. This interferes with ventilation and venous return and can lead to cardiopulmonary arrest and gastric rupture. If this occurs, an emergency decompressive gastrostomy may be lifesaving. Unfortunately, insertion of a gastrostomy may be lifesaving, but it may substitute one problem for another. Airflow resistance through the fistula–stomach–gastrostomy may be so low that ventilation of the lungs becomes impossible. The gastrostomy may need to be intermittently clamped and unclamped or left partially clamped through the procedure. Some have advocated the use of a Fogarty catheter, placed through either a bronchoscope or a gastric endoscope, to occlude the fistula tract if this becomes a problem.[119] Great caution must be exercised when using a Fogarty catheter passed alongside an endotracheal tube. If the catheter slips out of the fistula tract into the trachea, it can completely occlude the end of the endotracheal tube. Because of these myriad problems with positive-pressure ventilation, many anesthesiologists recommend an anesthetic technique that uses spontaneous ventilation with sevoflurane. Alternatively, others believe that paralysis may be a safe and effective alternative, as long as the fistula can be effectively isolated by careful positioning of the endotracheal tube.

In our experience, sufficient anesthetization with sevoflurane of a spontaneously breathing newborn without compromising blood pressure and oxygenation is rarely possible. This is particularly true in the repair of an

esophageal atresia with tracheoesophageal fistula because this surgery is performed in the lateral position. An intriguing new option, which is our preferred technique, is to supplement the general inhalational anesthetic with a caudal (or thoracic) epidural anesthetic technique.[120,121]

The caudal approach to the epidural space is remarkably easy to perform in the newborn. It does not require specialized equipment even though small-diameter Crawford needles (19–20 gauge) and catheters (24–26F) are commercially available. The epidural space of young children and infants is filled with loosely packed fat and blood vessels, making possible the advancement of a caudally placed catheter as far as the thorax. Typically, either 0.5–1 mL/kg of 0.25% bupivacaine with epinephrine (5 μg/mL) or 0.5 mL/kg of 3% chloroprocaine (15 mg/kg) with epinephrine is administered, and the inspired sevoflurane concentration is significantly reduced.[122] Using this combination technique, patients can be adequately anesthetized and hemodynamically stable even while breathing spontaneously. Analgesia can be maintained with this technique postoperatively as well.

Surgery is performed in the left lateral decubitus position. During the surgical repair, the right lung is compressed and packed away, which may result in hypoxia. Additionally, the infant may become hypoxemic if the trachea and/or endotracheal tube is compressed and occluded by the surgeon. Alternatively, the endotracheal tube can become obstructed by blood clots or may migrate into the fistula tract. To provide a greater margin of safety, we routinely use 100% oxygen during these anesthetics, even in premature infants who are at risk for developing the ROP.

Meningomyelocele

Failure of neural tube closure early in intrauterine development results in a spectrum of abnormalities, ranging from spina bifida occulta, a relatively benign process, to myelomeningocele, an abnormality involving vertebral bodies, spinal cord, and brainstem.[123] The brainstem lesion—Arnold-Chiari malformation—may be the cause, rather than the effect, of the failure of neural tube closure. Ninety percent of infants with myelomeningocele have the Arnold-Chiari malformation, which consists of downward displacement of the brainstem and cerebellar tonsils through the cervical spinal canal. This together with obliteration of the foramina of the fourth ventricle blocks the normal circulation of cerebral spinal fluid and leads to progressive hydrocephalus. Associated skeletal anomalies, particularly of the lower extremities, and urodynamic problems are common, and patients born with this defect undergo multiple corrective surgical procedures in their lifetimes.[124] For this reason, fetal corrective surgery has been proposed and has shown some preliminary positive results.

Infants with a meningomyelocele are transported to the operating room in the prone position. The defect is covered with moist sterile dressings, and great care is taken to prevent contamination and infection. If the meningocele is ruptured, lactated Ringer solution is used to replace cerebral spinal fluid losses, milliliter for milliliter or at an approximate rate of 4–6 mL/kg/h.

The infant must be turned supine for intubation, and positioning is crucial to facilitate the intubation. A foam head ring, or operating room towels folded into a ring, is covered with a sterile drape or towel. The baby is turned to the supine position, with the defect resting in the pocket of the ring. Towels are placed under the child's back to build up a level platform for intubation (Fig. 62–7). Anesthesia is induced with either inhalational or intravenous agents (thiopental or propofol). Virtually any anesthetic technique is possible for this surgery as long as it allows for rapid extubation following surgery. Succinylcholine does not cause catastrophic hyperkalemia in patients with this defect.[125] Once the trachea is intubated, the endotracheal tube is secured with a "fishmouth" technique (Fig. 62–4), and the child is turned to the prone position for surgery.

Spinal anesthesia can be used alone or in combination with general anesthesia for this surgery. When combined with a general anesthetic, the patient is induced as described previously. Once the patient is turned and surgery starts, the surgeon drops 0.5–0.7 mg/kg of hyperbaric tetracaine (5 mg/mL) directly into the open meningomyelocele sac.[126] Within minutes the concentration of inhaled general anesthetic is reduced to a level that provides immobility and allows the child to tolerate the endotracheal tube. Less commonly, spinal anesthesia is used as the sole anesthetic for this repair. Using a small-gauge needle, 0.5–0.7 mg/kg of hyperbaric tetracaine (5 mg/mL) with epinephrine is injected into the most inferior region of the meningomyelocele sac. Supplemental doses are administered as described for the combined approach.[126]

The decision to place a ventriculoperitoneal (VP) shunt at the time of initial surgery or several days later is a surgical one. Some surgeons defer placement of the VP shunt because of fear that the drain will become infected. Additionally because 5–10% of these patients do not develop hydrocephalus, some surgeons prefer to wait until the condition develops rather than treating it expectantly.

Patent Ductus Arteriosus

Following birth, the increase in arterial oxygen that occurs by breathing room air results in closure of the ductus arteriosus. This process may not occur in premature infants and often results in a large left-to-right shunt, heart fail-

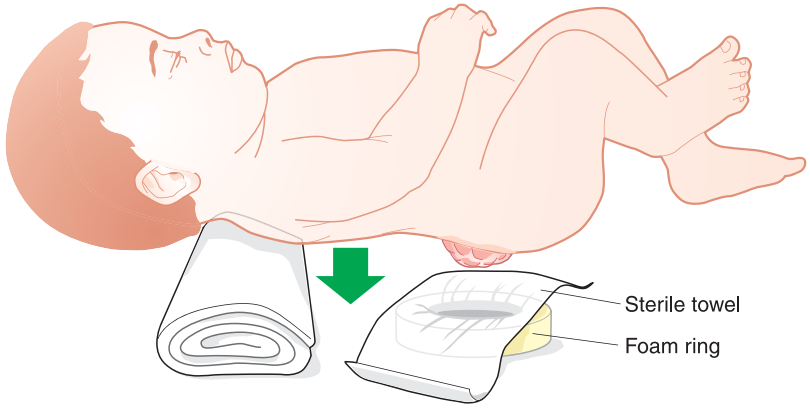

FIGURE 62–7. Positioning of newborn with myelomeningocele for endotracheal intubation.

ure, pulmonary edema, and an inability to be weaned from mechanical ventilation. Medical management consists of fluid restriction, diuretic therapy, digoxin, and the cyclooxygenase inhibitor indomethacin 0.2 mg/kg. Other cyclooxygenase inhibitors, such as ibuprofen, also may be effective.[127] When medical management fails, surgical correction becomes essential if the child is to be weaned from mechanical ventilation.[128] Unfortunately, in the smallest of premature infants (weight <1000 g), indomethacin often is unsuccessful because it significantly impairs renal function.

Because these children have been fluid restricted and are intravascularly volume depleted prior to surgery, volume expansion with lactated Ringer solution is essential to prevent profound hypotension on induction of anesthesia, even when a fentanyl anesthetic is used. Fentanyl 10–50 μg/kg has become the most common anesthetic technique used.[8,46] Obviously, nitrous oxide must be avoided, and 100% oxygen is often required to maintain oxyhemoglobin concentrations >90%, especially once the chest is opened and the lung is retracted. Lung retraction, which is necessary to provide surgical exposure, may result in vagal stimulation, and bradycardia and hypotension results if the child has not been pretreated with either atropine or pancuronium. During closure of the ductus, hemorrhage and exsanguination may occur if this fragile structure is inadvertently torn by the surgeon. Thus, type and crossed blood should always be available prior to the start of surgery. Additionally, closure of the ductus is associated with an abrupt rise in diastolic blood pressure, which may contribute to the development of intraventricular hemorrhage in this patient population.

Recently epidural anesthesia has been used to treat postoperative pain in these infants and to reduce intraoperative anesthetic requirements. Both local anesthetics and epidurally administered opioids are effective. Typically opioids are administered via a caudal approach, and local anesthetics are administered via a caudally placed catheter that has been advanced to the thorax. Because these infants are so fragile, many centers advocate closure of a patent ductus in the nursery rather than transporting the infant to the operating room.[129]

SUMMARY

Except for extraordinary circumstances, all newborns require anesthesia and analgesia for surgery. During the first month of life, the newborn must function independently and adapt to extrauterine life. This process involves anatomic, physiologic, and pharmacologic changes to maintain homeostasis and to ensure the infant's survival. Disease, congenital anomalies, surgery, and anesthesia may interfere with these adaptations and threaten survival. This chapter provided an in-depth review of developmental physiology, pathophysiology, and pharmacology, as well as common management techniques that are essential in the provision of safe anesthesia to the newborn.

CHAPTER 63

Anesthesia for Children

Lucinda L. Everett, MD

INTRODUCTION: HALLMARKS OF PEDIATRIC ANESTHESIA

Perioperative care of infants and children presents a number of special challenges. The anesthesia care team must evaluate and interface with both child and parents and must consider psychological as well as physiologic factors. In the United States, anesthesia for elective surgery in children is frequently initiated with an inhalation induction, which is significantly different from the intravenous induction commonly performed in adults. Physiologic differences, such as an increased rate of oxygen consumption, create the potential for rapid arterial blood desaturation with apnea or hemodynamic compromise. Finally, specific technical skills are required in infants and children.

RISK AND OUTCOME IN PEDIATRIC ANESTHESIA

Overall, safety in pediatric anesthesia is excellent. Complications are uncommon and improvements over the past several decades are attributed to better monitoring (pulse oximetry and capnography), safer anesthetic agents, and better understanding of specific areas of increased risk. A number of large outcome studies dating from the late 1980s[1] to the current era[2] have identified increased rates of complications and cardiac arrest during anesthesia in children younger than 1 year, although in some studies the risk appears to be explained by coexisting diseases. American Society of Anesthesiologists (ASA) classification and emergency status also have been predictors of increased risk in pediatric anesthesia outcome studies.

Respiratory Risk

Anesthetic audits report that a high percentage of respiratory complications continue to occur in children, particularly infants. These complications include laryngospasm, bronchospasm, airway obstruction, and decreased systemic oxygen saturation. Factors that may contribute to respiratory risk include younger age, concurrent disease (syndromes, airway anomalies, or obstructive sleep apnea), recent upper respiratory infection,[3] and airway procedures (tonsillectomy, airway surgery,

KEY POINTS

1. Overall, pediatric anesthesia is extremely safe in the hands of experienced providers. Factors that may increase risk include age <1 year and coexisting disease. Careful attention to maintenance of a patent airway is critical to the safe care of infants and children.
2. One of the challenges of pediatric anesthesia for trainees is selecting appropriately sized equipment and supplies. Endotracheal tubes are generally selected to yield a leak at 15–30 cm H_2O. Cuffed tubes are gaining wider use in young children as well as those older than 8 years. Straight blades are most commonly used for intubation in infants, with the usual choices being Miller 0 for neonates and Miller 1 for infants. A Wis-Hipple 1.5 blade is often used in toddlers, with progression to Macintosh size 2 for children 3 years and older.
3. The physiologic and psychological contexts must be considered in planning an anesthetic for any child. Premedication and/or parental presence may be appropriate for children. Induction of anesthesia for elective surgery in young children frequently is accomplished by inhalation of a volatile anesthetic. Sevoflurane is the most common choice in modern practice based on the drug's rapid effect, low degree of airway irritation, and cardiovascular stability.
4. Succinylcholine is no longer used routinely in children because of the potential for hyperkalemia in undiagnosed myopathy. Succinylcholine may still be used when indicated for rapid sequence induction or treatment of laryngospasm.
5. Regional anesthesia is a useful adjunct to general anesthesia in children for a variety of procedures. Surgery with a regional anesthetic alone is uncommon in young children; one exception is the use of spinal anesthesia in premature infants at risk for postoperative apnea. For common outpatient surgery such as hernia repair or orchidopexy, caudal blockade with a local anesthetic such as ropivacaine provides good intraoperative and postoperative analgesia. Epidural catheters also may be placed in children for more major procedures and generally are placed after induction of general anesthesia in children too young to cooperate.
6. Selection of an appropriate plan for postoperative analgesia is important for both inpatient and outpatient situations. Adequate doses of acetaminophen, nonsteroidal antiinflammatory drugs where not contraindicated, and regional anesthesia may be appropriate in addition to, or in place of, opioid analgesia, depending on the procedure. Postoperative vomiting is common in children and may occur more frequently during certain procedures, such as strabismus surgery, and in patients with a history of motion sickness or postoperative vomiting. Prophylaxis frequently includes use of a 5-hydroxytryptamine3 (5-HT_3) receptor antagonist and/or a steroid such as dexamethasone. Because of restrictions on the use of droperidol, 5-HT_3 receptor antagonists are generally used as first-line treatment of postoperative nausea and vomiting in children.
7. Emergence agitation occurs in a significant number of toddlers and young children, particularly after use of a volatile anesthetic. Appropriate analgesia and possibly supplemental sedation may be helpful. The results in the literature are mixed with regard to links with specific agents (e.g., sevoflurane); patient and parental anxiety may contribute to the development of agitation.
8. Many of the procedures performed in children involve concepts similar to those used in parallel adult cases (e.g., neurosurgery, thoracic surgery). The concepts related to the surgical subspecialty must be integrated with those specific to the anesthetic care of children. Procedures specific to the pediatric population are discussed.

cleft palate repair). With early detection and skillful management, few complicating events will result in adverse outcomes; therefore, screening for potential airway abnormalities, a backup plan for managing airway difficulties, and rapid attention to respiratory changes are critical components of pediatric anesthetic care.

Pulmonary aspiration of gastric contents is a rare but feared complication of anesthesia. Studies of pediatric patients report a range similar to that seen in adults (1–10 cases per 10,000 anesthetics).[4] Aspiration occurs more frequently in emergency cases and in "full stomach" situations such as bowel obstruction. The majority of cases of aspiration occur during laryngoscopy, particularly with coughing or unexpected airway difficulties, but some cases occur during maintenance or emergence from anesthesia. In pediatric cases reported to date, intraoperative aspiration while using a laryngeal mask has generally been related to a predisposing factor such as inadequate depth of anesthesia, GI disease or full stomach, lithotomy position, movement of the laryngeal mask airway (LMA), or multiple insertion attempts.[5] Clinical signs (decreased oxygen saturation, coughing, wheezing) and radiographic abnormalities that do occur generally develop in the first 2 hours after aspiration. The long-term outcome usually is good in healthy pediatric patients who aspirate gastric contents, but acutely these patients may require suctioning, intubation, and mechanical ventilation. The acuity of perioperative care may be higher than would otherwise have been planned.

Infants born prematurely have an increased risk of apnea and bradycardia following general anesthesia. The best available information comes from a combined analysis published by Cote et al.,[6] who demonstrated that risk was inversely proportional to both gestational and postconceptual age, and risk of apnea was increased by anemia. The administration of caffeine[7] or the use of spinal anesthesia without sedation[8] reduces the risk of postoperative apnea. Newer anesthetic agents, such as sevoflurane, are not free of the risk of apnea in infants born prematurely.[9] Many individual hospitals require postoperative overnight admission for monitoring until 50–60 weeks' postconceptual age in infants born before 37 weeks; they also may consider anemia, prior apnea, and coexisting disease. Little specific evidence about apnea risk in term infants is available. Some facilities restrict the lower age for day surgery procedures to older than 44–46 weeks' postconceptual age in term infants or require a longer observation period (e.g., 4 hours) prior to discharge.

Cardiac Risk

The ASA Closed Claims Study evaluates outcomes from closed malpractice claims. An analysis of pediatric cases from this database found claims in infants and children were more likely to be related to respiratory events, were more often classified as "preventable" (e.g., by better monitoring), and resulted in greater injury severity and mortality than adult claims.[10] The Pediatric Perioperative Cardiac Arrest (POCA) Registry was created in 1994 to gain further insight into the epidemiology of anesthetic-related cardiac arrest in patients aged 18 years and younger. Data from arrests as well as total numbers of pediatric anesthetics are reported from participating institutions. POCA data published in the year 2000 summarized the first 289 cases reported: the overall incidence of anesthetic-related cardiac arrest was 1.4 per 10,000 anesthetics, with a reporting base of just over one million anesthetics from 63 institutions.[11] Cardiac arrest was most frequent in patients younger than 1 year (55% of cases) and in those with severe underlying disease (ASA classes 3, 4, and 5). Among healthy patients (ASA classes 1 and 2), the most common causes of cardiac arrest were respiratory (20%) and medication related (64%). Cardiac arrest initiated by respiratory events divided into two major categories: laryngospasm (30%), occurring primarily in healthy patients, and "airway obstruction," usually in the setting of congenital or acquired anatomic abnormalities (micrognathia, laryngeal papillomatosis). Medication-related cardiac arrests were primarily due to halothane, either alone or in combination with other drugs. In the more recent period, reports of cardiac arrests related to potent inhalational anesthetics have declined.[12] Several factors contributed to this decrease. Sevoflurane, now the agent most commonly used for anesthetic induction in children, causes less myocardial depression than halothane, and the vaporizer delivers fewer minimum alveolar concentration equivalents at maximal output. Recognition of this pattern of anesthetic cardiac arrest may have changed practice, and/or children may be better hydrated prior to anesthetic induction since the ASA in 1999 liberalized the fasting guidelines with adoption of a 2-hour fasting from clear liquids.

Cardiac arrest related to succinylcholine administration was reported in several apparently healthy children in the late 1980s,[13] leading to a "black box" U.S. Food and Drug Administration (FDA) drug label warning regarding its use in pediatric anesthesia. The patients were found to have unrecognized myopathy with the development of hyperkalemia after succinylcholine administration. In the initial cases, a lack of understanding of the pathophysiology contributed to the failure to treat and resuscitate appropriately. Succinylcholine now is used with caution in pediatric patients but is considered an appropriate choice for muscle relaxation when rapid control of the airway is required, that is, when the history or physical examination dictates performing a rapid sequence induction, or for treatment of laryngospasm.

Facility and Provider Expertise

One of the complex administrative issues in pediatric anesthesia is determining which patients require care by an anesthesiologist who specializes in the care of children, and just what is the precise definition of a pediatric anesthesiologist? In the United States, pediatric anesthesia fellowship programs are accredited by the Accreditation Council for Graduate Medical Education, but at this time there is no subspecialty board certification in pediatric anesthesia. Although the link between provider qualifications and outcomes has not been extensively studied, some evidence suggests that children have fewer adverse outcomes when cared for by anesthesiologists with frequent ongoing experience in anesthetizing children.[14,15] Several organizations have put forth guidelines for the care of pediatric patients. The American Academy of Pediatrics (AAP) suggests that each facility define the spectrum of pediatric patients and cases for which it will provide care and the number of cases of each required for the facility to maintain its competence.[16] The AAP further recommends that anesthesiologists caring

for children designated by the facility as being at increased risk either should be fellowship trained in pediatric anesthesiology or have equivalent experience. The ASA and the Society for Pediatric Anesthesia have made similar recommendations. Some states also are instituting requirements that anesthesiologists caring for children meet certain minimum annual number of cases. The AAP guidelines have implications for facilities providing anesthesia care of children. The guidelines recommend having airway and monitoring equipment in sizes suitable for pediatric patients, a separate preoperative area for children and their families, and operating room and recovery staff with age-specific competencies and resuscitation skills.

EQUIPMENT FOR PEDIATRIC ANESTHESIA

Breathing Circuits and Ventilators

Anesthetic breathing circuits for pediatric use, like other equipment for use in children, have evolved significantly. In traditional teaching of pediatric anesthesia, a valveless system such as the Mapleson D or Jackson Rees circuit was best for children to avoid respiratory resistance added by one-way valves. These systems, which are simple modifications of a T-piece, offer the advantages of being lightweight and flexible with minimal resistance to gas flow. Potential disadvantages include rebreathing of carbon dioxide (CO_2) if the fresh gas inflow rate is inadequate to wash out the exhaled gas and significant tidal volume lost to expanding the expiratory limb during controlled ventilation. In addition, an adaptor generally is required in order to use a Mapleson circuit with modern anesthesia machines. The circle system is a unidirectional circuit with a CO_2 absorber; pediatric circle systems are now widely available. Although the work of breathing is higher with the pediatric circle than with a Jackson Rees circuit in spontaneously ventilating infants, with modern anesthesia machines the minor resistance of the valves is generally not clinically significant. However, avoidance of prolonged spontaneous respiration by small infants is prudent. Modern pediatric circle systems have a smaller diameter and lower compliance than adult circuits. Lower fresh gas flows can be used with resultant conservation of volatile anesthetic agents and airway moisture. Even with low flows, the humidity in pediatric circle systems may be inadequate, causing drying of respiratory secretions. Use of a heat and moisture exchanger in the circuit may prove valuable.

Exothermic reactions have been reported when desiccated CO_2 absorbents interact with sevoflurane, in some cases resulting in an explosion or fire. Current recommendations are to avoid absorbents containing a strong base and to turn off fresh gas flows when machines are not in use to avoid drying the absorbent. Changing the absorbent frequently rather than waiting for it to be exhausted is prudent.

Performance varies widely among ventilator models. Circuit compliance does not significantly impact on delivered tidal volume when a peak inspiratory pressure is chosen that provides good chest movement.[17] However, with a compliant circuit on older anesthesia ventilators, the measured tidal volume will be much higher than the volume delivered to the patient. Some recent anesthesia ventilators measure and compensate for circuit compliance, thus more accurately delivering the set tidal volume. Pressure mode ventilation may be best in infants, particularly if there is a leak around an endotracheal tube. Leaks may require the use of higher fresh gas flow. When pressure mode ventilation is used, trends in delivered tidal volume must be followed because changes in pulmonary and chest wall compliance will result in significant changes in minute ventilation. In some older anesthesia ventilators, fresh gas flow contributes to tidal volume, so a large increase in gas flow can cause barotrauma. A good understanding of the characteristics of the ventilator and circuit being used are essential to safe ventilation of a child.

Monitoring

Pulse oximetry has vastly improved the safety of pediatric anesthesia, but capnography, auscultation, feeling movement in the anesthesia bag, and observation of chest motion all contribute to the clinical assessment of airway patency and should detect airway obstruction prior to desaturation. Electrocardiographic (ECG) monitoring in healthy children is primarily geared toward monitoring heart rate and rhythm. Ischemic changes are extremely rare except in pediatric cardiac surgery; however, should ischemic changes occur, rapid assessment of the etiology must be undertaken with efforts to improve coronary perfusion. Noninvasive blood pressure monitoring can be used on an upper or lower extremity in children. The decision to place invasive intravascular monitoring catheters (arterial or central venous lines) is based on the severity of illness or the extent and potential complications of the procedure. Temperature should be monitored for all but the shortest cases. For minor procedures, adhesive skin temperature indicators are sufficient. For longer or major procedures, an esophageal, rectal, nasopharyngeal, or tympanic membrane temperature indicator should be used.

Warming Devices

Children are at relatively high risk for development of hypothermia if they are exposed in the operating room for significant periods (see Chapter 19). The operating room should be warm [80°F (27°C) for neonates and small infants], at least during induction and until the patient is covered with drapes. Radiant warmers may be helpful when small children require multiple procedures, such as line placement prior to the start of surgery. Fluid-filled warming blankets will warm the surface of the operating room table; forced hot-air warming is more effective overall in warming patients. Fluid warmers should be considered, particularly when large-volume intravenous fluid administration is anticipated, and should have small priming volumes for use in children.

APPROACH TO THE PEDIATRIC PATIENT: THE ANESTHETIC PLAN

Developing an anesthetic plan for the pediatric patient involves several decisions. Is the procedure elective or emergent? Does the child have significant coexisting disease, airway concerns, or behavioral challenges? Are there expectations of how the anesthetic will be conducted based on prior experiences of the child and/or the child's family or friends? Time spent in exploring patient and family expectations and providing explana-

TABLE 63–1.

Premedication Options

Drug	Route	Dose	Onset	Advantages	Disadvantages
Midazolam	Oral	0.5–0.75 mg/kg Max 15–20 mg	10–15 min	Effective Minimal effect on respiratory function in healthy patients	Bitter taste Possible contribution to postoperative delirium
Midazolam	Rectal	0.5–0.75 mg/kg	10–15 min	Effective Minimal effect on respiratory function in healthy patients	May not be appropriate route for older children Possible contribution to postoperative delirium
Midazolam	Nasal	0.2–0.3 mg/kg	5–10 min	Effective Minimal effect on respiratory function in healthy patients	Burns on administration; bitter Reduced effectiveness if crying or copious nasal secretions Possible contribution to postoperative delirium
Midazolam	Intravenous	0.05 mg/kg increments	1–2 min	Effective Minimal effect on respiratory function in healthy patients	Requires intravenous access
Fentanyl	Oral transmucosal (Oralet or lozenge)	5–10 μg/kg	10–20 min	Better taste than midazolam Analgesia	Pruritus Nausea and vomiting Potential for "stiff chest" with large doses Variable absorption
Ketamine	Oral	6–9 mg/kg	15–20 min	Better taste than midazolam Analgesia	Nystagmus, possibility of hallucination Delayed emergence if combined with midazolam at this dose Increased salivation
Ketamine/midazolam combination	Oral	2.5 mg/kg ketamine with 0.25 mg/kg midazolam	10 min	May have slightly better onset and recovery than midazolam alone	Need to combine drugs
Ketamine	Intramuscular	2–3 mg/kg	3–5 min	Useful for combative or uncooperative patients	Secretions, may be diminished with antisialagogue
Ketamine	Intramuscular (induction)	10 mg/kg	3–5 min	Useful for combative or uncooperative patients Deeper sedation than smaller dose	Delayed emergence
Methohexital	Rectal (induction)	30 mg/kg	6 min	Smooth induction for frightened or uncooperative small children	Higher incidence of airway obstruction than with midazolam

tions and reassurance is time well spent.

Preparation and Premedication

Many children younger than 6–9 months will separate from their parents easily if they are kept engaged. Older children, or those who seem anxious or fussy, may benefit from premedication prior to entering the operating room. Midazolam is commonly given orally as a premedication; other routes and doses are summarized in Table 63–1. Oral transmucosal fentanyl is infrequently used because of its relatively common side effects of nausea/vomiting and pruritus, but it may be a reasonable option when other premedication is not well accepted or when an opioid is indicated for analgesia. Oral ketamine is not commonly given but may be useful when analgesia is desired. Intramuscular ketamine is administered to patients who are combative or difficult to approach; a sedative dose usually will result in adequate cooperation to obtain intravenous access or complete induction by administering an inhalation agent. Fi-

nally, rectal administration of methohexital is really an induction rather than a premedication. If used, it should be given in a monitored setting with the anesthesiologist present and prepared to move the patient into the operating room or procedure area.

Parental presence during induction can be used in addition to, or in place of, pharmacologic premedication (see Chapter 19). Premedication and parental presence are approximately equivalent in producing cooperation with a mask induction.[18] The child's behavior and family dynamics must be considered; transmitted parental anxiety may limit the value of parental presence. Even with thorough preoperative teaching, some parents are distressed by the appearance of their child during an inhalation induction; however, most parents feel that they are contributing to the child's well-being and would choose to be present for future anesthetic induction.[19]

FIGURE 63–1. Mask induction of anesthesia. (Courtesy of Scott Tolle.)

Anesthetic Induction

Induction of anesthesia in elective situations for children younger than 8–10 years frequently occurs by inhalation to avoid venipuncture until the child is asleep. This is common practice in the United States but less so in other countries where topical anesthesia and intravenous induction have become the norm and are well accepted by children and parents. Regardless of the route of induction, interacting with the child in a quiet, reassuring voice is important; distraction such as storytelling or magic tricks can be used. Operating room personnel should have an understanding as to who will be interacting with the child so that multiple people will not be competing for the child's attention. Parents, if they are to be in the operating room, should be told that those present in the room must speak quietly and maintain a calming demeanor.

Sevoflurane provides a smooth, rapid inhalation induction with good cardiovascular stability and has largely replaced halothane for inhalation induction. Desflurane is contraindicated for inhalation induction and isoflurane is rarely used because both cause airway irritation. In a cooperative child, mask induction can be initiated with 50–70% nitrous oxide in oxygen, which will provide some initial sedation (Fig. 63–1). After 1–2 minutes, sevoflurane is introduced either incrementally or at 8%. If the child is agitated initially or becomes combative during the initial stages of induction, a rapid decision must be made either to stop and pursue premedication options or to proceed rapidly with a high inspired concentration of sevoflurane. As soon as the child's eyes close, parents (if present) are escorted out, and attention is turned to maintaining a patent airway. Nitrous oxide can be discontinued at this time to improve oxygen reserves. An "excitement phase" is frequently seen with inhalation induction and may include some degree of airway obstruction, spontaneous limb movement, rigidity, rapid respirations, and tachycardia, all of which usually disappear over several minutes as the anesthetic deepens. Epileptiform activity has been described during inhalation induction with sevoflurane.[20] When the child has passed the excitement phase, intravenous access is established for all but very brief cases.

As noted earlier, children often develop some degree of airway obstruction during inhalation induction. Keeping the right hand on the breathing bag to feel gas movement, auscultation by precordial stethoscope, and observation of the end-tidal CO_2 tracing and chest movement all provide the anesthesiologist with useful information. Lack of gas exchange during inhalation induction should be assessed rapidly to differentiate central apnea (from high concentration of anesthetic agent) from airway obstruction by attempting a gentle positive-pressure breath. If the patient is easily ventilated, slow manual ventilation using a lower concentration of volatile agent should result in resumption of spontaneous respiration. If airway obstruction is present, further evaluation must attempt to distinguish upper airway obstruction from laryngospasm. Upper airway obstruction in a child often can be managed by opening the mouth slightly to displace the tongue from the roof of the mouth and lifting the jaw anteriorly. Pressure on the soft tissues beneath the chin may worsen airway obstruction in a child. Administering continuous positive airway pressure (CPAP) of 5–10 cm H_2O may help maintain airway patency. An oral airway can be inserted if anesthetic depth is sufficient or if the other maneuvers are unsuccessful. If these measures fail to open the airway, an LMA is inserted if upper airway obstruction is believed to be the cause of obstruction, or treatment of laryngospasm can be pursued with 100% oxygen, CPAP, and succinylcholine for muscle relaxation when necessary. Succinylcholine 4 mg/kg can be administered intramuscularly if intravenous access has not been established. Sublingual administration also has been described.

Sevoflurane provides excellent cardiovascular stability in most children, with less myocardial depression than is seen with halothane.[21] However, cardiac arrest is possible with high concentrations of any volatile agent. Maintaining spontaneous respiration during an anesthetic induction may afford a degree of safety in that apnea or marked respiratory depression is likely to precede cardiovascular depression, and hypoventilation will

TABLE 63–2.

Induction Drugs for Children

Induction Drugs	Dose	Indications	Potential Side Effects
Propofol	1–3 mg/kg	Routine induction, particularly for shorter procedures or to decrease potential for postoperative nausea and vomiting	Burning on injection Occasional myoclonus
Thiopental sodium	3–6 mg/kg	Routine induction	Precipitation with other drugs, particularly steroidal nondepolarizing muscle relaxant
Etomidate	0.2–0.3 mg/kg	Cardiovascular instability	Mild discomfort on injection Myoclonus Adrenal suppression reported
Ketamine	1–2 mg/kg	Cardiovascular instability Bronchospasm	Increases cerebral blood flow Increases secretions Nystagmus Possible dysphoria

limit further uptake of volatile inhalational agents. If ventilation is assisted or controlled, the concentration of inspired agent should be reduced.

Intravenous induction is generally chosen for older children and adolescents, for children at risk for aspiration of gastric contents, and for children of any age who present with intravenous access already in place, unless airway considerations make an inhalation induction preferable. Preoxygenation is important in children but may be difficult to accomplish; judicious premedication may be helpful in gaining their cooperation. Propofol is frequently used as an induction agent in pediatric anesthesia unless there are hemodynamic contraindications. The sensation of burning upon injection of propofol into a peripheral IV may be distressing and may be minimized with earlier injection of lidocaine and/or an opioid. Thiopental is an alternative for induction and may cause less distress upon injection. Ketamine or etomidate is used for induction for specific indications such as hemodynamic instability. Pediatric dosing for induction drugs is summarized in Table 63–2.

Neuromuscular blockade can be used to facilitate endotracheal intubation or may be required to provide optimal surgical conditions. As noted earlier, in the section on cardiac risk, succinylcholine is indicated in infants and children only when rapid control of the airway is required (laryngospasm or rapid sequence intubation). Some practitioners administer atropine prior to succinylcholine in infants and young children to minimize the potential for bradycardia. The nondepolarizing muscle relaxants all can be used safely in pediatric practice. Mivacurium has the shortest duration but does not provide as reliable an onset or intubating conditions as does succinylcholine; with larger doses, histamine release is frequently seen. Rocuronium is the best alternative for rapid sequence intubation, but the effective dose of 1 mg/kg will have a duration longer than 1 hour. Pediatric doses for muscle relaxants are listed in Table 63–3 and are generally similar to those used in adult practice. Infants appear to have a somewhat increased volume of distribution but also an increased sensitivity to relaxants, so the initial dose remains similar to that used for adults. Rocuronium may have a longer duration of action in infants compared with older children or adults when given in the standard 0.6 mg/kg dose; a smaller dose (0.45 mg/kg) has been shown to produce good intubating conditions with a shorter duration.[22]

Reversal of nondepolarizing neuromuscular blockade is advisable unless significant time has elapsed (2 hours after a routine intubating dose) or unless the patient clearly exhibits clinical signs of completely regaining full neuromuscular function. An anticholinergic agent (atropine or glycopyrrolate) is administered with reversal agents to prevent bradycardia. If reversal is accomplished with edrophonium, atropine should be given first and a positive response noted prior to administration of edrophonium because of this agent's rapid onset and strong potential to cause bradycardia. Neostigmine in a dose of 0.05–0.075 mg/kg is most commonly administered for reversal. Alternatively, edrophonium can be given at 0.5–1.0 mg/kg, although it may be less effective for reversal of profound neuromuscular block.

Airway Management

Unique anatomic and physiologic aspects of the pediatric airway are discussed in Chapter 19. Because infants and younger children have a large occiput, a cloth roll placed under their shoulders may help to maintain a neutral (and patent) airway (Fig. 63–2). If

TABLE 63–3.

Neuromuscular Blockade in Children

Drug	Dose	Duration
Succinylcholine	1.5–2.0 mg/kg	Short
Mivacurium	0.2–0.25 mg/kg	Short
Cisatracurium	0.1–0.2 mg/kg	Intermediate
Vecuronium	0.1 mg/kg	Intermediate
Rocuronium	0.45–0.6 mg/kg routine 1 mg/kg rapid sequence	Intermediate Long
Pancuronium	0.1 mg/kg	Long

FIGURE 63–2. Positioning in infants and toddlers. Because of the relatively large head, a roll under the shoulders may avoid flexion at the neck and maintain a patent airway. (Courtesy of Scott Tolle.)

FIGURE 63–3. Infant glottis. (Courtesy of A. Inglis, MD.)

the mask airway is stable after inhalation induction, maintenance anesthesia can be administered by a face mask, as commonly done for ear tubes and other minor surgical procedures. An oropharyngeal airway can be inserted when needed to maintain airway patency or if positioning of the mask airway requires frequent manipulation. A properly selected oral airway will reach from the lips to the angle of the jaw when held next to the child's face and, when inserted, will lift the tongue off the posterior pharynx. If access to the face will be limited but intubation is not required, an LMA can be used. Use of the LMA may offer an advantage over endotracheal intubation by decreasing adverse respiratory events in children with an upper respiratory tract infection.[23] Appropriate LMA sizes for various patient weights are listed in Table 63–4. Newer laryngeal mask devices, such as those that afford the ability to vent the stomach, are now being produced in pediatric sizes.

Laryngoscopy in infants and young children has some technical differences from laryngoscopy in adults because of age-related anatomic differences (see Chapter 19). The glottis is higher in the infant and at laryngoscopy appears more "anterior." The child's epiglottis is longer and "U shaped," and although rigid it is "slippery" and may be difficult to control with the laryngoscope blade (Fig. 63–3). In the United States, a straight blade is most commonly used in patients younger than 2 years. When performing a laryngoscopy with a straight blade, it is important to sweep the tongue to the patient's left; passing the tube down the flange of the blade will obscure the view of the glottis and reduce the likelihood of successful tracheal intubation. If the glottis is not seen after passing under the epiglottis, most likely the blade has already gone too deep and posteriorly; withdrawing the blade slowly with gentle cricoid pressure often will bring the glottic opening into view. Choice of laryngoscope blade size by patient age is summarized in Table 63–5. Intubation can be accomplished with use of a muscle relaxant, with a volatile agent supplemented with propofol and/or narcotic, or with deep inhalation anesthesia alone. When intubation is performed with a volatile agent alone, particularly sevoflurane, it must be accomplished quickly while the patient is at an adequate depth of anesthesia.

Traditionally, pediatric endotracheal tubes are selected to allow a small paratracheal gas leak at 20–25 cm H_2O. Because the narrowest portion of a young child's airway is subglottic, the tube must not be forced if any resistance is felt, even if the tube has passed the glottis easily. Approximate endotracheal tube sizes by age are listed in Table 63–5. Tube size can be selected based on age or height, or by selecting a tube with an outer diameter similar to the child's fifth finger. Because tubes are packaged according to internal diameter, specialized endotracheal tubes, such as reinforced tubes, may have a much larger outer diameter for a given internal diameter.

Traditionally, uncuffed endotracheal tubes have been used in children younger than 8–10 years because of concerns of pressure injury to the tracheal mucosa. Recent reports suggest that inappropriately large tubes may cause mucosal injury, but that complications related to cuffed tubes per se are not a significant concern in children with modern tubes made of less reactive materials. A randomized trial in children (term newborns to age 8 years) undergoing elective surgery showed no difference in postoperative complications. When cuffed tubes were used, the need to change tubes in order to achieve an appropriate fit was less common.[24] Specific indications necessitating cuffed tubes include aspiration risk and poor pulmonary compliance requiring ventilation with high peak inspiratory pressures. Advantages of cuffed tubes include the ability to use lower fresh gas flow rates and a decrease in operating room pollution from volatile anesthetics. A potential disadvantage is the slightly smaller internal diameter, as a tube one-half size smaller is generally chosen when a cuffed tube is placed. Balloon inflation must be performed carefully, and ideally cuff pressure should be measured. Smaller pediatric endotracheal

tubes tend to have low-volume, high-pressure cuffs. Although the lower residual volume and reduced compliance offer some protection against size increases or herniation, a small increase in volume may cause a significant increase in pressure on the tracheal wall. In larger-size pediatric tubes with low-pressure, high-volume cuffs, care should be used with inflation because the cuff size may reach twice the age-corresponding internal diameter of the trachea.[25] If nitrous oxide is used, cuff pressures should be checked or the cuff inflation adjusted periodically because nitrous oxide can diffuse into the cuff.

The small distance from vocal cords to carina leaves relatively little margin between correct placement and endobronchial location in small children. For cuffed tubes, the cuff should pass just a short distance below the cords. With uncuffed tubes, options include positioning based on the line markings at the distal end of the tube, deliberate endobronchial intubation and withdrawal until bilateral breath sounds are heard, or use of various approximation formulas, with the most common being tracheal tube (TT) depth (cm) = 3 × TT size [mm inner diameter (ID)]. Auscultation of bilateral breath sounds does not guarantee proper TT position; a fluoroscopic study showed a 12% incidence of endobronchial intubation in children with bilateral breath sounds, possibly related to ventilation through the Murphy eye.[26]

We are fortunate that modern anesthetic practice has brought with it a wider range of options for dealing with the difficult pediatric airway. In contrast to adult practice, an inhalation induction with spontaneous respiration is used in most pediatric patients with a difficult airway, simply because the majority do not readily cooperate with awake or sedated intubation. Insufflation of gas through a nasal airway or endotracheal tube advanced into the nasopharynx may provide a stable airway to allow fiberoptic intubation in an anesthetized child. Awake or sedated intubation can be performed in infants and children and should be considered when there is no obvious way to ventilate the patient, as in congenital abnormalities that may preclude achieving a mask seal or when an LMA cannot be inserted. Topical anesthesia can be provided by allowing an infant to suck on a gloved finger with a small amount of local anesthetic jelly or by nebulized administration. In anesthetized patients, the LMA can serve as a rescue device in the setting of upper airway obstruction; it also can be used as a conduit for fiberoptic intubation. Fiberoptic technology and operator facility with fiberoptic intubation have improved significantly over time. Rigid fiberoptic laryngoscopes such as the Bullard scope are made in pediatric sizes, and intubation guided by a flexible lighted stylet is another technique. Skill with these options should be gained first in patients with normal airways.

Anesthetic Maintenance

The entire spectrum of maintenance anesthetic techniques may be appropriate in various pediatric cases depending on the patient's status and type of surgery. Opinion varies as to whether one volatile agent has a significant advantage over another for pediatric anesthetic use (see Emergence Delirium below). Total intravenous anesthesia is being used more frequently for a variety of pediatric indications, such as minor procedures with spontaneous respiration and longer cases such as neurosurgical procedures where monitoring, particularly of motor evoked potentials, may be less affected than with volatile anesthetics. Metabolic acidosis related to prolonged propofol infusion has been of concern in pediatric intensive care patients.[27] Although propofol infusion is widely used in pediatric anesthesia, no clear cutoff exists regarding safe case duration.

Extubation Choices

Endotracheal tubes can be removed either when the patient awakens or while the child is deeply anesthetized. The choice depends partly on the preferences and experience of the practitioner. Those who advocate extubation under deep anesthesia cite a smoother emergence with less coughing. Risks include laryngospasm and airway obstruction as the child emerges, which could occur in a rapid turnover setting after the anesthesiologist has left the recovery area. Deep extubation is discussed in some detail not to advocate its routine use but to emphasize that it requires particular attention to detail and should not be undertaken by individuals inexperienced with the technique, in institutions without proper support for anesthetized pediatric patients in a recovery area, or in patients with full stomachs or who are unable to protect or maintain a patent airway. A nonirritating anesthetic agent (e.g., sevoflurane or halothane) may prevent coughing during emergence.[28] If deep extubation is chosen, a stable pattern of spontaneous respiration must be established while the patient still is breathing oxygen and anesthetic gas. The patient should be moved and positioned prior to discontinuation of the anesthetic, and the patient should have no response to suctioning the oropharynx, stimulation such as jaw thrust, or slight in and out movement of the endotracheal tube. If the patient meets all of these criteria, the tube is removed carefully, with close attention to gas exchange after extubation. Evidence supporting or refuting the safety of deep extubation is inconclusive; existing studies are small and cover variable patient populations. Smoother emergence, particularly decreased coughing, has also been suggested when an LMA is removed during deep anesthesia rather than in awake children.[29] The type of surgery may impact this decision if blood or secretions

are present in the oropharynx or airway. Suctioning the emerging patient may produce laryngospasm.

Fluid Therapy

Fluid therapy in pediatric anesthesia is based on calculation and replacement of the fasting deficit, maintenance fluid requirement, insensible and third space losses, and blood loss. Maintenance fluid and fasting deficits are based on rates of 4 mL/kg/h for the first 10 kg, 2 mL/kg/h for the second 10 kg, and 1 mL/kg/hr for weight >20 kg. Insensible and third space losses can be high in abdominal surgery, where the starting replacement volume is 10 mL/kg/hr with titration to normal heart rate, blood pressure, urine output, and clinical signs of perfusion. No evidence favors colloid over crystalloid as a generalization, but colloid replacement may have a role in maintaining oncotic pressure when administered volumes are high. Fluid boluses for volume-depleted children are given in increments of 10–20 mL/kg, followed by assessment of clinical parameters. Fluids should be warmed if large volumes are given.

Most healthy children do not need supplemental dextrose to maintain plasma glucose levels unless they have undergone prolonged fasting,[30] and liberalization of fasting guidelines may have further reduced any risk of hypoglycemia in healthy children. Patients in whom intravenous dextrose administration should be strongly considered include neonates, critically ill children with limited metabolic reserve or hepatic failure, and children who receive concentrated tube feedings or intravenous hyperalimentation. If the choice is made to administer dextrose, then the dextrose preferably is administered at a maintenance rate after replacement of the deficit or as a separate infusion. For neonates or high-risk patients, concentrated dextrose solutions may be appropriate; for healthy older children, 1–2.5% dextrose solutions are preferred to prevent hyperglycemia.

Blood and Blood Products

Calculation of circulating blood volume and allowable blood loss are covered in depth in Chapter 19. As a useful quick estimate, children who start at a relatively normal hematocrit can lose at least 20% of their blood volume before requiring transfusion if they are kept normovolemic. The patient's clinical condition as well as the rapidity of blood loss and expected further loss should be considered in deciding when to begin transfusion. As in adults, blood loss that is being replaced with crystalloid should be given in a 3:1 ratio. Packed cells 10 mL/kg will raise the hematocrit by approximately 10 percentage points. The amount required to replace the estimated blood loss also can be calculated based on a hematocrit of 70% contained in packed cells:

$$\text{Transfusion volume} = \text{Patient's blood volume} \times [(\text{Desired} - \text{Current Hct})/\text{Hct of unit pRBCs}],$$

where Hct = hematocrit, and pRBCs = packed red blood cells.

When total transfused volumes of packed cells approach the patient's blood volume, both thrombocytopenia and depletion of clotting factors are common occurrences. Ideally these parameters are measured intraoperatively to guide replacement therapy, but on occasion rapidly changing clinical circumstances dictate empirical blood component therapy. Platelets usually are administered in a volume of 5–10 mL/kg; 10 mL/kg can be expected to raise the platelet concentration by 100,000/mm^3. Thawed fresh-frozen plasma when indicated is also started at 10 mL/kg. Infused packed cells and/or plasma may cause hypocalcemia if given too rapidly as a result of binding of ionized calcium by citrate. In the setting of large-volume transfusions, potassium release from banked blood may be significant; requesting fresh units or washing the cells may prevent hyperkalemia.

PEDIATRIC REGIONAL ANESTHESIA

Overview and Safety

Regional anesthesia can provide a useful adjunct to general anesthesia for a variety of procedures in pediatric patients, either as a single injection or with postoperative infusion of local anesthetic. Advantages of regional anesthesia, such as good postoperative analgesia, avoidance of narcotic therapy with decreased nausea and vomiting, and early discharge from the recovery area, apply to the pediatric patient. In this chapter, techniques with particular application in pediatric anesthesia are presented. For details of standard regional anesthetic techniques, the reader is referred to Chapters 46–48.

Performing a regional anesthetic in children who are too young to cooperate may require that the block be done during deep sedation or general anesthesia. Using a nerve stimulator to perform "surface mapping" prior to placing the needle may improve accuracy and decrease the number of attempts required.[31] Ultrasound techniques for imaging both neuraxial and peripheral blocks in children are under development. Potential complications of regional techniques in anesthetized patients include intraneural injection, direct needle damage, and local anesthetic toxicity. Few reports of intraneural injection or direct nerve injury from a needle are available. One case of a pediatric patient with spinal cord edema that caused a deficit for nearly 2 months after placement of a thoracic epidural has been reported.[32] A large retrospective study in France identified five serious adverse neurologic outcomes in 24,000 pediatric regional anesthetics (16,100 caudal and 7200 epidural), which were believed due to cerebrovascular air embolism or ischemic injury.[33] Venous air embolism with hemodynamic consequences has been described during caudal or epidural placement in small children; loss of resistance to air is not a recommended technique in pediatric patients. The pediatric anesthesia community has endorsed epidural placement under anesthesia as appropriate practice when there is a risk that the patient might otherwise move during the block, and when it is perceived that the patient will benefit from having the regional anesthetic technique as a component of the anesthetic and/or for postoperative pain management.[34] The risks and benefits must be weighed in each individual pediatric patient, especially if the procedure is technically difficult.

Local anesthetic toxicity may result from intravascular injection, rapid absorption of an inappropriately large dose, or intravascular accumulation of drug over time. If combinations of local anesthetic agents are used, the toxicity of the agents should be considered to be additive. Local anesthetic blood levels after caudal blocks and peripheral blocks in pediatric patients are generally within acceptable limits.

Several cases of toxicity due to accumulation of high levels in blood occurred in the early 1990s in the setting of postoperative infusion of local anesthetics. As a result of these reports, the recommendations of doses for pediatric infusion were revised, with a maximum dose of 0.4–0.5 mg/kg/h bupivacaine.[35] Infants may be at higher risk for toxicity because of their lower levels of plasma binding proteins and/or diminished clearance; this enhances the risk with re-dosing or catheter infusion techniques. It is recommended that maximum infusion rates of 0.25–0.3 mg/kg/h bupivacaine be given to patients 6 months and younger.

Because signs of local anesthetic toxicity may not be obvious in the anesthetized patient, use of a test dose is recommended to detect inadvertent intravascular injection. Aspiration of blood may not reliably occur, and CNS signs usually are not present in the anesthetized child. Heart rate changes may be less sensitive in the pediatric population, particularly when volatile anesthetics are being administered; changes in T-wave morphology on the ECG are a useful indicator of intravascular injection. Criteria for a positive test dose in an anesthetized child are heart rate increase >10 bpm, systolic blood pressure increase >15 mm Hg, and change in T-wave amplitude >25% in lead II. The recommended test dose in children is 0.5 μg/kg epinephrine (0.1 mL/kg of local anesthetic containing 1:200,000 epinephrine),[36] up to the 15-μg adult test dose. Use of a short-beveled needle or Angiocath may minimize the risk of intravascular injection. In addition, a slow incremental injection of local anesthetic is recommended (after test dose, administer total dose over 1–2 minutes). Because small veins may easily collapse, observing for passive blood return may be useful in addition to aspiration.

FIGURE 63–4. Surface landmarks for caudal block. Both sacral cornua and the lateral borders of the sacrococcygeal hiatus can be palpated and outlined. The needle is inserted at the midpoint of the triangle at an approximately 45° angle to start.

Specific Techniques for Pediatric Regional Anesthesia

Caudal Blocks and Alternatives

Caudal blocks are frequently performed in young children. This approach to the epidural space is simple, easy to learn, and has a good safety record (Fig. 63–4). Several large series, when combined, report results for >17,000 pediatric caudal blocks without long-term neurologic complications. Potential complications in the anesthetized patient include intravascular injection of local anesthetic, which occurs in approximately 4 in 10,000 patients, and intrathecal injection with total spinal, with a reported incidence of 2.6 per 10,000 cases.[37] Although subarachnoid injection of a small dose of local anesthetic will result in the onset of spinal anesthesia, which is readily detected in the awake patient, detection is more difficult in the anesthetized patient. Children may not develop hypotension or bradycardia, even in the presence of a total spinal, but apnea may still occur due to medullary blockade.

Caudal blocks provide excellent analgesia for lower extremity, lower abdominal, and penoscrotal surgery. A short-beveled needle is placed through the sacral hiatus until a typical "pop" is felt and the needle is anchored in the sacrococcygeal ligament (Fig. 63–5). Aspiration and free drainage should be negative for blood and cerebrospinal fluid. With correct placement, injection will be easy and will not result in swelling of the subcutaneous tissue. After an epinephrine-containing test dose, the full dose is injected incrementally. Clinical signs of correct placement are generally adequate, but use of a nerve stimulator to confirm caudal needle placement has been described. Laxity of the anal sphincter after placement of a caudal block has been shown to predict success of the block.[38] If there is doubt as to efficacy this sign may assist with the decision to provide additional analgesia. Although time to first urination may be longer than without a caudal block, urinary retention is generally not a significant clinical problem. Hemodynamic changes after a

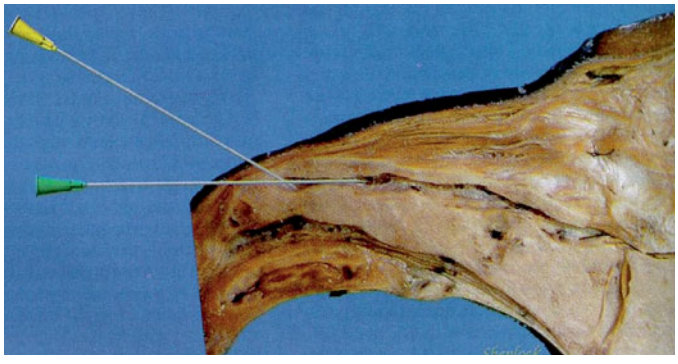

FIGURE 63–5. Caudal block. (Reprinted from Hahn MB, McQuillan PM, Sheplock GJ, eds. Regional Anesthesia: An Atlas of Anatomy and Techniques. St. Louis: Mosby, 1996, with permission.)

caudal block usually are minimal in normovolemic patients. In traditional teaching, children do not show the effects of a sympathectomy because of relatively low sympathetic tone; however, esophageal Doppler studies show that caudal block results in a decrease in lower body vascular resistance and that blood pressure is maintained through compensatory upper extremity vasoconstriction.[39]

Bupivacaine in concentrations of 0.125–0.25% traditionally has been used for caudal blocks in children. Freshly added epinephrine to a concentration of 1:200,000 (5 μg/mL) may improve the duration of analgesia. For simplicity of dilution and dosing, many practitioners choose 1 mL/kg of either 0.125% or 0.25%. Because the block will begin to regress after several hours, for longer procedures a more concentrated solution or re-dosing the block at the end of the case is appropriate. Duration of analgesia from a single-shot caudal injection ranges from 4–12 hours. Blocks often are performed just after anesthetic induction to gain the benefit of the regional technique intraoperatively. Use of a larger volume of local anesthetic to achieve a higher level may block stimulation from traction during procedures such as orchidopexy.[40] The newer local anesthetics ropivacaine and levobupivacaine offer the advantages of decreased cardiac toxicity (demonstrated in animal studies)[41] and reduced motor block. Ropivacaine and levobupivacaine have equivalent efficacy at either 0.2% or 0.25% compared with bupivacaine 0.25% (all given at 1 mL/kg); ropivacaine produced the least motor blockade.[42]

A number of drugs have been used for analgesia by the caudal route either in addition to local anesthetics or alone. Caudally administered clonidine has shown good efficacy for augmenting and prolonging the analgesia produced by local anesthetics in a variety of procedures,[43] although one study reported no added effect from clonidine when given in conjunction with dilute local anesthetic.[44] Another study reported no difference in efficacy and side effects between clonidine administered caudally or intravenously.[45] Most studies of caudal or epidural administration of clonidine in children have shown good safety at single doses of 1–2 μg/kg with a lower incidence of nausea and vomiting than produced by opioids. Some sedation is seen at the higher dose of 5 μg/kg. Most studies have not shown respiratory depression with epidural or caudal clonidine. Two case reports suggest the possibility that postoperative apnea in premature infants resulted from clonidine, although a causal relationship was not clearly established. Use of epidural or caudal clonidine is fairly common in children in the United States, although an FDA "black box" label warning regarding its use in acute postoperative pain management remains on the package related to hypotension in adult patients following epidural clonidine administration.

Ketamine has been shown to have good efficacy by the caudal route, but appropriate preparations of preservative-free *S*-ketamine are not universally available. Ketamine prolongs analgesia when combined with local anesthetic for caudal block. One study suggests a higher incidence of hallucinations in children receiving ketamine 0.5 mg/kg with local anesthetic in a caudal block.[46]

Although "single-shot" caudals are commonly performed for relatively minor procedures, catheters can be threaded via the caudal route either to allow re-dosing for longer infraumbilical surgery or for the purpose of threading the tip of the catheter to a higher thoracic or lumbar level.[47] In general, the ability to thread the catheter cephalad is best in infants because the epidural fat is not as dense as in older patients. The type of catheter may affect the success rate, and some recommend using a styletted catheter. Radiographic confirmation of tip placement may be helpful.[48] Use of a nerve stimulator to monitor tip placement by stimulation of the trunk musculature has been described.[49]

Ilioinguinal/iliohypogastric nerve blocks can be performed for procedures such as hernia repair and orchidopexy in children. The block can be performed preoperatively by the anesthesiologist or intraoperatively by the surgeon. Some surgeons believe that the injected local anesthetic distorts the surgical dissection planes and prefer to perform the block at the end of surgery. In this situation, a caudal block might be preferable to allow a contribution of the block during the anesthetic period. Many studies have compared caudal block to ilioinguinal block for hernia repair, with an overall equivalent efficacy. Ilioinguinal blocks are considered safe and easy to perform but may have a relatively high failure rate; the success rate will depend on the operator's experience and approach. Cadaver dissection has shown that the optimal insertion site is more lateral than is generally taught and is located approximately 2.5 mm medial to the anterior superior iliac spine on both sides of a line drawn between the anterior superior iliac spine and the umbilicus.[50] Ilioinguinal/iliohypogastric nerve blocks can be performed with significantly smaller volumes of local anesthesia and a much higher success rate when ultrasound guidance is used.[51] Although quite safe, complications such as puncture of the bowel wall with hematoma formation have been reported after ilioinguinal block. Other techniques, such as paravertebral or lumbar plexus blockade, have been used in pediatric patients in select settings. Further experience with these techniques is needed before their use can be recommended outside of centers performing high volumes of these techniques.

Penile block is frequently performed for circumcision and sometimes for simple hypospadias repair. Epinephrine should never be injected in a penile block because of the risk for vascular compromise. As with ilioinguinal blocks, many studies have compared caudal and penile blocks with variable results; most suggest that they are approximately equal. In the traditional dorsal penile block, the needle is passed from the base of the penis until the symphysis pubis is contacted, then withdrawn slightly and redirected to each side of the midline before local anesthetic is deposited. Because of the small risk of hematoma or damage to the dorsal penile vessels, some advocate a "ring block" or subcutaneous injection around the base of the penis. A combination of dorsal and ring blocks may provide the best analgesia. Simple application of topical anesthetic cream [eutectic mixture of local anesthetics (EMLA)] provided equivalent analgesia to dorsal penile block, but the duration of blockade was significantly longer with the injected nerve block.[52]

Spinal Anesthesia

The primary use of spinal anesthesia in the pediatric population is for her-

nia repair or other relatively minor surgery in infants considered to be at risk for postoperative apnea. The dose requirement on a weight basis is significantly higher than in adults, and the duration is relatively shorter: 1 mg/kg hyperbaric bupivacaine has a duration of 1–2 hours. Levobupivacaine and ropivacaine also have been used. Clonidine has been shown to prolong analgesia but may increase apnea risk.[53] The decision to administer spinal anesthesia should depend on the patient's medical condition and the extent of the procedure. The perceived benefit of a reduced apnea frequency in comparison to general anesthesia in premature or former premature infants is valid only if no sedation is given. Spinal anesthesia may not be a good choice for a large or incarcerated hernia because of the limited duration and the fact that unsedated babies may fuss and strain. Some centers use spinal anesthesia in older children, in conjunction with sedation, for lower abdominal or lower extremity procedures.[54]

Epidural Analgesia

Either thoracic or lumbar epidural catheters can be placed in children; safety considerations for placement in anesthetized patients are discussed in Overview and Safety. Postoperative epidural analgesia may be of benefit to pediatric patients after major thoracic, abdominal, urologic, and lower extremity surgery. Various regression formulas have been developed to predict the depth of the epidural space based on either the patient's weight or age (Table 63–6). Very roughly, for patients between 10 and 25 kg, the approximate depth of the epidural space in millimeters will be predicted by the weight in kilograms. Postoperative infusions should be prescribed to optimize analgesia and minimize side effects. Patient-controlled epidural analgesia (PCEA) can be given to children and may decrease total drug administration.[55] Patients as young as 5 years may be capable of using PCEA. The pediatric orthopedic community has expressed concern that epidural analgesia may "mask" development of a compartment syndrome, but in the reported cases pain was out of proportion to what was expected and was unrelieved by the epidural.[56] Nevertheless, complications other than inadequate epidural analgesia must always be considered and evaluated promptly.

Extremity Blocks

Regional anesthesia of the upper extremity can be used in children for procedures that will be performed on the arm and hand. Axillary blockade is the most common brachial plexus approach in children, although various infraclavicular approaches have been reported. Because of case reports of syrinx formation in adults after interscalene blocks placed under general anesthesia or deep sedation,[57] this approach is not recommended unless the patient can cooperate with block placement with minimal sedation. Performing the entire surgical procedure under a regional technique is less common in children than in adults. In conjunction with general anesthesia, even distal blocks can provide excellent analgesia for hand procedures.

A number of regional techniques can be performed in children for lower extremity surgery. Psoas compartment approach to the lumbar plexus has been described in children using a nerve stimulator; this block can be used for unilateral surgery on the hip, thigh, or knee.[58] Description of this block suggests a relatively slow learning curve, with 36% of patients requiring two or more attempts.[59] No serious complications were observed; however, vascular puncture occurred in 16% of patients. Femoral nerve blocks are useful in managing pain from a femur fracture, even preoperatively. The "fascia iliaca" block has a high rate of success in children when anesthesia of the obturator and lateral femoral cutaneous nerves is needed in addition to the femoral nerve. The sciatic nerve can be blocked by the traditional posterior approach, at the midthigh, or in the popliteal fossa.

POSTOPERATIVE PAIN MANAGEMENT

The anesthetic plan should include management of pain both in the immediate postoperative period and during later recovery, whether the patient is admitted to the hospital or sent home following surgery. Managing pain in children is a special challenge because our ability to evaluate their pain, and their ability to communicate their needs, may be limited. Pain scales based on behavior and facial expressions are available for younger children. Comprehensive postoperative pain management may include opioid or nonopioid analgesics, regional or local anesthesia, or a multimodal approach. When a regional anesthetic is the primary analgesic for the early postoperative period, the patient and parent should be told what to expect in terms of duration of effect, and plans for a transition to other types of analgesia should be formulated. Particularly for the outpatient, parents should be instructed to begin administering oral analgesics before the child is in severe pain.

Acetaminophen and nonsteroidal antiinflammatory drugs (NSAIDs) can provide significant postoperative pain relief and may have an opioid-sparing effect. Recent pharmacokinetic research has given us new insights into dosing for acetaminophen, particularly for rectal administration, where the onset time is slow and absorption is variable. After a rectal loading dose of acetaminophen, peak plasma concentration occurs at approximately 200 minutes. The current recommendation for rectal acetaminophen is for a loading dose of 40 mg/kg followed by 20 mg/kg every 6 hours; this dose does not appear to result in drug accumulation in the first 24 hours.[60] Oral administration of acetaminophen provides a faster onset and more reliable absorption. An oral loading dose of 40 mg/kg (compared with the traditional dose of

15 mg/kg) resulted in plasma levels at 30 and 60 minutes in an effective range to treat pain (after tonsillectomy) and below levels considered to be toxic.[61] Although higher doses are considered safe and effective in healthy children, parents of outpatients must understand the instructions regarding the concentration and amount to be administered. Smaller doses may be appropriate in critically ill patients or those with impaired drug clearance. Injectable forms of acetaminophen are in development but are not available in the United States; these may offer an advantage in eliminating the variability of onset time.

NSAIDs are used in children where there is no contraindication. Ketorolac has been used in strabismus surgery, orthopedics, general pediatric surgery, and urologic surgery with good safety and efficacy. As with many drugs, detailed data are not available for infants, but in limited studies ketorolac appears to be a safe and effective analgesic for infants. NSAIDs appear to be effective in treating pain after tonsillectomy, but studies are mixed as to whether this causes an increased bleeding risk due to inhibition of platelet aggregation.

Opioid analgesics are needed after many pediatric procedures. Side effects include somnolence, vomiting, pruritus, and risk of respiratory depression. Codeine, which has commonly been prescribed to children after surgery, is dependent on conversion to morphine for its effect; genetic variability in metabolism makes dosing relatively unreliable.[62] Fentanyl is given intravenously at a dose of 1–2 μg/kg for short procedures. For more major procedures, a loading dose ≥5 μg/kg is followed by hourly dosing of 1–3 μg/kg as needed. Morphine can be administered as a sole analgesic in a total dose of 0.1 mg/kg or titrated in smaller increments (0.02 mg/kg) after the initial use of fentanyl or another opioid intraoperatively. Nasal administration of fentanyl has been shown to be effective and is useful for minor procedures where intravenous access is not established, such as myringotomy with tubes.[63] Remifentanil can be infused as a component of a general anesthetic technique, offering intraoperative titration and rapid emergence, but it provides no residual postoperative analgesia. Tramadol, a synthetic codeine derivative with a low affinity for μ-opioid receptors, may produce a lower incidence of side effects than traditional opioids. Tramadol has been shown to have some analgesic efficacy in pediatric patients but may not be as effective as morphine.[64] Other adjunctive drugs, such as ketamine, clonidine, and dexmedetomidine, are being explored for their role in pediatric postoperative pain management. Regardless of the technique chosen, frequent assessment of analgesic efficacy and side effects, as well as access to appropriate breakthrough pain medication, is important to providing postoperative pain relief for children.

RECOVERY PROBLEMS

Postoperative Nausea and Vomiting

Postoperative vomiting is distressing to children and their parents, and may delay or prevent discharge of postsurgical patients from the recovery room. In the pediatric population, because nausea may be difficult to quantify, most studies focus on the incidence of vomiting. Overall, the incidence of vomiting is higher in children than in adults; the incidence rate appears to increase with age up to puberty and then further decrease.[65] The traditional wisdom that postoperative nausea and vomiting was linked to specific high-risk procedures has become controversial in adults. Procedures with a high incidence of postoperative vomiting in children include strabismus surgery, adenotonsillectomy, and orchidopexy. Gender differences are not believed to be a major factor until puberty. Opioids even in small doses increase the incidence of postoperative vomiting in children.

Risk indices of vomiting developed in adult populations do not apply well to children.[66] A four-component pediatric risk score has been proposed using the following factors: surgery ≥30 minutes, age ≥3 years, strabismus surgery, and positive history of postoperative vomiting in the patient, parents, or siblings.[67] Prospective validation in >1200 patients showed incidences of vomiting of 9%, 10%, 30%, 55%, and 70% with 0, 1, 2, 3, or 4 risk factors, suggesting the value of giving prophylactic antiemetics to patients with ≥2 risk factors. This study did not report an increased risk of vomiting with adenotonsillectomy or middle ear surgery. Postoperative administration of an opioid was linked to increased risk but was not identified as a major predictor.

For patients at risk for postoperative vomiting, tailoring the anesthetic technique may be of benefit, using propofol rather than volatile anesthetics[68] and regional anesthesia, NSAIDs, and acetaminophen rather than opioids. The impact of nitrous oxide use in pediatric patients is as controversial as in adults, but one comparison of sevoflurane-anesthetized children did not show an increase in postoperative vomiting when nitrous oxide was used.[69] Adequate hydration intraoperatively and avoiding early oral intake may help reduce postoperative vomiting.

In patients at moderate to high risk of postoperative vomiting, prophylactic antiemetic therapy may be cost-effective. Pediatric dosing for antiemetic agents is summarized in Table 63–7. Droperidol has a dose-related antiemetic effect and is best administered near the end of surgery. Studies vary as to the optimal droperidol dose to maximize efficacy and minimize side effects, but the majority found best efficacy in the range from 50–75 μg/kg. Meta-analysis suggested that droperidol was as effective as ondansetron in adults but not in children,[70] whereas several individual pediatric studies found equal efficacy at higher doses of droperidol. The FDA issued a "black box" drug label warning on droperidol related to case reports of torsade de points and recommended that droperi-

TABLE 63–7.

Antiemetic Doses for Children

Drug	Dose
Ondansetron	50–100 μg/kg up to 4 mg
Dolasetron	350 μg/kg up to 12.5 mg
Dexamethasone	150 μg/kg up to 8 mg
Droperidol	50–75 μg/kg up to 1.25 mg (reserve for refractory vomiting and use under monitored conditions)
Dimenhydrinate	0.5 mg/kg
Perphenazine	70 μg/kg

From Gan et al.[65] with permission.

dol use be reserved for refractory nausea and vomiting and administered under ECG-monitored conditions.

Ondansetron and the newer 5-hydroxytryptamine$_3$ (5-HT$_3$) receptor antagonists dolasetron and granisetron have excellent efficacy for prophylaxis and treatment of postoperative vomiting in children. The FDA approved dose of ondansetron is 0.1 mg/kg, which appears equivalent to 0.35 mg/kg dolasetron.[71] Some dose-related improvement in antiemetic efficacy is seen, but for most patients the lack of a significantly important effect does not justify the added expense of a larger dose. As with droperidol, administering ondansetron early in a case appears to be of no "preemptive" value; effect duration relates to the half-life of the drug.

Dexamethasone initially was used in tonsillectomy to prevent edema but was noted to reduce postoperative vomiting and improve pain scores. Subsequent studies showed that dexamethasone was efficacious as a prophylactic antiemetic in strabismus and other surgical procedures. Whereas the initial doses of dexamethasone used were quite large, it appears not to have a significant dose–response relationship, and doses as small as 0.05 mg/kg have been shown to be effective.[72] A combination of dexamethasone and ondansetron is frequently given for antiemetic prophylaxis and may be more effective than ondansetron alone.[73]

Metoclopramide, which has commonly been given for postoperative emesis, is no more effective than placebo.[74] Finally, there is interest in nonpharmacologic antiemetic therapy in children; acupuncture or electrostimulation may be as effective as the available medications.[75]

Emergence Delirium

Postanesthetic agitation is a common problem in toddlers and young children. Many studies of the problem have been reported, but most were small and descriptive, with often conflicting results. The clinical impression of many anesthesiologists and postanesthesia care unit (PACU) nurses is that agitation is significantly more common with sevoflurane, but it occurs with variable frequency after anesthetics with all volatile agents.[76] The overall incidence of agitation is lower after propofol, and crossover studies between sevoflurane and propofol show a lower incidence with propofol in individual patients, but a small percentage of children receiving repeat anesthetics exhibit severe agitation after propofol.

Pain is a contributing factor in postanesthetic agitation, but emergence agitation also is exhibited after anesthesia for nonpainful procedures, such as MRI, in children.[77] Agents that provide analgesia as well as sedation have shown efficacy in reducing agitation; these include fentanyl, ketamine, clonidine, and dexmedetomidine. Results have been mixed as to whether residual postoperative sedation with benzodiazepines or propofol reduces agitation. One study found a higher incidence of emergence delirium in children who had received midazolam premedication.[78]

The perceived prominence of agitation after sevoflurane may be due to a higher incidence in the very early postoperative period, whereas the overall PACU incidence may be similar among the inhalation agents.[79] The actual rate of emergence does not appear to be the cause of postanesthetic delirium. Agitation may be exhibited by children who have arrived asleep in the recovery room. A comparison between sevoflurane and propofol with children emerging at the same rate showed a significantly higher agitation rate in the sevoflurane group.[80] Delaying emergence by continuing the volatile anesthetic into the postoperative period does not appear to decrease the incidence of agitation,[81] although using nitrous oxide during the washout period may reduce the incidence.[82]

In addition to acute postoperative agitation, children may develop postoperative maladaptive behavioral changes, such as changes in sleep or eating patterns, separation anxiety, and withdrawn or aggressive behavior. Two prospective comparisons found no difference in the incidence of these disturbances in children receiving halothane or sevoflurane, although the results were mixed as to the incidence of emergence delirium with sevoflurane and halothane.[83,84] Kain et al.[85] identified an association between preoperative anxiety in both the child and the parent, emergence delirium, and maladaptive behaviors after discharge. They suggest that some children, based on their own personality traits and those of their parents, may be more susceptible to developing these changes after the experience of anesthesia and surgery. Negative behavioral changes are more common in younger children.

SELECTED CLINICAL AREAS IN PEDIATRIC ANESTHESIA

The remainder of this chapter is devoted to certain specific clinical scenarios that are unique to pediatric anesthesia. In some situations, this may complement the basic concepts discussed more thoroughly in chapters on other subspecialties of anesthesiology. For example, specific types of pediatric craniotomy are discussed in this chapter, but general concepts of the management of intracranial pressure and intracranial procedures are discussed in Chapter 50. Other cases in pediatric anesthesia are presented within specialty chapters in this text (spine surgery in Chapter 64, tonsillectomy and pediatric airway surgery in Chapter 66, and anesthesia for MRI, radiation therapy, etc. in Chapter 69).

Pediatric General Surgery and Urology

Children present for a variety of general surgical and urologic procedures. Elective surgery in healthy children typically are initiated with an inhalational anesthetic and for shorter, simpler procedures maintained with a mask or LMA. General anesthesia may be supplemented with a regional technique. Hernia surgery is frequently performed in infants and children. Surgical practice varies with regard to indications for exploration of the contralateral side if no clinical evidence of a hernia is seen; this also can be done laparoscopically. For boys with undescended testes, orchidopexy is performed through a groin incision when the patient has a palpable testis or may be combined with laparoscopy when the testis cannot be distinctly palpated. Having a clear understanding of the surgical plan helps the anesthesiologist choose an appropriate anesthetic technique. Although orchidopexy is performed through a groin incision similar to herniorrhaphy, orchidopexy patients tend to have more severe pain of longer duration; multimodal analgesia including a regional technique may be helpful. During both of these procedures, the occurrence of sudden intraoperative stimulation due to traction on the spermatic cord should be anticipated.

Hypospadias comprises a spectrum of lesions, and repair may require from 30 minutes to several hours. Complex lesions may require skin grafting or staged repairs. Caudal or penile blocks are frequently performed for these anesthetics; a urethral stent may be left in at the end of surgery. Recognition of vesicoureteral reflux in children has led to an increasing number of ureteral reimplantation procedures. Surgery usually is performed through a low transverse abdominal incision. Children are hospitalized for 2–3 days and may have a urinary catheter in place overnight. Advances in the operative management of ureteral reimplantation (e.g., minimizing use of catheters) have shortened the postoperative course. Bladder spasms may occur and can be treated with ketorolac.[86] Caudal and epidural analgesia also are frequently used for this surgery. Congenital anomalies of the kidney and ureters may lead to infection; these usually are repaired either through a flank incision or by laparoscopy.

Laparoscopy in Children

Laparoscopy has become a common procedure in children for a variety of indications. Laparoscopic operations performed in children include transperitoneal procedures such as cholecystectomy, fundoplication, appendectomy, and exploration for undescended testes; retroperitoneal approaches to the kidney and urinary tract; and use of the laparoscope to visualize the contralateral side in inguinal hernia repair. Before or during laparoscopy, producing a pneumoperitoneum with CO_2 may cause systemic hypercarbia, and a higher peak airway pressure may be needed to produce adequate ventilation and oxygenation. Hemodynamic compromise from impairment of venous return or from gas embolism during insufflation is possible. Another potential source of gas embolization is use of the argon beam coagulator during laparoscopic procedures such as partial nephrectomy.[87] Although early studies suggested a decrease in aortic blood flow and stroke volume with a compensatory increase in systemic vascular resistance, other studies in healthy children having low-pressure insufflation for laparoscopic procedures showed that the cardiac index is preserved or minimally affected.[88] Respiratory parameters are predictably impacted by CO_2 insufflation. In children undergoing laparoscopy for urologic surgery, significant increases in end-tidal CO_2 and peak airway pressures were measured.[89] Pulmonary mechanics of infants may be impaired even at low inflation pressures. Transient oliguria or anuria may occur during laparoscopy, particularly in younger children. This appears to be a reversible phenomenon in brief procedures.[90]

Laparoscopy in children usually is performed with general anesthesia. Many anesthesiologists prefer endotracheal intubation to control respiratory changes, although an LMA may be acceptable if low intraabdominal inflation pressures are used. Analgesia usually can be satisfactorily provided by some combination of local anesthetic infiltration, acetaminophen, and NSAIDs. Caudal or epidural analgesia can be used as a supplement, but for uncomplicated laparoscopy they may not provide any benefit over simple local infiltration.

Thoracotomy and Thoracoscopy

Children present for thoracic procedures for a number of reasons, such as primary lung processes, tumor, or drainage of empyema, as well as for access to tracheal structures or vascular anomalies. Many of the same considerations apply to thoracic anesthesia in children as in adults; however, systemic hypoxia may be a problem in small children because of their nonrigid rib cage and the potential for compression of the dependent lung.[91]

Video-assisted thoracoscopic surgery (VATS) is used in pediatric patients for biopsy or limited resection of a tumor or infectious lesions and for drainage and decortication of an empyema. Empyema may develop as a complication of community-acquired pneumonia even in otherwise healthy patients. In the pediatric population, several studies have suggested that early VATS results in a shorter overall hospital stay in empyema patients compared with tube thoracostomy, with shorter time to intervention and fewer invasive interventions. Earlier intervention with VATS also resulted in shorter surgical time and fewer postoperative complications, perhaps because disease progression was minimized.[92]

Historically, thoracotomy in children was performed with the surgeon packing one lung out of the surgical field. Technically, VATS is much easier to perform if one lung can be deflated. As surgeons gained more exposure to one-lung ventilation with these procedures, it has become more commonly requested for open thoracotomy as well. Improvements in equipment (bronchial blockers, fiberoptic bronchoscopes) have enhanced our ability to perform independent lung ventilation in children.

When selecting a method for one-lung ventilation in children, the outer diameter of available tubes must be considered carefully and compared to the expected tracheal and bronchial sizes.[93] Double-lumen tubes, when available in appropriate sizes, allow suctioning of each lung and provision of oxygen and CPAP to the deflated lung. The smallest available double-lumen tube is 26 F, with an outer diameter of 9.3 mm. This is slightly larger than a 6.5-mm ID endotracheal tube and can be used in children as young as 8 years. A double-lumen tube for infants has been described but is not in common use. The Univent tube, which is a single-lumen tube with a built-in bronchial blocker, has a significantly larger outer diameter than standard single-lumen tubes of the same internal diameter. A 3.5-mm ID Univent tube is roughly comparable to a standard 6.0 endotracheal tube and should be able to be used in children 6 years of age and older. In children younger than 6 years of age, options for one-lung ventilation include use of a bronchial blocker with a standard endotracheal tube or intentional mainstem bronchial intubation. A bronchial blocker or Fogarty embolectomy catheter can be placed with the assistance of rigid or fiberoptic bronchoscopy. If technically feasible, fiberoptic placement is preferred to minimize the risk of dislodgement with other instrumentation; adaptors allow ventilation during manipulation and positioning of the bronchial blocker. Mainstem bronchial intubation can be performed blindly or with fiberoptic guidance. If mainstem intubation is planned, a smaller endotracheal tube must be used than what would be chosen for tracheal placement. Use of a small cuffed tube in this situation will allow inflation of the cuff once the tube is withdrawn into the tracheal, thus allowing reinflation and two-lung ventilation without the need to reintubate.

Options for one-lung ventilation in children are summarized in Table 63–8.

Other considerations for pediatric thoracic surgery include adequate venous access and appropriate monitoring. Use of an arterial catheter depends on the extent of the procedure and the underlying lung function. With use of pulse oximetry and capnography, the majority of children having VATS may not require arterial monitoring. In infants or those with severe lung disease, the ability to obtain blood gas samples may be vital. Most children can be extubated after a thoracotomy or VATS unless respiratory function is severely impaired. Appropriate analgesia is helpful in speeding recovery; for open procedures, this may include administration of a local anesthetic with or without an opioid through a thoracic epidural catheter or via a caudal catheter threaded to the thoracic region in small children.

TABLE 63–8.

Tube Selection for Single Lung Ventilation in Children

Age (y)	ETT (ID) (mm)[a]	BB (F)[b]	Univent (ID) (mm)[c]	DLT (F)[d]
0.5–1	3.5–4	5		
1-2	4.0–4.5	5		
2–4	4.5–5.0	5		
4–6	5.0–5.5	5		
6–8	5.5–6	6	3.5	
8–10	6.0 cuffed	6	4.5	26
10–12	6.5 cuffed	6	4.5	26–28
12–14	6.5–7.0 cuffed	6	4.5	32
14–16	7.0 cuffed	7	6.0	35
16–18	7.0–8.0 cuffed	7	7.0	35

BB, bronchial blocker; DLT, double–lumen tube; ETT, endotracheal tube; ID, internal diameter.

Pectus Excavatum and the Nuss Procedure

Pectus excavatum is the most common congenital chest wall deformity of children. Left uncorrected, it can result in respiratory compromise and cardiac compression. Traditionally, pectus excavatum was corrected during the teenage years by an open approach. More recently, a convex steel bar is inserted ("Nuss procedure") to mechanically raise the sternum. Cartilage remodels over time, and the bar is removed several years later. After bar removal, patients have a subjective improvement in functional status and quality of life and a small but significant improvement in pulmonary function studies.[94]

Early studies of the Nuss procedure included a moderate intraoperative complication rate, including cardiac compression, disruption of great vessels with significant hemorrhage, and tension pneumothorax. A very low rate of complications occurs now because of improved surgeon experience and refinement of the surgical technique, particularly the use of thoracoscopy to guide bar placement.[95] Postoperative complications include dislodgement of the bar (which has been minimized through use of lateral stabilizers), pneumothorax, pneumonia, and significant pain. Outcomes appear better in younger patients, and the trend is toward correcting these deformities in the preteen years.

Preoperative evaluation should search for cardiorespiratory compromise. Most patients have some mild degree of exercise limitation, but significant dyspnea should prompt further evaluation. The mechanism of exercise limitation in pectus excavatum remains controversial but may reflect a combination of restrictive lung disease and impaired right ventricular function. Pulmonary function testing and echocardiography are frequently performed but probably are not essential except for patients with significant symptoms. In some centers, these tests are considered a part of the routine preoperative pathway before pectus excavatum repair.

A standard general anesthetic is provided, often in conjunction with a thoracic epidural. In the early years of pectus bar placement, arterial lines were frequently placed because of concern for hemodynamic compromise and blood loss. This step is rarely considered necessary today with the surgical advances noted. Duration of surgery is approximately 2 hours; patients can be extubated at the end of the procedure unless they experienced intraoperative difficulties. Although pectus bar placement is considered a minimally invasive procedure, the initial postoperative period can involve significant pain due to the pressure of the bar. Thoracic epidural analgesia is commonly used, infusing a combination of local anesthetic and opioid. Patients are generally hospitalized for 4–5 days after Nuss repair, and the epidural is maintained for the first 2–3 days.

Cancer-Related Procedures in Children

Abdominal Tumors

Neuroblastoma, the most common extracranial solid tumor of childhood, arises from neural crest cells. Risk varies depending on clinical stage and biologic features of the individual tumor. Children with neuroblastoma require biopsy for diagnosis and multiple imaging studies during treatment. Treatment may include either limited or aggressive surgical resection, chemotherapy, and/or radiation therapy. High-risk patients may receive a bone marrow transplant. Considerations before anesthesia for resection include adequate venous access, arterial monitoring if extensive blood loss is expected, and a complete blood count if chemotherapy has been given prior to surgery. A subset of these tumors may produce significant catecholamine secretion causing perioperative hemodynamic lability.

Wilms tumor (nephroblastoma) most commonly occurs in young children. If diagnosed in its early stages, it can be approached by laparoscopic nephrectomy. However, the tumor may remain asymptomatic until the mass is quite large, and resection may involve a more extensive procedure. If vascular and intracardiac extension have oc-

curred, then cardiopulmonary bypass may be required for resection. Renin production or renovascular compression may result in hypertension. Treatment and prognosis are stratified by surgical stage and histologic type.

Mediastinal Mass

One other specific scenario in the pediatric population is management of mediastinal masses. Tumors, particularly lymphoma, may develop rapidly and present with respiratory symptoms related to mediastinal involvement. Anesthetic management of the child with a mediastinal mass is challenging. Inducing general anesthesia may lead to compression of the airway and/or vascular structures when thoracic muscle tone is reduced, with catastrophic results. A careful history should include questioning for exercise tolerance and tolerance of the supine position. This may give some idea of the severity of disease, but absence of symptoms does not eliminate the possibility of difficulties during anesthetic induction. Where possible, respiratory flow–volume loops are helpful in delineating the extent of airway compression. Unless the possibility of airway and vascular compression can be ruled out with preoperative tests, serious consideration should be given to performing a minimal procedure with local anesthesia to obtain the diagnosis and deferring more major interventions until after initial treatment with radiation therapy to reduce the mass of the tumor. If general anesthesia is required, maintenance of spontaneous respiration is the preferred technique. This is most commonly accomplished with inhalational anesthesia but also can be provided with intravenous agents (propofol, opioids, ketamine). A head-up or lateral induction position may prove helpful. Rigid bronchoscopy and cardiopulmonary bypass are considered emergency backup, and a plan should be formulated prior to inducction.[96]

Anesthesia for Diagnostic and Therapeutic Procedures

Children with leukemia, lymphoma, neuroblastoma, and certain CNS tumors typically require repeated lumbar punctures and/or bone marrow biopsies for initial diagnosis and treatment followup. In some cases, intrathecal chemotherapy is administered as well. These procedures are frequently performed with sedation or a brief general anesthetic. Use of topical local anesthetic cream over the site can be useful in minimizing anesthetic requirements. Sedation depends on the individual patient but might include a combination of benzodiazepine and opioid (e.g., midazolam and fentanyl). Intravenous anesthesia is commonly provided with propofol with or without a short-acting narcotic.

ANESTHESIA FOR PEDIATRIC NEUROSURGERY

Even in the absence of overt signs or symptoms of increased intracranial pressure, children presenting for ventriculoperitoneal shunt revision, resection of a brain tumor, or posterior fossa decompression may be near the point of decompensation and should be managed so that intracranial pressure does not increase. The history should address recent nausea and vomiting and the potential for volume depletion as well as aspiration risk. Preoperatively, oversedation should be avoided because of the risk for hypercarbia, but individual patients may benefit from judicious premedication in a monitored setting to minimize agitation. Intraoperatively, the various inhalational agents may cause a slight increase of intracranial pressure; maintenance of mean arterial pressure is critical to maintain the cerebral perfusion pressure.[97] Continuation of steroids and/or anticonvulsant medications may be appropriate in the perioperative period. If acute treatment of increased intracranial pressure is needed, hyperventilation, mannitol infusion (0.5–1 gm/kg), increasing anesthetic depth, and drainage of cerebrospinal fluid (when feasible) all may be appropriate.

Ventriculoperitoneal Shunt

Ventriculoperitoneal shunts in infants are discussed in detail in Chapter 62. Older children may require replacement or revision of shunts because of malfunction or growth, or they may require new shunts after tumor resection or discovery of other intracranial pathology. In some cases of cysts or other obstruction to cerebrospinal fluid outflow, endoscopic ventriculostomy may restore normal flow patterns and obviate the need for shunting. Patients with multiple shunts may have an acquired latex allergy or may be receiving treatment in a latex-free environment to prevent development of an allergy.

Craniotomy for Tumor

A higher percentage of brain tumors are infratentorial in pediatric patients than in adults, with medulloblastoma and astrocytoma being the common posterior fossa lesions. Other common tumors include the supratentorial counterparts of medulloblastoma (pineoblastoma and primitive neuroectodermal tumor), glioma, and ependymoma. Anesthetic management for craniotomy is discussed in more depth in Chapter 50. In general for a pediatric craniotomy, adequate peripheral venous access and an arterial line are needed. Central lines are of limited use for aspirating air in the pediatric population and usually are not placed for this purpose in smaller children. If the anatomy and positioning suggest a risk of venous air embolus, then precordial Doppler monitoring should be used. Depending on the location of the tumor and the course of surgery, development of diabetes insipidus or other endocrine abnormalities may occur during or after surgery.

Posterior Fossa Decompression

Chiari type I malformation, a caudal displacement of the cerebellar tonsils through the foramen magnum into the spinal canal, may result in a variety of symptoms, including headache or other pain, weakness, ataxia, and sensory loss. Patients may have brainstem and spinal cord dysfunction, the latter often as a result of syrinx formation. Surgical management consists of suboccipital craniectomy with posterior fossa decompression. Extreme flexion should be avoided to minimize the risk of brainstem compression. Postoperatively, these patients may have respiratory abnormalities, perhaps related to ischemia or edema of the brainstem respiratory centers.

Craniosynostosis

Craniosynostosis represents premature closure of one or more cranial sutures. The incidence is approximately 1 in 2000 births, with more males than females affected. Uncorrected, craniosynostosis may lead to increased intracranial pressure. Correction may be performed for cosmetic reasons. Simple craniosynostoses usually are corrected between 3 and 6 months of

age. More complex craniofacial reconstruction usually is performed after 9 months of age. Although reconstruction is an extradural procedure, significant blood loss from the scalp and cranium may occur. Adequate venous access, an arterial line for monitoring blood pressure and hemoglobin concentration, and availability of blood and blood products are critical to safe management. Overall, morbidity and mortality are low for craniosynostosis surgery. Adverse events are significantly associated with secondary versus primary operation and in patients with craniofacial syndromes.

Craniosynostosis may be an isolated defect or form part of a craniofacial syndrome, such as Crouzon or Apert syndrome, which can include a difficult airway, cleft palate, syndactyly, and cardiac or other abnormalities. Preoperative evaluation should be geared toward evaluation of the airway, vascular access, baseline neurologic status, and other anomalies. Children with uncorrected complex craniosynostosis may have increased intracranial pressure, decreased cerebral perfusion pressure, and obstructive respiratory symptoms, particularly during sleep.[98]

Preparation for the case includes consideration of positioning, including access to the patient and lines, and avoidance of soft-tissue or ischemic injury. Surgeons may request elevation of the head to enhance venous drainage; however, the advantage must be weighed against the risk of venous air entrainment. Goals of anesthetic management include minimizing severe increases in intracranial pressure. Hyperventilation and/or administration of mannitol may be indicated if the craniectomy is technically difficult. Monitoring must include evaluation of circulating blood volume status, blood loss, and associated metabolic changes, and maintenance of temperature. Ideally, an anesthetic technique is chosen so that surgery is completed with adequate analgesia and a calm patient, but with the ability to evaluate neurologic status.

Several studies suggest that venous air embolism occurs frequently during craniosynostosis repair, although the majority of episodes are not hemodynamically significant.[99] Sequelae of air embolus include hypotension and a paradoxical embolus if a right-to-left intracardiac shunt exists. Steps that may prevent a significant air embolus include maintenance of adequate vascular volume, positive-pressure ventilation, and monitoring for early detection. Use of precordial Doppler has been shown to be effective in detecting air embolism and is more sensitive than end-tidal nitrogen measurement. Transesophageal echocardiography is extremely sensitive but may have some practical limitations. Management of venous air embolism includes communication with the surgeon to reposition the patient, flood the field with saline, and use bone wax in an attempt to limit the amount of entrained air. If nitrous oxide has been given, it should be discontinued. Compression of the jugular veins may increase venous pressure and prevent further air entrainment. Aspiration of air is technically difficult to achieve in small children. Factors contributing to the high frequency of air embolus in children include a relatively large head size, as a result of which the surgical field may be unintentionally positioned above the heart. The infant scalp is highly vascular, and when rapid blood loss and a decrease in central venous pressure occur, the pressure gradient will favor entrainment of air. The volume of entrained air is greater in comparison to the child's cardiac and vascular volume, leading to the possibility of more pronounced hypotension. In addition, the existence of a persistent patent foramen ovale in 50% of children younger than 5 years increases the potential for paradoxical air embolus.

Blood loss during craniosynostosis repair frequently requires transfusion, almost 95% of patients in most studies. Newer surgical techniques may result in reduced blood loss. These techniques include earlier surgical reconstruction, when the skull is less well formed; use of spring-mediated cranial expansion rather than full cranial vault reconstruction[100]; and endoscopic strip craniectomy, which may have a lower risk for air embolus. Techniques that have been used to minimize allogeneic blood transfusion include preoperative administration of erythropoietin, selection of an optimal age to achieve a favorable balance between fetal and adult hemoglobin, preoperative preparation of an autologous blood supply, and intraoperative and postoperative blood salvage and reinfusion. When massive transfusion is required, coagulopathy may develop. In one series of craniosynostosis patients, the subgroup requiring a larger than average amount of packed cells developed a coagulopathy that was primarily related to a dilutional lack of clotting factors.[101]

After routine craniosynostosis repair, most patients with a normal airway can be extubated. Ongoing blood loss from drains may require further transfusions during the next 24 hours. If the procedure was extensive or blood loss was very large, hemodynamic stability or swelling may suggest the need to leave the patient intubated and perhaps mechanically ventilated in the early postoperative period.

Pediatric Ambulatory Surgery

Some of the procedures described here, as well as many ear, nose, and throat (ENT) and ophthalmologic procedures discussed elsewhere in this textbook, can be performed on an outpatient basis. Ambulatory surgery is frequently performed in a mixed adult/pediatric setting, but facilities, equipment, and staff competencies must be suitable for the pediatric population being treated. General concepts of ambulatory anesthesia are discussed in Chapter 67, and many of these concepts apply to children: the anesthetic should be tailored to rapid recovery with attention to pain management and control of postoperative vomiting. A qualified caregiver for the pediatric patient should be present at home for the remainder of the day and night, and parents must be given careful instructions about postoperative medications and any signs or symptoms that should evoke their concern or a return to the hospital.

CONCLUSION

The practice of pediatric anesthesia encompasses a broad spectrum of surgery and patients and creates many challenges in terms of patient and family dynamics, technical skills, and anatomic and physiologic factors. Meticulous attention to detail and anticipation of common perioperative problems are essential, as are training and ongoing experience in the care of children.

CHAPTER 64

Anesthesia for Orthopedic Surgery

Gavin Martin, MB,
Dara Breslin, MB, and
Todd Stevens, MD

Orthopedic anesthesia presents many challenges to the anesthesiologist. Patients range in age from infant to centurion. This patient population shows the full spectrum of comorbidities. Many of the procedures are associated with significant postoperative pain. Surgery on isolated extremities can be performed using a variety of regional anesthetic techniques for both anesthesia and postoperative analgesia. However, providing adequate analgesia using central neuraxial techniques can be challenging, especially when deep venous thrombosis (DVT) prophylaxis with low-molecular-weight heparin (LMWH) is needed. This challenge has led to the development of many peripheral nerve block techniques and advances in the equipment used for these techniques, including continuous nerve catheters and ultrasound for identification of nerve plexuses. Recent literature has shown a benefit of regional anesthesia over general anesthesia with respect to mortality, morbidity, postoperative analgesia, and functional recovery. In this chapter, we consider the factors pertinent to anesthesia for orthopedic surgery and review the appropriate management.

SPECIFIC PROBLEMS IN THE ORTHOPEDIC PATIENT

Rheumatoid Arthritis

Because of the nature of the disease, patients with rheumatoid arthritis present for many orthopedic procedures, ranging from joint replacement surgery to cervical spine surgery. These patients can be very challenging to treat for a variety of reasons. Deformities of the extremities are common, which may make arterial and intravenous access and positioning of the patient more difficult. Great care must be taken when positioning patients, with adequate padding needed to prevent pressure necrosis of the patient's skin. Positioning the patient while he/she is awake often is useful. Of major concern in any patient with rheumatoid arthritis is the possibility of cervical spine instability.[1] Cervical spine involvement occurs in more than half of patients with rheumatoid arthritis, with atlantoaxial dislocation the most common abnormality. Pain and evidence of spinal cord injury are the main symptoms and signs of cervical spine involvement. However, the presence of symptoms may not correlate with the severity of radiologic abnormalities. Computed tomography and magnetic resonance imaging provide detailed images of the bone and spinal cord and should be considered in at-risk patients before anesthesia is provided. Flexion and extension cervical x-ray views may be required to exclude instability. Cervical spine instability may be overlooked in some patients based on clinical examination alone. Temporomandibular involvement may further restrict the anesthesiologist's ability to gain adequate access to the airway.[2] Both atlantoaxial instability and temporomandibular involvement may necessitate an awake fiberoptic intubation. Another airway problem is related to the potential for cricoarytenoid arthritis, which makes passage of an endotracheal tube extremely difficult.[2] Passing of an endotracheal tube in itself may cause dislocation of the laryngeal cartilages. Hoarseness and inspiratory stridor may indicate the presence of cricoarytenoid arthritis.

As a systemic disease, rheumatoid arthritis may result in a variety of organ dysfunctions (Table 64–1). Pulmonary, cardiac, renal, and hematologic changes are important to the anesthesiologist. All these systems must be thoroughly assessed before any surgical procedure. Patients with rheumatoid arthritis are commonly managed with a variety of drugs, including steroids and nonsteroidal anti-inflammatory drugs (NSAIDs). Thus, patients may require preoperative steroid supplementation to prevent acute adrenocortical insufficiency and cardiovascular collapse during anesthesia. However, use of NSAIDS is controversial because of implications with regard to their effects on gastric mucosa, renal toxicity, platelet dysfunction, and cardiovascular effects.

Blood Loss

Orthopedic surgery can be associated with significant blood loss, particularly trauma surgery, multilevel back surgery, redo arthroplasty surgery, or surgery in which tourniquet use is precluded. Spinal and joint replacement surgeries offer a unique problem because of the large surface of cancellous bone that is exposed during surgery. Bleeding from cancellous bone is not easily controlled using standard techniques such as vessel ligation and cautery.

Despite improvement in the screening process for allogenic blood donations, there still exists the potential for transmission of infectious diseases and transfusion reactions. Bierbaum et al.[3] investigated the need for blood transfusion in 9482 patients who had undergone total hip or total knee replacement surgery. Fifty-five percent of patients undergoing hip surgery and 39% of the knee replacement patients required some form of blood transfusion. Of these patients, 66% received autologous blood and 34% received allogenic blood. Patients who receive a blood product transfusion are more likely to have infections and thus an

KEY POINTS

1. Orthopedic surgery is associated with high incidences of deep venous thrombosis and pulmonary embolism.
2. The need for anticoagulation results in anesthesia issues specifically related to the potential for neuroaxial hematomas.
3. Unique complications in orthopedic surgery are related to tourniquet use and fat embolism.
4. Regional anesthesia is associated with lower morbidity and mortality than is general anesthesia.
5. Prone spinal surgery cases have unique complications related to patient positioning, such as nerve injuries, ventilation problems, and blindness.

TABLE 64–1.

Extraarticular Manifestations of Rheumatoid Arthritis

Cardiovascular	Pericardial inflammation and effusions, myocarditis, vasculitis, valvular fibrosis
Pulmonary	Pleural effusions, pulmonary fibrosis, pulmonary granulomata, fibrotic nodules (Caplan syndrome)
Hematopoietic	Normocytic normochromic anemia, Felty syndrome (enlarged spleen, leucopenia, and recurrent infections), platelet dysfunction (nonsteroidal anti-inflammatory drug therapy)
Renal	Amyloidosis
Endocrine	Adrenal insufficiency (glucocorticoid therapy)

increased hospital stay. Techniques regularly used in orthopedic surgery to reduce the need for allogenic blood transfusion include hypotensive anesthesia, preoperative hemoglobin optimization using iron and erythropoietin, preoperative autologous blood donation, acute normovolemic hemodilution, and intraoperative and postoperative red blood cell salvage techniques.[4–6] Hypotensive anesthesia has been shown to significantly reduce blood loss during surgery. A study by Sharrock et al.[7] showed that intraoperative blood loss in 250 consecutive hip replacement patients was approximately 250 mL if the surgery was performed with hypotensive anesthesia. The lower arterial and central venous pressures and—importantly—lower peripheral venous blood pressure in the surgical wound may explain this difference. This study showed that hypotensive anesthesia produced by regional anesthesia is superior to general hypotensive anesthesia.[7] Of concern with any hypotensive technique is the potential for increasing ischemic cardiovascular and neurologic events, which was not seen in the study by Sharrock et al.[7] However, this technique should be used with caution in the elderly and in patients with a significant cardiovascular history.

Preoperative autologous blood donation has been widely used in orthopedic patients but has many drawbacks, including iatrogenic anemia, high cost, clerical errors resulting in transfusion reactions, and wastage of blood products. Its main benefit is the potential to reduce the transmission of infectious diseases and the avoidance of immune-mediated transfusion reactions such as acute lung injury. A benefit of intraoperative normovolemic hemodilution over autologous blood donation is that the blood is taken off and replaced with crystalloid or colloid just before incision, and the blood remains with the patient at all times. This process reduces the potential for clerical errors that lead to transfusion reactions and substantially reduces cost. Downsides to this technique are that it is labor intensive and that excessive hemodilution may result in coagulation disturbances. Recombinant human erythropoietin used either in conjunction with autologous blood donation or normovolemic hemodilution or alone has the potential to ensure higher preoperative hematocrits and reduce the need for allogenic blood transfusion.[8] Use of procoagulants, such as tranexamic acid (proteinase inhibitor), is not routine but may reduce intraoperative blood loss.[9,10] The concern with use of any procoagulant, especially in joint replacement surgery, is the possibility of an increased incidence of DVT, although studies have not shown this side effect.[11]

Cerebral Palsy and Pediatric Orthopedic Surgery

Cerebral palsy (CP) is a nonprogressive neurologic disorder that results from a variety of insults that may occur perinatally and during the first 2 years of life. The incidence of CP is estimated at 2.4 per 1000 live births.[12] Most cases of CP are of unknown etiology. Known causes of CP include antenatal infections, thyroid disease, asphyxia, meningitis, and trauma. Premature infants have a greater incidence of CP due to periventricular hemorrhages. A variety of classification systems for CP are available, with the Swedish classification the most commonly used.[13] Spastic CP constitutes 70% of cases, followed by dyskinetic CP (10%), ataxic CP (10%), and mixed CP (10%). Children with CP commonly present for orthopedic procedures, such as tenotomies and osteotomies, to improve their gait and posture. Another common orthopedic procedure is surgery for scoliosis correction. A number of anesthetic considerations must be considered when anesthetizing children with CP. These pediatric patients have a high incidence of chronic respiratory infections because of repeated aspiration and a restrictive lung pattern caused by the presence of scoliotic spine. The high incidence of aspiration is related to gastroesophageal reflux and the presence of bulbar palsies, which limit the child's ability to cough and clear oropharyngeal secretions. In fact, the second most common cause for surgery after orthopedic procedures is Nissan fundoplication for gastroesophageal reflux. These children should be seen preoperatively, with special assessment of their respiratory function. They may require antibiotics, bronchodilators, and physiotherapy to optimize their conditions before they undergo surgery. Approximately 30% of children with CP also have epilepsy, most commonly the spastic hemiplegia variety. Anticonvulsant medication should be continued up to time of surgery and restarted as soon as possible after surgery. Latex allergy resulting from the number of procedures these children undergo is common and should be sought in all children with CP. A latex-free environment for all CP cases should be practiced. Benzodiazepines and baclofen all have been used in CP children to reduce muscle tone. Baclofen acts as an inhibitor of γ-aminobutyric acid, an inhibitory neurotransmitter, and has been shown to reduce pain and the development of contractures associated with increased muscle spasms.[14] Baclofen can be given orally, but an intrathecal pump is the preferred route of administration. Because abrupt withdrawal of baclofen can result in seizures and hallucinations, it should be continued in the perioperative period.[14] Baclofen has been implicated in delayed arousal, bradycardia, and hypotension during general anesthesia.[15] Premedication with sedatives should be considered, but care is necessary, especially in the hypotonic child, because a sedative may easily compromise the child's airway. Antacids and prokinetics should be used because of

the high incidence of gastroesophageal reflux. Antisialagogues, such as glycopyrrolate, also should be considered to reduce the oropharyngeal secretions. The presence of gastroesophageal reflux may necessitate a rapid sequence induction, but the muscle relaxant of choice is controversial. Studies have shown an increased number of extrajunctional acetylcholine receptors at the neuromuscular junction in children with CP, making hyperkalemia a potential problem when succinylcholine is used for muscle relaxation.[16,17] In addition, use of succinylcholine in children is controversial because of the potential for reaction. Nondepolarizing agents show less potency in children with CP, so larger doses of nondepolarizing agents may be needed to maintain a neuromuscular block during surgery.[18] The mean alveolar concentrations of the inhalational agents are lower in children with CP compared with normal children.[19] Intraoperative hypothermia due to hypothalamic dysfunction is often a problem, and extra care is needed to maintain normothermia. Postoperative pain management can be an issue because of the child's inability to communicate adequately. Regional anesthetic techniques, such as caudals, epidurals, and peripheral nerve blocks, are very useful in these situations. Because of the young age of pediatric patients, these regional techniques often must be administered while the children are under general anesthesia. However, evidence indicates that this can be performed safely.[20] Epidural combinations of local anesthetics, opioids, and clonidine may be useful for postoperative pain management but require adequate postoperative management to detect oversedation and respiratory depression.

MAJOR ORTHOPEDIC PROCEDURES

Anesthesia for Extremity Surgery

A general anesthetic can be used as the anesthetic of choice for all orthopedic procedures. However, a regional anesthetic technique can be used to provide both anesthesia and postoperative analgesia for a variety of orthopedic procedures, including arthroscopic, fracture, and joint replacement surgery. For lower limb surgery, central neuroaxial techniques can be used in addition to peripheral nerve blocks.

Upper-Extremity Surgery

The variety of brachial plexus blocks available means that several options for block technique can be used for upper-extremity procedures.[21] The most important factor in choosing a block is the anticipated location of the incision, although other variables can affect the decision. Patient factors, such as weight, degree of pulmonary dysfunction, and coagulation status, also play a role. Choice of local anesthetic depends on balancing the time of onset with the desired duration of block. For procedures on the shoulder, interscalene block using 30–40 mL of local anesthetic is the preferred technique. This dose should ensure block of the suprascapular nerve, which branches off from the plexus quite proximally. Superficial cervical plexus block also is important, although it usually is achieved as an effect of an interscalene block. To cover anterior incision sites, supplemental intercostobrachial nerve block is needed as well. The sensory distribution of this nerve is highly variable. To cover posterior incision sites, paravertebral blocks of the T1 and T2 nerve roots or skin infiltration by the surgeon is necessary. If paravertebral blocks are used, separate injection of the intercostobrachial nerve is unnecessary. Anesthesia from the midhumerus to the hand can be achieved with a supraclavicular, infraclavicular, or axillary block. Each of these techniques has unique advantages and drawbacks that may make that technique particularly useful in a given patient. Ultrasound is playing an increasing role, particularly in more superficial upper-extremity blocks (Fig. 64–1). Supplemental injection of the peripheral nerves more distally can be performed to salvage partially successful proximal blocks. Bier block can be used to perform short-duration forearm and hand surgery, but it does not provide postoperative analgesia. A description of the various peripheral nerve block techniques is given in Chapter 48.

Shoulder Replacement Surgery

More than 80,000 shoulder arthroplasty procedures are performed annually in the United States. Shoulder replacement surgery, like knee and hip replacement surgery, can result in significant postoperative pain. Both general anesthesia and interscalene nerve blocks can be used for anesthesia, either alone or combination. Increasingly more shoulder procedures are performed on an outpatient basis, which has necessitated the use of a variety of techniques to improve postoperative pain. Use of interscalene nerve blocks alone for anesthesia and analgesia offers patients a significant advantage in terms of pain scores, time to ambulation, time to discharge, and need for unexpected admission compared with general anesthesia.[22] Other techniques used for postoperative pain include intraarticular infusions of local anesthetics and suprascapular nerve blocks. Suprascapular nerve blocks have been shown to be superior compared with patient-controlled intravenous analgesia.[23] Potential benefits of suprascapular nerve block compared with interscalene nerve block are ease of performance, lower volumes of local

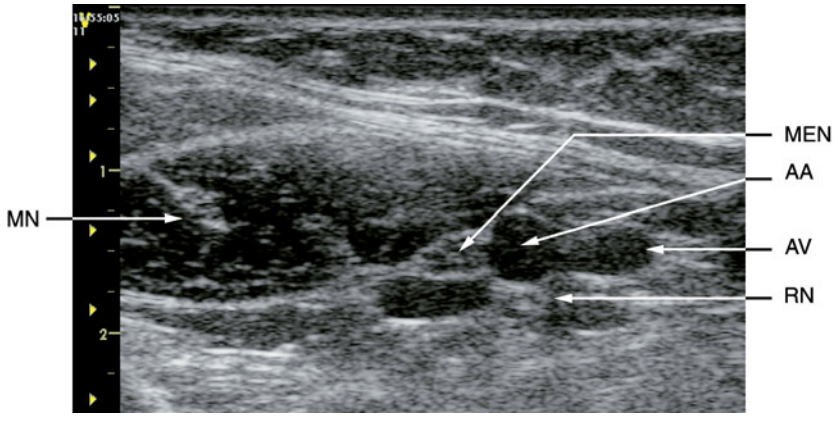

FIGURE 64–1. Axillary nerve block using ultrasound. AA, axillary artery; AV, axillary vein; MEN, median nerve; MN, musculocutaneous; RN, radial nerve.

anesthetics needed, and fewer complications such as phrenic nerve paralysis and intrathecal injection. The major drawback of suprascapular block compared with interscalene nerve block is that suprascapular nerve block must be combined with general anesthesia, thus necessitating airway manipulation and exposing the patient to the deleterious physiologic changes associated with general anesthesia. In some studies, intraarticular infusion of bupivacaine has shown no benefit compared with placebo.[24]

Many shoulder surgeries are undertaken with the patient placed in a 45° semirecumbent position (beachchair position). This position presents problems related to potential difficulties with airway access if a regional anesthetic is the sole anesthetic technique. It is essential to test whether the interscalene block is adequate for the surgical procedure before the procedure is started, because access to the airway during the case can be difficult. Another problem with this position is reduced venous return to the right side of the heart resulting in reduced preload and potential hypotension, especially with use of general anesthesia. This condition may result in the need for increased fluid resuscitation. Patients with significant cardiovascular problems should be positioned slowly, and the anesthesiologist should always be aware of the potential for venous air embolism, particularly with patients in the sitting position.

The problems of embolic phenomenon, as seen in hip or knee replacement surgery, are generally not seen in shoulder replacement surgery. In general, use of invasive lines, such as central lines and arterial lines, is not required for these cases, depending on the presence of comorbidities.

Lower-Extremity Surgery

Many different regional anesthesia techniques are available for lower-extremity orthopedic surgery.[25] Neuraxial techniques are appropriate for any lower-extremity procedure in most patients, but aggressive use of postoperative anticoagulation for prevention of DVT and pulmonary embolism may limit the use of postoperative epidural analgesia. Peripheral nerve blocks with or without continuous catheter use offer an alternative to neuraxial techniques, which may be safer in the setting of perioperative anticoagulation with efficacy at least equal to that of epidural analgesia. For procedures on the hip and proximal femur, lumbar plexus block[21] in conjunction with a proximal sciatic nerve block[26,27] provides acceptable analgesia. A femoral nerve block can be used instead of a lumbar plexus block, although it is less likely to provide block of the obturator and lateral femoral cutaneous nerves.[28] Addition of paravertebral nerve blocks at the first and second lumbar levels may be needed to provide complete anesthesia. Alternatively, the procedure can be accomplished using a spinal anesthetic alone or a combination of spinal anesthesia with a lumbar plexus and sciatic blocks or catheters for postoperative analgesia. Epidural or combined spinal epidural anesthesia provides a simpler route of anesthesia and analgesia[29] and may be acceptable for postoperative use if the epidural is managed in accordance with 2003 guidelines of the American Society of Regional Anesthesia and Pain Medicine (ASRA).[30] In general, hip procedures are associated with less postoperative pain than are knee procedures, making prolonged regional analgesia less important. Anesthesia and analgesia for procedures involving the knee and distal femur can be accomplished with either neuraxial techniques or peripheral nerve blocks. Lumbar plexus block offers more complete anesthesia of the thigh than does femoral block but is deeper and may be more difficult in obese patients or those with a history of lumbar spine surgery (Figure 64–2).[28] Sciatic nerve block is crucial for coverage of the posterior cutaneous nerve of the thigh and for the knee joint itself.[31] Procedures involving the foot and ankle, as well as those involving the tibia and fibula, are primarily covered by a sciatic nerve block. This can be achieved by blockade of the sciatic nerve at the popliteal level. Figure 64–3 shows an ultrasound scan of the popliteal nerve. Block of the saphenous nerve may be necessary, depending on the location of the incision and the need for tourniquet. The saphenous nerve can be blocked via either femoral nerve block or a distal dedicated saphenous nerve block. Ankle block without the use of epinephrine is adequate for procedures on the foot if no tourniquet use is expected.

The question as to whether general or regional anesthesia is superior with respect to outcome is controversial. A number of studies have shown no improvement in outcome with respect to mortality and morbidity.[32,33] However, other studies have shown that regional anesthesia and analgesia may reduce morbidity and mortality after surgery.[34–36] In a meta-analysis study, Rodgers et al.[35] showed a 33% reduction in mortality. They also showed a significant decrease in the incidences of myocardial ischemic events, respiratory depression, rate of DVT formation, and blood loss. Wu et al.[37] showed a death rate of 5.8 per 1000 [95% confidence interval (CI): 2.9–8.7] at 30 days postsurgery for cases using epidurals versus a death rate of 9.9 per 1000 (95% CI: 8.6–11.3) for cases using only general anesthesia. However, this benefit to patients must be considered in the context of the risk of epidural hematomas when neuroaxial anesthesia is given in the presence of anticoagulants such as LMWH. The risk, although small, has led to the publication of guidelines for use of regional anesthesia in patients receiving anticoagulants.[30] This has resulted in the reinvention and development of many peripheral nerve block techniques, including continuous peripheral nerve catheter techniques,[38] and use of ultrasound to place these regional nerve blocks.[39,40] Figure 64–2 shows ultrasound images of sciatic and femoral nerves.

Hip and Knee Joint Replacement Surgery

With the population of the United States aging and the prospect of "baby boomers" reaching retirement age in the next couple of decades, the number of patients requiring joint replacement will increase greatly. It is estimated that more than one million joint replacement procedures per year will be performed in the United States during the next decade. A variety of anesthetic techniques, consisting of general, spinal, epidural, combined spinal and epidural, and peripheral nerve blocks, are available to the anesthesiologist. These techniques have been shown to be superior to routine patient-controlled analgesia and as efficacious as epidural anesthesia but with fewer side effects.[41–43] Some evidence suggests that regional techniques may result in earlier discharge and improved functional outcome.[42,44]

Knee replacement surgery is especially associated with significant postoperative pain, and patients under-

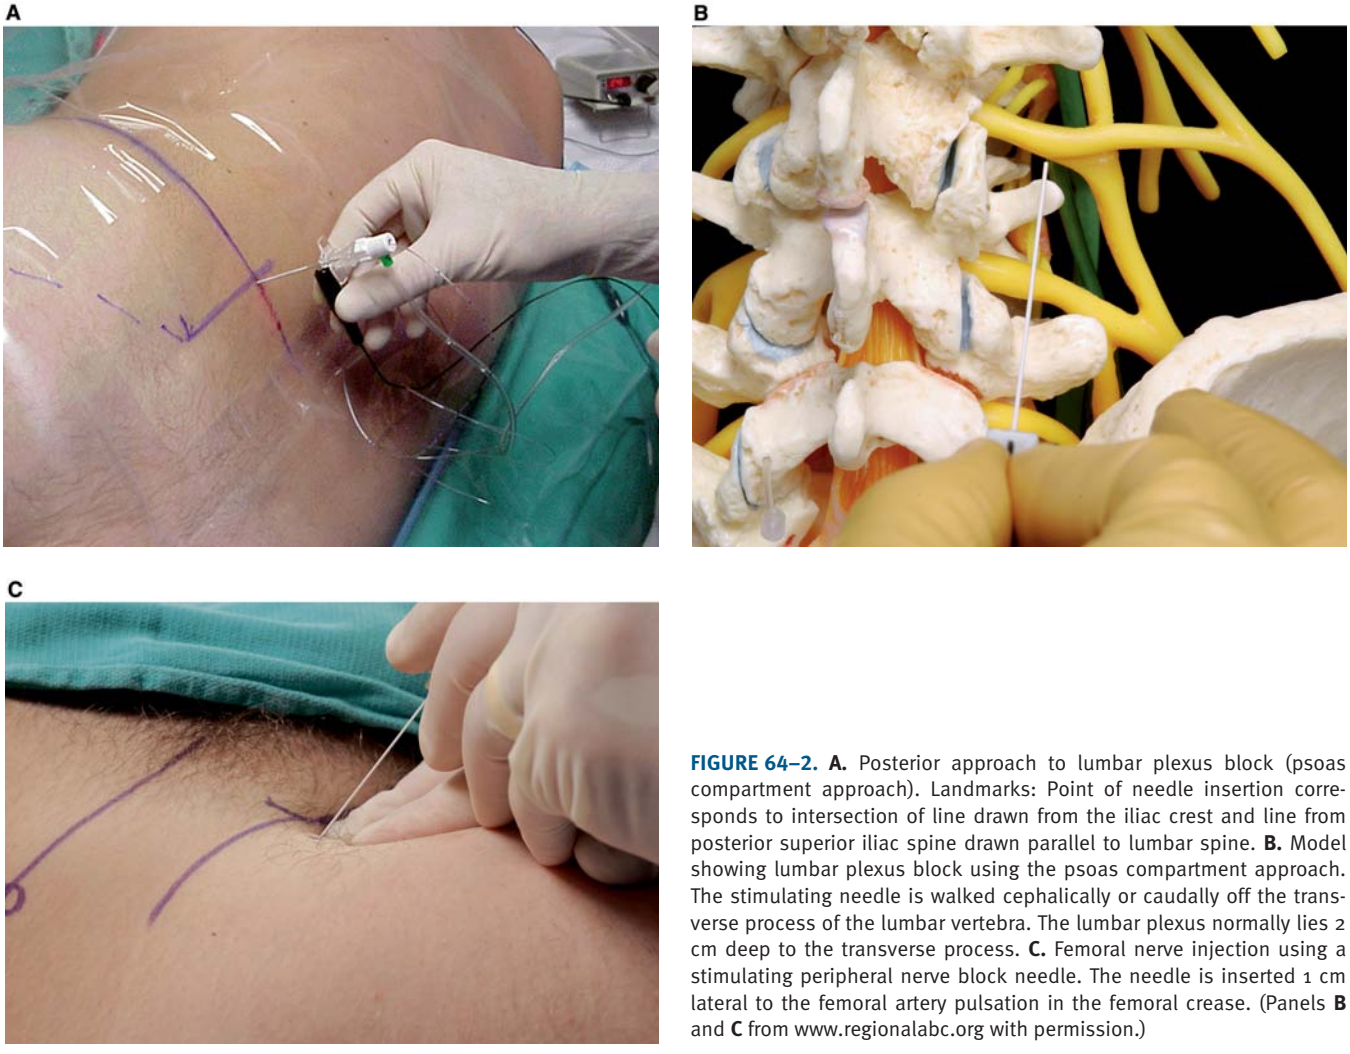

FIGURE 64–2. **A.** Posterior approach to lumbar plexus block (psoas compartment approach). Landmarks: Point of needle insertion corresponds to intersection of line drawn from the iliac crest and line from posterior superior iliac spine drawn parallel to lumbar spine. **B.** Model showing lumbar plexus block using the psoas compartment approach. The stimulating needle is walked cephalically or caudally off the transverse process of the lumbar vertebra. The lumbar plexus normally lies 2 cm deep to the transverse process. **C.** Femoral nerve injection using a stimulating peripheral nerve block needle. The needle is inserted 1 cm lateral to the femoral artery pulsation in the femoral crease. (Panels **B** and **C** from www.regionalabc.org with permission.)

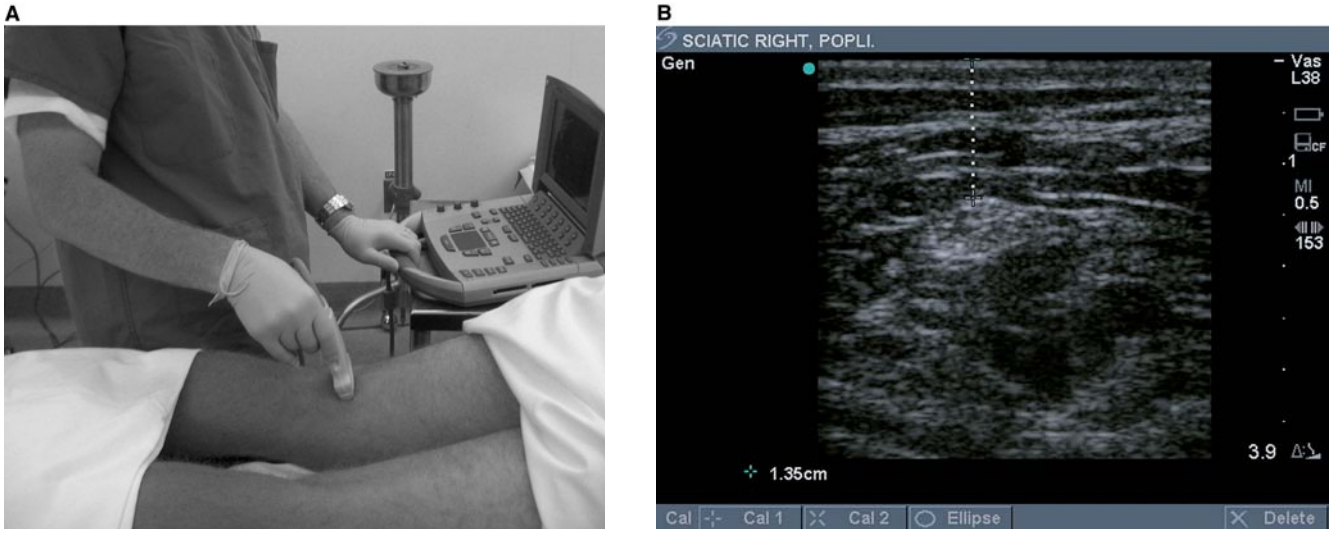

FIGURE 64–3. **A.** Popliteal nerve block performed with ultrasound in a patient in the prone position. **B.** Ultrasound scan of the sciatic nerve 7 cm above the popliteal crease. Note that the nerve lies 1.5 cm below the skin (dotted line). Distal to this scan, the nerve divides into its two major branches—common peroneal and tibial. (Panel **A** from www.regionalabc.org with permission.)

going this surgery benefit greatly from some form of postoperative regional analgesia. Use of epidurals in the joint replacement setting has been severely restricted by the widespread use of LMWH. A variety of peripheral nerve blocks have been used for analgesia in knee replacement surgery. They include psoas compartment blocks (lumbar plexus), femoral nerve blocks (Fig. 64–2), and sciatic nerve blocks. The psoas compartment approach may be superior to the femoral approach because it is associated with greater success in blocking the three main components of the lumbar plexus: femoral, obturator, and lateral femoral cutaneous nerves. Capdevila et al.[45] showed a 95% probability of blockade of all three nerves if the psoas compartment approach is used versus 33% if the femoral approach is used. A study by Macalou et al.[46] showed that addition of an obturator nerve block to a 3:1 femoral nerve block resulted in superior postoperative pain relief compared with a 3:1 femoral nerve block alone. The addition of a sciatic nerve block for postoperative pain management is controversial. Studies have shown a significant improvement in postoperative pain management if the sciatic nerve block is also used.[47,48] Other studies have shown no improvement in postoperative opioid requirements if a sciatic nerve block is used.[49]

Whether the addition of peripheral nerve blocks to general anesthesia or spinal anesthesia offers any benefit to patients undergoing hip arthroplasty surgery is not as clear as in the case of knee replacement surgery. Biboulet et al.[50] compared patient-controlled analgesia with morphine and a single injection of either a femoral or psoas compartment block. No difference in morphine consumption or pain scores was noted 4 hours after extubation. Other investigators have reported similar results using psoas compartment block for postoperative pain.[44] Thus, for hip replacement surgery, use of a spinal and/or epidural may offer benefits to patients compared with general anesthesia in terms of mortality, morbidity, and pain control, but the addition of peripheral nerve blocks for postoperative pain appears to be of limited benefit. This may be in part because the pain after hip replacement surgery is of much shorter duration than in knee replacement surgery.[44,50]

The maximum duration of a single-shot nerve block depends on the local anesthetic used and the site of injection (lidocaine 2%, mepivacaine 1.5%, 4–6 hours of analgesia vs ropivacaine 0.5%, bupivacaine 0.5%, 8–16 hours of analgesia). Administration of additives, such as clonidine (50–150 μg), may prolong the nerve block by another 2–3 hours. Use of continuous catheters in knee replacement surgery can extend the block indefinitely and can help patients avoid the severe pain experienced once the single-shot nerve block wears off. Evidence indicates that use of a stimulating nerve catheter improves the success rate of nerve catheters by avoiding subsequent failure of the catheter once the initial nerve block wears off (so-called "secondary block failure"). Salinas et al.[38] showed a 100% success block rate when using a stimulating nerve catheter compared with an 85% success rate when using a nonstimulating nerve catheter. Early mobilization and rehabilitation are important for the functional outcome of the patient. Use of a continuous catheter with local anesthetic causes motor weakness. Close collaboration among the anesthesia, orthopedic, and physiotherapy teams is needed to allow early mobilization with adequate analgesia. Lower concentrations of local anesthetic infusions produce less motor block but also may produce inferior analgesia. Starting patients on some form of oral analgesics before discontinuing the peripheral nerve catheters is essential to maintain adequate postoperative analgesia. An alternative to peripheral nerve block catheters is the use of continuous intraarticular infusion of local anesthetics for postoperative pain after joint arthroplasty. An advantage of this technique is that it is simpler to perform than peripheral nerve block, but whether this technique offers any benefit to the patient is controversial.[51]

A new approach to postoperative pain management in patients undergoing lower limb joint replacement is the use of extended-release epidural morphine sulfate (DepoDur, SkyePharma, London, UK). This technology is based on liposomal products into which doses of morphine 10–20 mg are incorporated (Figure 64–4). This form allows the slow release of morphine into the epidural space over a 48-hour period without the need for an epidural catheter, thus avoiding anticoagulation issues. A study of hip replacement patients has shown a significant reduction in postoperative fentanyl requirements and pain scores.[52] The side effects are similar to those of other neuroaxial opioids. The most serious potential side effect is respiratory depression, so patients must be monitored closely for 48 hours. Further developments of slow-release preparations of local anesthetics are awaited.

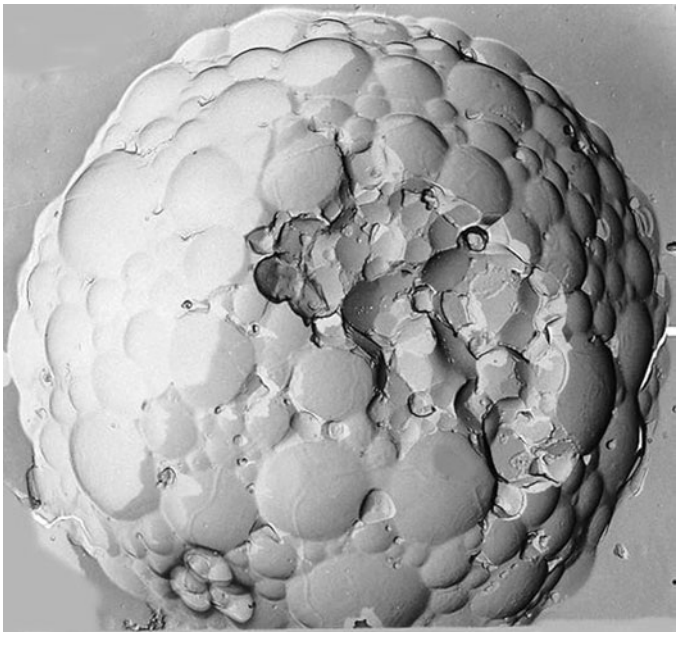

FIGURE 64–4. DepoFoam (SkyePharma, London, UK), an example of a liposomal delivery system used for epidural administration of 10–15 mg preservative-free morphine.

Invasive monitoring with arterial or central venous lines is generally not required except in patients with significant comorbidities or in patients undergoing revision of a previous joint replacement. Blood loss tends to be higher during revision joint replacement procedures. Methods used to reduce the requirement for blood transfusion are relevant to all patients undergoing joint replacement surgery (discussed earlier in this chapter in the section on blood loss).

Neck of Femur Fractures

Repairing neck of femur fractures is a common surgical procedure at trauma institutions. Management is generally surgical and involves either internal fixation with screws or plates or a hemiarthroplasty. Hip arthroplasty for management of femoral neck fractures is associated with a nearly 10-fold increase in the rate of perioperative mortality compared with elective hip arthroplasty. The 30-day mortality is 10%, and 20–30% of patients die within 1 year of surgery.[53,54] The reasons for this high mortality rate probably are the age of this population group (>70 years of age), the presence of comorbidities, and the high incidence of DVTs and pulmonary emboli. Optimization of patient medical conditions before surgery is generally but not always recommended, as delay of surgery because of the need for management of comorbidities may increase the mortality rate by 2.5 times.[55] Thus, appropriate and timely medical care is important before anesthesia and surgery.

Anesthesia involvement in the management of patients with neck of femur fractures can occur before the need for anesthesia for surgery and may involve the placement of a 3:1 femoral nerve block or fascia iliaca block in the emergency department for analgesia. Preoperative use of a femoral 3:1 block has been shown to be simple and to reduce the pain experienced, with few side effects.[56] The reduction in opioid doses required by patients can have substantial benefits. The question of whether general anesthesia or some form of regional anesthesia is best for these patients is controversial. We hold the opinion that regional anesthesia, including the use of spinal anesthesia, epidural anesthesia, combined spinal epidural anesthesia, or peripheral nerve blocks, is beneficial. Use of lumbar paravertebrals, lumbar plexus, and sciatic nerve block as the sole anesthetic technique for neck of femur fracture is a beneficial technique, especially in patients who, because of their comorbidities, cannot tolerate the drop in preload or afterload caused by spinal or epidural anesthesia.[27,57] An alternate method in this group of patients is the use a continuous spinal catheter.[58] This method allows the anesthesiologist to titrate intrathecally the local anesthetic in small amounts while still obtaining the desired effect without the usual hemodynamic changes associated with a single large dose of intrathecal local anesthetic. Invasive line monitoring, such as arterial and central lines, may be needed, depending on the presence of comorbidities. The need for blood transfusion is uncommon, but adequate intravenous access and a blood cross-match should always be available. Keeping patients warm during the procedure is especially important in this elderly population. Finally, this group is at a much higher risk for development of DVT and subsequent pulmonary embolism. All patients must be adequately anticoagulated during the postoperative period to prevent this complication (see Deep Vein Thrombosis).

Spinal Surgery

Spinal surgery is frequently a challenge for the anesthesiologist, involving a wide variety of procedures for treatment of different pathologies in the young to the very old patient population. It may involve surgery on the vertebrae of the spine in addition to the neural structures of the spinal cord.[59] Common pathologic reasons for surgery are listed in Table 64–2.

The required position of patients frequently is prone. The prone position requires extra care and attention because it may be associated with an increased incidence of complications. Major spinal surgery can be associated with extensive blood loss. Although the majority of spinal surgery is elective, urgent surgery may be required after trauma or in situations where spinal cord viability is a concern. Some patients undergoing spinal procedures require repeat surgery and may have high requirements for analgesics in the postoperative period.

Positioning

The majority of spinal surgery is performed with the patient in the prone position, although an anterior approach is sometimes used, particularly for cervical spine surgery. In addition, an anterior or lateral approach may be used for lumbar and thoracic spinal surgery. The ideal position allows easy access and maximal exposure to the site of surgery while allowing for a good operative field with minimal bleeding. Decompression of the stomach and bladder using an orogastric tube and a urinary catheter, along with avoiding compression of the abdomen, results in decreased pressure in the epidural veins and decreased blood loss. The site of surgery may be above the level of the heart, resulting in low venous pressure and decreased blood loss; however, it also is associated with a risk of venous air embolism. Hence, appropriate positioning of the patient is essential while being careful to avoid many of the potential complications. Although many different surgical tables and positions largely determined by surgeons' preference are available to improve exposure to the surgical site, many of the pertinent issues are common to all cases. First, extreme care must be taken when turning the patient, particularly the patient at risk for cord compromise. Particular attention should be paid to positioning of the head/neck and arms. Complications associated with malpositioning of the arms, including vascular and brachial plexus injury, have been reported (Table 64–3).[60] Such injuries are least likely to occur when the arms are placed by the patient's side. However, this position may invade the surgeon's space and restricts the anesthesiologist's access to arterial and venous access. Therefore, the patient is frequently positioned with the arms resting on padded arm boards and flexed at the elbow. The elbow should not be flexed more than 100° because such a position is associated with increased pressure within the cubital tunnel.[61] The abdomen, genitalia, and breasts all should be checked because

prolonged surgery in the prone position can result in injury to these areas. Adequate protection and padding of the eyes and head are essential. Blindness resulting from surgery performed with the patient in the prone position has been reported. Although its etiology probably is multifactorial but still is incompletely understood, prolonged surgery, hypotension, large blood loss (>1 L), anemia, edema, and changes in intraocular perfusion pressure all may contribute to blindness.[62] Changes in ocular perfusion pressure resulting in decreased blood flow to the optic nerve may result in ischemic optic neuropathy. Increases in intraocular pressure or decreases in mean arterial pressure result in decreased ocular perfusion pressure.[63,64] Avoidance of prolonged periods of hypotension and perioperative anemia may reduce the risk of perioperative blindness in patients in the prone position.[65] In addition, direct pressure on the eye can result in injury to the eye. Tape marks and facial skin loss may result, especially in the prone patient with significant facial edema and friable skin.

The sitting position occasionally is used for surgery on the cervical spine. The risks and complications associated with surgery performed in the sitting position are described elsewhere in the textbook.

Anesthetic Technique

A standard preoperative assessment is essential in patients undergoing spinal surgery. In addition to standard American Society of Anesthesiologists monitoring, use of invasive monitoring depends on patient comorbidities and the anticipated complexity of the surgical procedure and anticipated blood loss.[59] Surgeries involving multiple levels, repeat operations, and procedures for treatment of trauma and neoplasms typically are associated with increased blood loss.

A thorough airway examination should be performed. This assessment is critical, particularly in patients presenting for cervical spinal surgery and in patients with disease processes that affect the vertebral column, such as rheumatoid arthritis, ankylosing spondylitis, or generalized osteoarthritis. In addition, patients who have undergone previous neck surgery may have increased difficulty at intubation. The aim is to safely secure the airway while avoiding any damage to the spinal cord. This can be achieved safely in both awake and anesthetized patients using a variety of techniques, such as standard laryngoscopy, intubating aids, manual in-line stabilization, laryngeal mask airways (LMA North America, Inc., San Diego, CA), and fiberoptic intubations. The precise technique depends on the clinical situation; management of the difficult airway is discussed in Chapter 35. Remember that the majority of movement in the cervical spine during intubation occurs at the atlantooccipital joint and between the first two cervical vertebrae.[66,67] Particular caution should be exercised in the airway management of patients with C1/C2 injury and at-risk patient populations (rheumatoid arthritis, Down syndrome) that are more prone to pathology of C1/C2. Use of rigid collars may increase the difficulty of intubation but does not affect the degree of cervical spine movement. Once the airway is secured, the cervical collar alerts staff that the patient may have a neck injury. Awake intubation allows neurologic examination after intubation and positioning of the patient, although this may be difficult in the uncooperative patient. Thoracic spinal surgery may require use of a double-lumen tube or bronchial blocker if one-lung ventilation is required with an anterior or lateral approach.

Anesthesia induction can be either intravenous or inhalational, with intravenous induction appropriate for the majority of patients. Intubation and muscle relaxation can be facilitated with either nondepolarizing muscle relaxants or succinylcholine. Use of succinylcholine should be avoided in patients with muscular dystrophies and in patients with spinal cord injuries in whom an exaggerated hyperkalemic response may be seen. Use of succinylcholine probably is safe in the 48 hours immediately after spinal injury and again 9 months after the injury.[68] Intraoperative use of muscle relaxants may be avoided depending on whether motor-evoked responses are monitored and surgeon preference. This is relevant in patients at risk for nerve root injury during surgery in which nerve root stimulation results in muscle movement. Anesthesia can be maintained using either a potent volatile anesthetic in nitrous oxide/oxygen or air/oxygen mixture or intravenous anesthesia such as propofol infusions. Many opioids have been used as part of a balanced anesthetic technique, with remifentanil having the advantage of providing potent analgesia and rapid offset of action. This may assist in the early assessment of the patient's neurologic status in the early postoperative period. Remember that all anesthetic agents may affect the use of somatosensory and motor evoked potentials, which can be used to monitor spinal cord function (see Chapter 88). Changes in anesthetic concentrations and arterial blood pressure also affect the interpretation of evoked potentials. Spinal cord monitoring is discussed in Chapter 88.

Measures for minimizing intraoperative blood loss and reducing allogeneic blood transfusion in spinal surgery are particularly important. Careful positioning, avoidance of abdominal compression, surgical technique, hypotensive techniques, use of preoperative autologous donation, intraoperative normovolemic hemodilution, and use of intraoperative cell savers all may help avoid the use of allogeneic blood products. However, combinations of these techniques to reduce requirements for homologous blood products have not produced consistent results.[69,70] Use of antifibrinolytics may reduce intraoperative blood loss.[71] Hypotensive anesthesia is very effective at reducing blood loss, although it may be a contributory factor to the rare but devastating complication of posterior optic neuropathy. These techniques are particularly

important in spinal surgeries associated with large blood loss.

Use of endoscopic spinal surgical procedures is likely to increase. These procedures may provide many of the benefits of other endoscopic procedures, such as less pain, decreased blood loss, decreased hospital stay, and fewer postoperative complications.

Postoperative Care

Postoperative analgesia can be a challenge, particularly in patients who have experienced chronic back pain. Standard postoperative analgesia consists of the use of simple analgesics and opioids, especially patient-controlled opioid analgesia. Use of NSAIDs is controversial. They may reduce opioid requirements by up to 33% and reduce the incidence of opioid-related side effects such as nausea, vomiting, sedation, and respiratory depression.[72] However, they may interfere with bone healing.[73] Initial studies using cyclooxygenase-2 (COX-2) inhibitors suggest minimal effect on bone healing, particularly when used for short durations.

In some cases, surgeons insert a catheter under direct vision into the epidural space. Either epidural opioids or opioids in addition to local anesthetics may be infused. Low concentrations of local anesthetics typically are used to avoid a motor block, which may delay accurate diagnosis of motor dysfunction as a complication of surgery.[74]

The majority of patients undergoing spinal surgery can be managed in the post surgical unit postoperatively. Those who have undergone extensive surgery, suffered significant blood loss, received large fluid resuscitation, or experienced fluid shifts should be monitored postoperatively in an intensive care or step-down unit. Patients with significant facial and airway edema may require ventilation postoperatively. In addition, patients who have undergone certain cervical and thoracic spinal procedures may require postoperative ventilation, whereas those requiring extensive neurologic monitoring should be cared for in a monitored bed postoperatively.

Neurogenic shock is characterized by loss of sympathetic tone resulting in hemodynamic instability, as evident from significant hypotension and bradycardia. This may be accentuated by hypovolemia. Shock tends to occur in injuries above the T6 level, due to disruption of sympathetic outflow and unopposed vagal tone. Arterial and central venous pressure monitoring is helpful in the management of these patients. Fluid administration in addition to vasopressors may be required to treat the hypotension along with appropriate management of the bradycardia. Autonomic dysreflexia is a syndrome of sympathetic imbalance that may occur after the phase of spinal shock. It occurs more commonly in males and may result in hypertension associated with myocardial ischemia, retinal/cerebral hemorrhage, and seizures.

Ambulatory Orthopedic Surgery

The 1990's saw a dramatic increase in the number of surgical cases performed in the ambulatory setting. Nearly 60% of all cases now occur as outpatient procedures, with orthopedic surgery accounting for a large number of cases. This trend has huge socioeconomic implications, such as reduced costs, more rapid return to daily activity, and lower risk of nosocomial infections. Shoulder and knee procedures, including shoulder arthroplasty and anterior cruciate ligament repair, occur routinely on an outpatient basis. All ambulatory orthopedic surgical procedures can be performed under general anesthesia. However, these procedures may be most suited for a regional anesthetic technique. Despite the use of aggressive oral analgesics, postdischarge verbal analog pain scores range from 4–8 on a 10-point scale.[75] With more complicated procedures occurring on an outpatient basis, adoption of a multimodal approach to postoperative pain management is essential. This will allow better pain control with the need for less opioid medication, thus reducing the potential for side effects such as nausea and vomiting, which often can derail a timely discharge from the ambulatory center. The cornerstone of these techniques is frequently a peripheral nerve block. New disposable infusion devices allow patients to be discharged with peripheral nerve catheter infusions, further prolonging the effect of a single shot of peripheral nerve block.[76] When general anesthesia is required, the aim should be to provide adequate anesthesia and analgesia while minimizing perioperative-related side effects such as nausea and vomiting.

POSTOPERATIVE ANALGESIA IN ORTHOPEDICS

Limited evidence indicates that improvements in postoperative pain control result in better functional outcome and reduced morbidity and mortality.[35,42] The best approach to postoperative pain management is a multimodal approach of different agents and routes of administration used in a synergistic manner.[77,78] Using a multimodal approach, we have the potential to reduce or eliminate the amount of opioids required by patients and thus reduce side effects such as nausea and vomiting, respiratory depression, and oversedation.[78,79] The cornerstone of any multimodal approach is a regional technique, including epidural and peripheral nerve blocks (see Chapter 48). Other possibilities include subcutaneous or intraarticular infusions of local anesthetics. These techniques have been shown to be superior to opioids but inferior to epidurals and peripheral nerve blocks.[80,81] Their effectiveness appears to be short lived, lasting 2–4 hours.[82] Use of intraarticular opioids, such as morphine, after joint surgery is controversial, with some evidence of benefit.[83–88] Use of intraarticular morphine is based on the presence of opioid receptors on peripheral nerve endings within the capsule of joints. Administration of intraarticular opioids produces analgesia only in the presence of inflammation, and it has been postulated that the inflammatory process is necessary for activation of the opioid receptors.[89] Morphine doses between 1 and 5 mg have been shown to have an analgesic effect until 24 hours after intraarticular administration.[90] The side effects normally seen with systemic opioids are not seen with these doses of intraarticular opioids. Cryotherapy devices have been used in both shoulder and knee surgery to further augment postoperative analgesia.[85,91] Nonsteroidal agents play an important role in reducing postoperative opioid requirements.[92] COX-2 inhibitors have largely displaced the nonselective COX inhibitors because of their improved side effect profile with regard to the potential for gastric bleeds and coagulation disturbance. The recent controversy regarding rofecoxib (Vioxx, Merck & Co., Whitehouse Station, NJ), which was found to result in an increased incidence of death due to myocardial infarcts when used at

high doses and for long periods, has significantly reduced the use of other COX-2 inhibitors in the perioperative period.[93] Data are insufficient to recommend the use of other COX-2 inhibitors, such as celecoxib (Celebrex, Pfizer, New York, NY), which should be given with caution in the perioperative period.[94,95] Another important issue with COX-2 inhibitors is their potential to reduce bone healing in animal models. In vitro studies have shown that the presence of COX-2, but not COX-1, is essential for adequate bone healing.[96,97] However, no clinical evidence in humans shows the effect of reduced bone formation, particularly when COX-2 inhibitors are used for short-term treatment.[97]

FACTORS RELATED TO ORTHOPEDIC SURGERY

Tourniquets

Tourniquets (derived from the French *tourner* "to turn") are routinely used in orthopedic surgery to provide a bloodless field. This practice is purported to improve visualization of critical structures and decrease operative blood loss.[98] However, tourniquets have significant risks, and these risks and the strategies to minimize them should be part of the knowledge base of all practicing anesthesiologists.[99]

By inflating a cuff around an extremity, arterial inflow to the extremity distal to the cuff is eliminated. Careful exsanguination of the limb distal to the cuff immediately before cuff inflation, either via application of an elastic Esmarch bandage or elevation of the extremity for 5 minutes, empties the vascular system. The distal limb is thus rendered ischemic, which may have significant physiologic and biochemical implications.

Limb exsanguination causes an increase in central blood volume that is reflected as a transient rise in central venous pressure.[100] This increase in preload can be significant if multiple tourniquets are used, as in simultaneous bilateral knee arthroplasties. Tourniquet inflation also causes an increase in afterload. Patients with diminished cardiac function may not be able to tolerate this combined insult of increased preload and afterload. After tourniquet deflation, preload decreases acutely as blood reenters the affected extremity, which undergoes a period of postischemic reactive hyperemia. This is accompanied by an acute decrease in afterload that often produces hypotension.[101] Reperfusion of an extremity typically is associated with a drop in core temperature of up to 1.0°C.

During limb ischemia, oxygen and high-energy phosphate stores decrease progressively, and carbon dioxide and lactic acid levels rise as ischemic tissues convert to anaerobic metabolism.[102] The pH of the ischemic limb decreases as the duration of ischemia increases.[103] After tourniquet deflation, aerobic metabolism resumes, with marked increases in oxygen consumption and carbon dioxide production.[104] Systemic partial pressure of carbon dioxide increases in this interval, and pH transiently decreases as a result of combined metabolic and respiratory acidosis.[105] Spontaneously breathing patients increase minute ventilation markedly to compensate. The minute ventilation of mechanically ventilated patients must be increased to minimize the duration and magnitude of hypercapnia. The increase in carbon dioxide tension can produce a marked increase in cerebral blood flow, with potentially deleterious results in patients with increased intracranial pressure.[106] In this setting, it is especially critical to increase minute ventilation in patients who are unable to compensate effectively.

Ischemia of the affected limb causes significant changes on the cellular level. Tissue becomes progressively acidotic while the cuff is inflated.[102] Ultrastructural changes within the endothelium of the ischemic capillaries lead to diffuse capillary leak after reperfusion.[102] In conjunction with reactive hyperemia, significant edema can develop after tourniquet deflation. This can even lead to a compartment syndrome in the affected extremity. The coagulation system undergoes significant changes in the setting of tourniquet use. Platelet aggregation is increased by both tissue compression and pain due to the surgical insult and the tourniquet.[107] Capillary obstruction by red blood cells and platelets that accumulate during the period of stasis and the concomitant release of inflammatory mediators can lead to microvascular thrombosis, causing no-reflow phenomena and further exacerbating tissue injury.[102] Tissue acidosis also leads to release of tissue plasminogen activator, which causes a brief period of fibrinolysis after tourniquet deflation.[107] This is postulated to play a role in posttourniquet bleeding. Muscle is most susceptible to injury secondary to ischemia, with the duration of ischemia correlating with the severity of injury. Injury is most severe under the cuff as a result of the combined effect of tissue compression and ischemia.[108] Fortunately, these injuries are generally reversible when tourniquet time is not excessive. Rhabdomyolysis has been reported after tourniquet use. A practical guideline is to limit tourniquet time to 2 hours if possible. Experiments have shown that a 10-minute period of reperfusion every hour allows for disposal of accumulated waste products and regeneration of adenosine triphosphate stores in the involved limb, facilitating tissue recovery after completion of surgery and minimizing the extent of muscle injury.[102]

Cuff pressure is the most significant risk factor for nerve injury after tourniquet use.[109] Use of a wider cuff allows arterial occlusion at lower cuff pressures. Conical rather than rectangular cuffs can produce the desired effect at lower inflation pressures.[110,111] Numerous methods for determining the inflation pressure to be used in a particular situation are recommended. Inflating the cuff 50–75 mm Hg above the systolic pressure for upper-extremity procedures and 100–150 mm Hg above systolic pressure for lower-extremity operations appears reasonable. Others have recommended empirically determining the appropriate inflation pressure by first ascertaining via Doppler ultrasonography the pressure at which arterial inflow is occluded and then setting the cuff pressure 50 mm Hg higher. Using the lowest pressure possible decreases the risk of nerve injury. The incidence of significant nerve injury in the upper extremity is estimated at 1 in 11,000, with radial nerve palsy representing the most common injury; lower-extremity nerve injuries are believed to occur at a much lower rate. Most nerve injuries are not permanent and resolve with time.[112] Detailed neurologic examination should be obtained in a timely fashion if such an injury is suspected to document any preexisting dysfunction.

Careful padding of the limb under the cuff with cast padding, with care taken to avoid any wrinkles, decreases

the risk of skin injury from compression or pinching. The tourniquet should not be manipulated after it is applied to avoid bunching up the padding underneath the tourniquet. Creating an impervious barrier with adhesive plastic drapes to prevent cleaning solutions from seeping under the tourniquet is helpful in minimizing the risk of skin injury. The vascular system is not immune to injury from tourniquet application. Patients with atherosclerosis appear to be at highest risk for this type of injury. Mechanical forces applied to these vessels are believed capable of fracturing calcified plaque within the vessel wall.[113] This can lead to vascular compromise and potentially to limb loss. Tourniquet use is relatively contraindicated in patients with risk factors for peripheral vascular disease, absent distal pulses, and previous vascular surgery on the operative extremity.[114]

Use of a tourniquet can affect the pharmacokinetics of other drugs given during an anesthetic procedure. Drugs administered before tourniquet inflation can become sequestered in the ischemic limb. When the tourniquet is deflated at the end of surgery, a bolus of that particular drug is delivered to the central circulation.[115] This effect can be significant in elderly patients who have received opioids or benzodiazepines before tourniquet inflation. The volume of distribution is decreased for drugs administered after the tourniquet is inflated. This can produce a greater-than-expected effect from a given dose. Antibiotic administration must be coordinated with tourniquet inflation to ensure that adequate tissue penetration occurs at the surgical site. For most antibiotics, a minimum interval of 5 minutes is recommended between completion of drug administration and tourniquet inflation.[116] Muscle relaxants sequestered in an ischemic limb have not proved to be as significant a problem upon tourniquet release as anticipated.

Tourniquet pain is the final major issue that complicates use of a tourniquet. In an unsedated patient, it presents as dull, aching pain that becomes intolerable within approximately 30 minutes. This time period can be extended somewhat by intravenous administration of sedatives and analgesics.[117] During a general anesthetic, tourniquet pain manifests as increases in heart rate and both systolic and diastolic blood pressures 45–60 minutes after tourniquet inflation.[118] This typically is treated with only limited success by increasing the depth of anesthesia or administering additional analgesics. Ultimately, tourniquet deflation is the only factor that eliminates tourniquet pain, with resolution within 30 minutes. This phenomenon also has been reported during spinal and epidural anesthetics, with an apparently adequate level of anesthesia to pinprick.[119] An adequate level of anesthesia to touch is more predictive of prevention of tourniquet pain. The postulated mechanism for tourniquet pain is a differential conduction block of large myelinated A-δ fibers and small unmyelinated C fibers.

Fat Embolism Syndrome

Fat embolism syndrome (FES) was first described by Zencker in an article published in 1862. Nearly all patients with long bone fractures or patients who have undergone hip or knee replacement surgery experience some degree of fat embolization.[120,121] However, the incidence of clinically significant FES is only 0.5–3%.[122,123] The incidence may be higher (30%) in patients with multiple long bone fractures. FES is much more likely to occur with long bone fractures of the lower limb than with fractures of the upper limb. Likewise, the incidence of FES in children is much lower than in adults. Changes in surgeons' preference for early operative reduction and fixation of fractures have led to a marked decreased in FES incidence.

Fracture of the long bone causes an increase in intramedullary pressure. This coupled with disruption of the venous sinusoids within the long bones results in fat and bone debris entering the venous circulation. Manipulation and surgical preparation of the long bones, such as reaming, also can cause an increase in intramedullary pressure and result in fat embolization. Careful attention by the surgeon in clearing the femoral canal with adequate lavage can reduce the incidence of fat embolization (see Methylmethacrylate). Commonly, fat globules lodge in the pulmonary vasculature, resulting in obstruction of pulmonary circulation. Fat globules are hydrolyzed into free fatty acids that are directly toxic to the pulmonary endothelium and pneumocytes, resulting in endothelial damage, platelet adhesion with clot formation, capillary leakage, and perivascular bleeding. Some evidence indicates that elevated C-reactive protein levels resulting from trauma may cause chylomicrons to coalesce and form fat globules. These fat particles may pass into the systemic circulation via intracardiac (foramen ovale) and pulmonary shunts, resulting in cerebral and cutaneous manifestations.

FES may present intraoperatively as cardiorespiratory collapse after femoral reaming, insertion of intramedullary cemented prosthesis, or tourniquet release. FES also may present postoperatively as a variety of clinical signs and symptoms. Gurd and Wilson[124] described major and minor features of FES (Table 64–4). To make the diagnosis of FES, at least one major and four minor features must be present. The three major symptoms of FES are respiratory distress, cerebral manifestations, and petechial rash. The minor symptoms are fever, renal damage, retinal changes, hemolysis, lipuria, and jaundice. The Gurd criteria were criticized for not including assessment of the patient's oxygenation with the use of an arterial blood gas, which may be a useful early indicator of FES. The criteria of both Schonfeld et al.[125] and Lindeque et al.[126] include the measurement of arterial blood gases to determine the presence of hypoxemia. Respiratory distress consists of tachypnea, hypoxia, and hyperventilation and is seen in

TABLE 64–4.

Major and Minor Features of Fat Embolism Syndrome[a]

Major Features
Respiratory distress
Cerebral changes
Petechial rash
Arterial blood gas[b]
Minor Features
Fever
Renal damage
Retinal changes
Hemolysis
Lipuria
Jaundice

[a]As described by Gurd and Wilson.[124]
[b]Not an original major feature but added by Schonfeld et al.[125] and Lindeque et al.[126] in their classifications.

75% of patients with the syndrome.[127] The majority of patients present with PO_2 < 50 mm Hg. Chest radiographs classically show bilateral diffuse infiltrates, especially in the upper and middle lobes of the lung. Pulmonary function usually resolves in 7 days. Approximately 10% of patients require mechanical ventilation for respiratory failure. Cerebral involvement consists of a wide range of clinical symptoms, such as confusion, convulsions, drowsiness, and coma, and normally is present in 86% of presenting cases.[121] Petechial rash classically involves the conjunctiva, mucous membranes, and skin on the anterior aspect of the chest and neck and likewise is seen in 50–60% of cases.[124] Classically, these symptoms and signs do not present within the first 6–12 hours after the insult. Onset after 72 hours from the insult is unusual. The best treatment of this condition is prevention by early surgical reduction and immobilization of the fracture site. Management consists of supportive care that may include ventilation. Adequate fluid resuscitation is essential and may lessen the severity of the presentation. Steroids to reduce the inflammatory response caused by free fatty acids have long played an important role in the management of this condition, but studies that steroids are not as effective as previously believed.[128,129] There is no evidence supporting the use of heparin or intravenous alcohol in the management of FES. The overall mortality rate is high (7–20%), and death normally is related to pulmonary involvement.[121]

Methylmethacrylate

Use of cement, with its main component of methylmethacrylate (MMA), has been linked to a clinical scenario consisting of hypotension, bronchoconstriction, hypoxia, cardiac arrest, and sudden death. The terms *bone implantation syndrome* and *bone cement implantation syndrome* have been coined to describe this phenomenon. A study has shown rates of death in hip arthroplasty procedures between 0.02% and 0.5%.[130] These rates initially were believed to be due to a hypersensitivity reaction to the MMA resulting in acute vasodilatation and cardiac collapse. MMA given during in vitro studies has been shown to result in vasodilatation; however, plasma levels during use of MMA in clinical practice have been found to be 10- to 20-fold below the levels required to cause clinically significant vasodilatation and hypotension.[131] It has become clear that the phenomenon is due to embolization of fat particles and debris from the intramedullary canal of long bones during their manipulation, reaming, and cementing. During these procedures, intramedullary pressures may exceed pressures within the medullary venous plexuses, resulting in fat and debris entering the venous system. Use of transesophageal echocardiography can clearly demonstrate the increased load of debris entering the right atrium during cementing of the long bones.[132] Intramedullary pressure peaks are 680 mm Hg in humans with cement use compared with peaks < 100 mm Hg with noncemented arthroplasties.[133] In an attempt to minimize increased intramedullary pressure, orthopedic surgeons have used various techniques, such as new cementing devices, drilling distal venting holes within the long bones, and aggressive lavage of the canal before insertion of the cement and prosthesis to reduce the amount of intramedullary debris. The technique of venting results in significant extravasation of cement, and none of the techniques has been found to reliably prevent this phenomenon. Some surgeons use uncemented techniques for joint replacement procedures. Cemented prosthesis and the need for revision procedures have made the use of uncemented devices more appealing to surgeons. Clinical signs of bone implantation syndrome/bone cement implantation syndrome are similar to those found in pulmonary embolism or fat embolism. They include fever, tachycardia, hypotension, hypoxemia, and, in spontaneously breathing patients, dyspnea and tachypnea; end-tidal carbon dioxide may decrease with a large embolus. Other signs of fat emboli also may be seen. The electrocardiogram may show right axis deviation or right bundle-branch block. These signs reflect increased pulmonary artery pressure and intrapulmonary shunt, potentially leading to right ventricular failure and cardiac arrest.

Management of this phenomenon is similar to that caused by fat emboli. It requires both support of the cardiovascular system with aggressive fluid management and inotropic and vasopressor support. Oxygen therapy and ventilation often are required, depending on the severity of the response.

Deep Vein Thrombosis

The incidence of DVT in unprotected patients can be extremely high, varying between 80% and 90%, with a 2% incidence of fatal pulmonary emboli in hip and knee replacement surgery.[134] Hip fractures have an even higher occurrence of fatal pulmonary embolism, with an incidence of 4–7%. Hip replacement surgery typically results in thrombosis of vessels above the knee, whereas knee replacement surgery commonly involves vessels below the knee. Fatal pulmonary emboli are normally associated with thrombosis above the knee. The Virchow triad has classically been used to describe the etiology of DVT. The three main causes of DVT are prolonged stasis, damage to the intima of blood vessels, and increased viscosity of blood. All these factors may play a role in causing DVT in joint replacement surgery, but the problem is increased greatly for two reasons: extended use of tourniquets in total knee replacements, and distortion of lower limb blood vessels during manipulation and preparation of both the femur and tibia. This increase has necessitated the use of a variety of pharmacologic drugs and pneumatic devices to reduce the high incidence of DVT. Different regimens are used at various of institutions, with no best way to manage this problem. Whether warfarin (Coumadin) is superior to LMWH or vice versa is controversial.[135–137] In a study by Freedman et al.,[135] the risk of proximal DVT was lowest with warfarin (6.3%) compared with LMWH (7.7%), but no differences in the incidence of pulmonary embolism and mortality were noted. Miric et al.[136] found that LMWH was better than warfarin in preventing DVT in total hip replacements (4% vs 12%, respectively). What is clear is that use of unfractionated heparin does not offer sufficient DVT prophylaxis in patients undergoing joint replacement procedures and that LMWH compared with warfarin is classically associated with an increased incidence of minor and major wound blood loss.[135,138] According to the latest recommendations from The Seventh American College of Chest Physicians Consensus Conference, only warfarin, fondaparinux, and LMWH are adequate forms of DVT prophylaxis when used alone for hip or

knee replacement surgery.[139] Pharmacologic agents should always be combined with mechanical prophylaxis, which should begin intraoperatively if possible. Mechanical prophylaxis should be used alone only when there is a significant risk of bleeding. Use of the newer anticoagulants, particularly LMWH, has resulted in the need for anesthesiologists to modify their anesthetic plan. Vandermeulen[140] demonstrated a significant increase in the incidence of epidural hematomas if epidural anesthesia is used in conjunction with LMWH. This finding resulted in the addition of an FDA black box warning to LMWH prescribing information and a review of the current practice of regional anesthesia, particularly neuroaxial anesthesia and analgesia in the presence of certain anticoagulants.[141] The ASRA has developed guidelines for the use of regional techniques in the presence of a variety of anticoagulants.[30] The guidelines include not performing a neuroaxial technique within 12 hours after a dose of LMWH and waiting 2 hours after removal of an epidural catheter before initiating LMWH. This guideline has severely limited the use of epidural anesthesia for postoperative pain and resulted in the development of a number of new techniques (discussed earlier in this chapter in the section on anesthesia for extremity surgery and in the section on blood loss).

Compartment Syndrome

Volkmann first described compartment syndrome in 1881. The disfigurement of the upper limb that may result from the condition is still called a Volkmann contracture. Compartment syndrome is one of the most litigated topics in orthopedic surgery. A variety of injuries and medical conditions may initiate an acute compartment syndrome, including fractures, contusions, bleeding disorders, reperfusion injuries, burns, and trauma. Fractures of the tibial shaft are the most common fractures associated with compartment syndrome, accounting for 40% of cases, followed by forearm fractures, which account for 18%.[142] However, many cases of compartment syndrome can occur in the absence of a fracture and are solely related to soft-tissue damage (23%). Compartment syndrome occurs when the pressure within an osseofascial compartment increases to a level that decreases the perfusion gradient across tissue capillary beds, leading to cellular anoxia, muscle ischemia, and death, with eventual replacement of the muscle with fibrous tissue, leading to contractures and a nonfunctional limb. The normal compartmental pressure is <10–12 mm Hg, with compartmental perfusion pressures normally >70–80 mm Hg. Compartmental perfusion pressures can be calculated by subtracting compartmental pressures from mean arterial pressures. Thus, increasing compartmental pressures and decreasing mean arterial pressures can lead to a situation in which the compartment perfusion pressure is inadequate. It is not possible to determine the compartmental pressure value critical to perfusion because compartmental pressure at which perfusion problems occur can vary greatly among individuals. Delta p (Δp), which is diastolic pressure minus intracompartmental pressure, is much more reliable in determining the need for fasciotomy.[143] Δp <30 mm Hg in the presence of clinical signs of compartment syndrome requires a fasciotomy. Diagnosis is primarily clinical, supplemented by compartment pressure monitoring (Fig. 64–5). Signs include pain, especially with passive stretching of the involved muscle group, pallor of the limb, lack of a distal pulse, cold limb, paresthesia, paralysis, and a swollen and tense compartment.[144] The presence of a distal arterial pulse does not exclude the presence of compartment syndrome. These signs can be reliably diagnosed only in fully conscious patients. Patient who are unconscious or sedated should be monitored with continuous compartment pressures, and sometimes a prophylactic fasciotomy is needed. Complete fasciotomy of all compartments involved is required to reliably normalize compartment pressures and restore perfusion to affected tissues. Recognizing compartment syndromes requires having and maintaining a high index of suspicion, performing serial examinations in patients at risk, and carefully documenting changes over time. The earlier the diagnosis the better the outcome, with neural structures being much more at risk than muscle. Anesthesiologists must be aware of this condition to allow for early diagnosis. Compartment syndrome should be considered in any patient in whom the intensity of pain is out of proportion to the injury and in any patient with a long bone fracture who is not responding to normal amounts of analgesia. In choosing the anesthetic technique for cases that normally are associated with compartment syndrome, the anesthesiologist must avoid any postoperative technique, such as epidurals or peripheral nerve blocks, that may delay diagnosis of the syndrome. If these techniques are used and there is a potential for compartment syndrome, consideration should be given to continuously monitoring compartment pressures. The effect of anesthetic techniques, such as spinals and epidurals, that cause sympathectomy (and thus vasodilatation) is unclear. The increased blood flow to muscle compartments may cause a further increase in compartment pressures. What is clear is that in cases of suspected or potential compartment syndrome, the anesthesiologist should maintain a high mean arterial blood pressure during the case. Use of mannitol has been shown to reduce the occur-

FIGURE 64–5. Compartment pressure monitoring.

rence of compartment syndromes in revascularization cases and may be of help in other patients with compartment syndrome.

CHAPTER 65

Anesthesia for Ophthalmic Surgery

Salvatore J. Basta, MD

Ophthalmic surgery presents challenges to the anesthesiologist not seen in other surgical areas. Some of these challenges are listed in Box 65–1. Blind or potentially blind patients are especially apprehensive prior to surgery, and discussion of anesthetic procedures and expectations is extremely valuable. Ophthalmic surgery patients are especially likely to benefit from preoperative screening because they tend to be at the extremes of age, have a high incidence of systemic disease, and frequently are managed in an outpatient setting. In this chapter, we review the anatomy and physiology of the eye, preoperative medical preparation, regional and general anesthetic techniques, and anesthetic management of specific pediatric and adult surgical procedures.

OCULAR ANATOMY

A working knowledge of the ocular anatomy is necessary for anesthesiologists to understand ophthalmic procedures, perform and evaluate ophthalmic regional nerve blocks, evaluate and manage complications from these blocks, and appreciate the importance of intraocular pressure (IOP).

The eyes lie within two bony cavities of the skull (termed *orbits*). The orbit is pear shaped. The orbital entrance is approximately 35 mm in height and 45 mm in width, giving a volume of approximately 30 mL. The depth of the orbit varies with race and gender but averages slightly more than 40 mm. The optic nerve, ophthalmic artery, and sympathetic fibers from the carotid plexus pass through the optic foramen. Just lateral to the optic foramen is the superior orbital fissure. It is 22 mm long and conducts the lacrimal, frontal, and nasociliary branches of cranial nerve (CN) III (oculomotor), CN IV (trochlear), CN V (trigeminal and CN VI (abducens); superior ophthalmic vein; and sympathetic nerve plexus. The maxillary and pterygoid branches of CN V, a nerve from the pterygopalatine ganglion and the inferior ophthalmic vein, pass through the inferior orbital fissure, which is located just below the superior fissure and extends laterally.

The adult globe averages 24 mm in diameter.[1,2] The normal anteroposterior diameter varies between 21 and 26 mm. At birth, the anteroposterior diameter is

KEY POINTS

1. Cataract surgery under regional anesthesia is very-low-risk surgery. Patients often are high risk but can safely undergo surgery provided their medical condition is stable. They must be able to lie flat for approximately 1 hour, must be able to communicate with surgeon and anesthesiologist, must not have a major head and neck tremor, must not have a chronic, uncontrolled cough, and must understand that they will be awake.
2. Although ophthalmic surgery in general is low risk, general anesthesia may confer more risk than regional anesthesia. High-risk patients must be appropriately prepared to undergo the risks of general anesthesia and the needs of ophthalmic surgery.
3. The oculocardiac reflex (trigeminal–vagal) from pressure on the globe or traction on the extraocular muscles is more common during general than regional anesthesia. It can manifest as arrhythmias such as bradycardia, atrioventricular block, or asystole. High expectation of its potential for occurrence and prompt cessation of the inciting maneuver sometimes are sufficient therapy. Although it is a fatigable reflex, the oculocardiac reflex often must be blunted with atropine or glycopyrrolate. The reflex often can be abolished with a retrobulbar or peribulbar block.
4. Safe performance of regional block technique requires detailed knowledge of orbital and ocular anatomy and adequate education in, and supervision of, block technique by a qualified practitioner. Patients must be properly and adequately sedated and cooperative. A needle longer than 32 mm must never be used in the lateral orbit or 25 mm in the medial orbit.
5. Understand the complications (both local and systemic) that may be encountered during regional techniques and the treatment of those complications.
6. Know the axial length of the eye. Eyes >26 mm have greater potential for posterior or inferior staphyloma and scleral thinning and may not be appropriate for sub-Tenon block or injections within the muscular cone.
7. Nitrous oxide should be avoided, if possible, in vitreoretinal surgery when gas is being injected. At minimum, nitrous oxide should be discontinued at least 20 minutes prior to gas injection. Patients are at risk for bubble expansion for as long as 30 days.
8. Most vitreoretinal ophthalmic surgery requires akinesis. If necessary during regional techniques, a modified van Lindt block of the superior branch of facial nerve should be done.
9. General anesthesia must control hemodynamics intraoperatively to help prevent choroidal bleeding, prevent intraoperative coughing and patient movement, and provide a smooth wake-up. Control of pain and postoperative nausea and vomiting is essential. Regional anesthesia generally is not associated with pain and postoperative nausea and vomiting.
10. Pediatric ophthalmology requires knowledge of the comorbidities of prematurity as well as underlying congenital syndromes.
11. True ophthalmic emergencies are rare. Central retinal artery occlusion and chemical burns require immediate treatment. Medically uncontrolled glaucoma and threatened macula detachment should be accomplished within a few hours. Most other conditions, including some open globes, can be delayed to allow for improvement of the patient's condition.

BOX 65–1.

Special Concerns in Ophthalmic Anesthesiology

- Elderly patients with multiple systemic diseases
- Pediatric patients, often premature with congenital syndromes
- Patients anxious from their loss of vision
- Limited access to the airway
- Oculocardiac reflex
- Intraocular pressure and anesthetic interactions
- Systemic effects of ophthalmic medications

Reprinted from Bruce RA Jr, McGoldrick KE, Oppenheimer P, eds. Anesthesia for Ophthalmology. Birmingham, Alabama: Aesculapius Publishing, 1982, with permission from Elsevier.

approximately 16 mm but reaches approximately 23 mm by age 3 years. The globe reaches maximum size at puberty.

The transparent cornea occupies the center of the anterior pole of the globe and is approximately 11 to 12 mm in diameter. The cornea, lens, and aqueous humor form the main refractive elements of the eye. The curvature of the cornea contributes approximately one third of the refractive power. The limbus borders the cornea and is gray and translucent in appearance. The sclera is opaque and white and covers the remaining 80% of the globe. Tendons of the rectus muscles insert into the superficial scleral collagen.

The wall of the globe is composed of three layers: (1) sclera, (2) uveal tract, and (3) retina (Fig. 65–1). The middle layer is the uveal tract. It is composed of three specialized structures: (1) iris, (2) ciliary body located in the anterior uvea, and (3) choroid located in the posterior uvea. The iris contains dilator and sphincter muscle fibers that control the central aperture, the pupil. Parasympathetic stimulation originating from the CN III nucleus contracts iris sphincter fibers, causing pupillary constriction or miosis. Conversely, sympathetic fibers traveling with the ophthalmic division of CN V stimulate iris dilator fibers, dilating the pupil. Directly adjacent and behind the iris is the ciliary body. The ciliary body had two primary functions: production of aqueous humor and accommodation. Ciliary muscles within the ciliary body are responsible for fine-tuning visual focus by releasing tension on the suspensory fibers or zonules of the lens, increasing the refractive power of the lens. The contraction of ciliary muscles also opens space for increased aqueous drainage. The posterior part of the uveal tract is a layer of blood vessels and capillaries called the *choroid.* These vessels nourish the outer portion of the retina, providing oxygen and nutrients. Bleeding from the choroid layer can cause catastrophic intraoperative expulsive hemorrhage.

The retina is a thin, transparent structure that differentiates from the optic cup and constitutes the inner layer of the medioposterior wall of the globe. Photoreceptors of the retinal layer convert light into neural signals, which are processed and carried to the brain via the optic nerve.

The vitreous cavity occupies >80% of the volume of the globe. The transparent vitreous humor is important in the metabolism of the intraocular tissues; it provides a passageway for metabolites used by the lens, the ciliary body, and the retina. Although it has a gel-like structure, the vitreous is composed of 99% water. Vitreous adheres to the retina peripherally at the vitreous base, the disk margin, and onto the posterior margin. Separation of the vitreous from the inner retina proceeds with age and is the most common event associated with retinal detachment. Scarring, bleeding, or opacification of the vitreous is treated by its removal, or vitrectomy.

Extraocular muscles arise from a fibrous ring at the orbital apex and insert onto the sclera approximately 6 mm posterior to the limbus. These muscles produce eye movements within the orbit. Together, they form what has been termed a "cone" within the orbit, which contains the optic nerve, ophthalmic artery and vein, oculomotor and abducens nerves, and ciliary ganglion. The extraocular muscles are composed of two different types of cells: Fibrillenstruktur and Felderstruktur. Fibrillenstruktur muscles fibrils are believed to produce fast or twitch movements. The Felderstruktur muscle fibers are responsible for slow or tonic movements. Felderstrukturs appear to control the resting position of the extraocular muscles and may keep the eyes conjugate. These muscles are sensitive to the effects of acetylcholine and have been implicated in the exaggerated IOP response to succinylcholine and other depolarizing muscle relaxants. Extraocular movements are used to assess the success of ophthalmic nerve blocks. A summary of the function and innervation of the extraocular muscles is given in Table 65–1.

The conjunctiva is a mucous membrane that lines the inner surface of the eyelids and covers the anterior surface of the globe between the cornea and limbus. The bulbar extension of the conjunctiva fuses with the Tenon capsule and inserts into the limbus. The Tenon capsule is an incomplete fascial layer

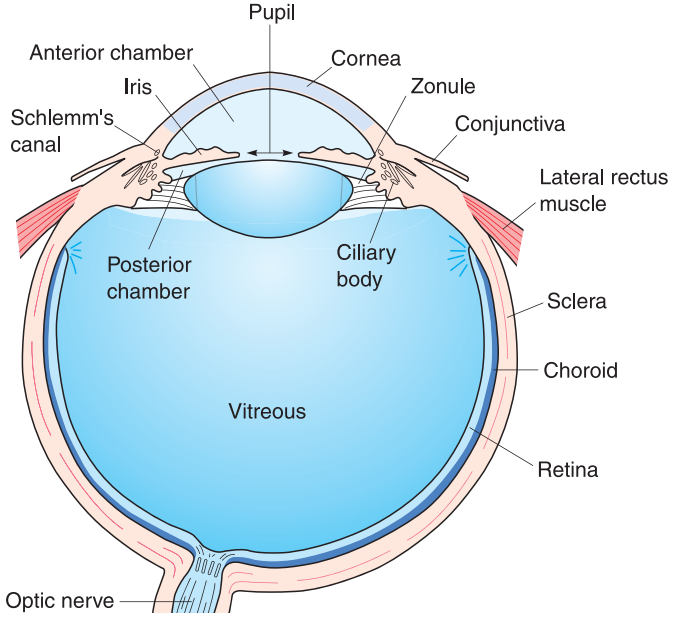

FIGURE 65–1. Anatomy of the eye. (Reprinted from Bruce RA Jr, McGoldrick KE, Oppenheimer P, eds. Anesthesia for Ophthalmology. Birmingham, Alabama: Aesculapius Publishing, 1982, with permission from Elsevier.)

TABLE 65–1.

Extraocular Muscles: Innervation and Function

Muscle	Innervation	Function
Superior rectus	III (oculomotor)	Elevation
Inferior rectus	III (oculomotor)	Depression
Medial rectus	III (oculomotor)	Adduction
Inferior oblique	III (oculomotor)	Elevation/abduction
Superior oblique	IV (trochlear)	Depression/adduction
Lateral rectus	VI (abducens)	Abduction

Reprinted from Bruce RA Jr, McGoldrick KE, Oppenheimer P, eds. Anesthesia for Ophthalmology. Birmingham, Alabama: Aesculapius Publishing, 1982, with permission from Elsevier.

composed of collagen fibers and fibroblasts. Anteriorly, it fuses with the conjunctiva and extends posteriorly, where it is perforated by the optic nerve sheath and the posterior ciliary vessels and nerves. The Tenon capsule and the intermuscular fibrous membranes surrounding the four rectus muscles fuse to form a type of fibrous sling or support. This structure may also be called the "cone," but it is important to understand that the cone is not continuous.

The eyelids are composed of an outer layer of skin, a muscle layer, a cartilaginous tarsal plate, and an inner layer of conjunctiva. The upper lid can be raised 15 mm by the action of the levator palpebrae superioris muscle, which is innervated by CN III. The orbicularis oculi muscle, innervated by CN VII (facial), allows tight closure of the eyelids.

The lacrimal gland is located in a shallow depression within the orbital portion of the frontal bone. Tears are formed here by the serous secretion of acinar and myoepithelial cells. Under both reflex and psychogenic stimulation, tears pass from the surface of the eye via the puncta, through either the upper or the lower canaliculi to the lacrimal sac and duct, and drain into the nasopharynx below the inferior turbinate.

The blood supply to the ocular structures is primarily the ophthalmic artery. The ophthalmic artery is a branch of the internal carotid artery just before the circle of Willis. Venous drainage flows though the superior and inferior ophthalmic veins directly to the cavernous sinus.

The cranial nerves innervate ocular structures. The optic nerve (CN II) carries the sensory information from the retina. Cranial nerves III, IV, and VI supply the extraocular muscles.

The optic nerve is a special sensory nerve, but it is not a true nerve. Developmentally speaking, both the retina and optic nerve are part of the brain. The optic nerve extends from the retina and enters the cranial cavity through the optic canal (optic foramen). The intraorbital part of the optic nerve is approximately 25 mm long. The optic nerve is enclosed by three sheaths that are continuous with the meninges of the brain. These sheaths extend as far as the back of the globe. The thick outer sheath is continuous with the dura mater of the brain and the sclera of the eye. The thin intermediate sheath is continuous with the arachnoid of the brain and is separated from the outer sheath by the subdural space and from the inner sheath by the subarachnoid space. The vascular inner sheath is continuous with the pia mater of the brain and closely invests the optic nerve. The inner sheath sends connective tissue partitions and blood vessels into the nerve. The ventral artery and vein of the retina pierce the dural and arachnoid coverings of the optic nerve approximately 1 cm behind the globe after a short course in the subarachnoid space, penetrate the optic nerve, and run within it to the inner aspect of the retina.

The oculomotor nerve (CN III) is the somatic motor nerve to four of the six muscles that move the eye and to the levator palpebrae superioris, the muscle that raises the eyelid. The oculomotor nerve was so named because it supplies most of the muscles that move the eye. It also contains parasympathetic fibers to the involuntary muscles that constrict the pupil and change the curvature of the lens (accommodation).

The trochlear (CN IV) nerve has the fewest nerve fibers of any cranial nerve, but it has the longest intracranial course. The trochlear nerve enters the orbit through the superior orbital fissure. It then extends superiorly to innervate the superior oblique muscle. This location of the nerve, outside of the muscle cone, delays the abolition of depression and adduction of the globe following retrobulbar block.

The trigeminal nerve (CN V) provides sensory innervation to the skin and conjunctiva of the lower lid via that maxillary nerve and to the upper lid and conjunctiva via the frontal branch of the ophthalmic nerve. The nasociliary branch of the ophthalmic nerve provides sensory innervation to the medial canthus, lacrimal sac, and canaliculi and sends sensory fibers to the ciliary ganglion.

The ciliary ganglion provides sensory innervation of the cornea, iris, and ciliary body. Parasympathetic motor fibers originating from the oculomotor nerve synapse in the ciliary ganglion before innervating the sphincter muscle of the iris and the ciliary muscle. Sympathetic motor fibers originating from the carotid plexus travel through the ciliary ganglion to innervate the dilator muscle of the iris.

The abducens nerve (CN VI) passes through the superior orbital fissure to innervate the lateral rectus muscle on its ocular surface. No sympathetic or parasympathetic fibers appear to accompany the motor fibers.

The facial nerve (CN VII) is a mixed nerve, but it is predominantly motor in function. It was given its name because of large motor branches that spread across the face. The facial nerve exits the skull through the stylomastoid foramen (along with the internal carotid artery) and passes into the substance of the parotid gland, where it divides into five branches that supply the muscles of facial expression. The orbicularis oculi muscle, innervated by the zygomatic branch of the facial nerve, allows the patient to close the eyelid tightly. Local anesthetic blockade of the facial nerve can be important in intraocular surgery by eliminating squeezing caused by contraction of the orbicularis oculi.

OCULOCARDIAC REFLEX

The oculocardiac reflex (OCR) is caused by traction on the extraocular muscles, manipulation of the globe, or increase in IOP. It is most commonly described as occurring during eye muscle surgery, but it also is prevalent during retinal detachment repair and enucle-

ation. The OCR has even been observed following retrobulbar block and retrobulbar hemorrhage. The OCR is most commonly manifested as bradycardia, but it also may appear as bigeminy, ectopic beats, nodal rhythms, atrioventricular block, or asystole. These dysrhythmias may persist as long as the stimuli are present. Repeated stimuli cause fatigue with diminished vagal effects.

The afferent pathway of the OCR is via the ciliary ganglion to the ophthalmic division of the trigeminal nerve, through the gasserian ganglion to the trigeminal nucleus in the fourth ventricle. The efferent pathway is exclusively through the vagus nerve. It is the vagus innervation to the abdominal viscera that causes nausea and vomiting that can accompany the cardiac manifestations. Alexander[3] reported that 90% of patients experienced OCR during traction of the extraocular muscles. The reported incidence of other cardiac dysrhythmias varies between 32% and 82%.

Diagnosis of the OCR relies upon continuous monitoring of the electrocardiogram (ECG). Treatment varies based upon the severity of the reflex. If the reflex manifests as bradycardia or infrequent ectopic beats and the blood pressure remains stable, no treatment may be warranted. If the dysrhythmias become significant, cessation of the surgical stimuli is indicated. Often the procedure may resume after a brief pause. The OCR fatigues easily and usually little or no OCR occurs after a brief pause in surgical stimuli. When the OCR is severe, treatment with anticholinergics (glycopyrrolate or atropine) is indicated. Caution must be exercised with large doses of atropine because more severe, prolonged tachydysrhythmias may result.[4]

ANESTHESIA AND IOP

IOP is the pressure exerted by the contents of the eye upon the cornea and sclera of the globe. The sclera is inelastic, making compliance of the globe low; small changes in volume result in large changes in pressure. The volume of the globe is principally determined by the aqueous humor and the blood vessels of the eye, particularly of the choroid. Aqueous humor volume is determined by the production and drainage of aqueous. Excessive increases in IOP interfere with choroidal and retinal blood supply as well as corneal metabolism, potentially causing retinal ischemia and corneal opacification. Decreased IOP or hypotony increases the risk of retinal detachment and vitreous hemorrhage.

The blood vessels of the choroid constitute a large and variable volume in the eye. Because choroidal vessels of the eye act much like intracranial vessels, it is useful to think of anesthetic effects upon IOP as being similar to anesthetic effects upon intracranial pressure. Choroidal vessels constrict with hyperventilation (hypocapnia) and cause a decrease in IOP. Hypoventilation (hypercapnia) causes vasodilatation and an increase in IOP. Similarly, hypoxia may contribute to increased IOP through vasodilatation of intraocular vessels.

Normal IOP is 16 $\pm$ 5 mm Hg in the sitting position and is generally maintained within this narrow range. IOP undergoes normal minor fluctuations because of (1) changes in body position (+1 mm Hg supine), (2) diurnal rhythm (2–3 mm Hg), (3) blood pressure oscillations (1–2 mm Hg), and (4) respiration (deep inspiration decreases IOP by 5 mm Hg). Changes in blood pressure are reflected in IOP: hypotension decreases IOP, whereas hypertension increases IOP.

The most severe increases in IOP usually are caused by blockage of aqueous outflow by acute venous congestion. Any straining, bucking, breathholding, or obstructed airway during induction of or emergence from general anesthesia will increase venous congestion in the ophthalmic veins and therefore raise IOP. Coughing, Valsalva maneuvers, or straining can increase IOP to 30–40 mm Hg. Endotracheal intubation is another potent stimuli for increasing IOP. External pressure from face mask, fingers, orbital tumors, contraction of the orbicularis oculi muscle, or retrobulbar hemorrhage will increase IOP.

Aqueous humor is formed by the ciliary body, which is the vascular component of the uveal tract located in front of the pars plana and behind the fibers of the suspensory ligament of the lens (Fig. 65–2). The ciliary body is folded over into a series of 80 folds, each 2–3 mm, termed *processes,* which extend to the posterior aspect of the iris. This structure is supplied by a vascular plexus and covered with epithelium that is impervious to proteins and high-molecular-weight substances.

Aqueous humor is the major transport system in the eye for oxygen, glucose, proteins, medications, and inflammatory cells. It provides nourishment for the lens and the corneal endothelium. Approximately half of the cornea's oxygen supply comes from aqueous; the remainder comes from diffusion with the air. Drugs may enter the eye with aqueous humor via the cellular pumping action of the ciliary body, but as just noted, a distinct blood–aqueous barrier prevents

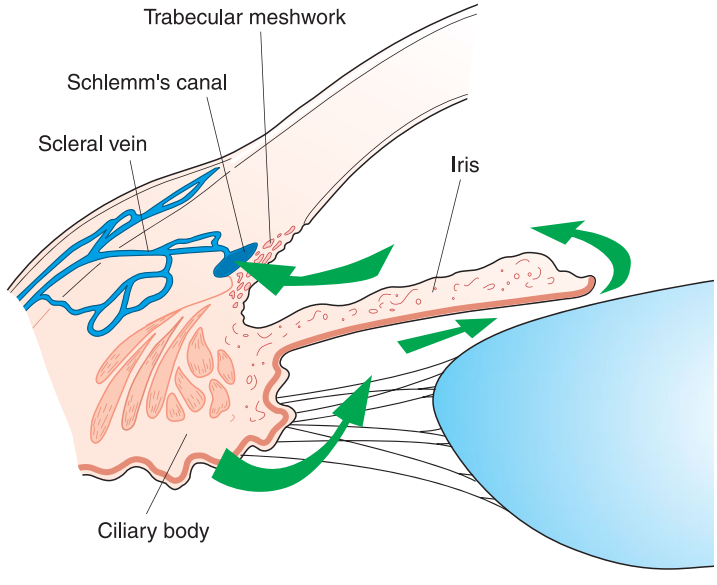

FIGURE 65–2. Anatomy of aqueous flow. Reprinted from Bruce RA Jr, McGoldrick KE, Oppenheimer P, eds. Anesthesia for Ophthalmology. Birmingham, Alabama: Aesculapius Publishing, 1982, with permission from Elsevier.

high-molecular-weight drugs from entering aqueous from the blood.

The aqueous flows forward from the suspensory ligament of the lens and passes between the anterior capsule of the lens and posterior surface of the iris through the pupil to the anterior chamber. Flow then proceeds laterally to the meshwork of the trabecula and into the circular canal of Schlemm. This lateral drainage area is termed the "angle." Episcleral veins drain aqueous to the venous system. Approximately one third of the aqueous produced is reabsorbed through the veins in the iris and choroid.

Altered circulation of aqueous can produce an increase in IOP, termed *glaucoma,* or a decrease in IOP, termed *phthisis*. Glaucoma usually is caused by obstruction to outflow of aqueous humor. Glaucoma is rarely caused by an abnormal increase in aqueous production. In these cases, vascular abnormalities or diseases lead to increased vascularity of the eye.

Acute glaucoma is the sudden occlusion of the drainage angle. This occlusion often is associated with a narrow anatomic angle, a pupil dilated by atropinergic compounds, or an iris propelled anteriorly. Often the patient has a history of an episode of coughing or straining.

The onset of *chronic glaucoma* is insidious. Although peripheral vision is gradually lost in the early stages of the disease, the angle is found open and the trabecula appears to operate normally. Chronic glaucoma may be congenital, associated with a familial diathesis or increasing age.

IOP is clinically measured indirectly. Invasive measurements are not common because of the risk of eye damage, danger of infection, and likelihood that the measurement itself may alter IOP. IOP is measured via an indentation technique (Schiotz) or applanation (Goldmann).

The Schiotz technique uses a plunger activated by a small weight to indent the cornea. The plunger is connected to a lever that points to a number on an arbitrary scale. This number, along with the weight used in the measurement, allows determination of IOP from a normogram. A small amount of aqueous is forced out of the eye with each indentation. Because of this action and because of the mechanical friction of the tonometer, Schiotz readings decrease as the measurements are repeated. The applanation method exerts graduated pressures to the cornea and results in a more reproducible IOP measurement.

Many drugs alter the production or drainage of aqueous and consequently IOP (Table 65–2). The method and speed of administration of drugs is important. Inhalational and intravenous drugs have the most rapid and pronounced effect upon IOP. Most medications exhibit a "dose–response" relationship with IOP. Initial dosing has minimal effects, then a rapid linear response occurs leading to a plateau effect, where increasing dosages have little or no effect upon IOP.

Deep inhalational or thiopental and propofol anesthesia reduces IOP 30–40%

TABLE 65–2.

Effects of Drugs on Intraocular Pressure

	Dose	Route	Comments
Drugs that increase intraocular pressure			
Ketamine	1–2 mg/kg	IV	Increase
Ketamine	5 mg	IM	Slight increase
Succinylcholine	1–2 mg/kg	IV	18% increase
No effect or unknown			
Alfentanil	5 µg/kg	IV	No effect
Atracurium	0.4–0.5 mg/kg	IV	No effect
Atropine	0.4–1.0 mg	IM	No effect
Desflurane	6–12%	Inhalation	Unknown, probable decrease
Flumazenil	0.0025 mg/kg	IV	No effect
Glycopyrrolate	0.2–0.4 mg	IV	No effect
Meperidine	50–100 mg	IM	May increase, normally no effect
Nitrous oxide	70%	Inhalation	No effect
Remifentanil	0.5 µg/kg	IV	No effect
Scopolamine	0.4 mg	IM	No effect
Vecuronium	0.08–0.1 mg/kg	IV	No effect
Drugs that decrease intraocular pressure			
Chlorpromazine	10–25 mg	IM	20–30% decrease
Curare	0.5–0.6 mg/kg	IV	Slight decrease
Dexmedetomidine	1 µg/kg	IV	40% decrease
Diazepam	10 mg	IV	Decrease
Dilaudid	1–2 mg	IV	Decrease
Droperidol	5–10 mg	IV	12% decrease
Enflurane	1% with N_2O	Inhalation	35–40% decrease
Etomidate	0.3 mg/kg	IV	30% decrease
Fentanyl	50–100 mg	IM	20% decrease
Haloperidol	0.5 mg	IV	15% decrease
Halothane	1 MAC	Inhalation	14–33% decrease
Isoflurane	1–3%	Inhalation	40% decrease
Lidocaine	1.5 mg/kg	IV	Decrease
Methohexital	6 mg/kg	IV	Decrease
Metocurine	0.3–0.4 mg/kg	IV	Slight decrease
Midazolam	0.15 mg/kg	IV	25% decrease
Morphine	8–15 mg	IM	Decrease
Pancuronium	0.05 mg/kg	IV	Slight decrease
Pentothal	3–5 mg/kg	IV	30% decrease
Propofol	1–2 mg/kg	IV	Decrease
Sevoflurane	1–3% with N_2O	Inhalation	40% decrease
Sufentanil	1–2 µg/kg	IV	Decrease
Thiamylal	4–5 mg/kg	IV	Decrease
Thiopentone	2.5 mg/kg	IV	30% decrease

in a dose-related manner.[5,6] Narcotics generally cause a small decrease in IOP. Atropine in usual doses is not a problem, even in patients with open-angle glaucoma. Ketamine may cause a modest-to-significant increase in IOP. Most of this increase can be explained by increased blood pressure.[7]

Succinylcholine causes a 6–12 mm Hg increase in IOP, which can be sustained for 5–10 minutes.[8–11] This increase has been ascribed to contraction of the extraocular muscles leading to compression of the globe. This contraction could potentially extrude globe contents in a patient with an open-globe injury. Katz et al.[12] studied patients undergoing elective enucleation and compared IOP between the normal eye and the diseased eye, in which all extraocular muscles were detached, after administration of succinylcholine. No difference between the two eyes was found in baseline or peak IOP. Nonetheless, both eyes exhibited a precipitous rise in IOP, leading the authors to conclude that extraocular muscle contraction does not contribute to the increase in IOP after succinylcholine administration. "Self-taming" doses,[13,14] precurarization,[15] diazepam,[16] and lidocaine do not completely abolish the response. Use of succinylcholine for induction in cases of open-globe injury is controversial, although vitreous loss in precurarized patients due to succinylcholine has not been reported.

SYSTEMIC EFFECTS OF OPHTHALMIC DRUGS

Some ophthalmic medications given in the perioperative period are sufficiently potent to have systemic effects. Ocular drugs applied topically can act as readily as if they were given intravenously. Although the medication is absorbed slowly from the conjunctival sac, much more rapid absorption can occur via the mucosal surfaces of the nasolacrimal duct. Systemic absorption may be altered in a diseased or postsurgical eye.

Phenylephrine is commonly used as a mydriatic. There is little increase in mydriasis when solutions with concentrations >5% are used.[17] This response is important because significant complications have been reported with 10% phenylephrine. A single drop of this high-concentration solution may contain 5 mg of phenylephrine (100 mg/mL ÷ 20 drops/mL). Complications seen include myocardial infarction, hypertension, reflex bradycardia, and cardiac dysrhythmias.[18]

Topical application of 2% *epinephrine* solution to the eye causes a decrease in aqueous secretion and improves outflow, both of which act to reduce IOP in open-angle glaucoma. Complications include hypertension, tachycardia, dysrhythmias, and fainting. Because a single drop of 2% solution contains 0.5–1.0 mg of epinephrine, it is reasonable to expect systemic complications to occur. *Intraocular* epinephrine administered during halothane anesthesia is poorly absorbed and has no significant cardiac effects.[19]

β-*Adrenergic antagonists* (e.g., timolol) are used in the treatment of glaucoma. This class of medication acts to reduce aqueous humor secretion, with minimal effects on aqueous outflow. Pupillary size is not affected. Patients may complain of lightheadedness, fatigue, and disorientation and may exhibit a general depression of central nervous system function. Excessive dosage of β-adrenergic antagonists may lead to cardiovascular dysfunction, including bradycardia, palpitations, syncope, increase in heart block, and congestive heart failure.[20] Rare exacerbations of asthma have been reported.[21] Particular caution should be exercised with neonates receiving timolol eye drops because cases of apnea have been reported.[22]

Apraclonidine is a relatively new α_2-adrenergic agonist that has found a role as a topical antiglaucoma medication. Like epinephrine, it causes a decrease in aqueous formation and improves aqueous outflow. Systemic absorption may cause significant sedation and drowsiness. Hypotension is a possible complication but has not been reported. Acute withdrawal from long-term therapy may result in rebound hypertension.

Echothiophate iodide is a long-acting anticholinesterase drug still used to treat glaucoma. The pupil is constricted and aqueous drainage is increased. Its duration of action is 4–6 weeks. Three weeks after cessation of treatment with echothiophate, plasma cholinesterase activity remains at 50% of normal.[23] If a patient receives succinylcholine, a relative overdose of succinylcholine leads to 2–3 times the usual duration of action. Careful titration of succinylcholine with use of a peripheral nerve stimulator will avoid prolonged paralysis. The effects of ester local anesthetics (procaine and chloroprocaine) may be significantly prolonged. Amide-type local anesthetics may be a better choice for regional anesthesia.

Muscarinic agonists are given to cause prolonged mydriasis. A drop of *atropine* 1% solution contains 0.2–0.5 mg of the drug. One drop of 0.5% *scopolamine* contains 0.2 mg of the drug. Systemic reactions have been seen in both young and elderly patients following administration of topical ocular atropine or scopolamine. These reactions are manifest by tachycardia, flushing, thirst, and dry skin. Elderly patients may show agitation. CNS excitement and agitation can be treated with incremental doses of physostigmine 0.15 mg/kg IV.

Carbonic anhydrase inhibition of *acetazolamide* interferes with the formation of aqueous humor and lowers IOP. Aside from a metabolic acidosis with depletion of sodium and potassium, long-term therapy may result in dyspepsia. Given rapidly IV, the patient may exhibit an acute decrease in blood pressure. Caution should be exercised in patients with renal disease, dehydration, and sodium or potassium depletion.

PREOPERATIVE EVALUATION

By virtue of the nature of the surgical specialty, patients coming to the operating room for ophthalmologic surgery tend to be extremely young, very old, or have comorbid conditions. Very fragile, tiny infants often present with apnea, respiratory distress (later bronchopulmonary dysplasia), patent ductus arteriosus, or persistent pulmonary hypertension. Congenital glaucoma often is associated with other conditions, such as Hurler syndrome. Congenital strabismus may signify a myopathy that often is associated with malignant hyperthermia. The elderly present with coronary artery disease, atherosclerosis, hypertension, vascular heart disease, chronic obstructive pulmonary disease, type 1 or type 2 diabetes, cerebrovascular disease, dementia, Parkinson disease, renal or hepatic disease, arthritis, osteoporosis, or cancer. Moreover, since 1990 the proportion of Medicare patients requiring surgical treatment of chronic eye dis-

eases grew from 13.4% to 45.4%.[24] In a study by Kraushar and Turner[25] on medical litigation in cataract surgery, failure of proper coordination of preoperative care among anesthesiologists, surgeons, and internists resulted in indemnity findings in 16% of patients. Couple this situation with the fact that a large number of *adult* ophthalmologic patients are operated on as outpatients, and especially as outpatients in free-standing day surgery facilities, the degree of preoperative evaluation often is an informed negotiation among primary care physicians, ophthalmic surgeons, consultant physicians, and anesthesiologists.

Fortunately most ophthalmologic procedures are of low risk because there are no major physiologic derangements, blood loss, or fluid shifts. Much of the systemic risk to patients occurs with general anesthesia during induction and emergence, and most of the risk to the eye associated with anesthesia relates to patient movement, changes in IOP, and postoperative nausea and vomiting (PONV). Thus, the morbidity and mortality of ophthalmic surgery is low[26] despite the high-risk population. The anesthesiologist can draw on several sources as guides when designing an appropriate and safe preoperative evaluation[27–31] using as one's basis that surgical risk is low and that for routine patients only the highest risk is excluded.

All patients must provide a history and undergo physical examination assessing chronic medical conditions, any acute conditions, and their current state (Table 65–3). Ideally these assessments should be performed by the patient's primary care physician and should be available for review 1–2 days prior to the procedure by the anesthesiologist. In the absence of a primary care physician, the assessments can be subsumed by the existing local perioperative protocols for credentialed practioners for history and physical.[32]

If the case is a cataract, the patient has no acute medical issues, and the procedure will be performed under local anesthesia, no laboratory testing, including an ECG, need be done.[31] However, the patient must meet the following criteria: able to lie flat for 45 minutes, have no or treated gastric reflex, have no neuropsychiatric disturbances (e.g., claustrophobia or dementia), have no tremor affecting the head and neck, have no chronic uncontrollable cough, have sufficient command of English or some other common language so as to be able to communicate, follow commands, understand the nature of local/regional anesthesia and be able to consent to it, and comprehend he/she will be awake and at most will be only mildly sedated (Table 65–4).[30]

TABLE 65–3.

Preoperative Basic Health Assessment

- Medical History
  - Indications for surgery
  - Allergies to medications
  - Intolerance to medications
  - Allergies or intolerance to foods, environments
  - Known chronic medical problems
  - Prior surgical history
  - Current medications and reason for taking
- Acute Medical History
  - Status of known problems
    - Cardiac
    - Pulmonary
    - Hemostatic
    - Symptomatic anemia
    - Smoking and alcohol
    - Possibly pregnancy
    - Personal/familial history of anesthesia problems
    - Functional status
      - >4 METS
      - <4 METS secondary to physical limitations
- Physical Exam
  - Height and weight
  - Blood pressure, each arm
  - Pulse (rate and regularity)
  - Respiratory rate
  - Heart sounds
  - Breath sounds

TABLE 65–4.

Basic Requirements for Cataract Surgery

- Lie flat for 45 minutes
- No symptomatic reflux
- No head and neck tremor
- Ability to control cough
- No dementia or claustrophobia
- Knowledge of English or other common language
  - follow directions
  - communicate
  - understand will be awake

For patients undergoing prolonged (>3 hours) procedures under regional or general anesthesia, additional history documenting the ability to achieve 4 METS (metabolic equivalents) should be sought. This level is equivalent to walking four blocks without stopping or climbing two flights of stairs. Inability to achieve 4 METS might be indicative of significant coronary artery disease or congestive heart failure and left ventricular dysfunction. At minimum, this finding should trigger at least a discussion with the primary care physician or medical consultant on the potential need for further evaluation, as both Reilly et al.[33] and Sgura et al.[34] have demonstrated increased risk in patients unable to achieve the plateau of 4 METS.

Routine laboratory tests are of no proven value unless indicated by the history and physical examination.[31] Suggestions drawn from the Institute for Clinical Systems Improvement[32] and American Society of Anesthesiologists Task Force on Preoperative Evaluation[28] are listed in Table 65–5. Of note, for most patients without acute changes in medical history,

TABLE 65–5.

Lab Tests Indicated by History and Surgical/Anesthesia Risk

Test	Possible Indication
Hematocrit	History suggesting severe anemia or recent severe blood loss
Potassium	Digoxin Diuretics and myocardial irritability
Coagulation studies	History of coagulopathy Anticoagulation as a medical treatment
ECG	None within last year in patients with diabetes, hypertension, angina, CHF, smoking, PVD, inability to exercise Signs of new or unstable cardiac disease

ECGs are not needed if they were recorded within the past year.

Anesthesiologists should at minimum review these data in advance according to local protocol. If possible, a preoperative visit should be conducted to allay anxiety, explain the anesthesia plan, and educate the patient regarding medications to be continued on the day of surgery (β-blockers, antihypertensives, insulin therapy) and medications that may be of value to discontinue (antiplatelet agents and other anticoagulants). In patients with severe life-threatening diseases who are further compromised by their inability to see and who compassionately seek care in order to have some continued functionality, an attempt should be made to improve their emotional condition and to have a frank discussion with them of the risks of anesthesia. After obtaining detailed informed consent, one can proceed with the surgery and anesthesia.

Hypertension is a major risk factor for coronary artery disease, congestive heart failure, renal disease, and cerebrovascular disease. In an extensive literature review and meta-analysis of 30 observational studies, Glanz et al.[35] reasoned that hypertensive patients experienced a 1.31 times greater incidence of adverse cardiac experiences. This is a modest increase, is fraught with analytical challenges, and, in most cases, does not support the cancellation of surgery based only on uncontrolled hypertension. What then is the approach to high-risk patients who, on the day of their low-risk surgical procedure, such as cataract extraction or intraocular lens placement under regional anesthesia, arrive with blood pressure >185 systolic mm Hg or >110 mm Hg diastolic? Part of the thought process is the safety of administering topical phenylephrine (≤ 5% solution) in these cataract patients or epinephrine (2% solution) in open-angle glaucoma patients, knowing that further hypertension and bradycardia in the former and further hypertension, tachycardia, and arrhythmias in the latter are assured. In an elective case of an untreated and uncontrolled hypertensive patient, the choice usually is made to refer the patient to a primary care physician or an internist at our institution prior to discharge for treatment and investigation of any end-organ damage. In treated hypertensive, elderly patients, the offending eye drops will not be administered unless the pressure is <180/90. In obviously frightened and anxious patients at the Massachusetts Eye and Ear Infirmary, treatment is started with mild sedation and anxiolysis. Subsequently, if a patient is taking β-blockers (or there is no contraindication to them), these or the patient's own medication can be given orally. We try not to give slow-onset, long-acting compounds for fear of postural hypotension later, when the patient is in transit or at home. Should these methods be ineffective, the patient is referred back to the primary care physician for better control and anxiolysis prior to rescheduling the procedure.

REGIONAL ANESTHESIA TECHNIQUES

Technical advances in ophthalmologic surgery have changed many of the requirements for ophthalmic anesthesia. Phacoemulsification extraction of cataracts with lens replacement via tiny incisions has lessoned the need for eye akinesia and IOP control. IOP control is much more under the surgeon's control. Regional anesthesia has been associated with lower perioperative morbidity compared with general anesthesia for ophthalmic surgery as long as heavy sedation is avoided.[35,36] This has made care for our especially ill patients systematically safe, even when ophthalmic surgery is performed on an outpatient basis. In fact, more than two million people undergo cataract surgery in the United States every year. At the Massachusetts Eye and Ear Infirmary, >8500 ophthalmic procedures are performed every year. Of these procedures, approximately 8000 are done with some form of regional anesthesia, and of those >80% are performed by the anesthesiologist. A brief review of ocular and orbital anatomy is given prior to discussion of the anesthetic procedures themselves.

In simplest terms, each orbital cavity is a truncated pyramid with an orbital axis of 45° measured medially at the apex. The orbit averages 35 mm high, 45 mm wide, and 42 mm deep. However, in an anatomic study by Katsev et al.,[37] up to 11% of orbits were on the order of 40 mm. Furthermore, the ciliary ganglion is consistently 7 mm anterior to the orbital apex. Consequently, these structures as well as the optical foramen could be reached by a 38-mm (1½-inch) retrobulbar needle. For this reason, any needle >32 mm (1¼ inch) should not be used. The orbit is mainly filled with adipose tissue suffused with fibrous septa. The globe, which occupies only 30% of the orbit, is suspended anteriorly within the orbit in this cushioning tissue mass. The optic nerve enters the orbit at its apex at the optical foramen and passes through the fibrous annulus of Zinn from which the four rectus muscles originate. These muscles insert anteriorly near the equator of the globe. The anterior attachments, the muscles themselves, and the posterior attachments form the so-called "cone." However, because no complete fibrous tissues connect the rectus muscles to each other, this "cone" space is not enclosed but communicates with the rest of the orbital adipose tissue.

Sensory innervation of the globe comes from the ophthalmic nerve (first branch of the trigeminal nerve). This nerve passes through the conal area. The cornea, iris, and sclera are innervated by the long ciliary branch of this same nerve. Motor innervation of the lateral rectus is supplied by the abducens nerve (CN VI). Motor supply to the superior oblique muscle is by the trochlear nerve (CN IV). The oculomotor nerve (CN III) supplies all others. Only the trochlear nerve does not pass within the cone. Also within the confines of the rectus muscles are the ophthalmic artery and veins, the optic nerve with its meningeal coverings, and the ciliary ganglion. The motor nerve to the orbicularis oculus muscle (which squeezes the lids closed) is from the zygomatic branch of the facial nerve. It is extraorbital and branches superiorly and inferiorly 1 cm posterior to the junction of the superior and inferior orbital rims laterally. Figures 65–3 to 65–20 assist in visualizing these relationships.

The Tenon capsule comprises a fibroelastic layer that encloses the whole scleral structure of the globe from the corneal limbus anteriorly to the optic nerve posteriorly. It encapsulates a potential space called the *episcleral* or *sub-Tenon space.* It has no actual volume until fluid is injected into it. At the globe's equator, where the oblique and rectus muscles insert, is a continu-

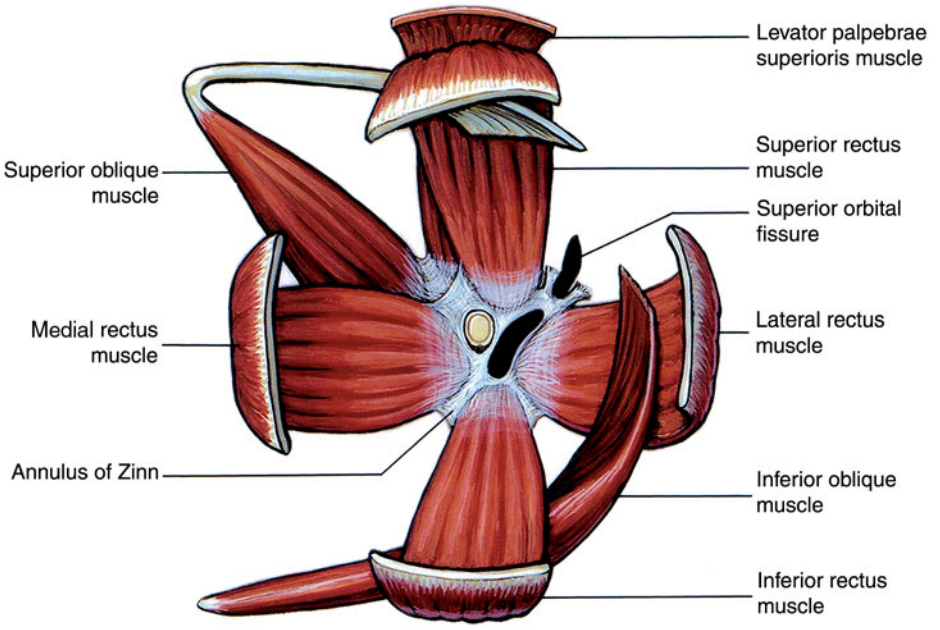

FIGURE 65–3. Extraocular muscles, front view. Area between rectus muscles is the "cone." (Reprinted from Dutton JJ. Atlas of Clinical Surgical Orbital Anatomy. Philadelphia: WB Saunders, 1994, with permission from Elsevier.)

ity between the Tenon capsule and the fascial sheaths of the muscles.

Topical Anesthesia

Topical anesthesia for phacoemulsification cataract surgery involves instillation of local anesthesia eye drops or gel. In this manner, the cornea, iris, sclera, and some conjunctiva are rapidly anesthetized via absorption through the corneal epithelium via the long ciliary nerve. Tetracaine 0.5%, proparacaine 0.5%, lidocaine 4%, and lidocaine gel 2–4% are often used. Most patients like the fact that no preprocedural injection is involved, and, because vision is retained, visual improvement is immediate after lens placement, with only a clear plastic eye protector used postprocedure. The duration of analgesia is brief and often requires supplementation with topical instillation or intracorneal injection.

Disadvantages include eyelid sensations, bright ophthalmic lights, and vision of surgical instruments, which can be bothersome to patients. Potentially bothersome to surgeons is the lack of IOP control, lack of akinesia, ability of patients to close the lids, and the poten-

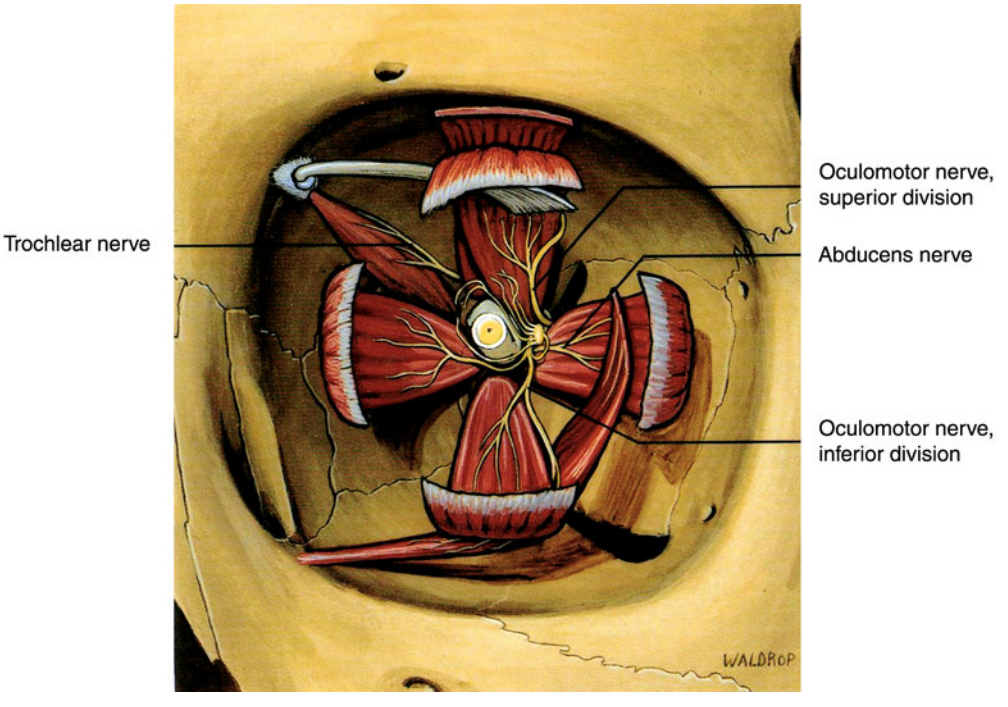

FIGURE 65–4. Frontal view of bony orbit showing motor nerves. Note trochlear nerve is outside the cone. Ciliary ganglion and optic nerve and sheath are seen. (Reprinted from Dutton JJ. Atlas of Clinical Surgical Orbital Anatomy. Philadelphia: WB Saunders, 1994, with permission from Elsevier.)

tial need for heavy sedation in uncooperative patients. Intraoperative comfort is more reliable with needle-based and sub-Tenon blocks. Interestingly, patients experiencing bilateral cataract extractions who were randomly assigned to topical for one eye and retrobulbar block for the other eye preferred the block technique by 71% to 10%.[38]

Topical anesthesia for phacoemulsification cataract extraction is appropriate for uncomplicated procedures, properly educated and cooperative patients, and procedures performed by surgeons adept at and comfortable with such techniques.

Sub-Tenon Anesthesia

Sub-Tenon block (also termed *episcleral block*) is accomplished by injecting local anesthetic into the episcleral space via needle or canula. Low-volume injection (3–5 mL) allows for good total globe analgesia, appropriate for most anterior chamber surgeries. Increasing the amount of local anesthetic (5–12 mL) will give reliable motor block as well, as this allows spread to the extraocular muscle sheaths. At this volume, some degree of chemosis (subconjunctival spread) is usually seen. Vitreoretinal surgery can readily be accomplished as well. Some surgeons also desire orbicularis oculi blocks, which will require block of the zygomatic branch of the facial nerve. The two techniques of sub-Tenon block are needle based and cannula based.

Needle-based sub-Tenon block has been described by Ripart et al.[39] and Mouvellon et al.[40] The needle is placed into the fornix between the semilunaris fold of the conjunctiva and the globe, tangential to the globe (Fig. 65–16). After the conjunctiva is entered, the needle is shifted slightly medially and advanced strictly posteriorly. This moves the globe medially. Once a small click is perceived (loss of resistance), the globe returns to primary gaze position. Ripart et al. describe this as a depth marker, indicating a depth of 10–15 mm prior to injection. At this time, local anesthetic is injected up to a volume of 10 mL. Volumes >6 mL produce reliable globe analgesia and eye akinesia. Mouvellon et al. report no serious complications in their review of 2000 cases. However, because the technique is needle based, it is not immune to needle misplacement and subsequent serious globe

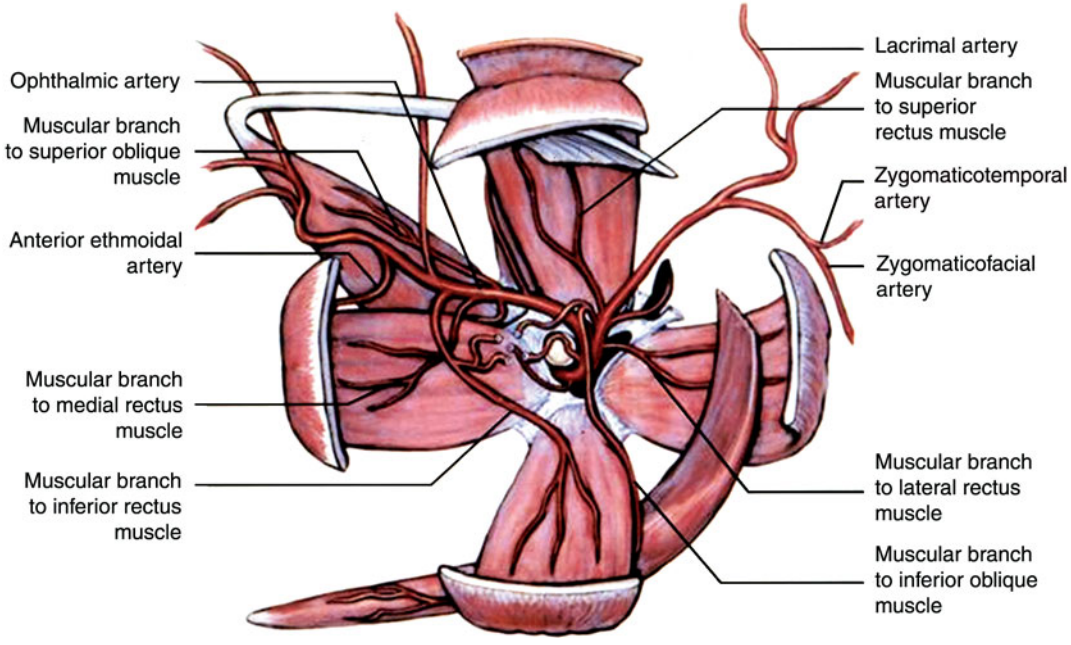

FIGURE 65–6. Orbital arteries. (Reprinted from Dutton JJ. Atlas of Clinical Surgical Orbital Anatomy. Philadelphia: WB Saunders, 1994, with permission from Elsevier.)

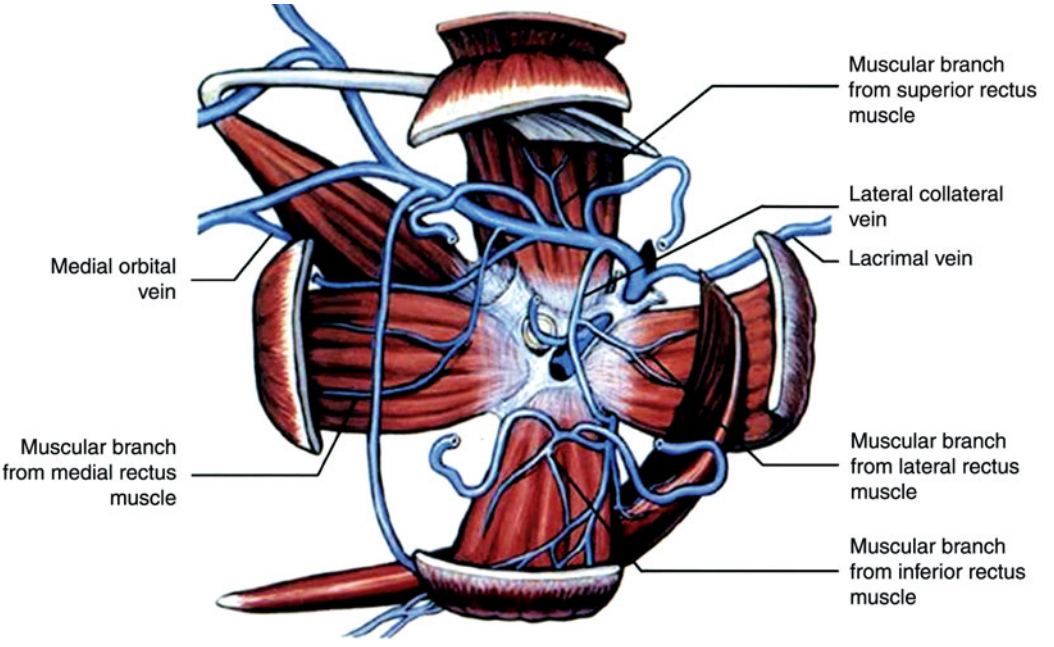

FIGURE 65–7. Orbital veins. (Reprinted from Dutton JJ. Atlas of Clinical Surgical Orbital Anatomy. Philadelphia: WB Saunders, 1994, with permission from Elsevier.)

injury. This block has not yet achieved wide popularity among anesthesiologists in the United States.

Cannula-based sub-Tenon block originally was described as a supplement to poor-quality or receding retrobulbar anesthesia.[41] Small volumes (3–5 mL) reliably produce good globe anesthesia, do not raise IOP pressure, and can be used with the globe open. In addition, it can be used as the primary anesthetic with larger volumes (5–10 mL) of local anesthesia.[42] The larger volumes are associated with better akinesia. This technique was developed as a way to avoid complications of retrobulbar blocks, but retrobulbar hemorrhage, globe perforation, and extraocular muscle injury have been reported. This technique may be contraindicated in patients with staphylomas or scleral thinning, highly myopic eyes, previous pterygium repairs, prior scleral buckling procedures, or prior vitreoretinal surgery. Orbicularis oculi often must be blocked separately.

Cannula-based sub-Tenon block is a minisurgical approach. The technique can be performed in the inferonasal, superonasal, superior, or temporal quadrants after sterile preparation and application of topical anesthetic drops or gel to the surface of the globe. The bulbar conjunctiva is grasped 5–10 mm from the limbus, and blunt Westcott scissors are used to create an opening into the conjunctiva and Tenon capsule to access the episcleral space. Specially designed blunt, often curved cannulas are advanced into the episcleral space, and the local anesthesia mixture is injected. Most often this technique is performed by the ophthalmologist, but more anesthesiologists are being trained on and are using the technique.

Retrobulbar or Peribulbar Anesthesia

Both retrobulbar block and peribulbar block are needle-based blocks that rely on local anesthetic installation into the orbit to bathe the nerves and muscles and provide analgesia and akinesia. Retrobulbar block is believed to have fast onset and provide reliable akinesia with use of small volumes (2–4 mL) of local anesthetic within the area behind the globe, demarcated by the insertions of the oblique and rectus muscles anteriorly and, as they pass posteriorly, to their origin at the annulus of Zinn. All sensory and motor

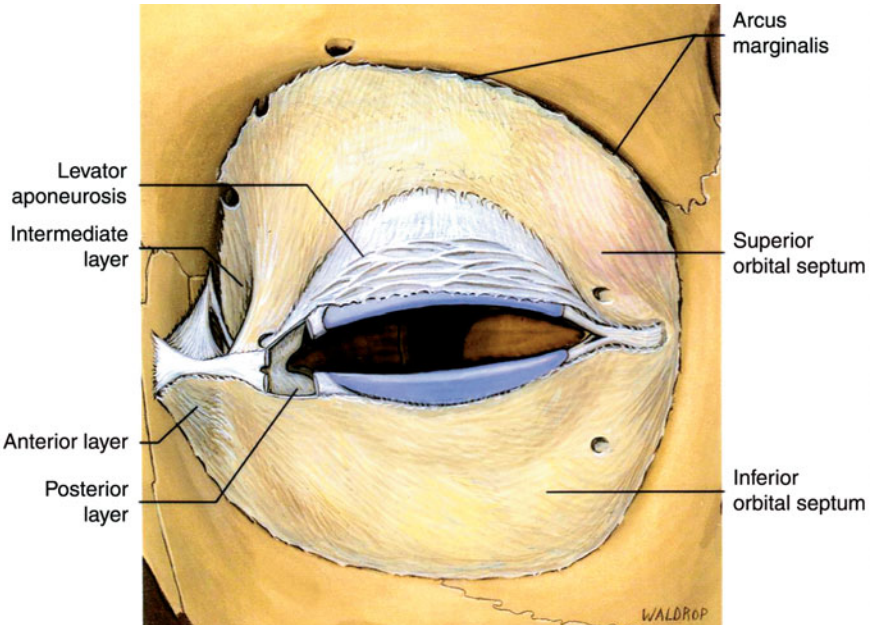

FIGURE 65–8. Preorbital septum. Disruption of levator aponeurosis by local anesthetic may lead to ptosis. (Reprinted from Dutton JJ. Atlas of Clinical Surgical Orbital Anatomy. Philadelphia: WB Saunders, 1994, with permission from Elsevier.)

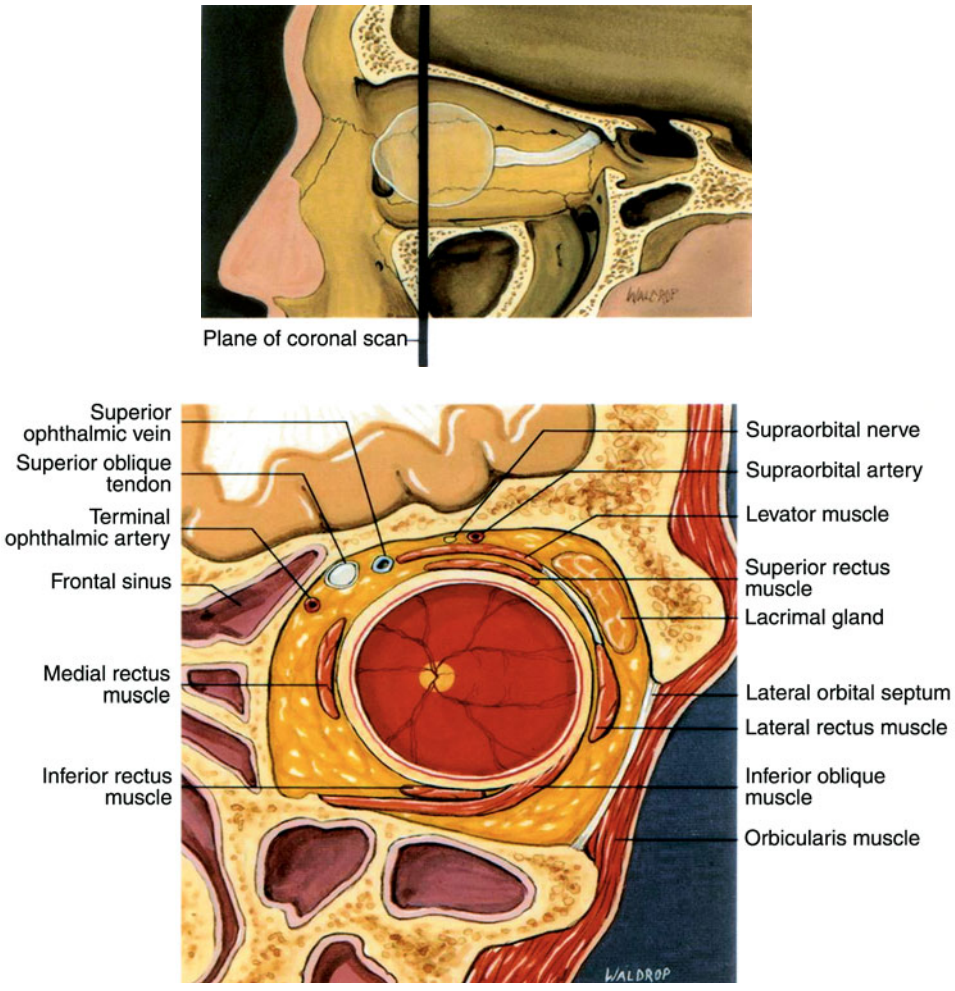

FIGURE 65–9. Coronal section through anterior globe and orbit. Note especially small space and important structures superonasally, superiorly, superotemporally, and inferomedially. Paucity of structures are located inferotemporally at the lateral canthus and medial canthus. (Reprinted from Dutton JJ. Atlas of Clinical Surgical Orbital Anatomy. Philadelphia: WB Saunders, 1994, with permission from Elsevier.)

nerves of the globe, except the motor nerve to the superior oblique, pass within this virtual cone. All important vascular and nervous structures, including the optic nerve and ciliary ganglion, pass within this cone and become more compact with proximity to the apex of the orbit. Certainly 1/2-inch ophthalmic needles can contact these structures, and in smaller orbits (< 40 mm) even 1/4-inch ophthalmic needles may reach these structures. Furthermore, small volumes of local anesthetic will always spare the extraorbital branch of the facial nerve to the orbicularis oculi.

Peribulbar block is predicated on the anatomic basis that the muscular cone is not an isolated enclosed space between the rectus muscles and that local anesthesia instilled more anteriorly in the orbit and external to the muscle cone will easily diffuse to reach the appropriate muscles and nerves. This premise enables use of ophthalmic needles ≤ 7/8 inch (23 mm). Note that peribulbar blocks require volumes of 5–10 mL. At higher volumes, local anesthetic often finds its way extraorbitally to reach the facial nerve branch to the orbicularis oculi. Provided sufficient volumes are used, peribulbar blocks are equally as efficacious as retrobulbar blocks.[43] Retrobulbar blocks, secondary to longer needles, have an inherently greater probability of block related serious life- or sight-threatening complications. On this basis, it is the practice of the Massachusetts Eye and Ear Infirmary to use peribulbar blocks with shorter needles unless there is reason not to do so. In patients presenting for multiple procedures, scarring or adhesions formed in the orbital adipose tissue after many blocks may be indications for a retrobulbar block. Additionally, if raising IOP is a concern, small volumes of local anesthesia placed retrobulbarly will avoid that problem. Peribulbar blocks can cause significant chemosis (potentially a problem for glaucoma procedures or pterygium excision), disruption of the preorbital septum, or disruption of the levator aponeurosis leading to exophthalmos or entropion (Fig. 65–8).

Before describing the technique for needle-based blocks, a few cautions are indicated. Do not use certain quadrants because of the ease of causing injury secondary to smaller insertion spaces and the presence of important structures: superonasal (superior oblique tendon, superior ophthalmic vein), superior (supraorbital nerve, levator muscle), and superotemporal (lacrimal gland). Use only ophthalmic needles that are ≤ 32 mm. Most peribulbar needles are < 24 mm.

Most needle-based techniques use the inferotemporal quadrant and pri-

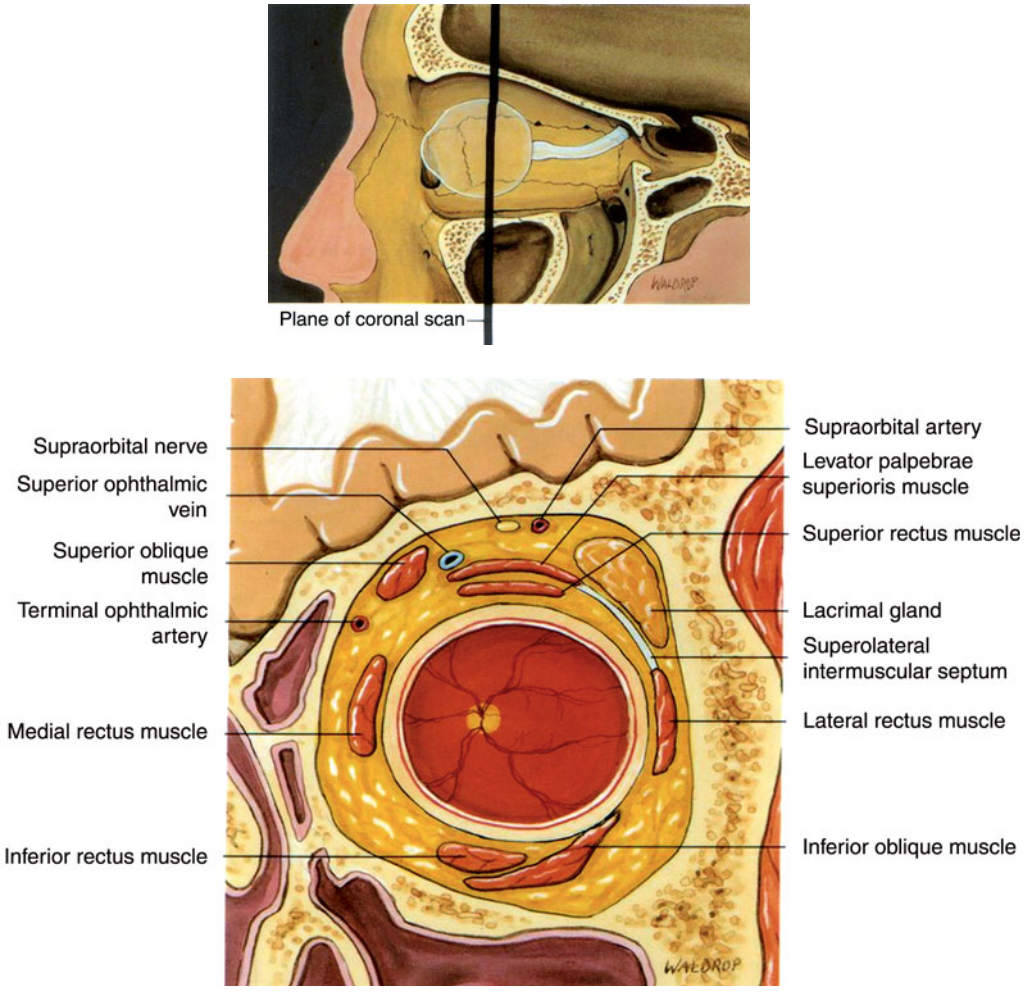

FIGURE 65–10. Coronal section through midglobe and anterior orbit. Figures 65–10, –11, –12 all use relationships first depicted in Fig. 65–9 (i.e. top panel is location of cut through orbit, which is shown in cross-section in lower panel). (Reprinted from Dutton JJ. Atlas of Clinical Surgical Orbital Anatomy. Philadelphia: WB Saunders, 1994, with permission from Elsevier.)

mary gaze position. Primary gaze is used because the Atkinson up-and-in position brings the optic nerve closer to the path of the needle, placing it under tension so that it is in danger of penetration by retrobulbar needles.[44] For both retrobulbar and peribulbar blocks, a single injection technique is used, and the same entrance point is used in the inferotemporal quadrant. For both blocks, patients look straight ahead (primary gaze), and the operator's palpitating finger identifies the lower part of the globe and elevates it slightly. The needle is inserted, with the bevel angled toward the globe, below the lateral canthus and just above the inferior orbital rim (Figs. 65–17 to 65–19). This modified (M) insertion point, rather than the traditional (T) insertion point at the junction of the middle and lateral third of the orbital rim, is used because it lessons the possibility of injuring the inferior rectus or inferior oblique muscle along with its neurovascular bundle (Fig. 65–14).[45] For both blocks, the needle initially is directed perpendicular to the skin in all planes. Resistance is encountered at the skin, and a "pop" may be felt upon passing through the orbital septum. The needle should seem to float in after this point. In retrobulbar blocks, once the needle passes the inferior equator of the globe, it should be directed slightly more superiorly to enter the "cone." To minimize the potential for injury to the optic nerve, never advance the retrobulbar needle past the ocular axis midline. After negative aspiration, 2–3 mL of anesthetic is administered. If blood is aspirated, withdraw the needle, apply intermittent digital pressure, and reevaluate the orbit with the ophthalmologist before proceeding further. After the block, tape the lids closed in order to protect the eye.

Technically, a peribulbar block is performed in much the same manner as a retrobulbar block but using a shorter needle (typically 23 mm). Insert below the lateral canthus above the inferior orbital rim after digitally elevating the globe slightly. Pass the needle perpendicular to the skin in all planes, through skin resistance and orbital septum "pop." At this point, no attempt is made to change the direction of the needle to enter the muscular "cone"; remain moving posteriorly and parallel with it. Aspirate and inject 5–10 mL of anesthetic solution. Stop and retract the needle 1–2 mm if resistance to injection is encountered. Inject slowly, no faster than 1 mL every 3 seconds. After the block, protect the eye from potential abrasion by taping the lids closed. Manual compression or a mechanical device such as a Honan balloon at 30 mm HG pressure is used for short periods to help decrease IOP resulting from the larger volumes of fluids. Check the block for efficacy in 5–10 minutes for developing akinesis.

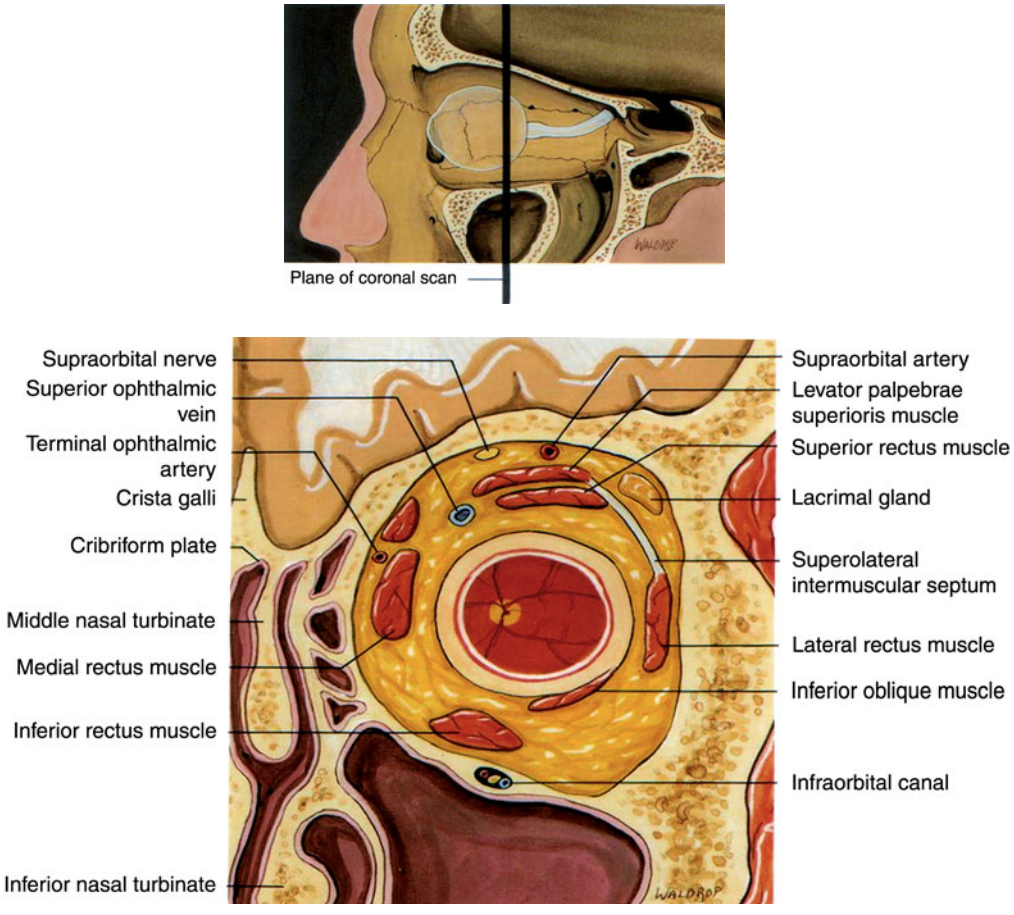

FIGURE 65–11. Coronal section, posterior globe. (Reprinted from Dutton JJ. Atlas of Clinical Surgical Orbital Anatomy. Philadelphia: WB Saunders, 1994, with permission from Elsevier.)

Complete akinesia usually is needed for vitreoretinal surgery, whereas partial akinesis is generally adequate for phacoemulsification cataract extraction. If required, a repeated block can be applied either at this site or at the medial canthus at the medial junction of the lids and nasal to the lacrimal caruncle as described by Husted et al.[46] (Fig. 65–16). For a supplemental injection, 3–6 mL can be used.

Modified Van Lindt Block

Any time paralysis of the orbicularis oculi is necessary to prevent squeezing the lids closed and the peribulbar block has been partially or totally ineffective, a modified van Lindt block is performed. The orbicularis oculi is innervated by the superior branch of the facial nerve given that it is extraorbital. The needle is inserted 1 cm lateral to the lateral junction of the superior and inferior orbital rims, and 2–4 mL of anesthetic is injected deeply on the periosteum just lateral to the superolateral and inferolateral orbital rim.

Regional Postoperative Analgesia

Postoperative pain relief is not an issue for most anterior segment surgery. Pain following cataract surgery is decidedly abnormal. In fact, such pain should prompt an urgent visit to the ophthalmologist because it may indicate infection or increased IOP. Postoperative pain is greater after posterior segment surgery. Inadequate pain relief can lead to nausea, vomiting, crying, and restlessness in children, hematoma formation, prolonged recovery and hospital admission, and reduced patient satisfaction. Use of opioids to treat pain also can lead to nausea and vomiting, resulting in admission or surgical complications. Currently, local anesthesia often is used at the end of prolonged vitreoretinal surgery to extend analgesia well into the postoperative period, most commonly via sub-Tenon block or retrobulbar irrigation. In adults and children undergoing appropriate ophthalmic procedures with general anesthesia, administration of sub-Tenon, retrobulbar, or peribulbar anesthesia should be considered. Some centers advocate the use of indwelling catheters associated with retrobulbar, peribulbar, and sub-Tenon blocks[47,48] to relieve postoperative pain, but this practice has not yet gained wide acceptance.

Commonly Used Drugs and Adjuvants

All available local anesthetic drugs have been used either alone or in combination. Onset and durations follow their usual pharmacologic profiles. Lidocaine, mepivacaine, ropivacaine, and bupivacaine are used most commonly. Lidocaine in concentrations >2% are potentially myotoxic and are not used.[45] A common combination is lidocaine 2% and bupivacaine 0.75% in equal amounts. Epinephrine 1:400,000 is sometimes used to prolong duration. Vasospasm with retinal ischemia does not seem to be a concern but is not universally accepted because of fear of optic nerve

ischemia in patients with vascular disease.[49]

Hyaluronidase is an enzyme that facilitates more rapid and wider spread within the tissues of the orbit. Although there is no obvious dose–effect relationship, most evidence suggests hyaluronidase increases the speed of onset of blocks, reduces the risk of extraocular muscle injuries, and contributes to a more rapid decrease in intraorbital pressure and hence IOP.[50–52] Common concentrations of hyaluronidase vary from 5–50 cc per milliliter. Until recently, hyaluronidase was available only through compounding pharmacies. The U.S. FDA has approved the manufacture and sale of hyaluronidase by two pharmaceutical companies.

Clonidine is often used in IV regional anesthesia for soft-tissue surgery to enhance the duration of postoperative analgesia. The same is true for ophthalmic anesthesia. Clonidine at a dose of 1 mg/kg is not associated with an increased incidence of somnolence or systemic hypotension.[53] It may help prevent intraoperative hypertension and may lower IOP.

COMPLICATIONS OF REGIONAL TECHNIQUES

The complications of regional ophthalmic nerve blocks are rare but have serious implications. They can be sight threatening and life threatening. The primary cause is needle misplacement. Risk factors include inadequate education of the practitioner, inadequate knowledge of orbital anatomy, anatomic variation, previous ophthalmic surgery, uncooperative patient, and failure to fastidiously adhere to safe techniques. By far the greatest risk is inadequate training and experience (Tables 65–6 and 65–7).

Spread of local anesthesia to the central nervous system can cause life-threatening problems. Inadvertent intraarterial injection allows retrograde flow into the cerebral circulation, usually from the ophthalmic artery through anterior cerebral or carotid artery. As little as 2 mL can produce seizures that require symptomatic treatment. This condition usually is associated with longer retrobulbar needle injections within the muscle cone

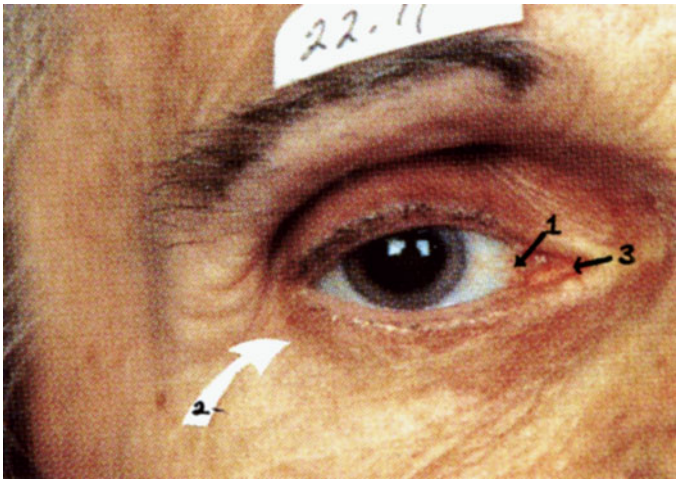

FIGURE 65–16. Right eye. *Arrow 1* indicates site of dissection for medial canthus episcleral (sub-Tenon) block. *Arrow 2* indicates entry point at lateral canthus on inferior orbital rim for inferotemporal peribulbar block. *Arrow 3* indicates entry point for medial canthus peribulbar block.

and failure to aspirate prior to injection. The second potentially life-threatening complication is inadvertent injection under the dural sheath of the optic nerve or directly through the optic foramen. Katsev et al.[37] indicated that this complication is possible in up to 11% of the population with orbital apices ≤ 40 mm. However, this complication has been reported following peribulbar anesthesia as well.[54] The result is subarachnoid spread of local anesthesia causing partial or complete brainstem anesthesia.[55] Onset usually is rapid but can occur as late as 20 minutes. Symptoms can progress through sympathetic activation, confusion, and restlessness to hypotension, bradycardia, total spinal anesthesia, and respiratory arrest. Oxygen, vasopressors, intubation, and ventilation all may be required until the anesthetic has worn off. The possibility of these complications dictates that resuscitation equipment and medications be available and that patients be fully monitored prior to block with blood pressure, ECG and pulse oximetry. This finding also serves as sufficient justification to observe appropriate nothing by mouth (NPO) guidelines.

Retrobulbar hemorrhage results from arterial injury. This may lead to a compressive hematoma sufficient to cause retinal ischemia. Intermittent manual compression should be instituted and the ophthalmologist consulted. Often a case need only be postponed but sometimes will require surgical decompression. Venous injury rarely results in a compressive hematoma.

Direct optic nerve injury secondary to needle trauma is rare but does occur, with resultant poor visual outcome, including blindness, from direct nerve injury or intraneural hematoma formation.

Unintentional globe perforation occurs with a variable frequency.[56,57] Often, the sedated patient experiences minimal pain or shows minimal reaction, necessitating a high degree of suspicion. The visual outcome depends on prompt consultation, location of injury, and presence of retinal detachment. Injection into the globe following a penetration leads to devastating injury to the eye. A risk factor for penetrating injuries is long axial length of the eye (>26 mm), but even more is the additional association of scleral thinning and posterior or inferior staphylomas common in severely myopic eyes (>26 mm).

Ocular and orbital muscle injuries are possible. Ptosis can be caused by surgical sutures on the lid speculum as well as disruption of the levator aponeurosis from trauma or stretching of the periorbital septum. Strabismus can be seen after injury to the rectus muscle by direct needle trauma, injection into the muscles, or toxicity from local anesthetics (less common with lidocaine <4% and use of hyaluronidase as an adjuvant to anesthetic dispersal).

Sub-Tenon block (via surgical technique) was developed to avoid complications from needle-based techniques; however, serious eye complications

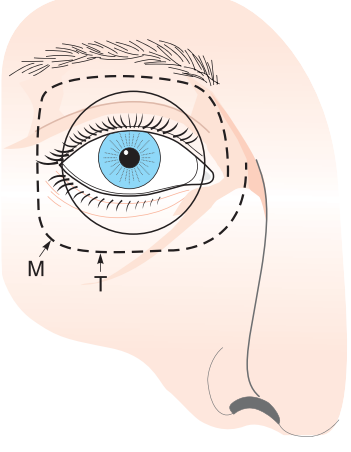

FIGURE 65–17. Traditional needle insertion site (T) for retrobulbar or peribulbar block at the junction of the medial and lateral third of the interior orbital rim. Recommended insertion site is at the modified (M) location, 4–5 mm inferior to the lateral canthus. The risk of injuring the inferior rectus, inferior oblique, and its nerve is lessened. FIGURE 65–20. A. "Normal" eye and axial length. **B.** Severely myopic eye, often associated with scleral thinning or staphylomas. Blocks intended to be intraconal rather than peribulbar have a higher incidence of global penetration, perforation, and global rupture from needle injury or intraocular injection. **C.** Representation of an eye with a prior scleral buckle, which is associated with the same complications as B.

have been reported.[58–61] Note that prior scleral buckling prevents posterior spread of anesthetic, prior retinal surgery may do the same secondary to scarring, sub-Tenon block may interfere with lifting of a flap in glaucoma surgery, and sub-Tenon block has not been evaluated in patients with coagulopathy.

Despite a very large study investigating anticoagulant and antiplatelet use in cataract surgery, no consensus exists regarding the dangers of hemorrhagic injury in the anticoagulated patient or the risk of thrombotic events in at-risk patients.[62] The incidence of events of any kind is very low. However, among patients whose eyes were actually examined within 24 hours of surgery, three times more hemorrhagic events than thrombotic events occurred in patients who continued taking aspirin < 14 days before operation and in those who continued warfarin (Coumadin) use < 4 days before operation. At the Massachusetts Eye and Ear Infirmary, the current protocol encourages discontinuation of warfarin 4 days before surgery and administration of an appropriate dose of fractionated heparin to patients 12 hours prior to surgical procedures. Our institution considers an international normalized ratio < 2.5 to be safe for needle-based blocks, although scant data in the literature support or refute this number. No information related to the newer antiplatelet medications is available.

SEDATION FOR NERVE BLOCKS

There are many reasons to sedate patients prior to performing needle-based regional anesthesia. Most basically, patients (especially the elderly) are extremely anxious about surgery on their eyes, particularly with regard to the needle under the eye. Second, the performance of these blocks can be moderately to very painful. Third, sedation and analgesia tend to keep the patient relaxed even after the block has been placed. Last, patient cooperation and immobility are important for the safe performance of a block. At the Massachusetts Eye and Ear Infirmary, a combination of midazolam and remifentanil appropriate for patient age and condition (0–2 mg midazolam and 0–90 mg remifentanil) is used. As is the case with other procedures, sedation is imprecise, so patients must be appropriately NPO and be fully monitored, and resuscitation equipment and drugs must be immediately available.

GENERAL ANESTHESIA

General anesthesia is used in approximately 35% of the ophthalmic surgery cases at our institution, the most common of which are lengthy retinal surgery and pediatric strabismus surgery. Indications for general anesthesia include the following:

- Inability of the patient to cooperate with monitored anesthesia care (MAC; e.g., children, adults with mental or psychologic deficits, tremor, inability to lie supine)
- Complete ocular akinesia desired by the surgeon
- Lengthy procedure (> 3–4 hours)
- Surgical field not amenable to regional, local, or topical anesthesia (e.g., large myopic globe, coagulopathy)
- Intrathecal or intravascular injection of local anesthetic
- Surgeon or patient preference

Controversy exists regarding the relative safety of general and regional anesthesia in ophthalmic surgery. Two techniques have shown no postoperative differences with regard to memory[63]: cognitive function[64] and oxygen satura-

TABLE 65–6.

Complications of Regional Blocks

Rare

Sight-Threatening	Life-Threatening
Corneal injury	Seizures
Myotoxicity/injury	Brain stem anesthesia
Direct nerve trauma	
Ocular penetration/perforation	
Detached retina	
Globe rupture	
Retrobulbar hemorrhage	
Peribulbar hemorrhage	
Retinal vascular occlusion	

TABLE 65–7.

Avoidance of Regional Complications

- Clear knowledge of orbital anatomy/individual variation
- Clear knowledge of ocular anatomy/individual variation
- Individual patient's ocular history e.g.,
  - Extreme myopia
  - Multiple eye surgeries
  - Presence of scleral buckle
- Training, supervision, practice under qualified instructor
- Fastidious technique every block
- Appropriate peri-block sedation
- Full basic monitoring
- Availability of emergency equipment and medication

tion.[65] The incidences of mortality and major complications are similar.[9] Regional anesthesia has been reported to be associated with fewer episodes of intraoperative oxygen desaturation, hemodynamic fluctuation, PONV,[9] and less initial postoperative pain.[66] Regional anesthesia for ophthalmic surgery also has been shown to be free of the hormonal stress response associated with general anesthesia.[67,68] With these considerations in mind, it seems prudent to avoid general anesthesia, if possible, in patients with severe cardiovascular or pulmonary disease, as well as those who are particularly prone to PONV.

The goals of general anesthesia for ophthalmic surgery include a smooth induction with a stable IOP, avoidance or treatment of severe OCRs, maintenance of a motionless field, a smooth emergence, and avoidance of PONV. These goals can be accomplished in a variety of ways, using inhalation anesthesia, IV agents, or a combined technique. Muscle relaxants are especially useful during intraocular microsurgery, when the slightest patient movement can be disastrous.

"Deep extubation" is a term used to describe the extubation of a patient before complete awakening has occurred. Other centers may define "deep extubation" somewhat differently. It is indicated in the presence of a compromised globe or intravitreal gas, or whenever an increase in IOP from tracheal stimulation must be avoided. Deep extubations are performed just after the patient has passed through stage 2 (classically described as "delirium") to stage 1 ("analgesia"). This stage of anesthesia is characterized by slow regular breathing with diaphragm and intercostal muscles, and the presence of a lid reflex. A patient extubated at this time experiences amnesia, analgesia, and sedation. Extubations at this point have minimal tracheal stimulation, but there is a small possibility of aspiration because airway reflexes have not completely returned. As such, patients with full stomachs (having recently ingested food or drink prior to surgery) or patients with a compromised airway are not good candidates for deep extubation.

ANESTHESIA FOR PEDIATRIC OPHTHALMOLOGY

Anesthesia for pediatric ophthalmology encompasses a diverse group of patients and procedures. It has been said that pediatric ophthalmic anesthesiology can be considered a separate subspecialty.[69] Patients range from newborns with medical problems associated with prematurity, to children with congenital syndromes, to healthy adolescents. The procedures performed on pediatric ophthalmic patients also are diverse. Many of the ophthalmic procedures performed in adults with MAC require general anesthesia in the pediatric population.

Measurement of IOP in the awake child is difficult because of their lack of cooperation and frequently requires general anesthesia (examination under anesthesia). IOP is affected by most anesthetic drugs and practices such as laryngoscopy and intubation. Therefore, most ophthalmologists prefer to measure IOP before a deep level of anesthesia has been reached and intubation has been performed. It is our practice to allow measurement of IOP soon after induction of anesthesia and before instrumentation of the airway has taken place. This is accomplished by positioning the mask and hand of the anesthesiologist so that the ophthalmologist has unobstructed access to the eye. Instillation of topical anesthetic drops into the eye may allow earlier IOP measurement than otherwise possible. If necessary, the mask can be removed to allow IOP measurement and then replaced. If further examination is required (e.g., ultrasound, gonioscopy), either the trachea is intubated or a laryngeal mask airway is inserted.

Measurement of IOP in the pediatric patient is performed to diagnose glaucoma or to follow the efficacy of therapy. Congenital glaucoma can be associated with several systemic syndromes (e.g., rubella, oculocerebrorenal [Lowe] syndrome). In addition, Sturge-Weber disease or congenital capillary hemangioma may affect the skin of the face, neck, mucous membranes, meninges, and choroid plexus. If the affected areas include the distribution of the fifth cranial nerve, glaucoma is commonly found. These patients also have seizure disorders. Children with Sturge-Weber disease come to the operating room for frequent examinations under anesthesia to follow the efficacy of surgical and medical interventions. Good rapport and appropriate use of premedicants allow a smooth induction of anesthesia and the most accurate measurement of IOP.

Strabismus surgery is the most common type of ophthalmic surgery performed in children. Numerous studies

have reported the incidence of PONV be >50%.[70,71] Many different anesthetic techniques and antiemetic regimens have been used in an attempt to decrease this high incidence of nausea and vomiting. Nothing found is absolutely preventative, and nothing has been found to be effective when children are at home and the incidence of PONV within 24–72 hours is high. Immediately perioperatively, Wachta et al.[70] showed that patients anesthetized solely with propofol following halothane induction had an incidence of emesis in the first 24 hours of 23%, compared to 50% in those who received halothane, nitrous oxide (N_2O), and droperidol. All patients in all groups received opioids for pain relief, a technique that undoubtedly contributed to the high incidence of PONV. At the Massachusetts Eye and Ear Infirmary, the standard practice with such high-risk groups is to change from inhalation anesthetic after induction to infusions of remifentanil and propofol and administration of serotonin ($5HT_3$) antagonists and dexamethasone (Decadron) in appropriate doses. Pain is minimized with nonopiate analgesics, most commonly ketorolac 0.2–0.5 mg/kg IV (not >30 mg and less in patients with compromised renal function). Remember that pediatric patients with congenital strabismus may have a tendency for malignant hyperthermia, which should be factored into anesthetic management.

The OCR is frequently elicited during strabismus surgery by traction on the extraocular muscles. The incidence of OCR appears to be higher in patients receiving propofol anesthesia compared with halothane anesthesia.[70]

Nasolacrimal duct probing for obstruction is another common procedure performed in pediatric ophthalmic patients. Successful relief of obstruction diminishes after the first year of life, so many of these patients are infants. Use of the laryngeal mask airway provides the surgeon with unobstructed access to the patient and protects the airway from the fluorescein dye that is injected into the nasolacrimal duct.

When an infant or young child presents with poor vision but normal ocular structures, electroretinography can help differentiate among retinal disorders. This procedure is generally performed in a completely dark laboratory and requires a period of approximately 20 minutes for the retina to dark adapt. General anesthesia or sedation is required because the child usually is not able to cooperate for the examination. Before beginning of the procedure, the anesthesiologist must become familiar with the location of the various pieces of equipment and power outlets and be completely satisfied with the setup.

Retinopathy of prematurity, previously called *retrolental fibroplasia,* usually occurs in premature infants. Although a disease of complex etiologies, it is believed to be primarily related to hyperoxic periods during neonatal intensive care. Nonetheless, full-term infants can have this condition, as can premature infants who have never received oxygen therapy. Following initial examination in the intensive care unit, the child may come to the operating room for multiple examinations under anesthesia and vitreoretinal procedures such as scleral buckling or vitrectomy. The care of the ex-premature infant is complex and must start with a thorough history and physical examination. Important historical data include gestational age at birth, birth weight, duration of intubation and ventilation, history of apneic episodes, and other congenital anomalies.[72] Hyaline membrane disease occurs in 60–80% of infants born at <28 weeks' gestation. Hyaline membrane disease may progress to the chronic pulmonary disease of prematurity called *bronchopulmonary dysplasia.* Although bronchopulmonary dysplasia improves with growth and development, these children should be considered at risk for increased airway reactivity.

If an inhalation induction is chosen, intravenous or inhalation anesthesia can be used for maintenance. Intravenous access is rapidly secured so that the amount of inhalational agent can be decreased and muscle relaxant administered. For retinal cases, paralysis is maintained throughout the procedure because a motionless field is critical. Conservative amounts of opioids, most commonly fentanyl, are administered. The very premature infant who required intubation and controlled ventilation after birth and who has recently been extubated may be difficult to extubate at the end of retinal surgery. Although extubation should be the goal at the conclusion of surgery, the endotracheal tube should be left in place if the child does not have a regular respiratory patter or is much less vigorous than preoperatively.

In 1982, anesthesiologists were first alerted to the occurrence of postoperative apnea in the ex-premature infant recovering from minor surgical procedures after general anesthesia.[73] Exactly when these infants are no longer at risk is not definitely known[74]; however, the incidence of apnea is known to be strongly related to gestational age and postconceptual age. Criterion for hospital admission for apnea monitoring after general anesthesia varies from institution to institution. A conservative range for admission is infants <50–54 weeks' postconceptual age.

Especially important in pediatric patients is calculating the amount of local anesthetic drug that is allowable to avoid toxicity. Also important is knowing whether these solutions contain epinephrine and the amount contained within. The dosages are calculated on a per kilogram basis and can be easily exceeded in the very small child. The recommended safe maximal dose of the commonly used local anesthetics in ophthalmology are as follows:

Lidocaine: 7 mg/kg

Bupivacaine: 3 mg/kg

In a patient anesthetized with halothane, 1.5 μg/kg epinephrine should not be exceeded; when isoflurane is used, up to 3 μg/kg is acceptable. These dosages of epinephrine are conservative and can be repeated after 10 minutes if no untoward effects are observed.

As noted earlier under Systemic Effects of Ophthalmic Drugs, drugs used in ophthalmology have systemic effects. Most of these drugs come in varying concentrations, and the least concentrated effective form should be used in small children to avoid toxicity. One drug used often in the operating room to produce mydriasis is phenylephrine hydrochloride. Only the 2.5% solution should be used in pediatric patients because excessive absorption can cause hypertension.

OPHTHALMIC PROCEDURES

Strabismus

Strabismus means ocular misalignment or deviation of one eye relative to the visual axis of the other. The etiology may be related to abnormalities in binocular vision or neuromuscular problems of ocular motility. A detailed nomenclature has evolved to describe the various patterns of stra-

bismus. The prefix "*eso-*" denotes deviation nasally, whereas "*exo-*" denotes temporal deviation. The suffix "*-phoria*" describes the tendency of one eye to turn outward, and "*-tropia*" describes inward deviation.

The surgical correction of strabismus is a repositioning of the extraocular muscles. To strengthen a muscle, a resection is performed. To weaken a muscle, a recession is performed. In severe cases, a resection may be performed on one muscle and a recession on the opposing muscle. Because visual maturation occurs by age 5 years, strabismus correction usually is attempted early in childhood. If left uncorrected, amblyopia, or a defect in central vision, occurs. Adjustable sutures are sometimes used to improve the chances of alignment with a single operation. The adjustment is performed in the immediate postoperative period, when the patient is fully awake and able to focus.

Pediatric patients undergoing strabismus surgery require general anesthesia. Some adult patients do well with a regional technique and intravenous sedation. Most patients prefer general anesthesia and have a particularly satisfactory result with propofol, remifentanil, $5HT_3$ antagonists, and/or dexamethasone, and nonopiates for pain.

Cornea

Penetrating Keratoplasty

Penetrating keratoplasty refers to surgical replacement of a portion of the cornea with donor tissue. Donor tissue that comes from the patient is called an *autograft*. Tissue that comes from another person is called an *allograft*. The indications for this procedure are many—corneal opacity, keratoconus, infection, and scarring are a few. Either regional or general anesthesia may be appropriate for this procedure. The importance of cough when the anterior chamber is open cannot be overemphasized.

Pterygium

A pterygium is a fold of conjunctiva and fibrovascular tissue that has invaded the superficial cornea. Excision is indicated when vision becomes impaired or the lesion causes irritation. Topical or injection anesthesia, with or without intravenous sedation, is satisfactory for removal.

Radial Keratotomy

Radical keratotomy is the surgical procedure used to correct myopia. Recall that the cornea contributes approximately 30% of the refractive element of vision. Under topical anesthesia, a series of incisions is made in the cornea in a spoke-like manner, causing positive diopter change in vision. The indications and rationale for radical keratotomy remain controversial. Typically, these procedures are performed with topical anesthesia only.

Cataracts

Cataracts are a common cause of visual impairment in older individuals. The pathogenesis of cataracts is multifactorial but basically results in opacity of the lens. Extracapsular cataract extraction (ECCE) is the preferred method of routine cataract extraction. The procedure is performed through a smaller incision and is less traumatic to the corneal endothelium. Removal of the lens with an intact posterior capsule provides for better positioning of an intraocular lens implant. Phacoemulsification is an ECCE technique performed through a 3- to 4-mm incision. The nucleus of the cataract is fragmented with an ultrasonic needle and then aspirated. Intracapsular cataract extraction (ICCE) is a technique that completely removes the lens with the capsule through a much larger incision. ICCE is performed in selected cases and in locations where sophisticated equipment is not available. Cataract extraction usually is performed with a retrobulbar or peribulbar injection and, if needed, a facial nerve block. Intravenous sedation and analgesia should be given for placement of the block. The procedure can be performed under topical anesthesia in selected patients.

Glaucoma

Glaucoma is a general term for a group of eye diseases characterized by increased IOP. Goniotomy is a procedure performed to treat infantile glaucoma. A superficial incision is made in the trabecular meshwork to improve outflow of aqueous humor from the anterior chamber. Infants and children require general anesthesia for this procedure. Trabeculectomy is the most commonly performed filtering procedure in adults. A block of limbal tissue is removed beneath a scleral flap, permitting outflow of aqueous. Antimetabolites, such at mitomycin, can be injected intraoperatively to help prevent surgical failures secondary to scarring. Many different tubes or shunts have been used to divert aqueous (e.g., Molteno valve). These implants are generally reserved for patients who have not responded to other management. Implants in current use have a plastic tube placed in the anterior chamber connected to a plate placed posterior to the limbus. Iridectomy usually is performed with an yttrium-aluminum-garnet (YAG) laser; however, an incisional iridectomy occasionally is required. Iridectomy is the definitive treatment for angle-closure glaucoma.

Anesthesia for glaucoma surgery in adults usually is performed with a retrobulbar or peribulbar injection and, if needed, a facial nerve block.

Vitreoretinal Surgery

Vitrectomy refers to surgical extraction of the contents of the vitreous chamber and their replacement with a physiologic solution. An anterior segment vitrectomy is performed for vitreous loss during cataract surgery and for late anterior segment vitreous complications. A posterior segment vitrectomy is indicated for removal of an intraocular foreign body, management of complicated retinal detachments with intraocular membranes, removal of media opacities, and alleviation of vitreous traction on the retina. Because the surgery may be prolonged and many patients have coexisting medical conditions (e.g., diabetes, renal disease, or cardiac disease), vitrectomy can offer difficult challenges to the anesthesiologist.

General anesthesia has been traditionally used for vitreoretinal surgery. However, using local anesthesia with MAC has become an attractive alternative. A retrobulbar or peribulbar block under MAC offers several advantages to the ophthalmologist.[75] Following retrobulbar block, the OCR usually is absent. The rapid recovery associated with MAC allows early prone positioning in the recovery room after posterior chamber gas injection. Patient comfort is increased because of less nausea and vomiting along with diminution of postoperative pain. Unfortunately, MAC is not suitable for long procedures. Procedures lasting longer than 3–4 hours exceed the tolerance of patients to lie supine and motionless. If necessary, a retrobulbar block can be supplemented during surgery with a sub-Tenon injection using a blunt, 19-gauge needle.

General anesthesia is appropriate for longer cases. It is a useful technique

when communication with the patient is difficult (e.g., those who are young, hard of hearing, infirm). General anesthesia has some disadvantages. An increase in IOP risks retinal repair, at induction and during extubation. The OCR is much more common during general anesthesia, frequently requiring anticholinergic treatment. Following general anesthesia, patients require more systemic postoperative analgesics and antiemetics. Somnolence, pain, and nausea may delay the proper positioning of patients postoperatively.

When general anesthesia is administered, use of long-acting retrobulbar blockade has significant advantages. Retrobulbar "irrigation" with 0.75% bupivacaine greatly reduces the need for parenteral analgesics within the first 24 hours after surgery.[76] In a prospective double-masked study of patients receiving general anesthesia with or without retrobulbar block with 0.5% bupivacaine, the group receiving the bupivacaine had significantly less pain and nausea postoperatively.[77] Alternatively, under direct vision, a blunt 19-gauge cannula can be used to directly inject the anesthetic agent into the retrobulbar space via a sub-Tenon approach. This technique minimizes the risk of scleral perforation.

It is important to recognize the danger of N_2O use when intravitreal gas is administered. To provide internal tamponade of the retina after reattachment, an intravitreal gas bubble [e.g., air, sulfur hexafluoride (SF_6), or Octafluoropropane (C_3F_8)] replaces some of the vitreous. N_2O is a very insoluble gas in blood but is 117 times more soluble than SF_6. N_2O enters the intraocular gas bubble more rapidly than SF_6 can exit. If N_2O administration continues after injection of SF_6 gas into the vitreal cavity, the injected gas bubble can expand up to three times its original volume. Similar effects can be seen when C_3F_8 is used. Within 19 minutes after placement in a closed eye, IOP will increase by 14–30 mm Hg. If N_2O is then discontinued, the bubble size will decrease by half within 18 minutes. The resulting decrease in IOP can lead to redetachment of the retina. Washout of N_2O from the lungs is 90% complete within 10 minutes, but to provide a margin of safety, N_2O should be discontinued at least 20 minutes *before* intravitreal injection of gas. It is important that patients returning for surgery within 3–4 weeks caution anesthesiologists that they have received an intravitreal gas injection. A similar hazard exists with air transport of patients. Because the aircraft cabin is pressurized to an altitude of approximately 2000 m above sea level, the gas bubble will expand, resulting in elevated IOP. Therefore, patients should avoid air travel for 3–4 weeks after infection of intravitreal gas.[78]

Oculoplastic Surgery

All of the following oculoplastic procedures can be performed with regional anesthesia on adult patients.

Ectropion Repair

An ectropion results from excess, loose eyelid tissue or scarring that causes the margin of the lid to turn outward, away from the globe (eversion). Repair consists of excising excess tissue and tightening the remaining lid, or release of the related scar tissue.

Entropion Repair

An entropion usually is caused by senile or involutional changes, primarily in the lower eyelids, which result in weakening of the lid retractor muscles and horizontal laxity. The lid margin is turned inward toward the globe (inversion). The goal of surgical repair is to increase the tension of the retractor muscles (e.g., by reattaching them) and tighten any horizontal laxity.

Ptosis Repair

Ptosis is a congenital or acquired drooping of the eyelid. Most often it is repaired by shortening or reattaching the levator palpebrae aponeurosis. In cases where levator function is inadequate, the upper lid can be suspended from the frontalis by a sling of fascia lata.

Blepharoplasty

Blepharoplasty is any plastic surgery of the eyelids, usually to remove redundant tissue. The procedure is performed to remove visual field obstruction and for cosmesis.

Dacryocystorhinostomy

Dacryocystorhinostomy is the creation of a communication between the lacrimal sac and the nasal cavity to allow for tear drainage. A Jones tube is sometimes used to bypass the canaliculi and form a conjunctivorhinostomy. Nasolacrimal duct probing is performed in children with congenital nasolacrimal duct obstruction. The duct is probed with a wire, then dye is injected into the duct and aspirated from the nasal cavity to test the patency of the duct. Silicon tubes can be inserted to act as stents.

Orbital Surgery

Most orbital surgery requires general anesthesia unless the procedure is limited to the anterior orbit and does not involve the bones of the orbit.

Orbitotomy

An orbitotomy is performed to gain surgical access to the orbit. Approaches include transconjunctival, transseptal, and transperiosteal. Indications for orbitotomy include tumor, abscess, foreign body, and orbital fractures.

Orbital Decompression

Orbital decompression is indicated for correction of exophthalmos resulting from Graves disease. Access to the orbit is obtained by either a transconjunctival or transperiosteal approach. Some surgeons use a coronal incision with reflection of the scalp anteriorly to the level of the orbit. Cases can be length (4+ hours), and blood loss can be large enough to require transfusion.

Open Globe, Full Stomach

Open globe, full stomach is a topic of interest primarily because of the theoretical problems with succinylcholine and its effects on IOP, its contractile effects on the extraocular muscles, and its fasciculatory effects on the other skeletal muscles. The fear is harm to the eye from extrusion of intraocular contents. Vachon et al.[79] reviewed the controversies surrounding this issue and the lack of actual evidence linking succinylcholine to extrusion of eye contents, and retrospective case reports support many of his contentions.[80,81] Does succinylcholine cause an increase in IOP? Yes, by 6–12 mm Hg for up to 10 minutes.[8–11] In the intact eye, the increase is caused directly by contraction of the extraocular muscles, fasciculations of the orbicularis oculi, venous congestion within the eye from abdominal muscle fasciculations affecting venous return, as well as changes in intraocular blood flow stemming from increases secondary to the hemodynamic effects of succinylcholine. These effects may be mitigated by a well-designed anesthetic induction. First, most anesthetic agents (except ketamine) reduce IOP and thus lessen the response to succinylcholine.

Second, the well-anesthetized patient has blunted hemodynamic responses to laryngoscopy, mitigating any rise in IOP. Finally, by pretreatment with a nondepolarizing relaxant, contraction and fasciculations can be abolished. However, when nondepolarizing agents are used in this manner, the anesthesia provider must administer a sufficient dose of succinylcholine to achieve flaccid paralysis (1.5 mg/kg) and wait a sufficient time period (90 seconds) to ensure equal quality muscle relaxation and good intubating conditions without coughing or bucking (which can raise IOP by 30–40 mm Hg). In this regard, Libonati et al.[80] and Donlon[81] are most instructive. In instances where succinylcholine is contraindicated, nondepolarizing relaxants can be used in higher doses to provide good intubating conditions. Anesthetists should be aware of the hemodynamic consequences of large doses of mivacurium and atracurium given rapidly, as well as the need for monitoring of neuromuscular function and adequate reversal before extubation.

Remember that not all open globes are equal. Injuries can range from very minor injuries to eyes that are unsalvageable. Discussion with the consultant surgeon is important in this regard, especially when dealing with a salvageable eye or a known or suspected difficult intubation. Not all bad outcomes are related to surgery and anesthesia. Vomiting, coughing, crying, rubbing the eye, and squinting all can result in further damage prior to anesthesia and surgical treatment.

The goals of anesthesia in these patients can be summarized as follows.

- Provide adequate preoperative anxiolysis, if safe to perform in the patient, to help prevent rubbing and squeezing the eye.
- Avoid excessive narcotic dosing so as to prevent hypercarbia-induced increases in IOP.
- Prevent coughing during induction and emergence.
- Avoid direct pressure on the eye from the mask or fingers.
- Ensure adequate depth of anesthesia and muscle relaxation prior to laryngoscopy and intubation.
- Ensure lack of movement and coughing during the procedure using neuromuscular blockade as necessary.
- Maintain appropriate hemodynamics to prevent choroidal hemorrhage.
- Extubate awake (for full-stomach patient) while minimizing coughing and bucking by judicious use of adjuvant medications such as lidocaine and remifentanil.

CHAPTER 66

Anesthesia for Otorhinolaryngolic (Ear, Nose, and Throat) Surgery

Bil Ragan, MD

Surgical procedures for otorhinolaryngology will challenge the creativity and skills of the finest anesthesiologist. On a routine basis, the anesthesiologist will provide mask anesthetics, spontaneous or jet ventilation, controlled hypotension, and extubations during deep levels of anesthesia. Most of these cases will be performed with little or no muscle relaxation. Moreover, in the contemporary surgical environment, the majority of these cases will be performed in an outpatient setting. This presents its own challenges in the areas of analgesia and the prevention of postoperative nausea and vomiting (PONV). The patient population will vary from neonates to the elderly, with a significant number of pediatric cases.

As a unique feature of this subspecialty, the anesthesiologist will work with a physician colleague who has an understanding and appreciation of the airway. This is unlike most other surgical experience. The complicated nature of these procedures demands nothing less than complete cooperation between these two specialties. Frequently the airway will be shared, and not uncommonly one practitioner will assist the other in times of difficulty. When a compromised airway is involved, any pretensions of ego are best removed from the setting.

For purposes of clarity and ease of use, this chapter is organized by anatomic regions. When anesthesia is being provided for a particular procedure, the performance of an additional, different procedure at the same time is unlikely. Furthermore, from an anesthesia point of view, the concerns for a particular anatomic region differ from those for other regions and should be discussed separately. Finally, recall that the first anesthetic was provided for removal of a neck tumor from patient James Venable. Therefore, it is only fitting that all subsequent anesthetic techniques have descended from the care of an ear, nose, and throat (ENT) patient.

ANESTHESIA FOR EAR SURGERY

As in other subspecialties, a broad range of interventional surgical techniques can be performed for the patient's benefit. For these procedures, patient positioning, facial nerve preservation, hemostasis, smooth emergence, prevention of PONV, and use of nitrous oxide (N_2O) become primary concerns for the anesthesiologist.

Ear Canal and Tympanic Membrane Disorders

Disorders of the ear canal and tympanic membrane all involve processes that interfere with the reception and transmission of sound from an external source to the middle ear. These cases are routinely performed under general anesthesia, but some patients can tolerate local anesthesia with sedation. After induction of anesthesia and with the airway secured, the patient's head is turned and fixed with the operative ear up. These cases are not necessarily lengthy. Some practitioners use a laryngeal mask airway (LMA), but most prefer endotracheal intubation. With canalplasties, use of N_2O is permitted but not encouraged. However, with tympanoplasties, use of N_2O is best avoided in order to prevent expansion and dislocation of the surgical graft.

Conductive Hearing Loss

These are disorders of the middle ear, with resulting decline in hearing due to compromised sound conduction. Commonly they are caused by either infectious or inflammatory processes.

KEY POINTS

1. Successful middle ear surgery depends upon: controlled hypotension to minimize blood loss and maintain a clear surgical field, use of short-acting muscle relaxants to promote facial nerve monitoring, avoidance of nitrous oxide to prevent graft disruption, and smooth extubations to prevent prosthesis displacement.
2. Middle ear surgery can result in profound postoperative nausea and vomiting, which require an aggressive, multimodal, pharmacologic approach for prevention and treatment.
3. Complications of sinus surgery include hemorrhage, eye injury, vision loss, venous air embolism, cerebrospinal fluid leak, permanent neurologic injury, and death.
4. Pediatric patients with obstructive sleep apnea syndrome may present with altered right ventricular diastolic function, pulmonary hypertension, arrhythmias, and silent carditis.
5. Posttonsillectomy hemorrhage is a surgical emergency. Patients may be profoundly hypovolemic and tachycardic before the complication is recognized, and anesthetic care includes both fluid resuscitation and meticulous airway management.
6. Careful preoperative planning will prevent the conversion of a partial airway obstruction into a complete airway obstruction when managing foreign body aspiration.
7. After radiation therapy to the head and neck, tissues become fixed, firm, and fibrotic. Despite a normal appearance, direct laryngoscopy may be extraordinarily difficult, if not impossible. Fiberoptic laryngoscopy is often the preferred approach for tracheal intubation.
8. Lasers can produce thermal injury, cause photochemical reactions, have mechanical effects, and release toxins including viable microorganisms. Most laser injuries result from reflected beams, with the eye being the most vulnerable organ.
9. No laser tube is perfect, and airway fires can occur under any condition. Precautions can reduce the risk of a surgical fire but cannot eliminate the risk.
10. Use of a Nerve Integrity Monitor (NIM®) endotracheal tube can greatly reduce the risk of recurrent laryngeal nerve injury during thyroid and parathyroid surgery.

Myringotomy is among the most frequently performed pediatric surgeries. In the hands of an experienced surgeon, bilateral myringotomies can be completed in as few as 3 minutes. Because of this, both induction and maintenance usually are performed with mask anesthesia using either halothane or sevoflurane. Postoperative discomfort can be addressed by acetaminophen given as a 40 mg/kg dose.[1,2] Recently the use of intranasal fentanyl has been advocated. Studies by Finkel et al.[3] and Galinkin et al.[4] both demonstrated a reduction in postoperative agitation when using fentanyl at a dose of 2 μg/kg. In certain patients, chronic otitis media can result in temporomandibular joint ankylosis,[5] which can make laryngoscopy difficult, if not impossible. Although instrumentation of the airway is not expected with this procedure, it is prudent to be aware of this possibility and to evaluate accordingly.

Stapedectomy is the removal or freeing of the stapes superstructure and replacement with a prosthesis. In most cases, this condition is caused by otosclerosis. Typically this procedure is performed under general anesthesia, although local anesthesia with sedation can be done. Lasers are frequently used to free the stapes, and appropriate precautions must be taken (see Lasers below). These cases usually last between 1 and 2 hours, and facial nerve monitoring may be performed. Hence, a short-acting muscle relaxant, if any, should be used. Ho et al.[6] found that facial twitch was quite vigorous when the ulnar nerve train of four began to return, suggesting that the surgeon should be able to identify the facial nerve by electrical stimulation even in the presence of some neuromuscular relaxation. Despite this, most practitioners limit the use of longer-acting relaxants to assure that neuromuscular blockade does not contribute to potential surgical complications.

Another goal is to reduce bleeding during this procedure. This is accomplished by injecting a mixed local anesthetic and epinephrine solution, by elevating the patient's head to improve venous drainage, and often by applying deliberate hypotension. A study by Marchal et al.[7] addressing these concerns found that preoperative clonidine reduced blood loss, blunted the response to intubation, and reduced isoflurane and fentanyl requirements. In similar studies by Degoute et al.[8] and Dal et al.,[9] the combination of remifentanil with a volatile agent provided mild hypotension and reduced blood loss.

While the surgeon is placing the prosthesis, it is absolutely essential that the patient be motionless. This requires a deeper plane of anesthesia using volatile anesthetics alone or in combination with a remifentanil infusion. Although N_2O can be used for earlier portions of the procedure, it should be avoided in the last portion to prevent tympanic membrane graft disruption and possible nausea and vomiting. Extubation must be smooth, without any bucking or violent motions, thus preventing displacement of the prosthesis. The success of the procedure may depend upon these details. It is best to have the patient breathing spontaneously and extubated during a deep plane of anesthesia.

The anesthesia concerns for ossiculoplasty are similar to those for stapedectomy. However, this procedure may last longer because these patients typically have long-standing disease that requires a lengthy dissection.

Looking to the future, it has been suggested that total intravenous anesthesia (TIVA) may allow better control and smoother emergence for these procedures. The results in a comparison trial by Mukherjee et al.[10] are promising. This investigation found that TIVA (i.e., by propofol and remifentanil infusions) provided better conditions for surgery and significantly less PONV in the early postoperative interval. However, patients who received TIVA had higher pain scores during recovery. Those who received balanced anesthesia had been given fentanyl and experienced less discomfort.

Nitrous Oxide Concerns

Nitrous oxide has been used as an anesthetic in millions of patients for more than 150 years. As with any drug, it has both beneficial and detrimental qualities. There are serious concerns with the use of N_2O in middle ear surgery.

The healthy middle ear contains airspaces that are intermittently ventilated and thus decompressed via the eustachian tube. If disease or trauma interferes with this venting, middle ear pressure can rise rapidly. When N_2O is used in any concentration, it can enter these airspaces much faster than nitrogen can exit. Likewise, once N_2O is discontinued, rapid absorption can result in profound negative pressure within the middle ear. Both of these processes reflect the 34-fold difference between the blood/gas partition coefficients of N_2O and nitrogen.[11]

These sudden changes in middle ear pressure can result in impaired middle ear function, with a decline in hearing, tympanic membrane rupture, graft disruption, or nausea and vomiting. Patients who are especially susceptible include those with concurrent upper airway infections, enlarged adenoids, otitis media, and a history of otologic surgery. For these reasons, N_2O should be used judiciously during middle ear surgery. If used at all, concentrations should be $<50\%$. It should be discontinued a minimum of 20 minutes before expected closure of the middle ear. It is helpful if the surgeon flushes the ear with air before closing the surgical incision. Given all of these factors, prudent practice implies that N_2O should be used only with considerable caution and for clear indications that cannot be met with other approaches.

Sensorineural Hearing Loss Disorders

Cochlear Implant

Patients who are profoundly deaf may have sufficient spiral ganglion cells for stimulation and thus possible recovery of hearing. With advances in electrode and processing technology, placement of cochlear implants has become a common procedure. These are lengthy cases that last anywhere from 4–6 hours. The surgeon will need to perform a mastoidotomy in order to place the signal coupler. Surgeons prefer the use of controlled hypotension, if appropriate and tolerated by the patient, to minimize blood loss. N_2O is not contraindicated from the surgical perspective but should be avoided to decrease PONV. Placement of electrodes must be precise, and a smooth, motionless extubation is expected. Any untoward movement can compromise the entire procedure.

Perilymphatic Fistula and PONV

Perilymph leakage has been implicated in sudden hearing loss, tinnitus, aural fullness, and both episodic and positional vertigo. Surgical treatment usually involves an exploratory tympanotomy, which is performed under

general anesthesia with endotracheal intubation.

These patients may have profound PONV. The approaches to prevention and treatment of PONV are considered in detail in Chapters 67 and 72. The association between middle ear surgery and this undesired complication should be prominent in the planning and management of anesthesia. In addition to avoiding N_2O use, limiting opioids, and administering aggressive hydration, prevention will require a multimodal pharmacologic approach,[12] including preoperative use of metoclopramide and postinduction gastric suctioning. For these and other reasons, our preferred anesthesia technique includes a volatile agent, oxygen, and air supplemented with a propofol infusion.

Mastoid Disorders and Other Ear Disorders

The introduction of antibiotics has greatly reduced the incidence of mastoiditis. However, it remains a disease with significant morbidity and even mortality. Untreated chronic otitis media remains the most common cause. Failed antibiotic response requires surgical intervention.

These procedures are performed under general anesthesia with endotracheal intubation. The surgeon's goal is to reestablish ventilation of the middle ear, debride infected material, and drain subperiosteal abscesses. Removal of osteitic bone can result in substantial blood loss. Controlled hypotension is helpful for the majority of the procedure. Facial nerve exposure is a possibility, and frequently the surgeon will seek to identify the nerve using a nerve stimulator. Short-acting muscle relaxants should be used. The return of neuromuscular responses should be documented and reported to the surgeon prior to attempted identification of the facial nerve and subsequent aggressive dissection.

Depending upon the clinical presentation, a mastoidectomy may last anywhere from 3–6 hours. Nitrous oxide is permitted but must be removed at least 20 minutes before tympanoplasty begins. Postoperatively these patients will have a large head dressing that takes 5–10 minutes to place. As with other anesthetics, if the patient is lightly anesthetized, this head movement can result in significant bucking and bleeding, which contribute to postoperative complications. Therefore, deeper planes of anesthesia should be maintained until these dressings are in place, even at the cost of a prolonged emergence.

Effort has been made to determine whether these cases can be performed as outpatient procedures. A study by Rowlands et al.[13] determined that the need for inpatient admission was significantly related to the extent of surgery. However, comparing outpatient complications and overall success, no significant differences were found between outpatient versus inpatient management. It is suggested that mastoidectomies can be done safely as outpatient procedures in selected patients. In a study by Suresh et al.,[14] regional block of the greater auricular nerve was investigated for postoperative pain relief. The initial study suggested benefit but a subsequent study was inconclusive, leaving the matter unresolved.

Patulous Eustachian Tube

Classically, a patulous eustachian tube will result in autophony ("rushing air" sound) that disappears in the supine position. Occasionally this experience is disturbing enough for the patient to seek surgical intervention. This is a rarely performed and challenging procedure for any otologist. With the patient in a supine position, this correction is accomplished by an intraoral approach. All the concerns and precautions of oral surgery (discussed later under Throat Surgery) apply to this technique.

Microtia

Auricular malformations, either congenital or acquired, can be severe. A normal-appearing ear is important to all patients young and old. The Centers for Disease Control and Prevention estimates the incidence of microtia to be 1:10,000. Although it may occur as an isolated finding, microtia can occur with a variety of syndromes, including Goldenhar and Treacher Collins. A study by Uezono et al.[15] noted that 42% of patients with bilateral microtia were likely to pose significant intubation challenges (i.e., probable "difficult intubation"). Any associated dysmorphic features should prompt a thorough evaluation of the patient prior to reconstruction.

Depending upon its extent, microtia usually is managed as a multistage repair. Initially a rib graft is obtained and carved to resemble a matching template. This is then placed subcutaneously and allowed to heal. The patient then returns for additional skin grafts and refinement to the superior auricle. General anesthesia is necessary, and postoperative pain relief frequently requires patient-controlled analgesia after rib harvest. Typically the surgeon infiltrates the donor site with local anesthetic, but it will remain a source of significant discomfort in the postoperative period.

Reconstruction in adults usually follows traumatic injury or excision of neoplastic disease; thus, the airway concerns associated with congenital microtia usually are not present. Depending upon the presentation and the patient, this operation can be accomplished with either general anesthesia or local anesthesia with sedation.

Temporal Bone Disorders

Within the temporal bone lies the facial nerve. Of the cranial motor nerves, it has the longest intraosseous course and is threatened by any disruption of the temporal bone. Tumors are relatively rare but can result in significant morbidity upon resection. Blunt trauma with fractures is far more common. Approximately 80% are longitudinal fractures caused by a blow to the front or side of the head. A blow to the occiput results in a transverse fracture, accounting for another 15%. The remaining types consist of complex or combination fractures. Prior to operation, the patient must be fully evaluated for any other injuries, such as cervical instability, other fractures, and cerebrospinal fluid (CSF) leaks. Besides hemostasis, the major postoperative concern with these procedures is persistent CSF leak with infection. Not uncommonly, neurosurgeons are involved with the repair.

ANESTHESIA FOR NOSE SURGERY

Procedures described in this section include those of the nose and sinuses. These structures are important components of the airway, and disorders can have a significant impact upon a patient's well-being. Nasal and sinus surgery is conducted with the airway secured by endotracheal intubation and general anesthesia. Recently, use of LMAs has become more common, but potential pulmonary aspiration remains a concern. If the patient is

debilitated and at increased risk for complications with general anesthesia, these procedures can be performed under local anesthesia with sedation.

External and Internal Nasal Deformity

Rhinoplasty is reconstruction of the external nose. Indications include trauma, neoplastic excision, deformity, and/or perceived malformation. Typically these patients are young and healthy. Following induction of anesthesia and intubation, the surgeon requests that the endotracheal tube be secured to the mandible in the midline position. This neutral position will prevent any soft-tissue distortion of the nose and allow the surgeon a more accurate reconstruction. Lubricant ("artificial tears") will be placed in the eyes, or the eyes will be taped at the lateral margins. This will minimize the risk of corneal abrasion and provide access to the bridge of the nose. Slight elevation of the head is common to provide better access and to promote venous drainage.

Despite the use of local anesthetics with vasoconstrictors, bleeding can be brisk. Suction of the gastric and oral cavities prior to emergence and extubation will decrease the likelihood of PONV. Swallowed blood on an empty stomach is a well-known emetic. From an analgesia point of view, this procedure is relatively benign, with one exception. Toward the latter part of the ,procedure the surgeon will do an osteotomy, which depends upon the patient's specific anatomy and what the surgeon wishes to accomplish. If the patient's anesthetic depth is inadequate, patient movement or bucking may occur, both of which are undesirable.

At the end of the procedure, nasal packs or stents are placed, and a small plastic or fiberglass cast is fitted. Nasal stents are preferred because they allow ventilation through the nasal passages postoperatively. Care must be taken not to press upon the nasal bridge with the face mask. Gently place the mask on the mandible with the superior portion free. The seal will not be good, but when combined with a jaw thrust sufficient gas exchange should occur. As an alternative, Erbay et al.[16] reported the beneficial use of a pediatric mask as a mouth mask in this scenario.

Rarely, neoplastic lesions require wide excision involving the entire nose and possibly underlying structures. These patients will subsequently present for total reconstruction. Each patient's airway must be fully examined. Depending upon their initial disease, the majority of patients will have patent posterior nasal passages. Other patients may present after partial reconstruction and have a completely obstructed nasal airway, or a maxillary prosthesis may obstruct the nasal passages. It is wise to discuss these cases well in advance with the surgeon to understand the surgical plan and the patient's pathology. The anesthetic arrangements and concerns are as previously described. Reconstructions usually involve a forehead flap and are performed as multistage repairs.

Septoplasty is a functional procedure intended to correct a deviated septum. This condition may have occurred due to trauma, deformity, or malformation. A malpositioned septum can lead to complete airway obstruction on the affected side. It also can lead to poor sinus drainage and result in chronic sinusitis. The anesthesia arrangements and concerns are the same for a septoplasty, open nasal fracture reduction, and rhinoplasty. These usually are brief cases lasting anywhere from 30 minutes to 1 hour.

Finally we must consider closed reduction of a nasal fracture. This is a very brief procedure that requires the surgeon to place his or her instrument against the fracture and apply vigorous pressure to realign structures. The definitive procedure literally takes seconds. To the awake patient, those seconds can be frightening and quite painful. An intense but brief general anesthetic usually is preferred. I prefer to have the patient in a semisitting position and premedicated with midazolam and fentanyl. Once the surgeon is in position with instrument ready, a single bolus of lidocaine and propofol is administered. Upon loss of consciousness, the reduction is accomplished. Typically emergence occurs as the cast is being fitted. This technique works very well as long as blood loss is minimal. If the reduction is expected to be more complicated or if blood loss is a concern, then the airway should be protected by LMA or preferably an endotracheal tube.

Choanal Atresia

This is an uncommon anomaly that occurs in approximately 1:5000–8000 births. Unilateral obstruction is more likely on the right and is twice as common as bilateral obstruction. Moreover, this condition is more frequent in female neonates. Other congenital anomalies are present in 20–50% of patients.

Bilateral choanal atresia classically presents as a newborn who experiences complete airway obstruction that is relieved by crying. Gujrathi et al.[17] have written a series review of the surgical techniques involved in these repairs. Recently an endoscopic approach has been promoted, but the "puncture, dilation, and stent" technique remains the standard. Specific to this repair, the anesthesiologist must be vigilant that the stents are secured postoperatively. If one or both become dislodged, complete airway obstruction can occur as with any other foreign body (FB). These stents will remain in the patient for several weeks.

Lim et al.[18] described a case of unilateral atresia repair complicated by a persistent buccopharyngeal membrane. One should remain wary for other sources of airway obstruction. These patients may return to the operating room multiple times for stent cleaning and granuloma debridement.

Sinus Disorders

Contemporary sinus surgery is performed almost entirely by fiberoptic endoscopy [fiberoptic endoscopic sinus surgery (FESS)]. An exception is open maxillary sinusotomy (Caldwell-Luc procedure). Indications for surgery include persistent sinusitis, recurrent nasal polyps, obstructed nasal ventilation, and CSF leak.

The anesthetic approach is similar to that used with other nasal procedures, except that the surgeon may desire the endotracheal tube to be secured on the left margin of the oral cavity. It is common for the surgeon to stand (or sit) on the patient's right with the patient's head turned slightly toward the operator. The surgeon also will request that the patient's eyes be lubricated and left open or taped on the lateral borders. The operator will want to observe the patient's eyes throughout the procedure, because some situations require activity in close proximity to the orbit. Any change in the eyes' appearance requires an extensive investigation before progressing further. Unfortunately, intraorbital eye injury has occurred in these cases, including vision loss secondary to intraorbital hematomas, eye muscle injury, and proptosis. Other complications include

venous air embolism, CSF leak, excessive bleeding, and permanent neurologic injury. Superficially, FESS appears to be a benign procedure, but the complications can be devastating. The advent of image-guided endoscopy (e.g., StealthStation®, Medtronic, Inc., Minneapolis, MN) has reduced some of the risks.

This is another procedure where controlled hypotension may be helpful. The sinuses are well vascularized, and blood loss of 300–500 mL is not uncommon in a routine case. If the patient has a bleeding disorder or is severely anemic, then transfusion of blood products may be warranted.

Surgeons will attempt to minimize bleeding by using local vasoconstriction, but such approaches are not without consequences. A study by Yang et al.[19] noted that low-dose epinephrine and lidocaine solutions caused brief but marked decreases in blood pressure. Often the vasoconstrictor is in the form of 4% topical cocaine. Cocaine is rapidly absorbed from the mucous membranes, and brief tachycardia and hypertension may occur. The effects of cocaine and other ester-linked local anesthetics can be prolonged in a patient who has pseudocholinesterase deficiency or one using pseudocholinesterase inhibitors (i.e., echothiophate). Systemic toxicity can result in seizures, coronary vasospasm, myocardial ischemia, and arrhythmias. Aggressive treatment with short-acting mixed α-/β-blockers, oxygen, and deeper anesthesia may become necessary.

At the end of the case, the surgeon will desire a smooth extubation with minimal movement or bucking of the patient. This can be a challenge when the oral cavity is filled with secretions and blood. A deep extubation can be performed, but this will place the patient at risk for laryngospasm as the anesthesia lightens. Deep extubations can be achieved with confidence if complete hemostasis has been obtained and if oral and gastric suctioning have been extensive. Stents or packing may be placed, and the mouth remains the most reliable airway.

In addition to PONV, analgesia must be addressed. FESS procedures are not known for being particularly painful. Local anesthetic will have used, and minimal amounts of narcotics can be added. Other analgesics also have been used. Turan achieved good results with a cyclooxygenase (COX)-2 inhibitor that is no longer available. Perhaps new studies with celecoxib will demonstrate similar success. In a later study, Turan et al.[20] found gabapentin to be useful for postoperative pain control, but patient dizziness was a limiting side effect.

Frontal Sinus Obliteration

Frontal sinus obliteration is a procedure for patients who have frontal sinusitis not responsive to other therapies. An internal approach can be used, or the scalp can be lowered and a bone flap raised over the frontal sinus. Following complete and meticulous debridement of the sinuses, they are packed or obliterated with donor adipose tissue harvested from the abdomen. Typically blood loss is not as severe as with a FESS procedure. Other concerns and anesthetic approaches are similar to those described for sinus disorders.

Cerebrospinal Fluid Leak

For various reasons, including trauma, neoplastic disease, and prior surgery, a patient may present with a persistent sinus CSF leak. A successful repair requires locating the precise source of the drainage. While in the preoperative holding area, the patient is prepped and draped for subarachnoid access. After a spinal needle is placed successfully, 0.5 mL of a 10% fluorescein dye is diluted with 9.5 mL of CSF and injected slowly. The patient then proceeds to the operating room and undergoes induction of general anesthesia. The fluorescein dye is expected to emerge in the sinuses approximately 20 minutes after injection, thus indicating the source of the leak. Other anesthetic considerations are similar to those for sinus disorders.

ANESTHESIA FOR THROAT SURGERY

The words "shared airway" evoke a subtle anxiety in the most experienced anesthesiologist. As a specialty we are known for our skills to secure, maintain, and control the airway. Any activity that threatens a secure airway is a source of concern, if not annoyance. All aspects of throat surgery involve sharing the airway with another airway expert. Like any relationship, it requires communication, understanding, and trust.

Abnormal Airway Disorders

Surgery to correct the abnormal airway will exercise all of the anesthesiologist's skills. Myriad disorders affect the airway, and patients can be of any age and present under any circumstances. The potential combinations of patient and airway are too numerous to allow detailed consideration of each possible scenario. This overview focuses on the most common disorders associated directly with supraglottic, glottic and subglottic structures.

As a conceptual approach, consider that the abnormal airway is any airway compromised by an acquired disorder, such as an infection, mass lesion, foreign body, and therapy (radiation), or by an anatomic disorder, such as congenital malformations, the malacias, and stenoses. These definitions are not strict, as it is apparent that some lesions share features of both disorders. They are characterized in this manner only for ease of understanding. Yellon[21] has summarized an excellent approach to management of the pediatric patient with an abnormal airway. The guiding principles include a thorough preoperative evaluation of the patient and careful planning between surgical and anesthesia teams. Physical examination may include endoscopy, laryngoscopy, and bronchoscopy to identify both dynamic and fixed lesions prior to performing any definitive surgical procedure. Safe, successful surgical and anesthetic outcomes depend upon these efforts. Many of the same considerations apply to the adult patient as well.

Acquired Airway Disorders

Infections

Epiglottitis is an acute bacterial infection that untreated can become a life-threatening disease. Most commonly it affects pediatric patients in the 2 to 7 year age range. *Haemophilus influenza* (type B) usually is the causative organism. With the use of *H. influenza* vaccine in children, epiglottitis is becoming a disease of adults. Age not withstanding, epiglottitis is a serious condition that must be treated aggressively.

In the classic presentation, the patient arrives with an abrupt high fever, sore throat, stridor, dysphagia, and drooling. Physical examination reveals an anxious, pale patient sitting in the sniffing position. Epiglottitis can be distinguished from croup by the lack of a spontaneous cough. A lateral neck

film will show a thickened, flat epiglottis akin to a "thumbprint." Supraglottitis is a newer term suggested for this condition as the inflammation involves all supraglottic structures.

Adult patients are admitted and treated conservatively. Rarely do they require intubation. In the pediatric population, total airway obstruction can occur at any time. These patients cannot be left unattended until the airway is secured. Once in a controlled setting with an ENT surgeon and anesthesiologist present, an inhalational induction is done in the sitting position. Muscle relaxation is to be avoided. Laryngoscopy confirms the diagnosis, and endotracheal intubation immediately follows. It is suggested that the endotracheal tube be 0.5–1 size smaller than usual. If the airway obstructs and intubation becomes impossible, rigid bronchoscopy or tracheotomy must be performed immediately. Epiglottitis usually responds to cephalosporin therapy after several days.

Croup is a benign disease typically affecting pediatric patients in the 3-month to 3-year age range. It follows 2–3 days after a respiratory tract infection (RTI), and parainfluenza virus is the most common cause. The subglottic structures are involved, and the patient will present with stridor, dyspnea, and the classic "barking cough." Croup can be distinguished from epiglottitis on clinical grounds, and lateral neck films are rarely needed. If obtained they should reveal a normal epiglottis. Treatment is conservative with oxygen, nebulized racemic epinephrine, and intravenous dexamethasone. Endotracheal intubation is indicated only for respiratory fatigue, progressive intercostal retractions, and cyanosis. As with epiglottitis, endotracheal intubation should be done in the operating room under similar controlled conditions and with surgical expertise immediately available.

Adenotonsillar Hypertrophy

Pediatric and Preoperative Concerns

A tonsillectomy probably is the most frequently performed airway surgical procedure. It is estimated that >300,000 tonsillectomies are done annually in North America alone. Indications for surgery include obstructive tonsillar hyperplasia, recurrent or chronic tonsillitis, and peritonsillar abscess. Often, a combined procedure including the adenoids is performed at the same time. Adenoidectomy is done to relieve nasopharyngeal obstruction caused by adenoid hyperplasia. Frequently these patients also suffer from reflux.

Encountering a young adult patient for tonsillectomy is not uncommon. However; the vast majority of patients will be in the pediatric age range. Pediatric patients are not "small adults." Compared with older patients, children have different physiologic responses and different psychological needs. When providing anesthesia to a child, one's primary focus is the child. In addition, one must address the concerns of the parents.

Typically the parents meet the anesthesiologist shortly before surgery. They are about to release the care of their child to a complete stranger. Even lay persons understand that undergoing anesthesia is a "near-death experience" and that their loved one will be "on the machine" for a while. This can be quite disturbing. Many times parents confess that their greatest fear is the anesthesia. A tremendous amount of trust is required for any parent to relinquish the care of their child to another person. Bear this in mind during the preoperative consultation. Remember, it is the duty of the practitioner to ease the parents of their fears. Remember too that there is another person observing this interaction.

Now consider the pediatric patient. Children are far more aware of their surroundings than we think. On the morning of surgery they know that something is different. Usually they were awakened earlier than normal and were not allowed to have breakfast. Then they realize their parents have a certain amount of anxiety and urgency. Finally they arrive in the preoperative area. It is here that they are surrounded by complete strangers who are dressed alike and who know their name. It is surprising that this experience does not evoke even greater fear than that observed.

On the morning of surgery, the parents will be asked whether or not the child has or has had a recent RTI. These infections are frequent in this population, and a concurrent illness can affect the anesthetic management. In the past, the presence of an RTI would result in immediate cancellation of an elective procedure. This issue has been the source of much investigation. In current practice, each child is evaluated on the day of surgery, and a decision is determined on a case-by-case basis. Most practitioners agree that children with a concurrent RTI have more respiratory complications. Most studies suggest that factors associated with these adverse events include endotracheal intubations, age <6 years, and an RTI within the past 2 weeks prior to planned surgery. According to the view of Tait and Malviya,[22] children with an RTI have more respiratory complications, but they are not associated with serious morbidity. The child who presents with an uncomplicated RTI can be managed safely as long as the practitioner understands and anticipates any likely adverse events, such as laryngospasm or bronchospasm. This view is further maintained in a review article by Mamie et al.[23]

Another preoperative issue is the anxiety or agitation level of the child. The day of surgery may be the only operating room experience for the patient and the child's parents. Although a thorough preoperative consultation can relieve much concern, some patients are still inconsolable. Should the child be premedicated? Any premedication will sedate the patient and can contribute to both preoperative and postoperative respiratory complications. Premedication also will delay emergence and the return of protective airway reflexes. It can also delay discharge from the recovery unit. Conversely, any child who has a very frightening experience will be difficult to bring back to the operating room, and this may contribute to a lifelong fear of the healthcare profession. Sedative premedication should not be given on a routine basis. Only very anxious and agitated children should be treated. For example, consider the child who is violently upset and presents a danger to himself and the staff. Orally administered midazolam (0.5 mg/kg, maximum 10 mg) given at least 20 minutes prior to operation is the most common sedative. Other sedatives that have been investigated include rectal ketamine, oral fentanyl, nasal fentanyl, clonidine, diazepam with midazolam, and dexmedetomidine. Oral dexmedetomidine was found to be especially effective in patients with neurobehavioral disorders resistant to previous sedative attempts.

Obstructive Sleep Apnea Syndrome (OSAS)

Pediatric patients with obstructive sleep apnea syndrome present additional challenges. These patients can demonstrate cardiovascular involvement, with altered right ventricular diastolic function, pulmonary hypertension, arrhythmias, and silent carditis. This diagnosis increases the risk of postoperative respiratory complications from approximately 1% to 20%. It is suggested that nocturnal oximetry studies be obtained in these patients prior to surgery. Other significant risk factors include abnormal sleep studies, carbon dioxide (CO_2) tension >50 mm Hg during rest while awake, witnessed severe upper airway obstruction, and nocturnal oxygen desaturations (<90%). These patients are not candidates for outpatient procedures and should be admitted for overnight observation.

Tonsillectomy can be performed in adults with obstructive sleep apnea, but the more common procedure for treatment of adult obstructive sleep apnea syndrome is uvulopalatopharyngoplasty (UPPP). This is a partial resection of the soft palate and is not a lengthy procedure. Extensive preoperative evaluation of the patient's airway is required. If the patient reports that nightly continuous positive airway pressure (CPAP) use relieves the symptoms, that is a good indication that the patient will be able to be ventilated with a mask. However, when in doubt, awake fiberoptic intubation remains the technique of choice for airway management. It also is suggested that intraoperative narcotics be kept to a minimum, if used at all, and that the trachea be extubated when the patient is awake. These patients are likely to be sensitive to sedatives. Moreover, they will be admitted for observation. Postoperatively, the uvulopalatopharyngoplasty procedure is known to be the most painful of ENT procedures. Pain control is a challenge because of the desire to limit the use of narcotics. Monitoring and careful observation are required to manage patient discomfort.

Adenotonsillectomy Anesthesia Induction

Pediatric anesthesia induction requires two persons. Both must be skilled in airway management and intravenous catheter placement. To perform a mask induction in a child by oneself is to invite disaster. Apart from the usual concerns of pediatric induction (laryngospasm, bradycardia–hypotension, lack of intravenous access), significant numbers of these patients will suffer from obstructive sleep apnea syndrome (OSAS). Several investigators have looked at different airway maneuvers to improve mask ventilation in this situation. Reber et al.[24] compared chin lift with continuous positive airway pressure versus jaw thrust with CPAP and found the latter to be superior. Meier et al.[25] was able to demonstrate that airway patency was improved predominately by CPAP. The opposite results were obtained in a study by Bruppacher et al.,[26] who found jaw thrust with CPAP better. Regardless of one's preferred technique, it is apparent that CPAP is effective in the partially obstructed child.

After the patient is anesthetized and intravenous access obtained, the airway must be secured by endotracheal intubation. Tonsillar hypertrophy can be extensive, and the challenge of laryngoscopy should not be underestimated. What may appear to be a routine intubation can quickly manifest as a difficult airway. Another source of difficulty is the presence of lingual tonsillar hypertrophy. Furthermore, trauma to fragile inflamed tonsils during laryngoscopy can cause bleeding.

There is no uniformity of opinion regarding the use of muscle relaxants during these procedures. An uncomplicated tonsillectomy will last anywhere from 15–30 minutes with an experienced surgeon. Relaxants, if used, should be of the short-acting variety. These patients will also receive narcotics for postoperative analgesia. Either alone or in combination, these drugs affect the child's ability to breathe. In a related issue, Khan and Memon[27] compared spontaneous with controlled ventilation for tonsillectomy. Their results suggest that controlled ventilation offers more hemodynamic stability and rapid recovery. It is my practice to give morphine immediately after intravenous access has been obtained and to intubate the trachea under the effects of both morphine and inhaled sevoflurane, thus avoiding muscle relaxants altogether.

Different techniques and drugs have been evaluated to facilitate tracheal intubation without the use of neuromuscular blockade. Woods and Allam[28] have provided an excellent review. Of the inhaled anesthetics, sevoflurane has emerged as the best choice, especially when combined with remifentanil. A study by Simon et al.[29] showed sevoflurane to be superior to a propofol–opioid combination. Of the intravenous agents, giving remifentanil followed by propofol seems to provide the best intubating conditions. Whatever approach is used, the avoidance of muscle relaxants allows the rapid return of spontaneous ventilation and protective airway reflexes (Figure 66–1).

Intraoperative Management

After the airway is secured, the surgeon places a mouth gag in the oral cavity to better expose the tonsils.

FIGURE 66–1. Twelve-year-old girl prepared for tonsillectomy. The endotracheal tube is secured midline on the mandible, and the mouth gag is in position with the handle placed on the operating room tray. (Courtesy of Michael Cunningham, MD, Massachusetts Eye and Ear Infirmary.)

Great care must be taken to accomplish this maneuver. This is a stimulating event with the potential for complications. Some surgeons disconnect the anesthetic circuit prior to placing the mouth gag. Others work around the endotracheal tube. During this manipulation, the endotracheal tube can be compressed, kinked, or displaced. Rarely, an unexpected extubation occurs. After the mouth gag is in place, one should recheck to verify bilateral breath sounds. The endotracheal tube is secured to the midline mandible; any extension can result in the tube moving several centimeters. Once the mouth gag is in position, the surgeon places the inferior handle of the mouth gag on the operating room instrument tray. If the child is lightly anesthetized and moves, potential cervical injury can occur. The other option is to place the handle on a stack of towels placed upon the patient's sternum. Should the child move, the mouth gag will move with him or her. This does place counterpressure on the patient's chest, which can affect spontaneous ventilation. Prior to incision, the surgeon usually requests that an antibiotic and antiinflammatory steroid be given.

Surgical techniques for tonsillectomy include guillotine resection (rare), cold dissection, bipolar dissection, and cold ablation (coblation) dissection. Each approach has its particular merits. Blood loss is greater but pain is less with the first two techniques. Bipolar dissection allows immediate coagulation and less blood loss. However, thermal injury to the surrounding healthy tissue is responsible for greater postoperative discomfort. Coblation is a relatively new technique. With this approach, a radiofrequency bipolar current is passed through a saline medium to produce a plasma field of sodium ions. Using a much lower frequency than standard bipolar diathermy, these ions essentially vaporize soft tissue at only 140°F (60°C). It also requires no electrical ground, and irrigating saline reduces thermal injury to adjacent tissue. Coblation offers the advantages of both cold dissection and bipolar diathermy, with less postoperative pain and blood loss.

Postoperative Management

At the end of the procedure, the patient should be breathing spontaneously. In addition to morphine, I also give ondansetron for emesis control. Once hemostasis has been achieved, the patient's stomach and oral cavity are suctioned. An awake extubation can be performed to ensure that the protective airway reflexes have returned. These children are at high risk for laryngospasm secondary to blood and secretions in the oral cavity. Some practitioners have advocated using intravenous lidocaine to suppress this complication. In a study by Gulhas et al.,[30] intravenous magnesium was used to good effect. An investigation by Tsui et al.[31] explored a "no touch" extubation technique. The patients were turned to a head-down lateral recovery position while they still were anesthetized. If the nondependent hip is flexed, the patient will easily stay in this position. The importance of the head-down position cannot be overemphasized. This arrangement allows pooling of blood and secretions to occur on the side of the mouth rather than midline. In addition, the upper airway of a child widens in the lateral position and is less likely to obstruct. Aside from oximetry monitoring, no additional stimulation was allowed with the technique. After the patient emerged from anesthesia confirmed by eye opening, extubation of the trachea was performed. No incidences of laryngospasm, oxygen desaturation, or coughing were observed.

Complications of tonsillectomy include hemorrhage (discussed below in Posttonsillectomy Hemorrhage), postoperative airway obstruction secondary to laryngeal edema, and dental trauma.

Analgesia and Antiemesis

Postoperative analgesia of some type is required after this procedure. Local anesthetic infiltration prior to incision has provided satisfactory results. However, bupivacaine infiltration has been implicated in short-term vocal cord paralysis, and large quantities of local anesthetic can suppress protective airway reflexes for several hours. Naja et al.[32] attempted to precisely identify specific anatomic areas for infiltration that will promote adequate analgesia while limiting the total amount of anesthetic injected. A follow-up study confirmed their earlier findings, and the technique appears promising.

Of the intravenous agents, ketamine, morphine, and meperidine all are proven potent analgesics. However, each has its own undesired side effects. Ketamine can cause an extreme dysphoric reaction if the patient is not pretreated with a benzodiazepine. It also can cause increased oral secretions, which is undesired in this patient group. The narcotics morphine and meperidine are very effective but they provoke nausea. They also have sedative effects, can cause pruritus, and are respiratory depressants. Mukherjee et al.[33] compared fentanyl with morphine and noted less PONV with fentanyl in the first 4 hours but a similar incidence at 24 hours. A study by White et al.[34] using fentanyl but not morphine noted a significant decrease in the incidence of PONV, while analgesia remained excellent.

Tramadol is a synthetic codeine derivative that behaves as a centrally acting atypical opioid. It lacks many of the opioid side effects while exhibiting both opioid and monoaminergic mechanisms of action. For adenotonsillectomy procedures, tramadol has been favorably compared to ketamine, morphine, and meperidine. Tramadol has been shown to have analgesic properties that are similar to those of morphine but without the associated respiratory depression. It is well tolerated with less nausea. Good results have been obtained when tramadol was combined with acetaminophen. However, a study by Arcioni et al.[35] noted that ondansetron has an inhibitory effect when used simultaneously with tramadol. Despite this concern, tramadol remains a promising analgesic agent.

The COX-2 inhibitors also have been studied for this scenario. These drugs are advantageous in this setting because they do not inhibit platelet aggregation or prolong bleeding time. Unfortunately, only celecoxib remains available for use in the United States; other COX-2 inhibitors were withdrawn from the market over concerns of adverse cardiac events when using high doses. Prior to its withdrawal, rofecoxib was the subject of several investigations. In essence, although increased bleeding was not found, the analgesic benefits were unimpressive.

Other nonsteroidal antiinflammatory drugs (NSAIDs) have been considered for postoperative analgesia. They provide excellent pain relief without the side effects of narcotics. NSAIDs also cause platelet dysfunction and prolonged bleeding time. Their use in adenotonsillectomies remains controversial. Moiniche et al.[36] did a quantitative review of 25 studies to examine

the relationship between NSAID use and postoperative bleeding. They concluded that NSAIDs offer similar analgesia and significantly less emesis than opioids, but they also contribute to more reoperations for hemostasis. A review by Marret et al.[37] went even further and suggested NSAIDs should not be used after tonsillectomy. Both of those reports contrast with a review by Cardwell et al.,[38] which found no increase in bleeding requiring a return to the operating room. Overall, the weight of the evidence appears to support avoidance of NSAIDs in adenotonsillectomy patients.

In addition to pain, PONV must be expected and treated. Even if narcotics are not used, swallowed blood can cause nausea. Several agents are available and should be used to aggressively treat this condition.

The last several years have seen a number of studies that promote dexamethasone as a potent antiemetic. It usually is requested by the surgeon to reduce postoperative swelling and pain. A study by Aouad et al.[39] found dexamethasone significantly better than placebo for both decreasing vomiting and promoting postoperative oral intake. Elhakim et al.[40] confirmed these findings and noted an analgesic benefit as well. Dexamethasone was also found to act synergistically when combined with serotonin ($5\text{-}HT_3$) antagonists.[41,42]

Posttonsillectomy Hemorrhage

Posttonsillectomy hemorrhage remains the most serious complication of this procedure. It is expected that a routine patient will lose approximately 4 mL/kg of blood. Posttonsillectomy hemorrhage occurs in approximately 5% of all cases and most often within 24 hours (primary hemorrhage). Secondary hemorrhage can occur anytime thereafter. A study by Brown et al.[43] noted that nearly half of posttonsillectomy hemorrhage cases occurred in patients with previously undiagnosed coagulation disorders. Typically posttonsillectomy hemorrhage is characterized by slow oozing. These patients can be hypovolemic and tachycardic before the complication is recognized. Bleeding can be quite brisk. I have seen a clot dislodge upon intubation and in a matter of seconds the entire oral cavity filled with blood. These patients also may demonstrate orthostatic hypotension and may have swallowed a large volume of blood.

Posttonsillectomy hemorrhage is a surgical emergency and should be treated as such. Windfuhr[44] reviewed several cases of lethal posttonsillectomy hemorrhage. He concluded that immediate surgical intervention may have prevented mortality in most cases. Before anesthesia induction, intravascular fluid expansion should be accomplished using either crystalloids or blood products if indicated. Failure to do so can result in fatal outcomes. Consider these patients to have full stomachs and secure the airway after a rapid sequence induction. Large-bore, high-volume suction should be available. The patient's stomach should be emptied after the airway is secured.

Windfuhr also described treatment of excessive posttonsillectomy hemorrhage by ligature of the external carotid artery. Berlucchi et al.[45] reported using the drug 1-deamino-8-D-arginine-vasopressin (DDAVP) with good results in patients with von Willebrand disease. All tonsillectomy patients should be carefully observed and evaluated prior to discharge.

Mass Lesions

Pharyngeal Abscesses (Peritonsillar, Retropharyngeal)

Patients who present with a pharyngeal abscess can have significant coexisting morbidity. As an example, I have seen an elderly man who arrived with progressive quadriplegia and somnolence. The underlying etiology was a retropharyngeal abscess compressing the patient's brainstem. Although of infectious origin, pharyngeal abscesses are "mass lesions."

In the majority of these cases, the patients either are pediatric age or young adults. Incision and drainage of the abscess usually are performed under general anesthesia, with the airway secured by endotracheal intubation. Conversely, if the abscess is relatively small and not compromising the airway, some surgeons perform the procedure in the emergency room under local anesthesia alone. This requires a cooperative patient with a high pain tolerance. Under this condition, the patient is at risk for aspiration and additional complications. For patient care and comfort reasons, these cases are best handled in the operating room.

Once a general anesthetic has been decided upon, a thorough examination of the airway is required. This includes reviewing the relevant CT scans with the surgeon. Airway obstruction can occur, and intubation can be difficult. Depending upon its extent, a retropharyngeal abscess can cause atlantoaxial subluxation. Furthermore, the underlying tissue may be quite friable, and the goal is to prevent any abscess contents from entering the trachea prior to securing the airway. This step should be a gentle intubation, attempting not to disturb the abscess. After the abscess is drained, the surgeon irrigates and suctions the oral cavity multiple times. These cases are not lengthy, and an awake extubation is indicated.

In a related scenario, patients who present with deep neck infections are considered to have compromised airways despite their appearance. The classic example is Ludwig's angina, which is a severe cellulitis involving the sublingual and submental spaces. Symptoms include tongue elevation, rapid breathing, difficulty swallowing, glottic edema, leukocytosis, and fever. Airway assessment is similar to that described above. An analysis and review by Ovassapian et al.[46] examined this problem and concluded that an awake fiberoptic intubation is the safest approach. If an awake fiberoptic intubation is not feasible, an awake tracheostomy under local anesthesia should be pursued.

Benign and Malignant Tumors

In addition to infectious masses, a wide variety of benign and malignant tumors may affect the throat and related structures. Hemangiomas can be found anywhere in the oral cavity. They are not treated unless they compromise the airway or interfere with function. Lasers are frequently used in the surgical management of these hemangiomas. Other benign masses include lymphangiomas of cavernous or cystic hygroma origin, and papillomas. Malignant tumors are no less diverse and can be ulcerative, exophytic, or infiltrative lesions. Patients may present prior to diagnosis or after multiple excisions and chemotherapy/radiation therapy.

It is essential to thoroughly review these cases with the surgeon prior to bringing the patient to the operating room. This includes discussing the surgical plans and the airway issues involved or expected. Examination of any relevant CT and MRI scans also is indicated. Any previous anesthesia records

should be located and reviewed, especially if prior diagnostic or therapeutic procedures have been performed, because the experiences of others can be helpful in guiding the anesthetic plan.

Finally, evaluation of the patient is mandatory. This is the most important portion of the preoperative plan. One must determine the extent of mouth opening and attempt to visualize the mass lesion. An awake fiberoptic intubation is suggested if any signs of obstruction, limited neck extension, or any other factor is encountered that can interfere with a direct laryngoscopy. Conversely, a small lesion in an otherwise normal-appearing airway is reassuring. When managing a mass lesion, regardless of origin, one must be prepared with multiple plans that can be invoked to secure the airway, including emergent surgical intervention.

Foreign Body Aspiration

Foreign body aspiration is a life-threatening emergency and a leading cause of death in 1- to 3-year-old children. The literature reviewing FB diagnosis and management is extensive. The variety of possible FBs is limited only by the imagination and, seemingly, local culture. If an object can be picked up and placed in the mouth, it will be. Where it may travel after that becomes the onus of the ENT surgeon and anesthesiologist. Most commonly FB ingestion or aspiration is encountered in the pediatric patient in the age range from 6 months to 5 years. Occasionally, one meets the young adult attempting to do a "party trick" while under the influence of alcohol and questionable friends. Alternatively, trauma to the neck can result in bone, cartilage, or soft tissue occupying previously open space akin to an FB. Airway assessment and management are similar.

Complete airway obstruction is rarely seen by the tertiary care team. Primary intervention by a Heimlich maneuver is the therapy of first choice, followed by digital extraction. Be aware that digital manipulation can push an obstructing FB further into the airway. If the patient has become hypoxic, cyanotic, and moribund, the only lifesaving option is emergent tracheotomy.

Partial airway obstruction is the clinical entity most frequently encountered. The guiding principle of management should be, "Do not convert a partial airway obstruction into a complete airway obstruction." The patient and family will arrive in an emotionally charged state. The child may be dyspneic, drooling, sitting forward, and frightened. Prominent, stridorous breathing may be noted and is indicative of supraglottic or glottic involvement. Wheezing is heard more often with subglottic obstruction. The nature of the FB and the context of its ingestion must be determined. Nonmetallic objects are difficult to visualize on plain films. Secondary radiographic findings, such as a hyperinflated lung or lobe, can help localize the object. If the patient is stable and the FB is fixed in position, one can wait and allow the stomach to empty before going to the operating room. However, this is not often the case.

Bronchoscopy and FB Management

Once the FB has been identified and located, a definitive management plan can be made. If the object lies near or within the trachea, the patient will require a laryngoscopy and bronchoscopy. Should the patient be cooperative, it is possible to perform a bronchoscopy under topical anesthesia, but most patients will require general anesthesia. Most practitioners advocate an inhalation induction for the patient with a partially obstructed airway, in order to avoid positive pressure that might displace the FB and convert partial obstruction to total obstruction or cause the FB to migrate more distally in the airway. After induction, a rigid ventilating bronchoscope allows maintenance gases and oxygenation to continue. However, there is a significant leak around the end of the bronchoscope, and the entrained air often dilutes the inhaled anesthetic gases. Inhalation anesthesia may be supplemented by intravenous drugs, given as a continuous infusion or intermittent boluses. Either alone or in combination, propofol, remifentanil, and fentanyl have been studied in this scenario. It appears that remifentanil provides greater hemodynamic stability and rapid recovery. An interesting study by Farrell[47] found good results with both spontaneous and positive-pressure ventilation. A report by Soodan etal.[48] suggested that controlled ventilation with muscle relaxation provided a more stable anesthetic.

Bronchoscopy under general anesthesia is a delicate procedure. Complications arise from poor ventilation (hypercapnia, hypoxemia) and light anesthesia (bronchospasm, bucking). Despite the intensity of the procedure, these cases should be handled in a deliberate calm manner that aims to provide appropriate surgical and anesthetic conditions.

Esophagoscopy and FB Management

Any FB ingestion posterior to the glottis will be managed by esophagoscopy. If the airway is not compromised, a rapid sequence induction with cricoid pressure can be performed. Once the airway is secured, there is no fear of aspiration. Rigid esophagoscopy is used for diagnostic purposes, FB removal, and tumor localization. The most serious complication is esophageal perforation, which frequently occurs in the hypopharynx. The consequences are significant; resulting mortality can range from 34–84%. Appropriate muscle relaxation can reduce the incidence by preventing unwanted movement or "bucking" during the procedure. In addition to perforation, other complications are compression of the endotracheal tube, dysrhythmias, and aspiration.

Flexible esophagoscopy is more of a diagnostic procedure and can be done as a minimum alveolar concentration (MAC) anesthetic with sedation. It is not indicated for FB management.

Iatrogenic Causes

Surgery and Radiation Therapy

Acquired airway disorders may result from other therapeutic activities that permanently alter the airway. Many otolaryngologic malignancies are treatable, and patients do survive. They will return to the operating room for additional biopsies and surveillance endoscopies, but their airways may be significantly deformed.

Common surgical procedures include wide intraoral excisions, laryngectomies, and radical neck dissections with free flap reconstruction. Many of these patients will present with a preexisting tracheotomy that makes their management straightforward. Others will present with an intact airway that has been greatly altered. As emphasized earlier, the case must be discussed well in advance with the surgeon. Previous anesthesia records must be reviewed, and the patient must be carefully examined.

These patients understand their postsurgical condition. They will be cooperative once the anesthesia concerns are explained to them. Unless the patient

has a near-normal airway (unlikely), an awake fiberoptic intubation is the approach of choice. Upon laryngoscopy, the glottis rarely is found in the midline position. It typically is displaced to one side, and, depending upon coexisting morbidity, the surrounding structures may be unrecognizable.

Another airway abnormality is caused by radiation therapy. Radiation, which can be imagined as a form of burn, leads to fibrosis and shrinkage of the affected tissues. A study by Schmitt et al.[49] described factors that better identify potential difficult fiberoptic intubations in patients after radiotherapy. Factors they cited include laryngeal edema, hoarseness, and stridor. The patient may appear to have a normal neck and mouth, but the difficulty of laryngoscopy should not be underestimated. After radiation, muscle tissue becomes very firm and fixed. The patient likely will not be able to extend the neck. The patient also will likely not be able to open the mouth more than a few millimeters. Muscle relaxants will be of little or no benefit in this scenario. Much like scar contractures caused by burn injuries, these patients have small, fixed upper airways. Laryngoscopies are extraordinarily difficult, if not impossible. Again, awake fiberoptic intubation is frequently the technique of choice.

Vocal Cord Disorders

Disorders of the vocal cords can profoundly affect a patient's quality of life and in certain conditions can threaten life itself. Lesions can be of infectious origin, such as papillomas; they can be benign masses, such as hemangiomas and granulomas; or they can be neoplastic masses. Besides mass mechanical effects, mobility can be affected by fibrosis, inflammation, and nerve injury. Whereas some diagnostic procedures can be accomplished by flexible endoscopy, most surgical procedures are done by laryngoscopy and microlaryngoscopy. Medialization or voice restoration operations (phonosurgery) typically are conducted under MAC. The patient must be able to phonate (e.g., say "EEE…") in order to guide the repair. If the lesion is well defined, general anesthesia can be used. Special techniques, such as apneic oxygenation and jet ventilation, may be necessary. Frequently, the surgeon requests profound muscle relaxation for a relatively brief procedure. Vocal cord surgery often uses lasers as the primary surgical instrument.

Using a combination of local and topical anesthesia can prepare the airway for laryngoscopy and some minor procedures. This will require blocking both superior laryngeal nerves and the glossopharyngeal nerves, and injecting the trachea with local anesthetic. More commonly, these procedures are done under general anesthesia. Laryngoscopy is a stimulating event. It can elicit hypertension and tachycardia, which in vulnerable patients can lead to myocardial ischemia or even infarction. Conversely, laryngeal stimulation in a lightly anesthetized patient can cause bradycardia and dysrhythmias. The mechanism is a reflex pathway between the superior laryngeal nerve afferent fibers and vagal cardioinhibitory fibers. As with any general anesthetic, the patient must be sufficiently anesthetized before laryngoscopy begins. Giving β-blockers or other agents may blunt the hemodynamic effects (Figure 66–2).

Microlaryngoscopy

Microlaryngoscopy with suspension is a technique that uses both a surgical laryngoscope and an operating room microscope. The surgical laryngoscope is attached to either an instrument tray or the operating room table by extension, and the patient's upper torso is practically suspended for the duration of the procedure. A small-diameter, laser-compatible endotracheal tube with a large cuff volume is used. The head and neck are padded and braced; should the patient move, injury can occur. Muscle relaxation is required for these procedures. Once the microscope is in position, this arrangement provides excellent exposure of the vocal cords. By using the microscope and laser, the surgeon can make precise excisions. Prolonged suspension can cause glottic edema resulting in airway obstruction in the recovery room. Intravenous steroids can reduce this risk (Figure 66–3).

Ventilation

Ventilation during this procedure is a challenge. Unless a cuffed endotracheal tube is used, all volatile anesthetics will be diluted by entrainment of air. Pollution of the operating room also may occur. Induction and maintenance of anesthesia are best accomplished using intravenous techniques.

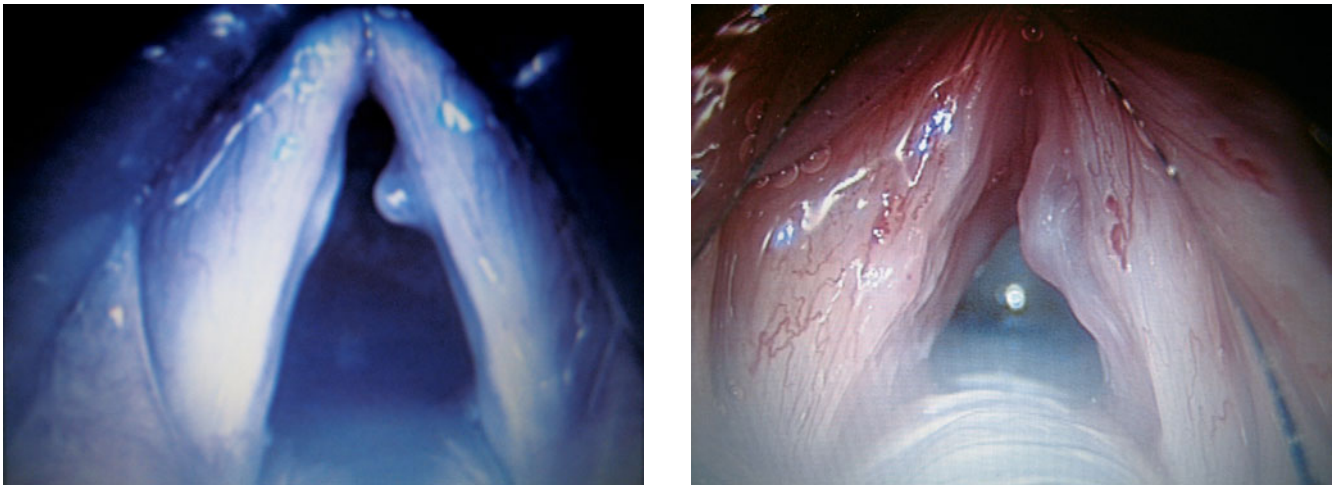

FIGURE 66–2. Left, Vocal cord cyst. **Right,** Bilateral vocal cord hemangiomas. (Courtesy of Christopher Hartnick, MD, Massachusetts Eye and Ear Infirmary.)

FIGURE 66–3. Patient positioned for microlaryngoscopy under suspension. Note that the patient has a tracheostomy and that a Xomed® laser endotracheal tube is being used. The laser is to the left. (Courtesy of Ramon Franco, MD, Massachusetts Eye and Ear Infirmary.)

Some anesthesiologists have used apneic oxygenation for brief procedures. Others have advocated an intermittent ventilation technique whereby an endotracheal tube is placed and removed multiple times until the operation is complete. This places the airway at risk and prolongs the time needed to finish the procedure. It also can lead to additional vocal cord irritation and trauma.

Jet Ventilation

Other practitioners have used jet ventilation to good effect. Jet ventilation was introduced in 1967 and has since undergone many refinements. Essentially, a volume of gas is compressed and delivered under high pressure through a small tube or catheter. In a tubeless technique, this gas can be given through a side port in the laryngoscope. Depending upon the needs of the particular patient, jet ventilation may be administered above, at, or below the glottis. Various devices are available to provide jet ventilation and all have at least three common components. A compressor provides a blend of oxygen and N_2O (or nitrogen, helium, etc.) under high pressure. This mixture then passes through a pressure regulator prior to patient exposure. For adults, the initial jet pressure should be ≤ 20 pounds per square inch (psi) and for children should be ≤ 10 psi. Actual gas delivery is controlled by a hand-operated valve.

Jet ventilation is advantageous because it provides an unobstructed operating field to the surgeon and increases safety during laser procedures. However, there are some significant concerns. Jet ventilation requires additional time, effort, and skill to set up and operate. Because ambient air is being entrained with the high-pressure gas via the Venturi principle, the patient will receive a diluted mixture. This can lead to operating room pollution and is insufficient for general anesthesia alone. General anesthesia must be maintained by intravenous agents when jet ventilation is used. Respiratory gas monitoring is inaccurate, and one must rely upon chest movement and pulse oximetry to assess ventilation. Air trapping can lead to barotrauma if a mass blocks expiration in a "ball-valve" phenomenon. Carbon dioxide can accumulate, leading to respiratory acidosis and its unwanted effects (tachycardia, arrhythmias, etc.). Moreover, the exit opening for the high-pressure gas, whether it is a needle, tube, or catheter, should not lie near the mucosa. The Hunsaker tube has extensions to keep it away from the airway surface. Barotrauma associated with jet ventilation can result in subcutaneous emphysema, pneumothorax, and pneumomediastinum. Biro et al.[50] investigated the effects of airway-occluding instruments on airway pressure during jet ventilation for bronchoscopy. They concluded that barotrauma should not occur as long as end-expiratory pressure never exceeds peak inspiratory pressure.

Most recent research on jet ventilation has focused upon ventilatory frequency. Hand-operated valves allow delivery of low-frequency jet ventilation, whereas newer, automated devices allow delivery of up to 600-Hz, high-frequency jet ventilation. First described in 1976, Ihra et al.[51] have written a thorough review of the development and use of high-frequency jet ventilation. This mode of jet ventilation is advantageous with certain types of airway pathology and in patients with severe pulmonary failure. High-frequency jet ventilation allows easy positioning in airway stenosis, decreases risks in laser surgery (no tube), decreases aspiration risk because of continuous outflow of gas, provides continuous ventilation, and allows cricothyroid rescue ventilation (see Unzueta et al.).[51a]

High-frequency jet ventilation has disadvantages. In a study by Hautman et al.,[52] complications of high-frequency jet ventilation included hypertension, hypotension, bronchospasm, hypercarbia, and hypoxia. Insufficient humidification is another concern. Histologic injury correlates with frequency of jet pulses and manifests as mucosal edema, congestion, and epithelial cell flattening, all of which can contribute to necrotizing tracheobronchitis. Aside from barotrauma, other complications include dysrhythmias, pneumoperitoneum, and gastric rupture secondary to misdirected gas flows. Some studies have suggested that preterm infants receiving high-frequency jet ventilation have a greater incidence of necrotizing enterocolitis. With these concerns in mind, other investigators have examined the benefits of using combined-frequency jet ventilation. These techniques use both low-frequency jet ventilation and high-frequency jet ventilation in differing ratios and have given satisfactory results. Regardless of the approach used, jet ventilation remains a useful and specialized anesthetic technique. It requires experience and should not be attempted by the unaccompanied novice.

Lasers

Schawlow and Townes first theoretically proposed lasers (Light Amplification by Stimulated Emission of Radia-

tion) as an optical variant of masers in 1958. Development followed rapidly, and in 1960 Maimon produced a laser by using a ruby crystal pumped with light from a flash lamp. Since that time, lasers have become commonplace and can be found transmitting phone calls, reading bar codes, providing precision cuts in industry, reading compact disks (CDs)/digital video disks (DVDs), and, of course, in the operating room. To provide appropriate anesthetic care, one must have a basic understanding of how lasers function and how they can be beneficial and harmful.

Visible light consists of a blend of wavelengths that spread in all directions. It can be described as incoherent (out of phase) and diffuse. Laser light is distinctly different. It can be described as monochromatic (same wavelength), coherent (in phase), and collimated (parallel waves). Among his many contributions, Einstein in 1917 suggested that such light could be a product of stimulated emission. By using energy to stimulate molecules of a particular medium, one can push their electrons to a higher state. This produces a "population inversion" with fewer electrons in the ground state. As these electrons fall to their original state, they release a photon of a specific wavelength. Such radiation leads other molecules in the medium to release photons of the same wavelength. When this occurs in a cylindrical chamber with reflective mirrors, the light becomes amplified. A laser beam created by this process can focus a large amount of energy on a small discrete area and produce its effects.

The components of each laser include an optical resonator with both an opaque mirror and partially transmitting mirror, a pumping or energy source, and an excitation or active medium. Laser modes include continuous, pulsed, and Q-switched. Most lasers are one of four types. *Dye lasers* use an active material (usually an organic dye) in a liquid suspension as the lasing medium. By changing the chemical composition of the dye, the laser can be "tuned" to different wavelengths. *Diode lasers* use an optical cavity to amplify light emitted from the energy-based gap that exists in semiconductors. *Gas lasers* consist of a gas-filled tube upon which a voltage is applied to excite molecules to a state of population inversion. *Free electron lasers* function by having an electron beam in an optical cavity pass through a wiggler-magnetic field. Free electron lasers can produce a wide variety of wavelengths (Figures 66–4 and 66–5).

Laser Effects and Safety

Lasers can focus a large amount of energy upon a discrete area to exert their effects. In biologic tissue, this can result in thermal effects via energy absorption, photochemical effects by the reaction of radiant energy with specific molecules, and mechanical effects by disruption secondary to propagation of photo acoustic shock waves. In addition, the smoke, or laser "plume," can contain known car-

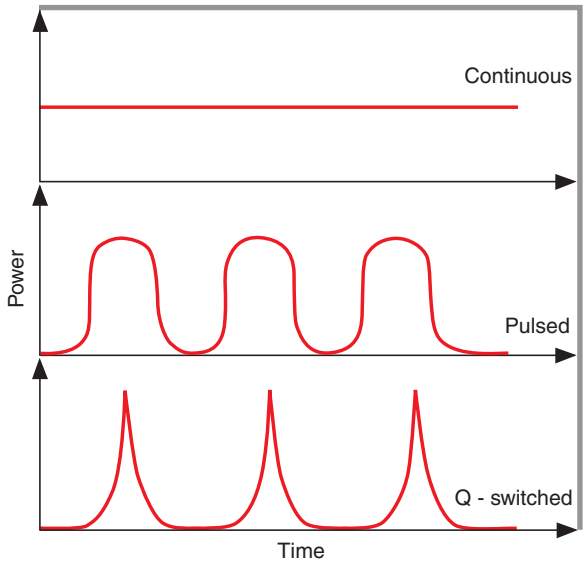

FIGURE 66–5. Power versus time graphs illustrating different laser modes. (Courtesy of Bob Galla, Massachusetts Eye and Ear Infirmary.)

cinogens, toxic gases, and viable microorganisms (Table 66–1).[53]

Every facility that uses medical lasers should have a laser safety officer or committee. The responsibilities should include education of healthcare providers, protocol formulation, and implementation of safety policies. When a laser is in use, signs and appropriate safety glasses must be available at all entrances. All persons in the operating room should wear safety glasses, and the patient's eyes should be taped closed and covered with soaked gauze.

As with any medical device, national standards have been established to ensure the safe use of lasers. In the United States, these can be found in the industry publication American National Standards Institute ANSI Z136.3–2005, *Safe Use of Lasers in Health Care Facilities*.[54] Two important concepts are emphasized in this handbook. One is the *nominal hazard zone* (NHZ). This is the minimal distance in which laser beams can have effects. For the majority of medical lasers, this distance varies between 0.46 and 178 m. The other concept is borrowed from radiation safety studies and is the *maximum permissible exposure* (MPE). This represents the maximal laser energy that can be absorbed without resulting in harm. Most laser injuries result from reflected beams, and the eye is most vulnerable. Eye injuries include photokeratitis, photochemical cataracts, thermal retinal injuries, and corneal burns. Within the eye, the retina is vulnerable to laser wavelengths of 400–1400 nm [argon, neodymium:yttrium-aluminum-garnet (Nd:YAG) lasers]. Wavelengths ≥ 1400 nm can damage the cornea. Aside from wavelength, the extent of eye injury is determined by pupil size, degree of pigmentation, size of retinal image, pulse duration, and pulse repetition rate (Table 66–2).

The safety glasses needed are wavelength specific and depend upon the laser being used. Argon (514 nm) pulse lasers exhibit a green beam and cause thermal effects. They require orange glasses. The potassium titanyl phophate (KTP; 532 nm) diode pulse laser also has thermal effects and requires orange glasses. Dye pulse lasers have both mechanical and thermal effects and require blue glasses. Nd:YAG (1064 nm) and CO_2 (10,600 nm) pulse lasers cause thermal effects and clear glasses are needed for protection (Table 66–3).

TABLE 66–1.

Laser Effects

Thermal Injury: Burns secondary to energy adsorption
Photochemical Reactions: Secondary to interaction between specific molecules and radiant energy
Mechanical Effects: Tissue disruption secondary to photoacoustic shock waves
Toxin release: Toxic gases, carcinogens, and viable microorganisms within the laser "plume"

Laser Fire and Laser Endotracheal Tubes

The greatest danger caused by a laser is an endotracheal tube airway fire. Although rare, the results of endotracheal tube airway fire can be catastrophic and fatal. If the endotracheal tube is penetrated by the laser beam, the oxygen-rich environment within the tube can produce a vivid intense flame. Every practitioner should have the image of a "blow torch" in his or her mind to appreciate the danger. All of the elements to support a fire are found in this setting: oxygen (supports combustion, along with N_2O), combustible material (endotracheal tube), and an ignition source (laser). Much effort has been expended to develop a laser-safe endotracheal tube but as of yet there are no "perfect" laser endotracheal tubes (Figure 66–6).

Metal endotracheal tubes are laser resistant but have other disadvantages. They are not as pliable or as easy to handle as conventional polyvinyl chloride (PVC) tubes. This characteristic can lead to unnecessary manipulation and potential vocal cord trauma. Metal endotracheal tubes do not have a cuff, and one cannot seal the trachea. Furthermore, the laser beam can reflect off the tube and damage healthy adjacent tissue. Metal tubes can transmit heat to surrounding tissue. A Mallinckrodt Laser-Flex® is a metal tube containing an inner PVC endotracheal tube fitted with tandem cuffs. Should one cuff be damaged, the remaining cuff still can maintain a seal. Despite its other advantages, the PVC cuff still conveys a risk of laser ignition.

The Xomed® Laser Shield II is a silicone endotracheal tube covered with metallic particles. Its cuff also has a metallic covering to improve its survivability. This is the endotracheal tube most commonly used at my institution, with safe, reliable results obtained. However, under certain circumstances this tube can burn.[55]

TABLE 66–3.

Commonly Used Medical Lasers (Pulse Mode)

Type of Laser	Wavelength (nm)	Primary Effect	Protective Eyewear
CO_2	10,600	Thermal	Clear
Nd-YAG	1064	Thermal	Clear
Dye	583–587	Therm/mech	Blue (dye specific)
KTP-Diode	532	Thermal	Orange
Argon	514	Thermal	Orange (argon specific)

Typically, a cool saline–blue dye mixture is used to inflate the cuff. This allows easy visualization of any cuff damage and provides a "heat sink" to slow potential ignition of the cuff.

A Sheridan 2® is a polyvinyl acetate (Merocel), copper foil–wrapped endotracheal tube. Red rubber tubes wrapped with metallic tape have been used safely for many years. One advantage is that ignited rubber tends to char rather than melt. In addition, more energy is required to ignite rubber than PVC. Great care must be taken when applying the metallic tape. Any exposed areas are liable to ignition. Rough or loose edges can injure the patient's airway. Like a metal tube, certain metallic tapes can reflect the laser beam onto healthy tissue.

Airway Fire Precautions and Management

To reduce the risk of an airway fire, certain precautions should be observed:

1. Consider a tubeless technique using spontaneous ventilation,[56] apneic techniques, or jet ventilation.
2. Use an appropriate laser endotracheal tube, such as metal, Mallinckrodt®, Xomed®, Sheridan®, or Red Rusch®.
3. Reduce inspired oxygen as tolerated by the patient to < 30%, ideally 21%.
4. Use either air or helium to dilute the oxygen; N_2O supports combustion.
5. Fill the endotracheal tube cuff with a saline–dye mixture or lidocaine jelly.
6. Completely soaked gauze should be placed within and around the airway to reduce ignition risk.
7. Use H_2O-based ointments; petroleum-based ointments are flammable.
8. Limit the duration and intensity of laser exposure; continuous mode allows heat buildup.
9. Maintain a ready source of water in case of fire (multiple 60-mL filled syringes).

These steps will not eliminate the risk of an airway fire, but they will reduce it.

Despite these precautions, what should the anesthesiologist do in the event of an airway fire? The ANSI has developed the following protocol:

1. Stop ventilation.
2. Disconnect the oxygen source and flood the airway with water.
3. Remove the burned endotracheal tube and examine the airway.
4. Mask ventilate the patient and reintubate.
5. Survey the extent of injury using a flexible bronchoscope.
6. Monitor the patient for 24 hours.
7. Administer steroids to reduce inflammation and edema.
8. Provide antibiotics and ventilatory support if indicated.

It is common practice at my institution not to tape or secure the endotracheal tube to the patient's face. This will allow rapid removal of the tube in the event of an airway fire; however, this raises a controversial point. In my own research (unpublished observations), it appears that the first step would be to remove the endotracheal tube as rapidly as possible, even if gas flows and ventilation are still occurring. Once ignited, even without gas flow, the endotracheal tube will continue to burn and cause injury. By the time an endotracheal tube fire is recognized, approximately 3–4 seconds have passed. It will take another 3–4 seconds to stop ventilation, stop gas flows, and flood the airway prior to removing the endotracheal tube. In contrast, simply removing an untaped endotracheal tube will take approximately 1 second, thus potentially reducing the amount of injury to the patient.

Besides endotracheal tubes, lasers can ignite surgical drapes and other flammable items within the operating room. Electrocautery can be a source of surgical fires. Barker and Polson[57] reviewed a case report of surgical fire and described a laboratory study that successfully replicated the original incident. Under the right conditions, drapes, towels, ointments, and gowns can be combustible. Only by taking all

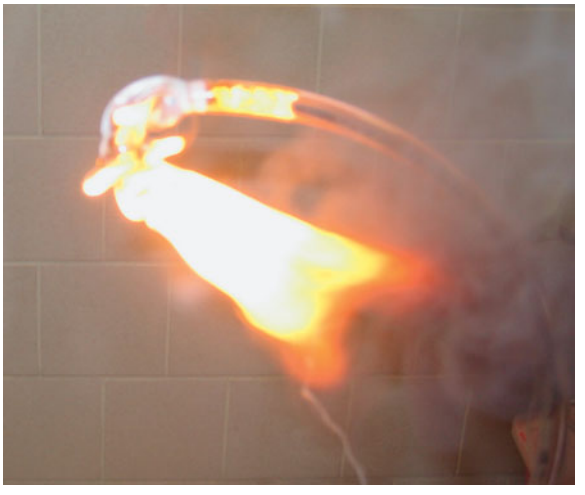

FIGURE 66–6. Standard polyvinyl chloride 7.5 endotracheal tube 3 seconds after ignition while receiving 1 L of oxygen and 2 L of nitrous oxide. The tip has collapsed downward and a "blow torch" is emerging, accompanied by a large volume of combustible products. Note that the flame is beginning to rise within the endotracheal tube. (Courtesy of Bil Ragan, MD, Massachusetts Eye and Ear Infirmary, and Artem Grush, MD, Massachusetts Eye and Ear Infirmary.)

possible precautions and practicing due diligence are surgical fires prevented. Every member of the operating room team must be aware and prepared to intervene if necessary (Tables 66–4 and 66–5).

Anatomic Airway Disorders

Congenital Malformations

These malformations were alluded to in the discussion of choanal atresia. In contemporary obstetric practice, it now is possible to identify and diagnose many airway lesions in the prenatal period. Polyhydramnios can be associated with atresia, webs, gastrointestinal obstruction, and neurologic disorders. Mass lesions include teratomas, cystic hygromas, and hemangiomas. If an airway lesion is undetected and the delivery unexpected, securing the airway may be difficult or impossible. Fatal outcomes can be prevented with advance planning.

A report by Farrell[58] examined this problem. Once a diagnosis has been established, an elective cesarian section is the preferred technique for delivering the fetus. It is scheduled early enough to avoid spontaneous labor and yet late enough to allow pulmonary maturation to occur. Such a complicated delivery requires two surgical teams: an obstetric team and a neonatal team. The neonatal team should include a pediatrician, pediatric anesthesiologist, and pediatric otorhinolaryngologist. Each team will have its own setup and equipment. The operating room for the procedure should be large enough to comfortably accommodate both groups. Careful planning and practice are necessary prior to delivery. Once the infant's head emerges, the neonate team will secure the airway as planned. This often will occur before umbilical separation.

Craniofacial abnormalities range from an incomplete cleft lip to complete centrofacial dysgenesia. Congenital malformations include Beckwith-Wiedemann syndrome, cleft lip and palate, craniocarpotarsal dysplasia/ Freeman-Sheldon/whistling face syndrome, craniofacial dystosis, fibrodysplasia ossificans progessiva, hemifacial microsomia, Klippel-Feil syndrome, mandibulofacial dystosis/Treacher-Collins syndrome, mucopolysaccharidosis, Pierre-Robin syndrome, trisomy 21/Down's syndrome, and vascular malformations. Nargozian[59] has written an excellent paper describing an approach to airway management in these special patients. Carenzi et al.[60] described the use of LMAs in two cases involving centrofacial dysgenesia. This overview briefly discusses cleft lip and palate repair.

Cleft Lip and Palate

Cleft malformations of the lip and palate affect 1:500 to 1:2000 births. They may be an isolated finding or associated with other syndromes. These infants have difficulty feeding and fail to gain weight. Aspiration may lead to pulmonary problems. Aside from feeding issues, cleft malformations are associated with chronic serous otitis, which can lead to hearing deficits and speech delay.

Parents of these infants will desire a timely repair for functional as well as cosmetic reasons. Initial lip repair may be done as a "lip adhesion" at approximately 6 weeks of age. This repair is simply a sutured approximation of the cleft edges. This will promote better feeding and weight gain prior to later procedures. The definitive repair will be done at approximately 12 weeks of age, with revisions after that as needed.

Like lips, cleft palates may be unilateral or bilateral, and they may be complete or incomplete (only soft palate involved). There is a strong association between an incomplete cleft palate, micrognathia, and various syndromes. A submucous cleft only involves the muscles beneath the mucous membranes and cannot be seen on visual examination. Some surgeons repair the soft palate with the lip at 12 weeks of age. Hard palate repair will be accomplished between 9 and 18 months; most surgeons prefer approximately 1 year of age. The maxilla will have better growth with later repair, but the infant will develop better speech with early repair. These procedures are managed with general anesthesia and endotracheal tube intubation. Securing the airway is not difficult if no other syndromic abnormalities are present.

Malacias

With the exception of reactive airway disease, the malacias are unique among airway disorders in exerting their effects by dynamic processes. These disorders can lead to significant morbidity and mortality and are a rare condition characterized by softness of the airway structures. A review article by Austin and Ali[61] fully describes the assessment, treatment, and management of tracheomalacia and bronchomalacia in children. Laryngomalacia can produce similar symptoms.[62] Malacias refer to conditions caused by cartilage softness that leads to airway collapse and obstruction (Figure 66–7).

Excessive intrathoracic pressure during expiration creates narrowing and airway collapse. The patient will have wheezing unresponsive to bronchodilators. Less commonly, extrathoracic causes produce collapse during inspiration demonstrated by stridor. Most patients suffering from airway malacia are neonates who have aortopulmonary malformations, bronchopulmonary dysplasia, or tracheoesophageal malformations. Congenital airway malacia may be an isolated finding or part of a syndrome. Acquired airway malacia results from chronic compression that limits cartilage growth. Thus, even after a "pexy procedure," airway collapse may still occur (Figure 66–8).

Being a dynamic airway disorder, malacia assessment is best accom-

TABLE 66–4.

Airway Fire Precautions

1. Use a laser endotracheal tube, or consider tubeless technique, apnea, or jet ventilation.
2. Reduce inspired O_2 <30%.
3. Avoid N_2O; use air or helium.
4. Fill endotracheal tube cuff with saline dye or lidocaine jelly.
5. Place soaked gauze around airway.
6. Use only H_2O-based solvents.
7. Limit laser exposure.
8. Maintain ready source of H_2O.

TABLE 66–5.

Airway Fire Protocol

1. Stop ventilation.
2. Stop O_2 flow and flood airway with water.
3. Remove endotracheal tube and examine the airway.
4. Mask ventilate the patient and reintubate.
5. Determine injury via bronchoscopy.
6. Monitor the patient for 24 hours.
7. Consider steroid administration.
8. Provide antibiotics and ventilatory support as needed.

FIGURE 66–7. Tracheomalacia as seen in an 11-month-old girl. Note how the posterior wall has collapsed into the tracheal lumen. (Courtesy of Christopher Hartnick, MD, Massachusetts Eye and Ear Infirmary.)

plished by flexible bronchoscopy in a spontaneously breathing patient. Typically this is accomplished by performing a mask induction on the neonate. Once the patient is under anesthesia, a bronchoscope is introduced to observe and record airway structures while the child is breathing. The patient receives 100% oxygen under insufflation and supplemental intravenous anesthesia during the study. Combinations of propofol and remifentanil, when titrated to effect, work very well. The goal of the anesthetic is to prevent airway collapse by using positive end-expiratory pressure/CPAP and to avert coughing. Videofluoroscopy with or without contrast can be useful. CT and MRI scans cannot show the dynamic processes but can reveal which anatomic structures may be compressing the airway. Spirometry data allow one to assess the functional impact of the disorder. As discussed by Austin and Ali, treatment can be (1) long-term ventilation/CPAP, (2) resection of the affected segment, (3) external splinting, (4) pexy procedures, and (5) stenting. At present, the last two modalities appear to offer the most promising results.

Subglottic Stenosis

Subglottic stenosis refers to any condition in which the trachea is narrowed by a fixed lesion that compromises air flow. Pediatric subglottic stenosis can result from congenital causes, such as abnormal cartilage, or acquired causes, such as prolonged intubation, trauma, burns (thermal and chemical), gastroesophageal reflux disease, and mass compression. Adult subglottic stenosis is almost entirely of the acquired variety. There are few experiences as frustrating to the anesthesiologist as an inability to advance an endotracheal tube beyond the vocal cords following what appeared to be a routine laryngoscopy.

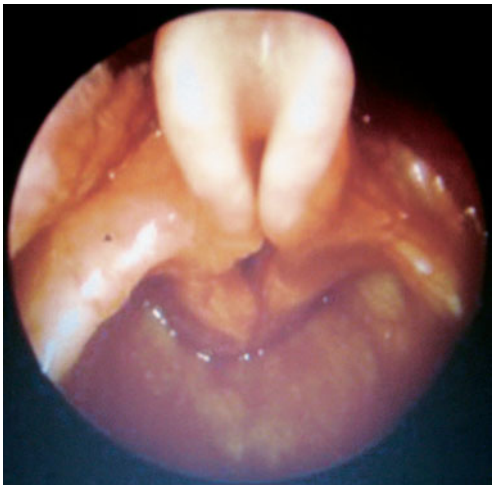

FIGURE 66–8. Laryngomalacia as seen in a 1-day-old neonate presenting with stridor. (Courtesy of Christopher Hartnick, MD, Massachusetts Eye and Ear Infirmary.)

A full-term infant has a subglottic diameter of approximately 5–6 mm. Congenital subglottic stenosis is defined as a subglottic diameter <4 mm or the inability to pass a 3.0-mm bronchoscope or 3.0-mm endotracheal tube. For premature infants weighing <1500 g, consider a smaller diameter, for example, the inability to pass a 2.5-mm endotracheal tube. A simple grading system is used to classify the severity of subglottic stenosis. Grade I lesions exhibit 0–50% obstruction. Grade II lesions exhibit 51–70% obstruction. Grade III lesions exhibit 71–99% obstruction. Grade IV lesions exhibit no detectable lumen and are incompatible with life unless a fistula or cleft is present, permitting air exchange. Typically, grade I and II lesions are mildly symptomatic. Grade III and IV lesions will require surgical repair (Figure 66–9).

The short-term solution is to intubate the patient's trachea. Long-term treatment options include observation (only for grade I and II lesions), endoscopic dilation, CO_2 laser ablation, tracheostomy, anterior cricoid split, laryngotracheal reconstruction, and cricotracheal resection. Endoscopic dilation may be of benefit in early stenosis but is ineffective in treating firm stenosis. CO_2 laser has been used for circumferential soft stenosis but is limited in other conditions. Zawadzke-Glos et al.[63] demonstrated promising results using argon plasma coagulation for treatment of laryngeal stenosis. A tracheostomy often is the initial step in management. It provides a safe airway, allows the infant to grow, optimizes the patient's pulmonary status, and allows for treatment of gastroesophageal reflux disease. Tracheostomy is not a benign procedure. Aside from quality-of-life issues, complications can result in significant morbidity and mortality. For these reasons, early airway reconstruction is desired.

The anterior cricoid split is a procedure that can be used with or without a cartilage graft. Duration of stenting is based upon the infant's weight. If the infant weights <2000 g, the stent will remain in place for at least 2 weeks. For infants weighing >2500 g, the stent will

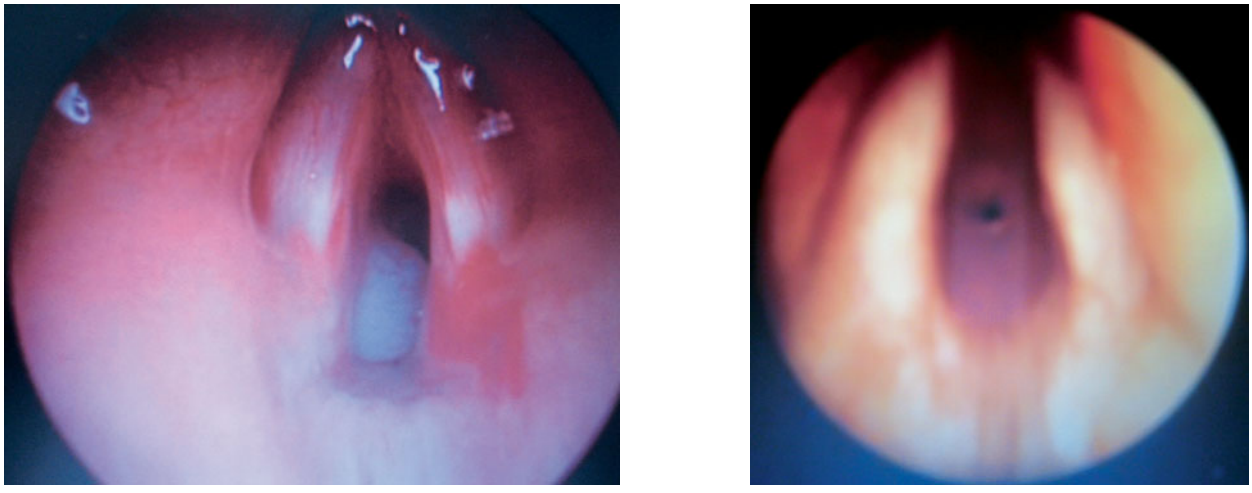

FIGURE 66–9. Left. Type II subglottic stenosis in a neonate caused by an hemangioma. **Right.** Type III subglottic stenosis secondary to trauma in an otherwise healthy 4-year-old boy. (Courtesy of Christopher Hartnick, MD, Massachusetts Eye and Ear Infirmary.)

be removed after 1 week. Indications for an anterior cricoid split include two or more previous extubation failures because of subglottic stenosis, weaned from the ventilator for at least 10 days, supplemental oxygen <30%, normotensive for at least 10 days, and no acute upper respiratory tract infection or congestive heart failure within the previous month. Ultimate decannulation success rates are approximately 75–80%. As an alternative to an anterior cricoid split, Forte et al.[64] achieved excellent results with thyroid ala cartilage reconstruction.

Tracheal Reconstruction or Resection

Laryngotracheal reconstruction is considered once an infant reaches a weight of 10 kg. A laryngotracheal reconstruction can be an anterior, posterior, or lateral repair, and the graft may be of rib, thyroid ala, or auricular origin. Single-stage laryngotracheal reconstruction procedures are indicated for older children with minimal glottic involvement and no pulmonary pathology. Usually only a single graft is involved. Indications for two-stage laryngotracheal reconstruction procedures include extensive grafting, concomitant glottic pathology, and significant tracheomalacia. Decannulation rates for grade II and III lesions vary from 91–97%. For grade IV lesions, the rate declines to 71% (see Walner).[64a]

Cricotracheal resection is an alternative in select patients with discrete grade III or IV lesions. The stenosis should be at least 4 mm distal to the vocal cords. This location will ensure later voice quality. Some investigators suggest these patients have less speech pathology compared to laryngotracheal reconstruction patients.[65,66] Triglia et al.[67] have provided an extensive review of the technique. The duration of postoperative stenting remains controversial, and there is a greater risk of recurrent laryngeal nerve injury with this procedure. Various studies have demonstrated decannulation rates of 85–100% for grade III and IV lesions.

At my institution, anterior cricoid split, single-stage, and two-stage laryngotracheal reconstructions are frequently performed. The patient typically arrives with a tracheostomy. Following an inhalation induction and establishment of intravenous access, the trach cannula is removed and replaced with an appropriate-size reinforced endotracheal tube. The graft is harvested next; this is the source of most postoperative discomfort. Once the graft is obtained and shaped, the resection and reconstruction begin. Depending upon the location of the lesion, the endotracheal tube may be advanced or withdrawn small distances to provide better surgical access. Once the reconstruction is complete, a nasal intubation is performed. The patient then is taken to the intensive care unit and kept intubated for 7–10 days. The entire operation takes from 4–6 hours to complete.

Tracheotomy and Tracheostomy

A tracheotomy is an incision or opening into the trachea. A tracheostomy is the creation of a permanent opening in the trachea such that the mucous membrane becomes continuous with the external epithelium. Tracheostomies are common surgical procedures familiar to every anesthesiologist and are not discussed at length. There are many indications for a surgical airway, and once established there is palpable relief within the operating room. A tracheostomy is rarely performed on the ideal 70-kg, otherwise healthy patient. Patients who are obese, who have undergone previous neck surgery, or have experienced trauma may present the surgeon with a significant technical challenge. If a patient is unstable and needs an urgent surgical airway, a tracheostomy can be performed using only local anesthesia with sedation.

Patients who require tracheostomy are brought to the operating room and placed in the supine position with the back slightly elevated. This position promotes respiratory effort and provides better surgical access. An inflatable shoulder roll or stack of towels is placed under the shoulders to extend the head and further expose the neck. If the patient is already intubated, the surgeon proceeds directly to the tracheotomy. This procedure is not without its complications. Rarely, the surgeon pierces the endotracheal tube cuff and produces a large leak. If ventilation becomes compromised, a throat pack can be placed or the endotracheal tube replaced. The surgeon also can approximate the wound to reduce the leak. Airway fires are known to occur, particularly if 100% oxygen or high concentrations of N_2O are used in the

presence of electrocautery. Once the trachea is fully exposed, the surgeon requests that the endotracheal tube cuff be deflated and the tube slowly retracted cephalad, but with the tube tip still below the glottis so that it can be advanced again if necessary. After electrocautery is completed, ventilation with 100% oxygen is performed for at least 60 seconds prior to withdrawal of the endotracheal tube and insertion of the tracheostomy cannula. After the tube is withdrawn cephalad, the surgeon inserts the tracheostomy cannula and passes the new circuit to the anesthesiologist. Great resistance to ventilation should immediately alert the practitioner to incorrect cannula placement. The presence of CO_2 via capnography, the presence of bilateral breath sounds, and the ability to ventilate the patient all indicate a successful tracheostomy. Only after ventilation is verified should the endotracheal tube be removed entirely.

The approach to pediatric tracheostomy is similar to that for adults, except that children will not cooperate for this procedure under local anesthesia. Indications for pediatric tracheostomy include prolonged ventilation, laryngotracheal malacia, subglottic stenosis, respiratory papillomatosis, alkali ingestion, and craniofacial syndromes.[68] A common technique is the percutaneous dilational tracheostomy first described by Ciaglia in 1985. A modified percutaneous dilational tracheostomy set called the Ciaglia Blue Rhino® has been introduced and used with good results.[69] Other tracheostomy sets include the Percu-Twist®[70] and Fanconi® translaryngeal tracheostomy.[71] Pediatric tracheostomies frequently are accomplished using bronchoscopic guidance.

Maxillofacial Reconstruction

Maxillofacial surgery is performed to repair facial trauma or correct facial deformity. Midface fractures are described using the Le Fort classification. In this approach, a class I fracture involves the lower third of the nasal septum and maxilla passing above nasal floor, and mobilizes the maxillary alveolar process, palate, part of the palatine bone, and lower third of the pterygoid plates. Oral or nasal intubation can be established, and the airway usually is intact. Nasal intubation is contraindicated in a Le Fort II fracture, which involves the upper nasal bone, under the zygomaticomaxillary suture and through the pterygoid plate. A Le Fort class III fracture separates the base of the skull from the midface and is another contraindication to nasal intubation. Prior to surgery, the patient must be fully evaluated for any airway compromise, other traumatic injury, and other preexisting medical problems. Depending on the nature of the injuries, a facial fracture repair may be delayed to stabilize the patient's condition.

Often, a nasal intubation is requested to provide better surgical access. As mentioned, however, nasal intubations are contraindicated in Le Fort II and III fractures and in the presence of CSF leak. Nasal intubations are not entirely benign. They can lead to bleeding, damage turbinates, increase the risk of sinusitis and otitis, and may be difficult to perform in the presence of a traumatized airway. It is unwise to blindly pass a nasal endotracheal tube into a potentially disrupted nasopharynx. The tube can be directed into a sinus, the orbit, the hypopharynx, and even intracranially. Nasal intubations are discussed in a separate section. A tracheostomy can be performed if facial trauma is too severe or in the presence of a basal skull fracture. Tracheostomies have complications, and the anterior neck itself may be injured.

Other options for securing the airway are available. Kannan et al.[72] described using an intubating LMA to facilitate an awake fiberoptic intubation in a severe facial trauma case. In another approach, in 1986 Altemir[73] first described placing a submental intubation. A submental intubation is a secure surgical airway that gives open access to the oral cavity and does not elicit the complications of a nasal intubation or tracheostomy. Essentially, a submental intubation is an oral intubation with the proximal end of the endotracheal tube passed through an incision in the floor of the mouth and connected externally to the anesthesia circuit. It is a useful airway technique for maxillofacial surgery in patients with severe oral, nasal, and neck trauma. In an interesting case, Arya et al.[74] described using a pharyngeal loop to place a retrograde submental intubation. It also is appropriate for patients undergoing elective procedures who are not expected to need prolonged postoperative ventilation. Submental intubations are used in European practice but have yet to be fully accepted in North American practice (Figure 66–10).

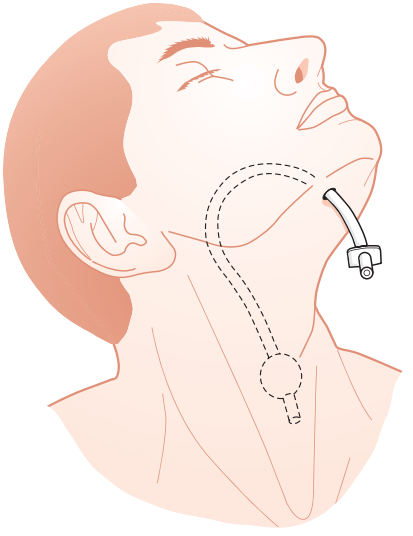

FIGURE 66–10. Submental intubation. Note that the proximal end of the endotracheal tube emerges just medial to the mandible. (Courtesy of Bob Galla, Massachusetts Eye and Ear Infirmary.)

An uncommon surgical procedure is facial bipartition. This is done to correct severe deformities or malformations. Mallory et al.[75] reviewed a series of 22 cases and noted the most significant complication was hemorrhage. Every patient required an intraoperative blood transfusion. Four of the 22 patients required postoperative ventilation, which was associated with younger age and major blood loss.

Oral and Dental Surgery

Orthognathic reconstructions are elective procedures to correct malocclusion or facial deformity. These cases are performed by oral or maxillofacial surgeons. Typically a sagittal split osteotomy of the mandible is done to advance or retract the lower jaw. The maxilla also can be moved forward or in a transverse direction. Care must be taken with the intubation. These patients may present to the operating room with semipermanent orthodontic devices in place. In addition, they may have anatomic abnormalities, such as prominent incisors, retrognathia, or small mouths.

Nasal intubations

Orthognathic surgery is an oral procedure, and the patient will require a nasotracheal intubation. As mentioned above in Maxillofacial Recon-

struction, nasal intubations are more traumatic than oral intubations and have their own complications. Hall and Shutt[76] have provided a complete and excellent review of nasotracheal intubations. Epistaxis, bacteremia, and possible posterior pharyngeal wall laceration are possible. It is also possible to enter the hypopharynx and create a false passage. Rarely, the tube becomes obstructed with avulsed tissue from the inferior turbinate. Other problems include maxillary sinusitis, otitis, and possible cuff rupture from passage through the turbinates or by the MacGill forceps.[76,77]

Contraindications to nasal intubation include the presence of a CSF leak, basal skull fracture (Le Fort III), Le Fort II fracture, presence of a nasal FB, and a traumatized nasopharynx. Relative contraindications include bleeding coagulopathy, cardiac valve disease, and immunocompromised condition.

Prior to a nasotracheal intubation, the patient should assist the practitioner and identify the more patent nasal passage prior to induction. If the patient is uncooperative, a steel blade can be placed beneath the nostrils and the side that steams greater is more open. It is helpful to administer vasoconstrictors to both sides and to use a local anesthetic lubricant. Other techniques are available to assist the anesthesiologist.[78] Use of a soft red rubber nasal tube to expand the nostril and spread the lubricant is helpful.

After induction and prior to laryngoscopy, the anesthesiologist should gently place the endotracheal tube in the selected nostril and advance the tube parallel to the palate. The endotracheal tube should not be advanced in a superior direction toward the nasal bridge. Advancement should stop once the tube is in the pharynx. There will be resistance in the nasal passage until deep posterior, where a sudden "give" is felt as the nasotracheal tube passes the inferior turbinate. Upon laryngoscopy, bloody secretions may be present in the oral cavity. Suctioning should reveal the tip of the endotracheal tube lying on the posterior pharyngeal wall. Examination of its location and the glottis will determine if the tube can be advanced into the trachea without using the MacGill forceps. This will lessen the chances of a torn cuff or more trauma from airway instruments. Once the trachea is intubated, inflate the cuff, ventilate, observe for CO_2 and condensation, and listen for bilateral breath sounds. When the tube is being secured, it should not pull upon the nose or pressure necrosis may occur. I like to place a band of tape completely around the patient's head just above the ears. This becomes the foundation on which the tube tape is secured. The circuit is brought down from the forehead and underneath the operating room table. The endotracheal tube and circuit should be secured in a manner that will allow flexion and extension of the head without jeopardizing their position.

Other problems may arise after surgery begins. During maxillary osteotomy, the osteotome may slice through the endotracheal tube and pilot tube. When this occurs, a secure airway must be quickly reestablished to prevent a life-threatening event. In a brief communication, Davies and Dyer[79] reported the successful use of an Obwegieser nasal septal osteotome. This instrument has two blunt horns that prevent direct contact with the endotracheal tube. I am familiar with a case in which extubation of a trachea became impossible after a palate expansion. CT scan revealed surgical wires passing through the nasotracheal tube, preventing its removal. These complications do occur, and one should be prepared.

Orthognathic Surgery

Hemorrhage may be significant with orthognathic surgery, especially when maxillary procedures are involved. Blood loss can vary between 300 and >2000 mL. Depending upon the procedure, it is recommended that autologous blood be available. Moreover, controlled hypotension with isoflurane or other agents may be helpful. These patients generally are young and otherwise healthy and will tolerate such techniques.

At the conclusion of surgery, the pharyngeal packs are removed and the stomach is suctioned. As with nasal or sinus procedures, swallowed blood can provoke nausea. Appropriate antiemetics should be administered well in advance of the expected extubation. Only after the patient is fully awake with airway reflexes intact should the endotracheal tube be removed. Rigid internal fixation is beginning to replace intermaxillary fixation and provides more postoperative comfort. Intermaxillary fixation will still be encountered and will result in the patient's jaws being "wired shut" using elastic bands or wires. This obviously blocks access to the airway, restricts suctioning, and makes reintubation practically impossible until the mandible is free. When intermaxillary fixation is used, without exception the patient must be fully awake prior to extubation. As long as the patient has intermaxillary fixation in place, cutting instruments to free the airway must be immediately available at the bedside.

Pain management begins early. Narcotics are supplemented by the surgeon providing local anesthetic infiltration directly into the wound. Enlund et al.[80] reported unintentional hypotension during this infiltration. Besides the usual narcotics, other analgesic classes have been investigated. Moller et al.[81] obtained good results with intravenous propacetamol. These results were supported by Van Aken et al.,[82] who found the analgesic qualities of propacetamol similar to those of morphine and better tolerated. The COX-2 inhibitors in general have shown promise as well. However, only celecoxib is available, and additional studies of this specific drug are required to document its efficacy in this circumstance.

Dental Surgery

In recent years dentists have reduced the use of N_2O in the office setting. This was prompted by a number of unfortunate events resulting in patient harm and subsequent increased legal liability. Most office procedures now are performed using a topical anesthetic supplemented by local anesthetic injections. If needed, a preoperative oral sedative (usually a benzodiazepam) can be prescribed.[83]

Because of this trend, it is becoming more common to provide general anesthesia to certain dental patients in a hospital operating room. The vast majority are pediatric patients who are uncooperative and have behavioral problems or who need an extensive amount of repair that is easier to accomplish in one operating room visit rather than multiple office visits.

All of the concerns regarding pediatric anesthesia and oral surgery apply here. Furthermore, the dentist may request a nasal intubation to provide better access to a small oral cavity. These patients may not have seen a pediatrician prior to arrival, and the preoperative physical examination may yield unexpected findings.[84] Pre-

operative anxiety may be an issue with any pediatric patient. In the dental patient with behavioral problems who has a preexisting "fear" of the dentist, this anxiety may manifest as sheer terror. In that circumstance, it may be best to cancel the procedure and reschedule for another day, after appropriate preparation of the patient, family, and clinicians. Appropriate doses of midazolam can be quite effective in this situation. Interestingly, Ong et al.[85] reported an additional analgesic benefit with midazolam.

In most older patients, these procedures are possible with conscious sedation as MAC anesthetics. Certainly the elderly patient needing total extractions prior to a cardiac valve replacement is a candidate for MAC. Some practitioners have reported success using combinations of propofol, midazolam, and even low concentrations of sevoflurane.[86,87,87a]

A final concern is the assistant to the dentist. This person usually is someone from the office who is not trained in standard operating room procedures. Instrument and supply counts are not routinely done. For example, it is not uncommon to find throat packs left behind. Great care and vigilance must be taken to ensure the mouth is empty and free of blood and foreign bodies prior to extubation.

Plastic Surgery

Plastic surgery is a broad surgical field that includes any procedure intended to repair or restore a structure to its perceived normal form. Many of the procedures already discussed as well as those in the section on head and neck surgery can be included in this category. This brief discussion focuses only on rhytidoplasty, commonly called "facelift."

Rhytidoplasty is an elective procedure, and the patient requires a routine preoperative evaluation. Frequently the patients are older, and some will have abused themselves with alcohol and tobacco use. Chronic bronchitis, chronic obstructive pulmonary disease, and coronary artery disease are not uncommon in this population. Conversely, one may encounter the young, otherwise healthy patient. Whereas some procedures can be done under local anesthesia with sedation, rhytidoplasty is commonly performed using general endotracheal anesthesia.

Typically the surgeon requests that the endotracheal tube be secured in the midline, to avoid distorting the face from one side or the other. The endotracheal tube must be well secured because the surgeon will move the head from side to side during the operation. This presents its own challenges in taping, as the surgeon will want to have the face maximally exposed. For this reason, most anesthesiologists will not use an LMA. In the classic technique, the surgeon will "elevate and advance" the skin toward the preauricular region. In addition, liposuction may be used in the submental and submandibular areas. Forehead wrinkles are addressed in the same manner. Initially a midscalp incision is made with the anterior scalp and forehead lowered over the face. The skin is freed, and the flap is raised again. Blepharoplasties can be accomplished by the ENT surgeon or an ophthalmologist specializing in oculoplastics. Chemodenervation by injection of botulin toxin may be done last. As with the use of any medication, anaphylactic reactions can occur.

Once the procedure is complete, the surgeon will be especially concerned about bleeding and edema in the subcutaneous tissues. The anesthetic goals include prevention of patient coughing and "bucking" during tracheal extubation and avoidance of retching associated with PONV. Both coughing and vomiting contribute to facial and orbital ecchymoses. Rama-Maceiras et al.[88] reported less PONV using propofol with remifentanil compared to propofol and fentanyl. Pretreatment with metoclopramide and ondansetron can decrease this risk. In addition, the patient should be fluid loaded and fully suctioned. Once spontaneous ventilation is well established and with the patient's upper torso slightly elevated, the trachea should be extubated during a moderately deep plane of anesthesia. Not uncommonly the face is wrapped in soft gauze and the eyes are covered with ice packs. This gauze may be wrapped tight enough to constrict the patient's airway, a matter that should receive special attention from the anesthesia provider.

ANESTHESIA FOR HEAD AND NECK SURGERY

Patients who present for head and neck surgery may undergo many of the procedures discussed previously as separate operations. The parotid gland, thyroid and parathyroid glands, and a variety of head and neck masses are included under this heading. Various macrosurgical and microsurgical techniques involving both soft tissue and bone may be used. Furthermore, reconstruction may include adjacent tissue or free tissue transfer. These cases can be complex and lengthy, lasting from a few hours to >30 hours on occasion. For the anesthesiologist, airway management, tissue preservation, and nerve monitoring become primary concerns.

Parotid Surgery

Of the three salivary glands, the parotid gland is the largest. Patients may have inflammatory disorders or, more commonly, mass lesions of the parotid gland. Parotid tumors may be classified as of epithelial origin or mesenchymal origin. The majority of patients arrive in the operating room with a presumptive diagnosis. Occasionally anesthesiologists have managed the airway with an LMA for some of these procedures. However, considering the length of the operation (2–4 hours) and a nonneutral head position, most anesthesiologists prefer endotracheal intubation to assure airway access, especially when subsequent access is compromised by the sterile surgical field. After the airway is secured, the patient is positioned with the operative side up and the back slightly elevated.

Facial Nerve Concerns

For the anesthesiologist and surgeon, preservation of the facial nerve is of utmost importance. Early in the dissection, the surgeon seeks to identify the facial nerve by electrical stimulation. With this in mind, it is essential to use a short-acting muscle relaxant or none at all. The surgeon should not begin dissection until a demonstrated train of four has returned. If for any reason the patient must be paralyzed, the operator should be informed of the patient's neuromuscular paralysis status.

Thyroid Surgery

Thyroid surgery is addressed here only briefly (for a more detailed discussion, see Chapter 59). Triiodothyronine (T_3) and thyroxine (T_4), acting in response to thyroid-stimulating hormone, have significant effects on growth and metabolic rates by increas-

ing carbohydrate and fat metabolism. Farling[89] has provided an excellent discussion of thyroid disease and its implications. Thyroid disease is common and is managed medically in the majority of cases. Surgical intervention is indicated for malignancy, obstructive symptoms, retrosternal goiter, unresponsive or recurrent hyperthyroidism, or cosmetic reasons.

Preoperative assessment of the patient undergoing thyroidectomy should include evaluation of coexisting morbidity. Cardiovascular disease can be exacerbated by untreated or poorly treated hyperthyroidism. The patient should be euthyroid prior to operation. Medullary carcinoma is rarely associated with pheochromocytoma. Apart from the routine concerns, the major focus of preoperative assessment is determining airway status. One should examine the patient and review radiographic images to look for any signs of tracheal compression or deviation. The surgeon should inform the anesthesiologist if airway difficulties are suspected. If so, more sophisticated imaging, such as CT or MRI scans, are indicated. If the patient experiences airway obstruction while supine, an awake fiberoptic intubation in the partially recumbent ("beach chair") position may be indicated. It is potentially catastrophic to perform a rapid sequence induction and fail to intubate or ventilate, then expect the surgeon to obtain an emergent tracheostomy through a large goiter. In an interesting study, Bouaggard et al.[90] found that a cancerous goiter but not a large goiter was associated with difficult intubation.

Recurrent Laryngeal Nerve and the NIM® Endotracheal Tube

Recurrent laryngeal nerve injury is a preventable surgical complication in most circumstances. In a study by Yumoto et al.,[91] 40% of surgically related recurrent laryngeal nerve palsies were due to thyroid procedures. The exceptions were patients in whom the malignancy had completely invested the nerve. With meticulous dissection and current monitoring techniques, one should not encounter a recurrent laryngeal nerve palsy after extubation, provided the palsy does not result from the tumor itself. For monitoring purposes, a short-acting muscle relaxant should be used, if at all. However, in a contrasting perspective, Marusch et al.[92] investigated the difference in paralysis between the adductor pollicis and vocalis muscles. They suggest reliable recurrent laryngeal nerve monitoring can be achieved even in the presence of some paralysis. That said, most anesthesiologists advocate recurrent laryngeal nerve monitoring without any evidence of relaxation, in order to assure that neuromuscular blockade is eliminated as an etiologic factor if nerve palsy should occur. A number of investigators have suggested that propofol induction alone can provide excellent conditions for intubation without paralysis.[93,94]

At my institution, a "nerve integrity monitor" (NIM®) endotracheal tube is routinely used for thyroid surgery (NIM® EMG Endotracheal Tube, Medtronic Xomed Surgical Products, Jacksonville, FL). This particular endotracheal tube has electrodes embedded within a band located just superior to the cuff. Under direct visualization, these electrodes are placed in contact with the vocal cords during intubation. The NIM® tube is softer than standard endotracheal tubes, making it more difficult to handle. It also is slightly larger than a standard endotracheal tube, and it is my practice to use a size smaller than that usually indicated for the individual patient (e.g., if inner diameter = 6.0 mm, then outer diameter = 8.8 mm, which is still large for an adult female). Just after induction and intubation, the patient's anesthetic is lightened and spontaneous ventilation is allowed to return. After the patient is positioned and prior to first incision, the nerve signal strength is confirmed and measured by the monitoring technician. Although reliable, the NIM® tube is expensive. As an alternative, Hemmerling et al.[95] used a disposable surface electrode attached to a standard endotracheal tube. They obtained good results in a series of 151 patients. In another approach, Hillerman et al.[96] used a microlaryngeal endotracheal tube, LMA, and fiberoptic scope to continuously observe arytenoid movement.

Complications of Thyroid Surgery

Complications of thyroid surgery can be life threatening. Postoperative hemorrhage can result in a rapidly expanding hematoma, which can directly compress the trachea. Venous and lymphatic obstruction by the hematoma also can produce laryngeal and pharyngeal edema. Recurrent laryngeal nerve injury can cause unilateral vocal cord paralysis, which manifests as hoarseness, breathlessness, glottic incompetence, poor cough, and aspiration. Bilateral recurrent laryngeal nerve injury producing bilateral vocal cord paralysis will lead to immediate stridor and require reintubation and probable tracheostomy. Chronic compression by a large goiter can lead to tracheomalacia. This condition leads to tracheal collapse, resulting in partial or complete obstruction. Unintentional parathyroidectomy can result in hypocalcemia. This may reveal itself several hours postoperatively. Hypocalcemia is suggested by a positive Chvostek's sign (painful facial twitching after tapping the facial nerve) or Trousseau's sign (carpopedal spasm following tourniquet inflation above systolic blood pressure for 3 minutes) and is confirmed by laboratory testing. Treatment involves intravenous administration of calcium chloride.

Thyroidectomies are well tolerated by most patients. They may have complaints of a stiff neck related to surgical positioning. Nonnarcotic analgesics, such as ketoprofen and COX-2 inhibitors, have been studied, with encouraging results, although only one COX-2 inhibitor currently remains on the market in the United States. In an interesting approach, Dieudonne et al.[97] used bilateral superficial cervical plexus blocks to treat postoperative pain. Although somewhat effective, it did not provide the best analgesia by itself. PONV remains a significant issue with these patients. Both 5-HT blockers and dexamethasone have been shown to be effective.

Parathyroid Surgery

Calcium metabolism is regulated by the parathyroid gland. Its hormonal product, parathyroid hormone (PTH), when released, elevates serum calcium levels via increased gastrointestinal absorption, bone resorption, inhibition of renal calcium excretion, and stimulation of renal hydroxylase. It also leads to increased phosphate excretion. Primary hyperparathyroidism is the enlargement and hyperfunction of one or more parathyroid glands. It typically is caused by an adenoma, carcinoma, or hyperplasia. It is manifested by hypercalcemia, hypophosphatemia, hyperchloremic acidosis, polyuria, and polydipsia. Secondary hyperparathyroidism usually results during renal failure following prolonged PTH secretion due to

low calcium concentrations. Other causes include rickets, malabsorption, osteomalacia, and abnormal vitamin D metabolism. Parathyroid surgery is discussed only briefly here. For greater details, see Chapter 59 and the review by Mihai and Farndon.[98]

The anesthesia concerns are similar to those encountered in thyroid surgery. A NIM® endotracheal tube or similar device should be used to assess recurrent laryngeal nerve function. Prior to anesthetic induction, the patient's volume status should be normalized. The greatest danger is cardiac dysrhythmias due to increased calcium levels. Use of normal saline and furosemide can decrease calcium concentrations to reasonable levels. If this method is not effective, intravenous biphosphates, plicamycin, glucocorticoids, calcitonin, or even dialysis can be used. Acidosis increases serum calcium, so hypoventilation should be avoided. Muscle relaxants should be used judiciously in the presence of hypercalcemia. Chronic hyperparathyroidism can result in weakened bones. Care must be taken during patient positioning, movement, and laryngoscopy.

Parathyroid surgery can be tedious, and even experienced surgeons can have difficulty identifying the glands. Prior to incision, a PTH level is drawn. Once the suspected gland is removed, a second PTH level is obtained. A significant decrease in PTH levels while the patient is still in the operating room indicates the offending source has been removed.

Head and Neck Cancers

Malignant disease of the head and neck represents approximately 5% of all human cancers. Surgical intervention includes laryngectomy, pharyngectomy, glossectomy, hemimandibulectomy, and neck dissection. Neck dissections are further described as "radical" or "modified radical." A modified radical neck dissection is intended to spare one or more of the nonlymphatic structures within the neck. This may include the sternocleidomastoid muscle, spinal accessory nerve, and jugular vein. Reconstruction follows dissection, and some of these cases may last anywhere from 12 to >30 hours.

Most patients who present for surgery are between 50 and 80 years old, with males exceeding females by a 2:1 margin. Frequently these patients have significant coexisting illness, including cardiovascular disease, chronic obstructive pulmonary disease, and renal disease. They often are heavy smokers and likely abuse alcohol. Consistent with this profile is poor nutrition; the patient may appear wasted and cachectic. If the patient appears to be an unreliable or devious historian, he or she should be observed closely for delirium tremens postoperatively. An extensive medical evaluation, including possible diagnosis and treatment of malnutrition, is indicated in an unusual number of these patients (see Chapter 16 for details regarding the preoperative evaluation of patients with malnutrition).

Patients may exhibit mass lesions that complicate their management. In an editorial review, Mason and Fielder[99] have given a practical approach to the assessment and management of these patients. A key point is that if a patient presents with severe stridor and gross anatomic distortion limiting endoscopic views, then the airway should be secured by a tracheostomy performed under local anesthesia. To illustrate what may be encountered, Bonner and Taylor[100] describe two cases of almost complete laryngeal obstruction (2 and 3 mm) resulting from tumor recurrence in the neck. Fiberoptic intubation proved impossible. One case was managed by an urgent awake tracheostomy. The other case was managed using a reinforced LMA and controlled ventilation. Awake fiberoptic intubation and an awake tracheostomy remain the techniques of choice with questionable airways. Preparation and sedation for an awake fiberoptic intubation are essential for success. Besides the usual agents, other medications have been examined in this setting, with remifentanil, dexmedetomidine, and low-dose ketamine showing promise. Finally, Bhatnager et al.[101] demonstrated the usefulness of the Fastrach LMA to facilitate fiberoptic intubation. Well before surgery, the anesthesiologist should be prepared with multiple plans for securing the airway.

Free Flap Reconstruction

If a reconstruction is planned, it is necessary to know the donor site prior to placing any intravenous or arterial cannulas. Donor tissue (flap) is used to reconstruct defects of the oral cavity, mandible, laryngopharynx, craniofacial region, and facial skin. Common pedicle flaps include the cervicothoracic skin, pectoralis major myocutaneous, sternocleidomastoid myocutaneous, temporoparietal fascial, and pericranial. A free flap is donor tissue removed entirely from a distant site, with loss of prior blood supply, and transplanted to the area of defect. Microsurgery techniques are used to reconstruct the vascular supply to ensure flap survival. Typical free flaps include the radial forearm, rectus abdominus, and latissimus dorsi. Composite free flaps contain both soft tissue and bone and are used for oromandibular reconstruction. These complex flaps include the scapular osteocutaneous, iliac crest osteomyocutaneous, and, most useful, the fibular osteocutaneous. The fibular flap contains up to 25 cm of bone, making total mandibular reconstruction possible.

Because these cases often are lengthy, temperature maintenance and fluid management are just two of many concerns. In addition to the standard monitors, one may wish to place a central venous or pulmonary arterial catheter if indicated by the patient's condition. Antecubital, femoral, or subclavian approaches may be used, depending upon the source of the free flap. Early in the procedure, a tracheostomy is performed to secure the airway and provide unrestricted access to the oropharyngeal cavity and neck. Blood loss can be substantial and rapid. An arterial cannula will provide continuous blood pressure monitoring, and allow blood gas, electrolyte, and hematocrit measurements. Slight elevation of the head may decrease venous bleeding but increases the risk of venous air embolism. A Foley catheter is needed to assess urine output and guide fluid replacement. Anesthesia is maintained by a combination of narcotics and volatile agents. Nerve monitoring is performed, so short-acting muscle relaxants should be used at least until the surgeon determines that nerve stimulation at the surgical site will no longer be necessary. Some investigators have examined continuous nerve blocks as a supplement to intravenous analgesics.[102,103]

The anesthesiologist's efforts should include a focus on factors that will promote flap survival. Success of the operation depends partially on maintaining intravascular volume and adequate blood pressure to enhance perfu-

sion in the donor tissue. This can be a challenge in the unhealthy patient who does not tolerate anesthesia well. Fluid management and perfusion pressure should be the mainstays of cardiovascular management; however, overloading runs the risk of pulmonary edema and flap congestion. Vasoconstrictors should be used only rarely to prevent vasoconstriction in the flap microcirculation. Use of fluids, lighter levels of anesthesia, and, briefly, a slight head-down position all contribute to donor graft circulation. To minimize microthrombosis, blood transfusions should be limited.

Complications of Neck Dissection

Both medical and surgical complications are not uncommon in these patients. Hemorrhage can be acute or delayed. It may warrant surgical exploration for a hematoma, which can compromise the airway as well as the vascular supply to the flap. If a tracheostomy has not been performed, laryngeal edema can produce rapid airway obstruction. Pneumothorax can occur by air entering at the apex of the lung or rupture of the mediastinal pleura. Because the head and neck are commonly elevated above the heart, venous air embolism can occur with potentially fatal results. Furthermore, I have witnessed asystole in a patient when cold irrigation was used on exposed carotid sinuses. Immediate administration of warm irrigation restored sinus rhythm within several seconds. Other cardiac abnormalities can occur.[104,105] Neck dissection can result in injury of the following nerves: superior laryngeal, facial, vagus, phrenic, hypoglossal, cervical sympathetics, spinal accessory, lingual, and brachial plexus. Rarer complications include a chylous fistula, subcutaneous emphysema, increased intracranial pressure, salivary fistula, wound infection, and gangrenous flap tissue. In spite of these issues, neck dissection with flap reconstruction has a success rate >90% (flap survival).

SUMMARY

Anesthesia for ENT surgery provides an extensive range of challenges for the anesthesiologist. It is absolutely essential to develop an open working relationship with one's surgical colleague. There are perhaps few other anesthesia subspecialties where intraoperative communication is so crucial.

Many of the skills used on a routine basis have applications in other areas. One can use mask, spontaneous, controlled, and jet ventilation in a single procedure. Likewise, it is not uncommon in one's daily practice to use controlled hypotension, perform deep extubations, assist in nerve monitoring, and treat seemingly intractable PONV.

The challenges are great, as are the rewards. When a patient is safely and successfully discharged home you may be the only who knows the difficulty encountered. That in itself can be immensely satisfying.

CHAPTER 67

Outpatient Anesthesia

J. Lance Lichtor, MD, and Suhas V. Kalghatgi, MBBS, MD, FFARCSI

Historians dispute whether Crawford Long, in 1842, or William Morton, in 1846, first used ether for anesthesia in the United States. What these two pioneers had in common was that their patients were outpatients. After that time and for more than 100 years after, hospitalization of patients both before and after operation was the norm. Although the primary reason was patient safety, current evidence shows that for most operations, safety is no different—or perhaps is better—when surgery is performed on an outpatient basis.

The majority of operations today are performed on an outpatient basis. The cynic might assert that the anesthetic used for an outpatient procedure is no different than that used for an inpatient procedure. However, some aspects of outpatient or office-based care are different from hospital care. For example, if an inpatient or outpatient undergoes a procedure in the hospital and experiences nausea, the patient simply is transferred to a hospital room. If an individual undergoes the same procedure in a doctor's office and requires hospital admission because of nausea, the patient must be transferred by ambulance to a hospital. For most freestanding ambulatory surgery centers (ASCs), the anesthesiologist must stay in the facility until the last patient leaves. In a hospital, on-call physicians usually are available, and a patient's anesthesiologist usually can leave at some point after the procedure has been completed.

Patient selection for an outpatient procedure is important both to ensure that the patient undergoing an outpatient procedure remains an outpatient after the procedure has been completed and to improve the efficiency of the outpatient facility. Preoperative screening, performed either in a clinic or by telephone, is essential for ensuring that medical management of any preexisting condition is optimized and that the patient is an appropriate candidate for outpatient surgery. Preoperative screening also reduces patient anxiety. Morbidity from an outpatient procedure performed on a patient with preexisting disease should be no greater than if the patient were hospitalized.

The length and complexity of operations performed in the ambulatory setting have increased. Although in the past only patients evaluated as American Society of Anesthesiologists (ASA) physical class I or II were candidates for ambulatory surgery, today patients in ASA physical class III or IV whose systemic disease is medically stable are candidates for outpatient procedures. This chapter addresses patient management and the selection of appropriate patients and procedures for ambulatory surgery.

PLACE, PROCEDURES, AND PATIENT SELECTION

Ambulatory procedures can be performed in a hospital, in a freestanding satellite facility that is either independent or affiliated with a hospital, or in a physician's office. Although the procedure may be the same wherever it is performed, the cost typically is less if the procedure is not performed in a hospital. One example is a study performed for the Federated Ambulatory Surgery Association in 2003.[1] Medicare claims that included at least one surgical procedure payable by Medicare in both ambulatory and outpatient settings were analyzed. The authors repriced the hospital outpatient claims to Medicare rules and rates for ASCs and found that the average claim was $320 less for a procedure performed in an ASC than in a hospital. Given the total number of procedures that could be switched, Medicare could have saved almost $1.6 billion in 2005. The article estimated that >80% of operations performed in the United States were performed as outpatient procedures and 20% were performed in ASCs.

For outpatient surgery, patients arrive and leave on the day of the procedure. If postoperative complications normally are high or intensive physician or nursing management is required after the procedure, then the procedure is not really an outpatient procedure. Postoperative management is changing, though; procedures that in the past were performed only on inpatients can be successfully managed today as outpatient procedures. For example, patients can be sent home with catheters (i.e., as in continuous regional techniques) for controlling postoperative pain that previously could be managed only in a hospital.

KEY POINTS

1. The majority of operations today are performed on an outpatient basis.
2. Although restrictions on the types of cases appropriate for ambulatory surgery have been reduced, hospital admissions after outpatient procedures should not be common.
3. Preoperative administration of the combination of midazolam and fentanyl can make patients sleepy up to 8 hours later. Preoperative sedation is not required for every patient.
4. Postoperative pain is less after regional anesthesia, although performing a block requires more time than does induction of general anesthesia and has a higher incidence of failure.
5. Even when thiopental is used only for induction, psychomotor impairment can be evident up to 5 hours after administration compared to only 1 hour after propofol.
6. Although some drugs have faster recovery time than others, actual discharge from an ambulatory center may depend more on administrative issues, such as obtaining the written discharge order from the surgeon or anesthesiologist.
7. Nausea probably is the most important factor contributing to a delay in discharge and an increase in admission after ambulatory surgery. Combination therapy probably is the most effective way to control postoperative nausea and vomiting.
8. Pain may be associated with nausea, and treatment of the pain frequently decreases nausea.

The list of procedures that can be performed appropriately only in outpatients can quickly become outdated. Length of surgery, and thus length of time for recovery, is not strictly a criterion for excluding a surgery as an outpatient procedure because there is little relationship between length of surgery and time to awakening after a procedure. If the intention is to close an outpatient facility at a certain time of day, then longer procedures should be performed earlier in the day. Most facilities would not perform an outpatient procedure if the need for a blood transfusion is anticipated.

An infant with a history of prematurity may not be an appropriate candidate for outpatient surgery. If an infant was born prematurely and at the time of the procedure is younger than 50 weeks postconception, then admission for 23 hours is recommended because of the strong relationship between apnea and postconceptual age (Fig. 67–1).[2] Spinal anesthesia is appropriate for some procedures, and the incidence of apnea after spinal anesthesia without the use of additional drugs for sedation is much less than after general anesthesia.[3] Because apnea might not be apparent for up to 12 hours, hospital admission probably is best for this group of patients.

Advanced age is not a reason to exclude a patient from undergoing an outpatient procedure, although the risk of concomitant systemic disease increases with age. No evidence indicates that recovery is longer with increasing age, although patient age certainly affects drug pharmacokinetics, and appropriate adjustments are necessary. Increased age is a risk factor for unexpected admission after ambulatory surgery.[4,5]

ASA physical status should not be a reason to avoid treatment in an outpatient facility. In a study of patients undergoing outpatient surgery, ASA I and II patients were compared with ASA III patients. The authors found no significant differences in unplanned admission rates, unplanned contact with healthcare services, or postoperative complications in the first 24 hours after discharge.[6] Specifically, when patients with specific diseases (e.g., morbid obesity and obstructive sleep apnea) were studied, no greater incidence of unplanned admissions or other adverse postoperative events were apparent.[7,8]

An ambulatory surgical procedure, whether performed in a hospital, office, or ASC, is performed on an outpatient basis. Patients must understand that they will go home on the day of surgery. They must have with them a responsible person who can escort them from the facility and ensure that postoperative instructions are followed. The patient must be able to tolerate pain from the procedure, assuming adequate pain therapy is provided. For certain operations performed on an outpatient basis, such as laparoscopic cholecystectomy or transurethral prostate resection, the patient must remain close to the medical facility in case he or she requires urgent care. Appropriate time or distance from a facility must be defined by the facility.

With proper patient selection and assuming no untoward intraoperative complications occur, hospital admission after an outpatient procedure should not be common. In ASCs connected to a hospital, admission after an ambulatory procedure is not difficult; a patient can simply be transferred to a hospital room. In freestanding ASCs, hospital admission entails transfer by ambulance. Such a transition may be traumatic to the patient and his or her family, as well as to the anesthesia practitioner. For these reasons, all patients, whether young or old, require a careful preoperative evaluation that includes a history and physical examination.

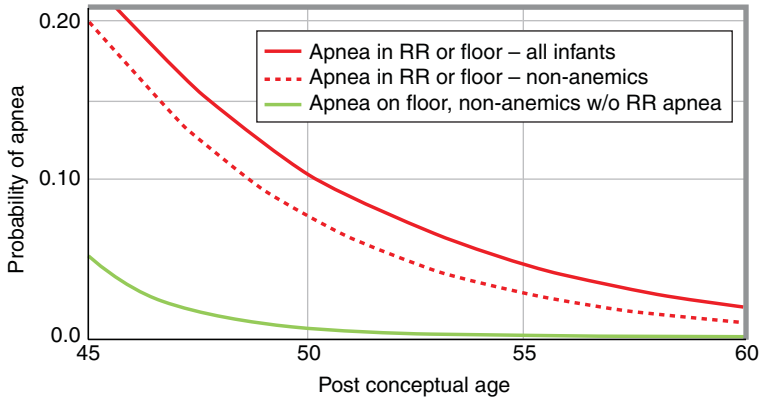

FIGURE 67–1. Risk for apnea after surgery is a function of gestational age, hematocrit, and presence of apnea in the postanesthesia care unit (PACU). The predicted probability for apnea by weeks postconception is shown for all infants (solid line), nonanemic infants (irregular line), and infants who were not anemic and did not have apnea in the PACU (broken line). (From Cote et al.[2] with permission.)

PREOPERATIVE EVALUATION AND REDUCTION OF PATIENT ANXIETY

Before an outpatient procedure, a patient can be screened either at the facility or by telephone. Preoperative screening will identify patient medical problems and suggest appropriate diagnostic and therapeutic measures; educate the patient on requirements that must be followed before surgery, such as abstaining from food or drink and wearing appropriate attire; educate the patient on transportation needs after the procedure; identify patient dependent care issues after the procedure; and instruct the patient on proper postprocedural care. Airway assessment is another important factor accomplished by a face-to-face interview. During the screening period, on the day before the procedure, the anesthesiologist possibly may speak with and establish rapport with the patient but may not be able to do because of clinical demands. Automatic history taking is useful, particularly when preoperative tests are ordered based on patient's history. Preoperative screening can help alleviate the patient's anxiety, particularly through reassurance from nonanesthesia staff. A patient who comes to the facility for preoperative screening can receive booklets or audiovisual instructions. Management of anxiety in pediatric patients is unique. Information modeling and coping-based programs have been shown to reduce anxiety in children, with maximal anxiety reduction obtained if performed immediately before surgery.

Upper Respiratory Tract Infection

If on the day of surgery a patient, particularly a child, presents with an upper respiratory tract infection (URI), it probably is safe to proceed

with the planned procedure as long as the patient does not have a fever or elevated respiratory rate (possibly indicating pneumonia), has a normal appetite, and does not appear toxic. In one study of more than 1000 children (ages 1 month to 18 years) examining the risk factors for adverse respiratory events in children with URIs, the authors found no difference in laryngospasm or bronchospasm if the children had active URIs, URI within the past 4 weeks, or no symptoms.[9] However, the children with active or recent URIs had more episodes of breathholding, more incidences of desaturation <90%, and more respiratory events compared to children without symptoms (Fig. 67–2). Independent risk factors for adverse respiratory events in children with URIs included use of an endotracheal tube [versus laryngeal mask airway (LMA) or face mask]; history of prematurity, reactive airway disease, or parental smoking; surgery involving the airway; presence of copious secretions; and nasal congestion.

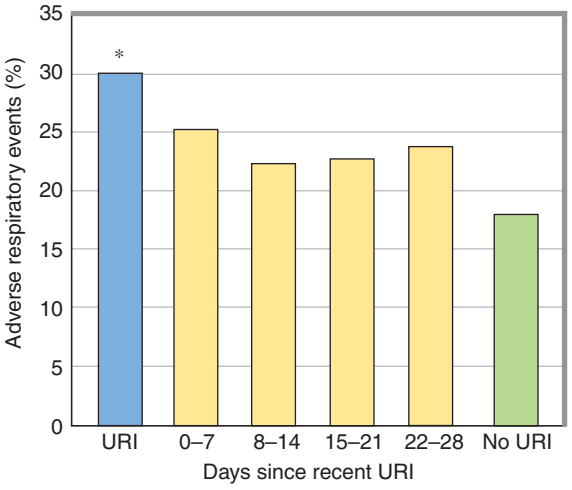

FIGURE 67–2. Adverse respiratory events are similar between children with an upper respiratory traction infection (URI) at the time of their anesthetic and those with a recent URI. The similarity persists for at least 4 weeks after the URI resolves. *P <0.05 vs no URI. (From Tait et al.[9] with permission.)

Restriction of Food and Liquids before Ambulatory Surgery

To decrease the risk of aspiration of gastric contents, patients are routinely asked not to eat or drink anything [nothing by mouth (NPO)] for at least 6–8 hours before surgery. However, prolonged fasting can be detrimental to the patient. One study showed that infants who fasted >8 hrs had greater drops in intraoperative blood pressure (Fig. 67–3).[10] No trial has shown that a shortened fluid fast increases the risk of aspiration. Gastric volumes actually are less when patients are allowed to drink some fluids before surgery. Admittedly, however, the majority of studies were not specifically performed in individuals at increased risk for aspiration. An excellent review of this topic has been published.[11]

The ASA has published practice guidelines for preoperative fasting.[12] The guidelines allow a patient to have a light meal up to 6 hours before an elective procedure. In one survey of anesthesiologist practices in outpatient settings based on the practice guidelines, only 35% of those surveyed said that their institution had a policy that would allow a light breakfast 6 hours before elective surgery, although 65% said they would proceed without delay.[13] The guidelines support a preoperative fasting period of 2 hours for clear liquids in all patients. Coffee is not transparent but is free of particulate matter and is accepted as a clear liquid. Coffee drinkers should follow fasting guidelines but should be encouraged to drink coffee prior to their procedure because physical signs of caffeine withdrawal (e.g., headache) can easily occur.[14] Because some surgeons are not aware of these guidelines, patients still may fast for longer periods of time. Some evidence indicates that shorter periods of preoperative fasting are accompanied by less postoperative nausea and vomiting (PONV), but whether rehydration during surgery is equivalent to a shorter fast before surgery in terms of PONV is unclear.

To ensure that patients receive optimal medical management before outpatient surgery given the guidelines that clear liquids can be consumed up to 2 hours before surgery, patients should be encouraged to take their usual chronic medications.

MANAGING THE ANESTHETIC: PREMEDICATION

The outpatient is not that different from the inpatient undergoing surgery. In both, premedication is useful to control anxiety, postoperative pain, and

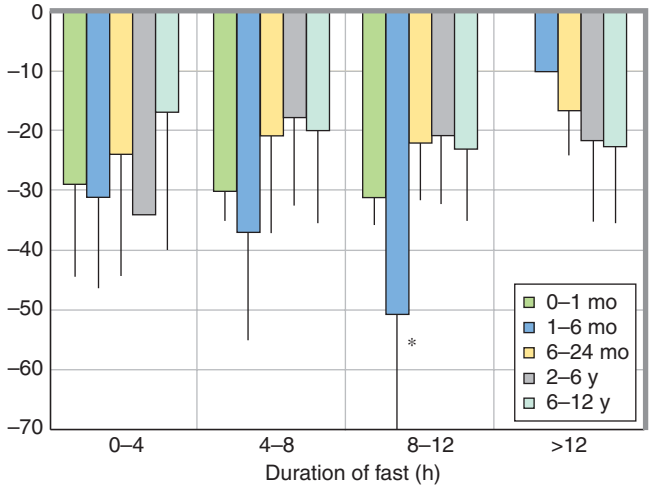

FIGURE 67–3. Blood pressure is lower in children 1–6 months old who fast for >8 hours compared to those who fast for <4 hours. Changes in systolic blood pressure from baseline to the time when 2 minimum alveolar anesthetic concentration (MAC) halothane was reached in 250 infants and children are shown. *P <0.05 vs group that fasted 0–4 hours. (From Friesen et al.[10] with permission.)

PONV and to reduce the risk of aspiration during induction of anesthesia. Because the outpatient is going home on the day of surgery, the drugs given before anesthesia should not hinder recovery afterward. Most premedicants do not prolong recovery when given in appropriate doses for correct indications, although drug effects may be apparent even after discharge.

Controlling Anxiety

Patients scheduled to undergo surgery may be anxious and may have been so long before coming to the outpatient area; however, not all outpatients actually are anxious. Insomnia and anxiety are related, and in a study of sleep characteristics of outpatients before elective surgery, no differences in sleep quality between patients before surgery and individuals in a community control group were seen.[15] Indeed, physicians tend to overestimate the anxiety actually experienced by their patients.[16] Some operations certainly can generate more anxiety than others. Even removing dentures is associated with increased preoperative stress. If in doubt about patient anxiety, ask. Visual analogue scales are an easy-to-use, accurate tool for assessing anxiety.[17]

Like adults, children should be given some idea of what to expect during a procedure. However, much of a child's anxiety before surgery is caused by concern over separation from a parent(s). A child is more likely to demonstrate problematic behavior from the time of separation from parents to induction of anesthesia if a procedure has not been explained preoperatively. Parents and children must be involved in some preoperative discussions together so that the anxiety of the parents is not transmitted to the child. The transmission of anxiety is at least as problematic as is the separation itself (e.g., experiences of children left with babysitters). If the parents are calm and can effectively manage the physical transfer to a warm and playful anesthesiologist or nurse, premedication is not necessary. Semisedation may be awkward, and recovery after premedication may be prolonged. A parent accompanying a child during induction of anesthesia can reduce the child's anxiety provided the parent is not overly anxious.

Although historically many classes of drugs (e.g., barbiturates and antihistamines) have been used to reduce anxiety and induce sedation, presently benzodiazepines are the drugs most commonly used. Propofol also has some anxiety-reducing properties.

Benzodiazepines

Midazolam is the benzodiazepine most commonly used preoperatively. It can be used intravenously (IV) and orally. In adults, midazolam can be used to control preoperative anxiety; it also can be used either alone or in combination with other drugs during a procedure for IV sedation. For children, oral midazolam in doses as low as 0.25 mg/kg produces effective sedation and reduces anxiety.[18] At this dose, most children can be effectively separated from their parents after 10 minutes, and satisfactory sedation can be maintained for 45 minutes.

Fatigue associated with the effects of anxiolytics may delay or prevent the discharge of patients on the day of surgery, although more frequently patients are not discharged because of the effects of the operation. With regard to anesthesia effects, patients normally stay in the hospital not because they are too sleepy but because they are nauseous. In adults, particularly when midazolam is combined with fentanyl, patients can remain sleepy for up to 8 hours (Fig. 67–4).[19] Although children may be sleepier after oral midazolam than if midazolam is not prescribed, discharge times are not affected.[20]

Oral diazepam is useful for controlling anxiety in adult patients, given either the day before or the day of surgery for which an IV line will be inserted. In one study, investigators believed that insertion of an IV line was easier after the patient was given 5 mg oral diazepam.[21]

At proper doses, midazolam places patients at no additional risk for cardiovascular and respiratory depression than does diazepam. Decreased oxygen saturation has been reported after midazolam injection. Routine administration of supplemental oxygen with or without continuous monitoring of arterial oxygenation is recommended whenever benzodiazepines are given IV. This precaution is important not only when midazolam is given as a premedicant but also when midazolam is used either alone or in combination with other drugs for conscious sedation.

The potential for amnesia after premedication is another concern, espe-

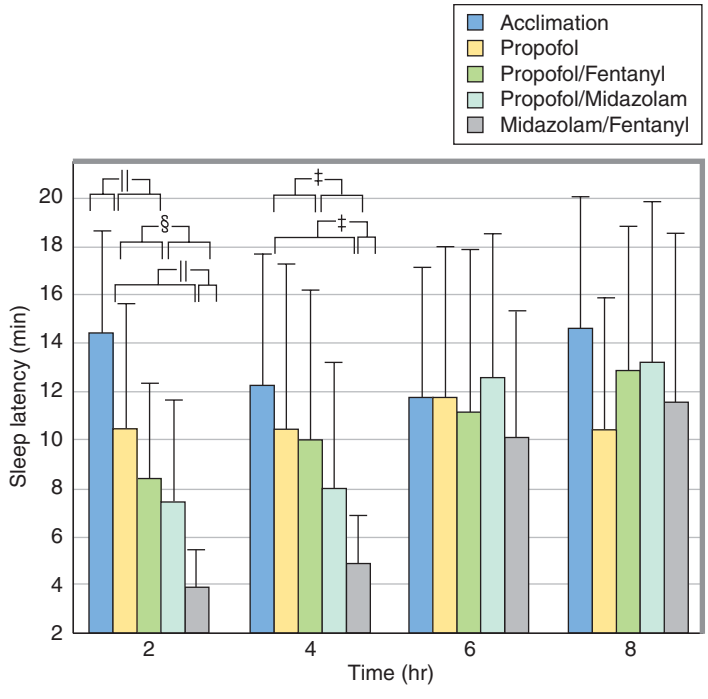

FIGURE 67–4. Patients can remain sleepy up to 8 hours after administration of midazolam and fentanyl. The abscissa represents time (in hours) after sedation. The ordinate represents sleep latency (i.e., time to fall asleep). Data are mean times to fall asleep. An individual is considered sleepier if less time is required to fall asleep. Subjects who received the midazolam and fentanyl combination were much sleepier than were subjects who received the other types of sedation. Up to 8 hours after sedation, some subjects were sleepier than before they received drug (data not shown). (From Lichtor et al.[19] with permission.)

cially for patients undergoing ambulatory surgery. Anterograde amnesia certainly occurs, but benzodiazepines actually facilitate retrograde memory.[22] For midazolam, amnesia is a function of serum concentration, and the effects on memory are separate from the effects on sedation.[23] In addition, amnesia is not simply an effect of drug administration but, among other factors, is a function of stimulus intensity.

Opioids and Nonsteroidal Analgesics

Opioids can be administered preoperatively to sedate patients, to control hypertension during tracheal intubation, and to decrease pain before surgery. Meperidine (but not morphine or fentanyl) is sometimes helpful in controlling shivering in the operating room or postanesthesia care unit (PACU), although treatment usually is instituted at the time of shivering and not in anticipation of the event. The effectiveness of opioids in relieving anxiety is controversial and probably nonexistent, particularly in adults.

Opioids are useful in controlling hypertension during tracheal intubation. Opioid premedication prevents increases in systolic pressure in a dose-dependent fashion. After tracheal intubation, however, systolic, diastolic, and mean arterial blood pressures sometimes decrease below baseline values.

Preoperative administration of opioids or nonsteroidal antiinflammatory drugs (NSAIDs) is useful for controlling pain in the early postoperative period. For example, controlled-release oxycodone 10 mg, when given before surgery, was very effective in managing pain after laparoscopic tubal ligation surgery and was associated with less PONV.[24] Celecoxib, up to 400 mg, is effective in reducing postoperative pain.[25] In a comparison of celecoxib 200 mg and rofecoxib 50 mg, rofecoxib was more effective.[26] Ibuprofen or acetaminophen can be given rectally to children around the time of induction. Nonsteroidal analgesics are associated with less nausea compared to narcotics.[27] If rectal acetaminophen is used, an initial loading dose of 40 mg/kg is appropriate; subsequent doses of 20 mg/kg every 6 hours can be used.[28]

Preoperative sedation is not needed for every patient. The following is our practice when patients require drugs to relieve anxiety. For the patient who was seen at least 24 hours before a scheduled procedure and expresses a desire for medication to relieve anxiety or has anxiety that cannot be relieved with comforting, oral diazepam 2–5 mg per 70 kg of body weight is prescribed for the night before surgery and for 6:00 AM on the day of surgery (even if surgery is scheduled for 1:00 PM or later). For patients seen for the first time in the preoperative holding area who seem to need medication, midazolam 0.03 mg/kg is administered IV, or the patient is brought into the operating room and propofol 0.7 mg/kg is injected IV. For children, oral midazolam 0.5 mg/kg is administered in the preoperative holding area, when necessary.

Controlling the Risk of Aspiration

Patients who undergo ambulatory surgery may be at some small risk for aspiration of gastric contents, although the risk is no greater for outpatients than for inpatients. Pregnant or morbidly obese patients or patients with hiatal hernia are at greater risk for aspiration. Preoperative anxiety probably has no effect on gastric acidity in individuals without a history of duodenal ulcer. H_2-receptor antagonists, such as cimetidine and ranitidine, omeprazole, sodium citrate, or metoclopramide can be used to control the risk of aspiration.

INTRAOPERATIVE MANAGEMENT: CHOICE OF ANESTHETIC METHOD

The choices among anesthetic methods are general anesthesia, regional anesthesia, and local anesthesia. Regional and local anesthesia can be used with or without sedation. Except for obstetric cases for which regional anesthesia may be safer than general anesthesia, all three types are equally safe. However, even for experienced anesthesiologists, there is a failure rate associated with regional anesthesia.

Some procedures are possible only with a general anesthetic. For other procedures, the preference of the patient, surgeon, or anesthesiologist may determine selection. Cost may be a factor; the cost of local or regional anesthesia with sedation usually is less than the cost of a general anesthetic. Time to recovery may influence the choice of anesthetic method. For example, in a study of adult patients undergoing strabismus surgery with either propofol sedation and local anesthesia or general anesthesia with inhalational agents, time to leave the hospital was much less after sedation.[29] For some procedures such as arthroscopy, patients might prefer a regional anesthetic simply because they are curious and wish to be awake during the procedure.[30] Postoperative pain is less after regional anesthesia (discussed in more detail below). Regional anesthesia or sedation may avoid some of the side effects of general anesthesia, although no form of medical care is without side effects. Whenever drugs that affect memory are given, patients may complain that they have difficulty remembering things after the procedure. With regional anesthesia, more time is required to place a block than is required to induce with a general anesthetic, and the success rate with regional anesthesia is not 100%. In one survey of orthopedic surgeons, the majority of surgeons who direct their patient's choice of anesthetic select regional anesthesia, yet delay in establishing a block and the unpredictable success detracted from their enthusiasm (Fig. 67–5).[31] In most instances after regional anesthesia, PACU time is shorter and patients frequently can bypass the first phase of the PACU.

One adverse effect associated with spinal anesthesia is headache, but patients also experience headaches after general anesthesia. The incidence of headache after either technique may be similar, especially when smaller-gauge spinal needles are used. In one study, the incidence of headache ranged between 11% and 15% after either method of anesthesia.[32] In that study, the incidence of backache was higher (26%) after spinal anesthesia than after general anesthesia (4%). However, the incidences of sore throat and nausea were higher after general anesthesia than after spinal anesthesia (24% vs 6% and 22% vs 6%, respectively). More studies comparing sedation with regional and general anesthesia in larger numbers of patients undergoing ambulatory surgery are needed.

Regional Techniques

Local anesthesia and regional anesthesia have long been used for ambulatory surgery. As early as 1963, 56% of ambulatory procedures were performed

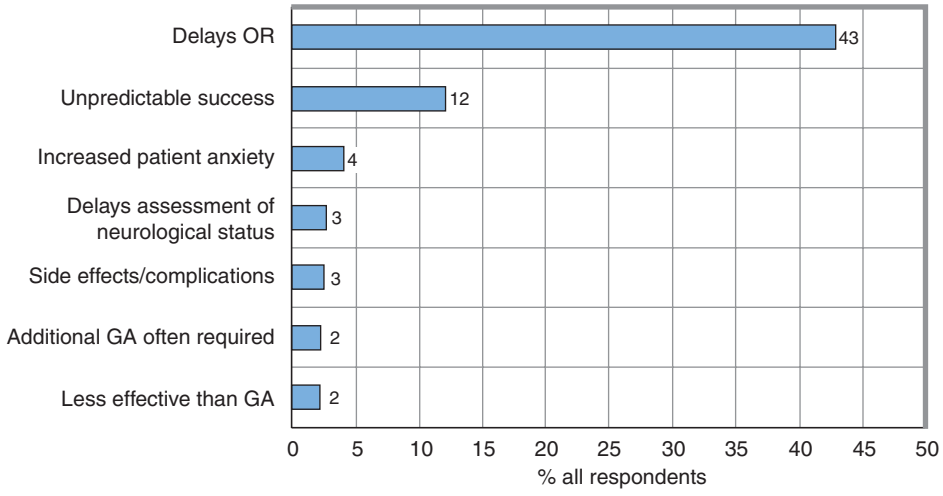

FIGURE 67–5. Operating room delays are the major reason why orthopedic surgeons do not favor regional anesthesia. GA, general anesthesia. (From Oldman et al.[31] with permission.)

using these techniques.[33] Regional techniques commonly used for ambulatory surgery, in addition to spinal and epidural anesthesia, are local infiltration, brachial plexus and other peripheral nerve blocks, and IV regional anesthesia. General anesthesia can be supplemented with regional nerve blocks.

Performing a block requires more time than inducing general anesthesia, and the incidence of failure is higher. Performing the block in a preoperative holding area, provided monitored care is available, can obviate unnecessary delays. In addition, because a postoperative nursing intervention, usually associated with general anesthesia, is associated with a 27- to 45-minute delay, the increased setup time may be associated with a shorter time to discharge.[34] Even though the duration of effect of the newer general anesthetics and muscle relaxants is very short, postoperative pain control is best with regional techniques.

Occasionally a patient experiences syncope when the needle for regional block is inserted. In the experience of oral and maxillofacial surgeons in Massachusetts in the late 1990s, one of 160 patients fainted when local anesthesia was injected.[35] When sedation accompanies local anesthesia injection, the incidence of syncope is reduced. Patients usually experience less postoperative pain when local or regional anesthesia has been used. Patients still might have a numb extremity (e.g., after a brachial plexus block) but otherwise might meet all criteria for discharge. In such instances, the extremity must be well protected with a sling, and patients must be cautioned to protect against injury because they are without normal sensations that would warn them of vulnerability. Reassurance that sensation will return should be provided. Subsequent followup either by a visiting nurse or by telephone to assess the duration and effect of the regional block not only is good anesthetic practice but may help detect any complications attributable to the block.

Spinal Anesthesia

Spinal anesthesia is useful for ambulatory procedures in children born prematurely. The procedure is best performed with the child in the sitting position, with the head supported and somewhat extended, to prevent occlusion of the airway. Bupivacaine 0.5% hyperbaric, 1 mg/kg; or tetracaine, isobaric 1%, mixed with an equal volume of 10% dextrose, is injected into the L4–5 interspace with a 22-gauge, 3.75-cm Quincke needle. It is useful to apply an eutectic mixture of lidocaine and prilocaine (EMLA) patch to the lumbar puncture site 1 hour before the procedure. Because a leg raised may drive the spinal higher, the child must be kept flat, for example, when the Bovie pad is placed on the back. Hypotension is less common after spinal anesthesia in infants than in adults; when it occurs, typically the level of spinal anesthesia is very high. An IV line can be started in a lower extremity after the spinal has been placed, the extremity is anesthetized, and vasodilatation is present. The duration of spinal anesthesia with a local anesthetic alone may not be sufficient. In one study, when clonidine was added to bupivacaine, the length of spinal block increased from an average of 67 minutes to 111 minutes after 1 μg/kg clonidine (Fig. 67–6).[36] For a discussion as to whether a neonate should be discharged home on the same day of a spinal anesthetic, see section above (Place, Procedures, and Patient Selection).

Use of spinal needles with pencil-point, noncutting tips has prompted a resurgence in the use of spinal anesthesia for ambulatory surgery in adults. Epidural or spinal anesthesia is suitable for pelvic, lower abdominal, and lower-extremity surgery but not for laparoscopic procedures because most people have difficulty breathing in the head-down position with the abdomen distended with air. Motor block of the legs using either technique may delay a patient's ability to walk; however, use of a short-acting local anesthetic through an epidural catheter will minimize this problem while allowing the duration of anesthesia to match the sometimes unpredictable duration of surgery. Nausea is less frequent after epidural or spinal anesthesia than after general anesthesia.

Different drugs and drug concentrations have been used for spinal anesthesia. Lidocaine and mepivacaine are ideal for ambulatory surgery because of their short duration of action, although lidocaine use has been problematic because of transient neurologic symptoms. In one study comparing patients who underwent knee arthroscopy given either 45 mg 1.5% mepivacaine or 60 mg 2% lidocaine, 22% of patients who received lidocaine had

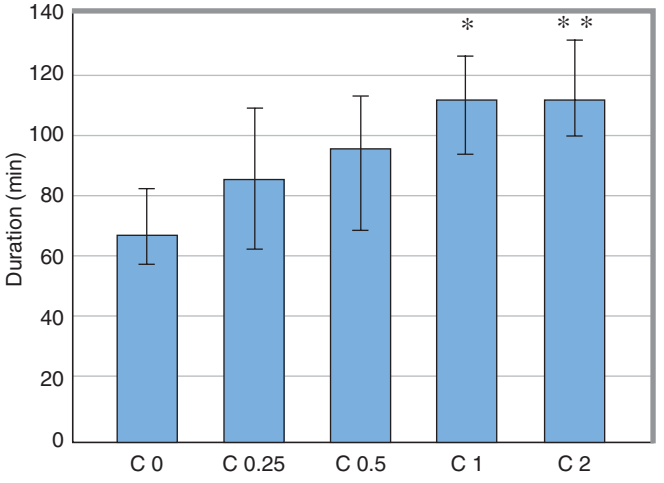

FIGURE 67–6. Clonidine prolongs spinal anesthesia in newborns. Median durations of spinal block with 25–75% confidence intervals are shown. Co, spinal with 0.5% isobaric bupivacaine 1 mg/kg; Co.25, bupivacaine with 0.25 μg/kg clonidine; Co.5, C1, C2, bupivacaine with 0.5, 1, and 2 μg/kg clonidine, respectively. *P <0.003; **P <0.006 vs Co. (From Rochette et al.[36] with permission.)

transient neurologic symptoms (back pain or dysesthesia).[37] The symptoms were treated by NSAIDs and resolved within 5 days. No patients who received mepivacaine developed transient neurologic symptoms. Chloroprocaine spinal anesthesia has rapid onset. In a study of nonpatient volunteers, after administration of 40 mg 2-chlorporcaine, the participants could void after 110 minutes.[38] In that study, when 20 μg fentanyl was included, regression time to L1 was lengthened and tourniquet tolerance was improved, although overall block length was minimally affected. Administration of 40 mg preservative-free 2-chloroprocaine produces similar onset time and block height compared to 40 mg lidocaine.[39] In that study, transient neurologic symptoms occurred in seven of eight volunteers who received lidocaine and in none of the volunteers who received 2-chloroprocaine. Low-dose bupivacaine is useful for some outpatient procedures, such as inguinal herniorrhaphy; however, in one study, patients could not be discharged until almost 7 hours after block initiation.[40]

Although headache is a known complication of lumbar puncture, smaller-gauge needles result in a lower incidence of postdural puncture headache. For patients who do receive spinal anesthesia, it is incumbent upon the anesthesiologist and the facility to initiate followup with telephone calls to ensure that no disabling symptoms of headache have developed. If the headache does not respond to bedrest, analgesics, and oral hydration, the patient must return to the hospital for a course of caffeine IV therapy or an immediate epidural blood patch.

Spinal anesthesia should not be avoided in ambulatory surgery patients simply because they may be more active postoperatively than inpatients. Bedrest does not reduce the frequency of headache. Indeed, early ambulation may decrease the incidence. Further study is needed to assess the relative risk-to-benefit ratio of spinal anesthesia as a technique for ambulatory surgery patients.

Epidural and Caudal Anesthesia

Epidural anesthesia require more time to perform than spinal anesthesia. Onset with spinal anesthesia is more rapid, although recovery may be the same with either technique. In one study of patients undergoing knee arthroscopy, spinal anesthesia with small-dose lidocaine and fentanyl was compared with 3% 2-chloroprocaine administered in the epidural space. Intraoperative conditions, discharge characteristics and times, and recovery profiles were similar.[41] Failure rates for the two techniques, although low, were the same. Some studies suggest that bicarbonate can be added to solutions for faster onset of epidural anesthesia. An advantage of the epidural block is that it can be performed outside the operating room and thus may help the surgeon commence the procedure earlier. The problem of postdural puncture headache usually is avoided.

Caudal anesthesia is a form of epidural anesthesia commonly used in children before surgery below the umbilicus as a supplement to general anesthesia and for control of postoperative pain. Bupivacaine 0.175–0.25% or ropivacaine 0.2%, in a volume of 0.5–1.0 mL/kg, can be used; the safe maximal dose is 2.5 mg/kg. Epinephrine 1:200,000, when added to the anesthetic solution, may allow earlier detection of IV, rather than epidural, injection. Other additives that are useful, albeit controversial, for increasing duration of blockade include narcotics, ketamine, clonidine, and neostigmine.[42] The block may be more difficult in children, particularly those who weigh >10 kg and are obese, if landmarks for the block are difficult to locate. The block usually is administered while the child is anesthetized. After injection, the depth of general anesthesia can be reduced. Because of better pain control after a caudal block, children usually can ambulate earlier and be discharged sooner than can children without a caudal block. Pain control and discharge times are no different whether the caudal block is placed before surgery or after surgery was completed.

Spinal and epidural blocks may cause urinary retention. It is important to ensure that the patient has voided before he or she is sent home.

Nerve Blocks

Nerve blocks control pain during surgical procedures, but certain procedures are quite painful, and hospitalization may be required to control the pain. An exciting new area in outpatient surgery pain control is the use of continuous infusion of low-dose analgesic solutions through catheters left in situ in the postoperative period. A paravertebral somatic nerve block can be used for breast surgery, followed by continuous perineural infusion of local anesthetic at home for 24–48 hours.[43] Perineural catheters in the sciatic nerve through the popliteal fossa can be used to control pain after foot surgery.[44] Interscalene perineural catheters have been used for patients undergoing moderately painful shoulder surgery.[45] Continuous cervical paravertebral block also may be useful for analgesia after shoulder surgery. The early return of motor function in

the hand, wrist, and elbow, seen with use of this block, may be useful for recovery after shoulder surgery (Fig. 67–7).[46] Patients must be taught about pump function, know the signs of local anesthesia toxicity, and have someone available at home who can provide assistance. In addition, patients must be able to communicate with someone by phone. The number of patients who have been sent home with catheters is not large; more study, particularly with regard to optimizing patient safety, is needed.

A survey mailed to members of the Society for Ambulatory Anesthesia in 2001 revealed widespread use of axillary and interscalene blocks for upper-extremity surgery and ankle and femoral blocks for lower-extremity surgery.[47] Using different nerve blocks improves postoperative patient satisfaction because postoperative pain and PONV are less. In addition, costs are reduced. In one nonrandomized study of outpatients in a university setting who received nerve blocks for anterior cruciate ligament reconstruction, PACU admissions, hospital cost, and unexpected hospital admission all were reduced.[48] For knee arthroscopy, psoas compartment block or spinal anesthesia is superior to general anesthesia in terms of postoperative pain management and patient satisfaction.[49] After more complex knee surgery, patients who received femoral–sciatic nerve block required fewer nursing interventions for pain. If patients received either femoral–sciatic nerve block or only a femoral nerve block, unplanned hospital admissions were less compared to patients who underwent the procedure without a block.[50] In a comparison of patients who underwent either infraclavicular brachial plexus block or general anesthesia for upper-extremity surgery, after brachial plexus block more patients were able to bypass phase I PACU care, patients had less pain on PACU arrival, and patients were discharged home much sooner (Fig. 67–8).[51]

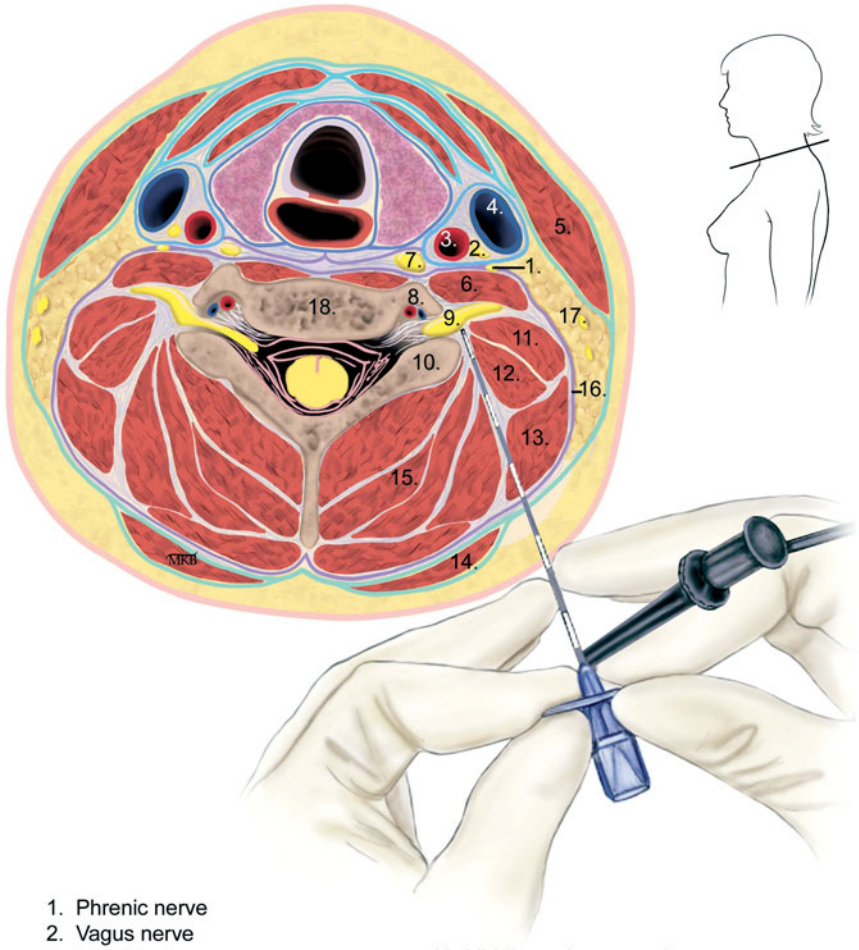

FIGURE 67–7. Continuous cervical paravertebral block can be placed prior to induction of anesthesia for shoulder surgery and then left in place for up to 7 days after surgery.[46] Path followed by the sheathed Tuohy needle, using the posterior approach, from the skin and then between the trapezius and levator scapulae muscles to the paravertebral space is shown. Sedation and Analgesia

Many patients who undergo surgery with local or regional anesthesia prefer to be sedated and to have no recollection of the procedure. Sedation is important, in part because injection with local anesthetics can be painful, and lying on a hard operating room table for any length of time can be uncomfortable. Levels of sedation vary from light, during which a patient's consciousness is minimally depressed, to very deep, in which protective reflexes are partially blocked and response to physical stimulation or verbal command may not be appropriate. When patients are unsuitable for outpatient general anesthesia, surgery often can be performed if local or regional anesthesia is supplemented with conscious sedation. Serious risk, such as death, probably is no different after sedation than after general anesthesia. Children undergoing surgery usually will not remain immobile unless they are deeply sedated or receive general anesthesia.

For adults, the proper dosage might be controlled by the patient. However, at least for ambulatory surgical procedures, patient-controlled sedation is not as popular as patient-controlled analgesia, possibly because a member of the anesthesia care team must always be present regardless of the circumstances.

General Anesthesia

The drugs selected for general anesthesia determine how long patients stay in the PACU after surgery and, for

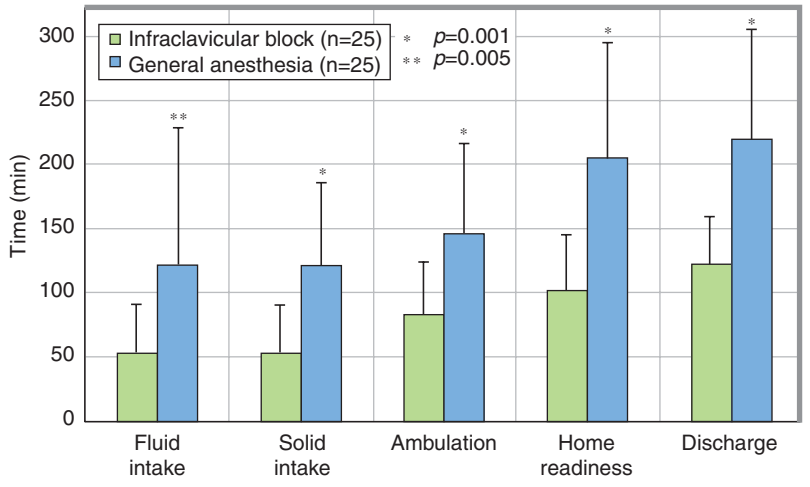

FIGURE 67–8. Recovery was faster when an infraclavicular brachial plexus block with a short-acting local anesthetic was used, compared with general anesthesia and wound infiltration for outpatients undergoing hand and wrist surgery. Times are calculated from the end of anesthesia. (From Hadzic et al.[51] with permission.)

some patients, whether or not they can be discharged home.

Induction

The popularity of propofol as an induction agent for outpatient surgery is related in part to its half-life. The elimination half-life of propofol is 1–3 hours, shorter than that of methohexital (6–8 hours) and thiopental (10–12 hours). Although the effect of drugs given for induction seems to be transient, these drugs can depress psychomotor performance for several hours. When induction doses of propofol and thiopental were compared, psychomotor impairment in patients was evident for up to 5 hours after thiopental but for only 1 hour after propofol.[52]

Pain on injection can be a problem with propofol. Pain is more likely on injection into dorsal hand veins but is minimized if forearm or larger antecubital veins are used. Some individuals experience pain if the drug is injected into proximal larger veins. Nonetheless, thrombophlebitis does not appear to be a problem after IV administration of this agent but can be evident after thiopental. IV lidocaine 0.2 mg/kg or 1% lidocaine mixed with propofol in a 10:1 volume ratio can be used to decrease the incidence and severity of pain.

Most children and some adults prefer not to have an IV catheter inserted before the start of anesthesia. Sevoflurane has a relatively low blood/gas partition coefficient, and its speed of induction is similar to, albeit somewhat slower than, that of propofol. Induction with sevoflurane can be hastened if the patient is told to breathe out to residual volume, take a vital capacity breath through a primed anesthesia circuit, and then hold the breath.

Parental presence is becoming more accepted during induction of anesthesia in children, even though scientific evidence of its advantages is not conclusive. Some studies show that children are less upset and have fewer behavioral changes after surgery if a parent is present during induction. Other studies have suggested that parents can become upset when they see their anesthetized child, who appears to be dead, albeit breathing and with a beating heart. Separation anxiety on the part of the parents probably is no different if the child is awake or asleep.

For short procedures, some patients may not require neuromuscular blocking drugs; others may need brief paralysis (i.e., with succinylcholine) to facilitate tracheal intubation. Nondepolarizing drugs can be used to facilitate intubation and during the procedure. Nondepolarizing drugs, such as rapacuronium (withdrawn from the market because of bronchospasm) and rocuronium, have rapid onset times similar to those of succinylcholine. Paralysis is not needed for insertion of an endotracheal tube; drug combinations such as propofol, alfentanil, and lidocaine obviate the need for paralysis.[53] Succinylcholine should be used with caution in children because of the possibility of cardiac arrest related to malignant hyperthermia or unsuspected muscular dystrophy, particularly Duchenne disease.

Anesthesia Maintenance and Wake-Up Times

Although many factors affect the choice of agents for maintenance of anesthesia, two primary concerns about ambulatory anesthesia are speed of wake-up and incidence of PONV.

Anesthesia Maintenance and Wake-Up Times Time to recovery can be measured using various criteria; however, for an ambulatory center, a patient may be considered awake when he or she is able to leave the center. Actual discharge from an ambulatory center may depend on administrative issues, such as obtaining the written order from the surgeon or anesthesiologist. The time needed before a patient can be taken from the operating room after completion of surgery, or a patient's ability to skip the PACU and go directly to a step-down unit, may be directly related to the anesthetic used and result in cost savings for an institution. Does the choice of maintenance agent affect recovery after anesthesia? Propofol, desflurane, and sevoflurane have characteristics that make them ideal for maintenance of anesthesia for ambulatory surgery. Propofol has a short half-life and, when used as a maintenance agent, results in rapid recovery and few side effects. Desflurane and sevoflurane, which are halogenated ether anesthetics with low blood/gas partition coefficients, seem to be ideal for general anesthesia for ambulatory surgery. Sevoflurane, unlike desflurane, facilitates a smooth inhalation induction of anesthesia, the preferred technique to ensure rapid recovery of children in ASCs. For children who receive either sevoflurane or halothane (or halothane and then desflurane) for induction and maintenance of anesthesia, recovery times are significantly shorter after sevoflurane or desflurane.

It is important to distinguish between wake-up time and discharge time. In a study of patients who had undergone laparoscopic surgery, patients emerged from anesthesia with desflurane and nitrous oxide (N_2O) significantly faster than after propofol or sevoflurane and N_2O, although the their ability to sit up, stand, and tolerate fluids and their time to fitness for

discharge were not different.[54] When the bispectral index (BIS) or other guide of anesthetic depth is used, the difference among drugs and wake-up times may not be as great. Conversely, if fast wake-up times can translate to bypass of phase I PACU care, there may be cost savings.

Intraoperative Management of PONV Nausea, with or without vomiting, probably is the most important factor contributing to a delay in discharge of patients and an increase in unanticipated admissions of both children and adults after ambulatory surgery. Patients hate vomiting. In one survey taken before surgery, patients rated vomiting as most undesirable and indicated that if they were given $100, they would spend most of the money to prevent it (Fig. 67–9).[55] Women, especially those who are pregnant, have a higher incidence of PONV. Other risk factors include a history of motion sickness or postanesthetic emesis; surgery within 1–7 days of the menstrual cycle; not smoking; and procedures such as laparoscopy, lithotripsy, major breast surgery, and ear, nose, or throat surgery. The greater the number of risk factors, the greater the risk for nausea or vomiting after surgery.[56] Inhalational agents are associated with an increased risk for PONV, particularly in the early stages of recovery. Postoperative narcotic use is associated with PONV more than 2 hours after surgery.[57]

The pathway for vomiting starts peripherally, where emetogens through enterochromaffin cells in the GI tract and/or other sensory neurons activate vagal afferents to the group of brainstem nuclei in the area postrema, nucleus tractus solitarius, and dorsal motor nucleus of the vagus. This area in the brain is also known as the *vomiting center.* Although the pathways for vomiting are not completely understood, the area postrema is highly vascular, lacks a complete blood–brain barrier, and has receptors for neurotransmitters and hormones.[58] Receptor antagonists, specifically selective serotonin antagonists (ondansetron, dolasetron, and granisetron), have similar efficacy in helping to alleviate the condition. Dopamine antagonists, antihistamines, and anticholinergic drugs are useful and generally less expensive, but they are associated with extensive side effects. Neurokinin-1 receptor (NK1) antagonists also may be useful for controlling PONV.

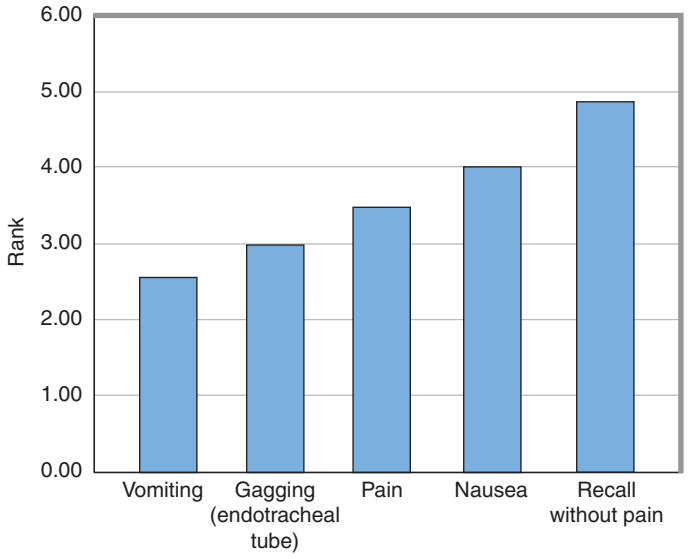

FIGURE 67–9. Patients were asked to rank 10 possible outcomes on a scale from most desirable to most undesirable. Shown in relative rank order are the top five undesirable outcomes; the lower the rank, the more undesirable is the outcome. (Adapted from Macario et al.[55] with permission.)

At this time, aprepitant, an NK1-receptor antagonist, has been shown to be more effective than standard therapy (ondansetron and dexamethasone) after highly emetogenic chemotherapy (Fig. 67–10),[59] but the drug's effectiveness in controlling PONV has not been demonstrated. Other therapies useful in controlling PONV include acupuncture (Fig. 67–11),[60] acupressure,[61] supplemental fluid therapy,[62] clonidine (perhaps in part because it decreases anesthesia requirement),[63] and dexamethasone.[64,65] Some investigator suggest that acupuncture therapy may be effective in controlling both PONV and postoperative pain.[66] Acupressure also might be useful.

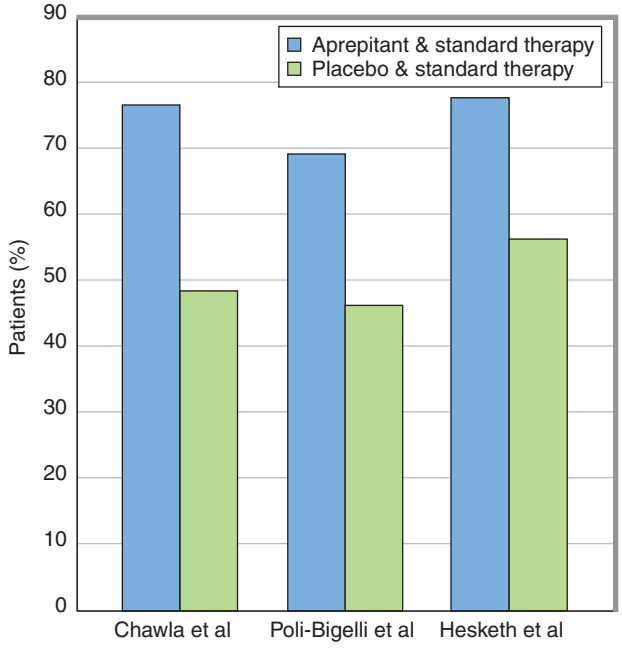

FIGURE 67–10. Based on three different multicenter randomized double-blind studies,[87–89] when oral aprepitant was combined with IV ondansetron and oral dexamethasone in adult patients who received one cycle of cisplatin-based chemotherapy, overall emetic events were significantly reduced (all $P < 0.01$) compared to standard therapy. (Adapted from Dando and Perry[59] with permission.)

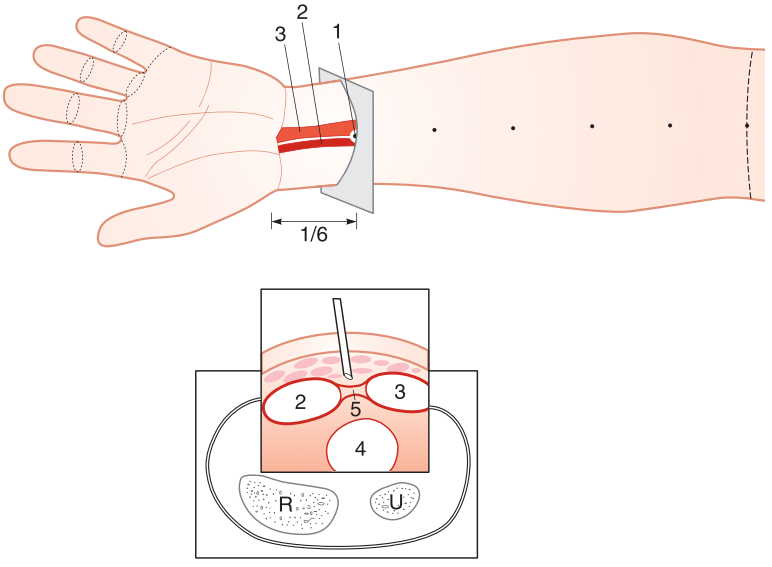

FIGURE 67–11. P6 acupuncture point in relation to other hand structures. 1, P6 acupuncture point; 2, palmaris long tendon; 3, flexor carpi radialis tendon; 4, median nerve; 5, palmar aponeurosis. (From Wang and Kain[60] with permission.)

Combination therapy probably is the most effective way to control PONV. In a study of children, low-dose ondansetron and dexamethasone was more effective than high-dose ondansetron in reducing PONV.[67] In another study, the need for treatment of symptomatic PONV in PACU patients was less when a total IV anesthetic without N_2O or paralysis, aggressive IV hydration, and three antiemetics was used, compared to both an inhalation-based anesthetic with paralysis and ondansetron and a third placebo group that was treated similarly to the previous group but did not receive ondansetron.[68] In a third study of women after laparoscopic surgery, ondansetron with cyclizine was more effective in reducing postoperative vomiting and the need for a rescue antiemetic than was ondansetron alone.[69] However, not all investigators have found combination therapy to be more effective. In a study of patients undergoing abdominal surgery, ondansetron with droperidol was not better than ondansetron alone.[70]

Because of its ability to decrease PONV, propofol is the best general anesthetic for ambulatory anesthesia. In a study of 5161 patients, propofol reduced nausea and vomiting by 19% compared to a volatile anesthetic, and nitrogen reduced the incidence by 12% compared to N_2O (Fig. 67–12).[65] Despite the greater initial cost of propofol, overall costs may be less because treatment of nausea and vomiting is eliminated. In a study of patients undergoing office-based surgical procedures, patients received either propofol or sevoflurane for induction and maintenance.[71] The costs of drugs used for anesthesia were the same, but when wasted propofol was considered, propofol costs were greater by approximately $5.00 per patient. Overall, however, average cost per patient was lowest when propofol was used for both induction and maintenance, primarily because of the costs of treating nausea and vomiting ($46 for propofol induction and maintenance, $63 for propofol induction and sevoflurane maintenance, $72 for sevoflurane induction and maintenance).

Use of N_2O for ambulatory anesthesia is an issue because the incidence of emesis may be greater after use of N_2O than after other inhalational agents. However, many studies have shown that N_2O can be used successfully for ambulatory anesthesia. A meta-analysis that included 26 trials from 24 studies was designed to determine if N_2O significantly reduced the odds of PONV.[72] Overall, use of N_2O increased the risk of PONV by 28%. The maximal benefit of N_2O avoidance was seen in female patients (46%).

Paralysis Muscle paralysis for ambulatory anesthesia extends beyond the time of paralysis for intubation, particularly when nondepolarizing drugs have been used. The clinical effect of the nondepolarizing agent mivacurium, given as a bolus injection to 25% recovery, lasts 12–18 minutes, the shortest duration of effect among the neuromuscular blockers. The duration of action of rocuronium, vecuronium, rapacuronium, and atracurium ranges from 25–40 minutes. Because mivacurium is dependent on plasma cholines-

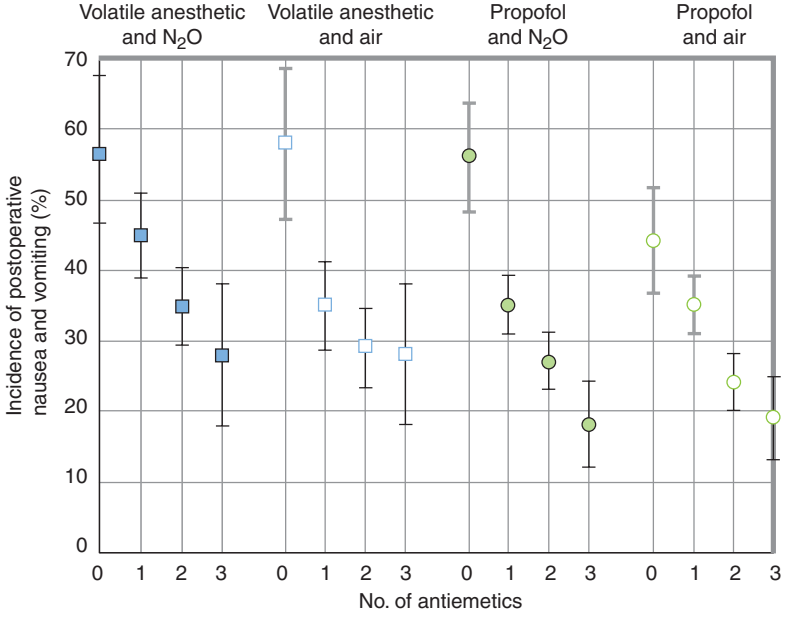

FIGURE 67–12. Postoperative nausea and vomiting (PONV) occurs least after a propofol anesthetic with air. Incidences of PONV after administration of different anesthetics and different numbers of prophylactic antiemetic treatments are shown. (Apfel CC, Korttila K, Abdalla M, et al. A factorial trial of six interventions for the prevention of postoperative nausea and vomiting. N Engl J Med 2004;350:2441. Copyright, 2004 Massachusetts Medical Society. All rights reserved.)

terase for metabolism, recovery can be prolonged in the presence of atypical plasma cholinesterase concentrations. In patients with normal plasma cholinesterase levels, postoperative vomiting might be reduced if reversal of mivacurium is not required. Mivacurium should not be used in patients with a history of bronchospasm.[73] Some controversy exists regarding the association of neostigmine with PONV.[74] Nonetheless, reversal agents must be used unless there is no doubt that muscle relaxation has been fully reversed. Mivacurium may not be indicated when an ambulatory surgery case is expected to last >30 minutes. Longer-acting drugs, such as pancuronium, can be used without sequelae, particularly in children in whom muscle relaxants generally have decreased potency, thereby enabling more rapid recovery.

Intraoperative Management of Postoperative Pain Opioids given intraoperatively are useful for supplementing both intraoperative and postoperative analgesia. Fentanyl probably is the most popular drug, although all other available narcotics have been tried. All narcotics can cause nausea, sedation, and dizziness, which can delay a patient's discharge. Nonsteroidal analgesics are not effective as supplements during general anesthesia, although they are useful in controlling postoperative pain, particularly when given before a skin incision. Combination therapy is most useful for controlling postoperative pain. In a study of outpatients undergoing inguinal hernia repair under general anesthesia, triple preincisional therapy that included rofecoxib 50 mg PO, ketamine 0.2 mg/kg IV, and a local anesthetic field block reduced pain scores and analgesic use in the first 24 hours after discharge compared to a placebo group.[75]

Depth of Anesthesia BIS, entropy, or auditory evoked potential monitors are believed to decrease the anesthesia requirement without sacrificing amnesia during general anesthesia. Because less anesthesia is used, titration of anesthesia with these monitors results in earlier emergence from anesthesia. In a meta-analysis of BIS monitoring for ambulatory anesthesia, BIS monitoring was shown to reduce anesthetic use by 19%, with more modest decreases in PACU duration (4 minutes) and PONV (6%; Fig. 67–13).[76] Results are even more modest, albeit mixed, in terms of later recovery end points. Because these monitors result in less anesthesia use, intraoperative awareness and myocardial ischemia might be increased. Sympatholytic drugs, instead of anesthesia, can be used to control autonomic responses to anesthesia. In fact, recovery is faster and side effects are fewer in ambulatory patients whose blood pressure is controlled by sympatholytics rather than inhalational agents.[77] In a study of almost 5000 patients who underwent general anesthesia and were paralyzed and/or intubated, awareness was significantly reduced in the group of patients who were monitored with BIS compared to the group of patients who were not monitored with BIS (Fig. 67–14).[78]

Airways Using an LMA or similar type of airway device offers several advantages that allow a patient to quickly return to baseline status. Muscle relaxants required for intubation can be avoided. Coughing is less than with tracheal intubation. Anesthetic requirements are reduced. Hoarseness and sore throat are reduced. Overall, cost savings result with use of LMAs, but nausea and vomiting may be greater because of gastric insufflation. LMA use has been described for laparoscopic procedures, although the potential for aspiration exists because of an inflated abdomen during laparoscopy.

MANAGEMENT OF POSTANESTHESIA CARE

Many issues associated with recovery are part of the patient selection process and perioperative management and must be considered before the patient enters the PACU. Quick and effective management of common problems occurring in the PACU is as important as appropriate patient selection and choice of anesthetic technique if the patient is to return home on the day of surgery. The three most common reasons for delay in patient discharge from the PACU are drowsiness, nausea and vomiting, and pain. All three are a function of intraoperative manage-

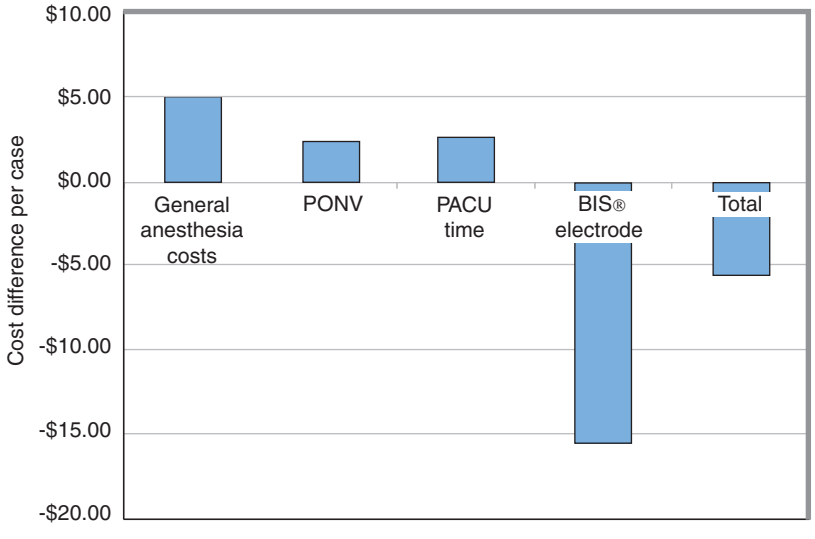

FIGURE 67–13. Bispectral index (BIS) monitoring reduces anesthetic consumption, cost of treat nausea and vomiting, and postanesthesia care unit time; however, the cost of the electrode reverses savings. The ordinate represents cost difference per case pooled from three studies (i.e., costs for control group minus cost for group that used BIS). The capital cost for the BIS monitor was not included. (From Liu[76] with permission.)

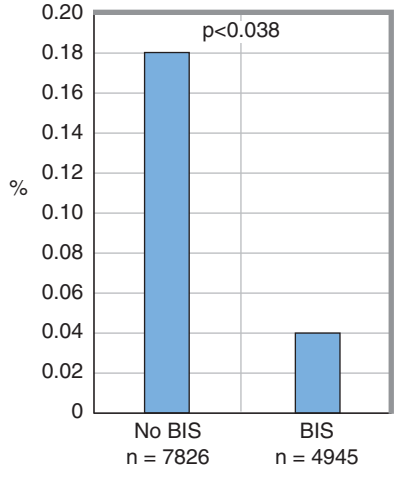

FIGURE 67–14. The incidence of awareness is reduced when a bispectral index monitor is used. (From Ekman et al.[78] with permission.)

ment, but pain and nausea and vomiting also can be treated in the PACU.

Reversal of Drug Effects

Reversal of muscle relaxants is not unique to the ambulatory surgery patient and is not discussed here. Reversal of opioids sometimes is necessary. Flumazenil, a benzodiazepine receptor antagonist, has been used primarily to reverse the effects of sedation after endoscopy and spinal anesthesia. Reversal of psychomotor impairment with flumazenil is not complete, and the subjective experience of sedation is not necessarily attenuated. Reversal of amnesia with flumazenil is only partial, and the duration of the reversal effect may not be sufficiently long to be clinically significant. Flumazenil should not be used routinely as a benzodiazepine antagonist; it should be used only when sedation appears to be excessive. Reversal of benzodiazepine-induced sedation by flumazenil should not replace appropriate ventilatory assistance and, if necessary, placement of an endotracheal tube.

Nausea and Vomiting

Nausea and vomiting are the most common reasons both children and adults have protracted stays in the PACU or unexpected hospital admission due to anesthesia. Nausea and vomiting also are the most common adverse effects in PACU patients. Much research has focused on prophylactic treatment of nausea and vomiting before surgery and on practice techniques used in the operating room that can minimize nausea and vomiting in the PACU. Treatment of this problem, once it occurs in the PACU, has not received as much study. A variety of drugs are effective in treating the problem. The serotonin ($5\text{-}HT_3$) antagonists seem particularly effective. In a study of children who underwent strabismus surgery and then were nauseous during the first 3 hours after recovery from anesthesia, emesis-free episodes were greater after granisetron 40 μg/kg (88%) compared to droperidol 50 μg/kg (63%) or metoclopramide 0.25 mg/kg (58%).[79] Similar findings were seen in a study of patients who underwent laparoscopic cholecystectomy and then experienced PONV during the first 3 hours after the procedure. Complete control was seen more commonly after granisetron 40 μg/kg (88%) compared to droperidol 20 μg/kg (60%) or metoclopramide 0.2 mg/kg (55%).[80] Hydroxyzine 25 mg also is effective. Midazolam and propofol are used more commonly for sedation, but their antiemetic effects are longer in duration than their effects on sedation. For example, when patients in the PACU were nauseous and then received either propofol 15 mg or midazolam 1 or 2 mg, subsequent nausea was no different than with ondansetron 4 mg.[81] Other authors have found that propofol 10 mg is effective. When a ReliefBand acustimulation device was compared to ondansetron in patients who had undergone laparoscopic surgery and then were nauseous in the PACU after receiving metoclopramide or droperidol, nausea was treated most effectively with the combination of ReliefBand and ondansetron, although either therapy was equally effective in treating PONV.[82] If patients already have received ondansetron prophylaxis in the operating room and then are nauseous in the PACU, another repeat dose might not be effective. In a multicenter study of patients who received ondansetron 4 mg during an outpatient procedure that included N_2O and then were nauseous in the PACU, complete response to treatment was no different if patients received either another dose of ondansetron 4 mg or placebo.[83] More work is needed to study effective therapies for treatment of PONV in the PACU. Because pain may be associated with nausea, treatment of pain frequently decreases nausea.

Pain

Postsurgical pain must be treated quickly and effectively. It is important that the practitioner differentiate postsurgical pain from the discomfort of hypoxemia, hypercapnia, or full bladder. Factors that correlate with greater postoperative pain are younger patient age, less serious illness, greater body mass index, operative site, and duration of surgery.[84] Medications for pain control should be given in small IV doses (e.g., morphine 1–3 mg per 70 kg body weight or fentanyl 10–25 μg per 70 kg body weight). Intramuscular (IM) injection of opioid for pain control in the PACU probably is not necessary. Onset of drug action is faster after IV than oral administration. Control of postoperative pain may include administration of opioid analgesics or NSAIDs, which are not associated with respiratory depression, nausea, or vomiting. Fentanyl is the narcotic most frequently used to control postoperative pain, although the effects of morphine last longer. Patients who receive fentanyl for pain control may require additional injections and go home no sooner than patients who receive morphine. NSAIDs (e.g., ketorolac and ibuprofen) can effectively control postoperative pain. Compared to narcotics, NSAIDs can provide longer periods of pain relief and are associated with less nausea and vomiting. NSAIDs can increase bleeding, although currently no evidence indicates such danger for most ambulatory surgery procedures. NSAIDs can be more effective than opioids in relieving postoperative swelling and pain.

We manage pain in both adults and children initially with either a short-acting opioid analgesic such as fentanyl 25 μg per 70 kg body weight or an injection (IM or IV) of ketorolac 60 mg per 70 kg body weight. Administration of fentanyl is repeated at 5-minute intervals until the pain is controlled. For children, we also use an elixir of acetaminophen containing codeine (120 mg acetaminophen and 12 mg codeine per 5 mL of solution), with 5 mL administered to children 3–6 years old and 10 mL to children 7–12 years old. Children are returned to parental care as soon as they are awake. We find that infants younger than 6 months usually need to be reunited with their mothers for nursing (or bottle feeding) after a procedure not associated with severe pain. For older infants and young children in the PACU, acetaminophen 60 mg per year of age (given orally or rectally) is commonly used to relieve mild pain. IV fentanyl (up to 2 μg/kg) is preferred for more severe pain. Meperidine 0.5 mg/kg and codeine 1–1.5 mg/kg can be given IM if an IV route has not been established.

Preparation for Discharging the Patient

In addition to having the PACU, many ASCs in the United States have another area, often known as a *phase II recovery room,* where patients can stay until they are able to tolerate liquids, walk, and/or void. With the anesthetics typically used in ambulatory surgery operating rooms, patients who are awakened in the operating room and are evaluated with a score of 9 or 10 according to the modified Aldrete scoring system can be transferred di-

rectly to phase II recovery from the operating room. Patients who undergo procedures under monitored anesthesia care usually can go straight from the operating room to the phase II area. After general anesthesia, LMA use and pain control with nonopioid analgesics facilitate fast tracking. In one study, 35–53% of patients who underwent laparoscopic gynecologic surgery were able to bypass the PACU.[85] In that study, residual sedation was the most common reason why the PACU was not bypassed. In a study of patients who underwent outpatient knee surgery, 31% of those in the phase II recovery area who bypassed the PACU required nursing interventions and were three times more likely to need a nursing intervention compared to 16% of patients who first went to the PACU and then required a nursing intervention. However, discharge times were shorter and unplanned hospital admissions were fewer among patients who were able to bypass the PACU.[86]

Some criteria for discharge to home have been created without scientific basis. One criterion is the patient's ability to tolerate liquids before discharge. Postoperative nausea may be greater if patients are required to drink liquids prior to discharge. Even though the ability to void is warranted after spinal or epidural anesthesia, the requirement that low-risk patients void before discharge may only lengthen stay in the hospital, particularly given that earlier discharged patients would be willing to return to a medical facility if they were unable to void. Practical criteria for patient discharge from the operating room, PACU, and phase II recovery area that in no way compromise patient safety are needed. The value of psychomotor tests to measure different phases of recovery (except for research purposes) is questionable.

Although scoring systems can be used to guide transfer from the PACU to the phase II recovery room and from phase II recovery room to home, they do little to test higher levels of function, such as the patient's ability to use the hands, drive a car, or remain alert long enough to drive. Patients may feel fine after they leave the hospital, but they should be advised against driving for at least 24 hours after a procedure. Patients and responsible parties should be reminded that patients should not operate power tools or be involved in major business decisions for up to 24 hours after a procedure. Once patients leave the medical facility, supervision may not be as extensive as it was in the hospital. Therefore, dressings should be checked before patients are discharged. The responsible person should be informed of all discharge instructions, which are best made available on printed forms.

Patients should be informed that they may experience pain, headache, nausea, vomiting, dizziness, and, if succinylcholine was used, muscle aches and pains apart from the incision for at least 24 hours after a procedure. Patient will be less stressed if they are told to expect the described symptoms during the course of a normal recovery. Written instructions are important. Providing written and oral informational techniques at discharge has a significant impact on improving patient compliance.

For patients whose native language is not English (e.g., in populations with a high percentage of immigrants), consent forms, procedural explanation, and discharge information written in languages other than English and/or the services of an interpreter may be necessary. Nursing staff should assess the adult who will take the patient home to determine whether the companion is, in fact, a responsible person. A responsible person is someone who is physically and intellectually able to take care of the patient at home. Facilities should develop a method for followup after the patient has been discharged. At some facilities, staff members telephone the patient the next day to determine the progress of recovery; others use followup postcards.

Whenever we become innovative in the management of our outpatients, we must assess how a cost-effective, "no frills" approach to patient care affects patient safety. We must determine what we can do for the patient who lives alone, for the patient whose responsible person is unable to manage his or her needs, for the patient without means of transportation, and for the patient with limited insurance coverage. Hospital beds can be set aside for patients who require observation. Patients who occupy these beds after an ambulatory surgical procedure still are considered outpatients. They are charged for the hours spent in the observation area. Some hospitals have joined with management firms to build a hospital hotel or medical motel close to the hospital itself. The hotel, usually a nonmedical facility, offers the outpatient a comfortable, inexpensive, convenient place to recuperate while receiving care by family or nurses. Home healthcare nursing may be appropriate after surgical procedures such as reduction mammoplasty, abdominoplasty, vaginal hysterectomy, and major open ligament repairs of the knee. The various services for management and/or observation of outpatients after surgery stand today where techniques for management of outpatients during surgery stood in the healthcare delivery system 20 years ago. Prospective studies are needed to assess the quality of care and the effect of these innovative approaches on patient safety.

On rare occasions, a patient requires unanticipated admission to an inpatient facility. Factors such as intractable pain, vomiting, failure of a responsible escort to show up, or more serious surgical complications may prevent discharge to home. In these circumstances, arrangements for safe transfer and subsequent proper management and followup of the patient are mandatory.

The patient, the procedure, the availability and quality of aftercare, and the anesthetic technique to be used must be assessed individually and collectively to determine the patient's acceptability for ambulatory surgery. A delicate balance must be maintained among the patient's physical status, the proposed surgical procedure, and the appropriate anesthetic technique, along with the expertise level of the anesthesiologist caring for a patient.

Anesthesia for ambulatory surgery is a rapidly evolving specialty. Patients once thought unsuitable for ambulatory surgery now are considered appropriate candidates. Operations once thought unsuitable for outpatients now are routinely performed in the morning so that patients can be discharged in the afternoon or evening of the same day. The appropriate anesthetic management of these patients before, during, and after their operation is the key to success. The availability of both shorter-acting anesthetics and longer-acting analgesics and antiemetics enables us to care effectively for patients in ambulatory centers.

CHAPTER 68

Monitored Anesthesia Care and Conscious Sedation

Robert S. Harris, MD, and Peter S. Sebel, MB, BS, PhD, MBA

DEFINITIONS

MAC

Monitored anesthesia care (MAC), a term first defined by the American Society of Anesthesiologists (ASA) in 1986, represents a comprehensive physician service provided to patients undergoing diagnostic or therapeutic procedures.[1] The ASA Position Statement, last updated in 1998, is as follows[1]:

> *Monitored anesthesia care is a specific anesthesia service in which an anesthesiologist has been requested to participate in the care of a patient undergoing a diagnostic or therapeutic procedure.*
>
> *Monitored anesthesia care includes all aspects of anesthesia care—a preprocedure visit, intraprocedure care and postprocedure anesthesia management.*
>
> *During monitored anesthesia care, the anesthesiologist or a member of the anesthesia care team provides a number of specific services, including but not limited to:*
>
> - *Monitoring of vital signs, maintenance of the patient's airway and continual evaluation of vital functions*
> - *Diagnosis and treatment of clinical problems which occur during the procedure*
> - *Administration of sedatives, analgesics, hypnotics, anesthetic agents or other medications as necessary to ensure patient safety and comfort*
> - *Provision of other medical services as needed to accomplish the safe completion of the procedure*
>
> *Monitored anesthesia care often includes the administration of doses of medications for which the loss of normal protective reflexes or loss of consciousness is likely. Monitored anesthesia care refers to those clinical situations in which the patient remains able to protect the airway for the majority of the procedure. If, for an extended period of time, the patient is rendered unconscious and/or loses normal protective reflexes, then anesthesia care shall be considered a general anesthetic.*
>
> *Because monitored anesthesia care is a physician service provided to an individual patient and is based on medical necessity, it should be subject to the same level of reimbursement as general or regional anesthesia. Accordingly, the ASA Relative Value Guide provides for the use of proper basic procedural units, time units and age and risk modifier units as the basis for determining reimbursement.*

Conscious Sedation

Conscious sedation is an obsolete term first introduced by the American Dental Association (ADA) and refers to a "minimally depressed level of consciousness that is produced by a pharmacologic method, a nonpharmacologic method, or a combination of both, in which the patient retains the ability to maintain an airway independently and continuously and to respond appropriately to physical stimulation or verbal command."[2] The term *conscious sedation* has been replaced by *moderate sedation*. Although the level of sedation and analgesia obtainable under moderate sedation may seem identical to that considered to be MAC by most healthcare providers, there are several

KEY POINTS

1. Monitored anesthesia care (MAC) is a comprehensive physician service that includes all aspects of anesthetic care—preprocedural visit, intraoperative care, and postprocedure anesthetic management.
2. The American Society of Anesthesiologists (ASA) practice guidelines for MAC have been established. These guidelines frequently are consistent with those for general or regional anesthesia and should be followed accordingly.
3. Although MAC is safe when administered by well-trained anesthesia personnel, ASA closed claims data demonstrate that rare and severe injuries or death can occur during MAC.
4. Clinicians must understand the pharmacokinetic and pharmacodynamic principles of drug administration (e.g., context-sensitive half-time, effect-site half-time) so that cognitive errors can be avoided. Proper drug dosing can optimize patient safety and recovery and discharge times.
5. Therapeutic windows for drugs administered during MAC are much smaller than those for general anesthesia.
6. When a drug combinations is used, the combination itself should be regarded as a novel drug, and it may have unpredictable properties that are markedly different from the properties of the individual drugs composing it.
7. Considering drug relationships to be either additive or synergistic is overly simplistic. Two drugs may be additive in one ratio and synergistic or even antagonistic in another. Response surface methodology is the technique by which the entire three-dimensional drug relationship can be elucidated. Although clinicians may not construct these models, they should use existing models reported in the literature to facilitate optimal drug dosing.
8. Drug administration via constant infusion allows more predictable plasma concentration, decreased total drug usage, and faster recovery time than administration via multiple bolus techniques.
9. Target-controlled infusion devices, by incorporating patient covariates (e.g., age, weight) into pharmacokinetic models, may improve the accuracy of drug administration.
10. Sedation with propofol is classified as deep sedation by the ASA. When used in doses consistent with MAC, significant changes occur in airway anatomy and cardiopulmonary physiology. These changes occur even in healthy patients and are amplified in the elderly and in patients with preexisting systemic disease. Propofol should be administered only by clinicians qualified to rescue patients from any level of sedation, including general anesthesia.

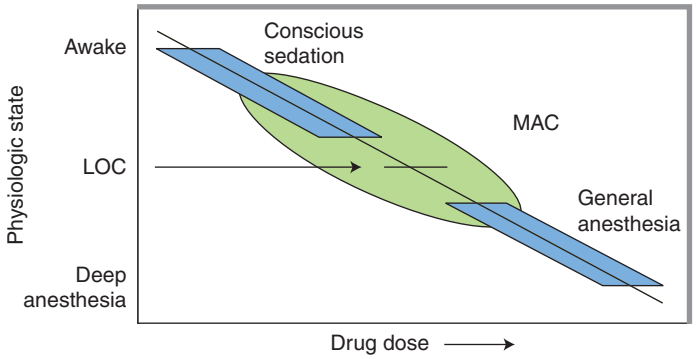

FIGURE 68–1. Graphical depiction of the distinct difference between conscious sedation and general anesthesia with regard to level of consciousness and dose of drugs usually involved. Monitored anesthesia care fills the gap and may overlap, to some extent, both of the other services. Novak LC. ASA updates its position on monitored anesthesia care. ASA Newsletter 1998; 62:22–23. Reprinted with permission of the American Association of Anesthesiologists, 520 N. Northwest Highway, Park Ridge, Illinois 60068-2573.

important distinctions between the two entities. MAC involves the continuous presence of a second independently functioning physician/anesthesiologist who either personally provides or medically directs care. In addition, the provider of MAC must be both prepared and qualified to convert any anesthetic to general anesthesia when required.[1] In contrast, moderate sedation may be directed by the same physician (or by nonphysician personnel) performing the procedure, and the depth of anesthesia attained should not lead to loss of the patient's ability to maintain airway integrity.[3] Furthermore, MAC implies a full array of preoperative and postoperative responsibilities, from the diagnosis and treatment of coexisting medical problems to the relief of postoperative pain. Finally, although there may be commonality in the depths of sedation achieved with moderate sedation and MAC, clearly MAC permits the safe administration of a maximal depth of sedation, even in fragile patients who might reach such levels after minimal sedation (Fig. 68–1).

Other Terminology

The ASA has developed a continuum of sedation states, ranging from minimal sedation (anxiolysis) to general anesthesia (Table 68–1). With the advent of improved pharmacologic agents and delivery devices, monitors, and medical technology, these techniques are being used increasingly in nontraditional anesthetic locations (e.g., endoscopy and interventional radiology suites).

Minimal Sedation (Anxiolysis): Drug-induced state during which patients respond normally to verbal commands. Although cognitive function and coordination may be impaired, ventilatory and cardiovascular functions are unaffected.

Moderate Sedation/Analgesia (Conscious Sedation): Drug-induced depression of consciousness during which patients respond purposefully to verbal commands, either alone or accompanied by light tactile stimulation. No interventions are required to maintain a patent airway, and spontaneous ventilation is adequate. Cardiovascular function usually is maintained.

Deep Sedation/Analgesia: Drug-induced depression of consciousness during which patients cannot be easily aroused but respond purposefully following repeated or painful stimulation. The ability to independently maintain ventilatory function may be impaired. Patients may require assistance in maintaining a patent airway, and spontaneous ventilation may be inadequate. Cardiovascular function usually is maintained.

General Anesthesia: Drug-induced loss of consciousness during which patients are not arousable, even by painful stimulation. The ability to independently maintain ventilatory function often is impaired. Patients often require assistance in maintaining a patent airway, and positive-pressure ventilation may be required because of depressed spontaneous ventilation or drug-induced depression of neuromuscular function. Cardiovascular function may be impaired.

PREOPERATIVE CONSIDERATIONS

Patient Selection

Because patients will be conscious during MAC, evaluation of the patient's ability to cooperate and remain still during the procedure is important.

TABLE 68–1.

Continuum of Depth of Sedation: Definition of General Anesthesia and Levels of Sedation/Analgesia[2]

	Minimal Sedation (Anxiolysis)	Moderate Sedation/ Analgesia (Conscious Sedation)	Deep Sedation/ Analgesia	General Anesthesia
Responsiveness	Normal responses to verbal stimulation	Purposeful,[a] response to verbal or tactile stimulation	Purposeful,[a] response after repeated or painful stimulation	Unarousable, even with painful stimulation
Airway	Unaffected	No intervention required	Intervention may be required	Intervention often required
Spontaneous ventilation	Unaffected	Adequate	May be inadequate	Frequently inadequate
Cardiovascular function	Unaffected	Usually maintained	Usually maintained	May be impaired

[a]Reflex withdrawal from a painful stimulus is not considered a purposeful response.

Although no patient is "too sick" for sedation and MAC, certain cognitive deficits or the presence of other conditions (e.g., severe cough) may confer an advantage to general anesthesia. Communication during the procedure may be of paramount importance, as a means of both monitoring the depth of sedation and reassuring or calming a moving or agitated patient. For this reason, the presence of a significant language barrier between patient and clinician may confer an advantage to general anesthesia in many cases.

Safety

Although public perception, if not heuristic reasoning, suggests that MAC is safer than either general or regional anesthesia, no consensus in the literature supports this view. Certainly selection bias (sickest and oldest patients undergoing MAC) is a consideration, but similar complications can occur regardless of type of anesthesia (e.g., airway obstruction, adverse drug reaction). In the ASA Closed Claims Database, MAC claims constitute 3% of all claims. The proportion of claims for MAC increased from 1.6% in the 1970s to 6.0% in the 1990s.[4] Because the denominator is unknown, the increase may just represent an increase in the number of MAC anesthetics relative to other anesthetics. Patients who had injuries during MAC were older and sicker than those who had injuries during other types of anesthesia.[4] Although MAC injuries represent a small proportion of the total claims, most claims for MAC involved severe injuries (Table 68–2). A greater proportion of permanent injuries was notable among MAC claims, along with a higher proportion of brain damage (19% vs 12% for general/regional claims) and death rate (34%) similar to general/regional claims.[4]

The cause or mechanism of the adverse outcome in MAC closed claims was respiratory in 26% of patients and cardiovascular in 10% (Table 68–3). The standard of care was judged to be appropriate in nearly half of MAC claims, and it was stated that better monitoring would not have prevented most injuries associated with MAC in the 1990s, albeit a decade in which pulse oximetry and capnometry became standards of care.[5] Payment for MAC claims ranged from $2000 to $6.3 million, and the median payment ($75,000) was similar to payments for claims associated with regional anesthesia and slightly lower than for claims associated with general anesthesia ($110,000).[4] In general, despite the rare risk of an adverse outcome, it appears that MAC anesthesia is safe when administered by well-trained anesthesia personnel.

None/unknown	19	25

Preoperative Assessment

Every patient undergoing MAC should have a thorough preanesthetic evaluation, equivalent to that for a general or regional anesthetic. Although no data link outcomes with the performance of a patient evaluation, ASA practice guidelines strongly stress its importance,[2] and the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) mandates an evaluation prior to moderate or deep sedation.[6] Pertinent components of the patient's medical history include (1) abnormalities of the major organ systems; (2) previous adverse experience with sedation/analgesia or any anesthesia; (3) current medications and drug allergies; (4) time and nature of last oral intake; and (5) history of tobacco, alcohol, or illicit substance abuse. It is important to elicit if patients are using herbal medicines as well, because some phytopharmaceuticals can prolong or augment the effects of anesthesia, increase bleeding risk, or raise blood pressure, among many interactions.[7] The preoperative visit is an appropriate time to inform patients of the risks, benefits, and alternatives of MAC. Informed consent can increase patient satisfaction and align patient and provider expectations such that the patient is not anticipating a general anesthetic and the absence of all sensation.

All patients should undergo a focused physical examination, including vital signs, auscultation of the heart and lungs, and evaluation of the airway. Preprocedural laboratory testing should be guided by the patient's underlying medical conditions and should not be based upon age, outdated institutional guidelines, or protection from legal liability. It is suggested that 60–70% of all ordered preoperative laboratory tests are unnecessary according to the patient's history and physical examination.[8] A landmark study in 2000 by Schein et al.[9] randomly assigned over 19,000 patients undergoing cataract surgery at nine centers to be tested either routinely or only if indicated. No difference in outcome, hospitalization, morbidity, or mortality was found between the two groups. An important qualifier was that patients in the "no test" group underwent tests "when the history or a finding on the physical examination would have indicated the need for a test even if surgery had not been planned." A followup case-cohort study by Imasogie et al.[10] examined >1200 patients undergoing cataract surgery. Unlike the previous study, no "crossovers" or patients in the nontesting group underwent subsequent testing. No differences in the perioperative event rate were observed, and a 90% reduction in laboratory costs per patient was achieved. The ASA Practice Advisory for Preanesthesia Evaluation, last modified in 2003, strongly opines against routine preoperative testing.[11] Selective preoperative testing is recommended after consideration of the pa-

tient's history, physical examination, and type or invasiveness of the planned procedure. The presence of a significant language barrier between provider and patient may preclude MAC and confer an advantage to general anesthesia, particularly during cases in which patient communication, cooperation, or lack of movement is paramount to the success of the procedure.

Preprocedural Fasting

Patients should receive instructions regarding fasting requirements during the preoperative assessment. It is important to convey the reasons for the nothing by mouth (NPO) recommendations, because patients may not appreciate that the level of "sedation" they might receive may impair airway protective mechanisms. The ASA practice guidelines (Table 68–4) apply to healthy patients undergoing elective procedures, and no distinction is noted between general anesthesia and sedation/analgesia.[12] The guidelines acknowledge, "there is insufficient published evidence to address the safety of any preoperative fasting period."[12] The guidelines have been extrapolated outside the operating room to include procedural sedation in the emergency room and other locations, although it may be impractical for a patient requiring an emergent procedure to adhere to a 6- to 8-hour preprocedural fasting protocol. Other patients with coexisting diseases or conditions that affect gastric emptying or fluid volume (e.g., pregnancy, diabetes, bowel obstruction) require special attention and modification of guidelines. Although prudent practice dictates that the ASA practice guidelines be followed, it is possible that no period of preprocedural fast or level of planned sedation short of general anesthesia will be safe to administer to some of these patients.

TABLE 68–4.

Summary of American Society of Anesthesiologists Fasting Recommendations for Reducing the Risk of Pulmonary Aspiration[12]

Ingested Material	Minimum Fasting Period (h)
Clear liquids[a]	2
Breast milk	4
Infant formula	6
Nonhuman milk	6
Light meals (e.g., toast and clear liquids)[b]	6

[a]Examples of clear liquids include water, fruit juices without pulp, carbonated beverages, clear tea, and black coffee.
[b]A light meal typically consists of toast and clear liquids. Meals that include fried or fatty foods or meat may prolong gastric emptying time. Both the amount and type of foods ingested must be considered when determining an appropriate fasting period.

MONITORING DURING MAC

ASA Standards

The ASA standards for basic anesthetic monitoring, approved in 1986 and last modified in 2004, apply to all anesthetics, including MAC (Box 68–1).[13] Although no definitive prospective, randomized studies have validated or refuted any relationship between the advent of specific monitors and decreased morbidity or mortality, circumstantial evidence suggests that routine noninvasive basic monitoring can improve patient safety.[2] Ethical concerns may preclude the undertaking of such investigations in the future. Retrospective data from the ASA Closed Claims Database suggest that approximately one third of MAC claims from the 1970s and 1980s would have been prevented by better monitoring, whereas an examination of claims from the 1990s (after the universal adoption of pulse oximetry and capnometry) failed to reveal substandard monitoring as a contributing factor.[4] Tinker et al.[14] examined the entire closed claims database to determine whether the application of additional monitoring at the time of injury would have prevented "anesthetic mishaps." They found that 17.7% of adverse outcomes in regional or MAC cases could have been prevented by the application of better monitoring (specifically pulse oximetry and/or capnometry in 97% of instances), with a disproportionate number of cases involving death or brain damage. Although retrospective in nature, these data underscore the potential importance of noninvasive monitoring during MAC anesthesia. It is useful to examine each component of the ASA standards and its application to MAC anesthesia.

BOX 68–1.

American Society of Anesthesiologists Standards for Basic Anesthetic Monitoring

- Standard 1: Qualified anesthesia personnel shall be present in the room throughout the conduct of all general anesthetics, regional and monitored anesthesia care
- Standard 2: Oxygenation, ventilation, circulation, and temperature shall be continually* evaluated
  - Oxygenation
    - Oxygen analyzer for inspired gases
    - Observation of the patient
    - Pulse oximetry
  - Ventilation
    - Auscultation
    - Observation of the patient
    - Observation of the reservoir bag
    - End-tidal carbon dioxide analysis
  - Circulation
    - Continuous electrocardiogram display
    - Heart rate and blood pressure recorded every 5 min
    - Evaluation of circulation: auscultation of heart sounds, palpation of pulse, pulse plethysmography, pulse oximetry, intraarterial pressure tracing
  - Temperature
    - Core temperature and/or skin temperature

*The term continually means prolonged without interruption while continually means repeated regularly and frequently. Data from Anonymous. Standards for Basic Anesthetic Monitoring. ASA Directory of Members, 2004.

Presence of "Qualified Anesthesia Personnel"

Arguably the most important "monitor" for MAC or sedation/analgesia procedures is a well-trained anesthesia provider, whose sole responsibility should be monitoring the patient. Although his or her effectiveness may be improved by the application of additional noninvasive monitoring, the presence of sophisticated monitoring in an operating room suite or ancillary facility may not adequately protect patients if the clinician responsible for interpreting the monitors is focused on performing other tasks. Continual observation of the patient's mucosal color, movement of the chest wall, rate and depth of respirations, presence of shivering or diaphoresis, and response to painful stimuli is necessary. In addition to observing the patient, it is critically important to assess the response to verbal or physical stimuli. Spoken responses

confirm a lack of general anesthesia as well as adequate ventilation and cerebral perfusion. During procedures in which access to the patient is limited or when patient movement might be hazardous or disruptive, a nonverbal cue such as a handgrip or "thumbs up" can suffice. During major vascular procedures, such as endovascular aortic stenting or carotid endarterectomy, communication with the patient is of paramount importance so that myocardial or cerebral ischemia can be diagnosed quickly. Unexpected patient discomfort, agitation, or loss of verbal responses demands rapid assessment. Although it is enticing to initially regard these patients as oversedated or undersedated, agitation during MAC should be considered to be related to hypoxia, hypercarbia, or major organ hypoperfusion until proven otherwise.

Oxygenation

In addition to observing the patient for signs of hypoxemia (e.g., cyanosis), the ASA standards[13] and JCAHO standards[6] mandate the use of a quantitative method of assessing oxygenation. Pulse oximetry was introduced in the mid-1980s and was rapidly and universally adopted. It is easy to interpret and allows continuous monitoring of patient oxygenation. Although retrospective closed claims data suggest that pulse oximetry has been a revolutionary advancement in patient monitoring and safety,[5] these data (e.g., "could have been prevented") are speculative and based on assumptions.[15] Moller et al.[16,17] published what may eventually be the only multiinstitutional, large-scale, prospective, randomized controlled study of the effect of pulse oximetry on the outcome of anesthesia. During the study of 20,802 patients, use of pulse oximetry was associated with a 19-fold increase in the incidence of diagnosed hypoxemia and related events (i.e., hypoventilation, bronchospasm). Patients in the oximetry group also received higher flows of supplemental oxygen. Despite these findings, no significant difference in clinical outcome could be identified.[17] Although no statistical significance was achieved in this study, issues with sample size limitations (beyond the $P < 0.05$ "proof" of efficacy) and selection bias (90% of patients were ASA I or II) preclude the invalidation of existing standards.[18] Eichhorn[19] emphasizes that the arduous burden of statistical "proof" ($P < 0.05$) lies in proving whether *any* monitor can prevent the occurrence of extremely rare events. Short of such evidence, it remains prudent to base our practices and standards of care on the synthesis of the best information available. Today, pulse oximetry is so strongly perceived as beneficial that it probably would remain a de facto standard of care, even if all published standards were to remove all references to it.[19]

Ventilation

ASA standards mandate that clinical signs of the adequacy of ventilation (chest excursion, auscultation of breath sounds) be continually monitored during MAC.[13] In addition to observing the patient, applying a simple precordial stethoscope to the suprasternal notch is a valuable and time-tested technique for continuous detection of airway obstruction, bronchospasm, hypoventilation (or apnea), and arrhythmias. According to Prielipp et al.,[20] the frequency of usage of the precordial stethoscope has fallen from ≥ 70% in the mid 1980s to as little as 11% (1995 data). The notable trend was that providers were *substituting* (rather than *supplementing*) pulse oximetry and capnography for continuous auscultation via a precordial stethoscope. Although the technique remains noninvasive, inexpensive, and useful, this trend is not likely to spontaneously reverse, as a "detraining" effect upon trainees from their mentors favors the preservation of the status quo.

Under the ASA monitoring standards, monitoring for the presence of exhaled carbon dioxide (CO_2) by capnography or capnometry is optional for MAC/sedation cases. During MAC, it is difficult to quantitatively measure expired CO_2 because dead space in the atmosphere mixes with the patient's expired gases. However, capnometry is a reliable *qualitative* monitor of respiratory rate and apnea during MAC.[21] Measures of tidal volume or minute ventilation are not obtainable with current techniques. Sampling of CO_2 can be performed through nasal cannulas for oxygen delivery that have been commercially modified with a port for respiratory gas sampling. Alternatively, the sampling lines from the capnograph can be attached to IV catheters and placed inside nasal oxygen probes or inside a face mask.

It remains important to emphasize that oxygenation and ventilation are separate physiologic processes. Monitoring oxygenation via pulse oximetry is not a substitute for monitoring ventilatory function. There is no ideal CO_2 monitor for the patient undergoing MAC. Optimal assessment of ventilation should utilize vigilance and observation, a precordial stethoscope, and capnography.

Circulation

ASA standards dictate that for all anesthetics, an electrocardiogram (ECG) must be continuously displayed throughout the procedure.[13] In addition, blood pressure and heart rate must be measured and recorded at least every 5 minutes. The pulse should be monitored by palpation, oximetry, or auscultation. The selection of additional monitoring (e.g., invasive blood pressure monitoring) should depend upon the cardiovascular status of the patient and the nature of the procedure.

Although the ECG provides valuable information on heart rate and rhythm, the detection of myocardial ischemia (generally via ST-segment changes) depends upon the choice and configuration of leads used for monitoring. When a common three-lead ECG is used, sensitivity is low. In pediatric or young healthy patients, this technique may suffice, as significant ST-segment changes in this population are not likely to represent myocardial ischemia. More commonly, a five-lead ECG with one precordial lead placed at V_5 is used. This convention is based on previous observations in which up to 90% of ischemic episodes occurring during exercise testing and up to 75% of intraoperative ischemic episodes were detected by V_5 alone.[22] Several studies have shown that visual detection of significant ST-segment changes (particularly those of short duration) is extremely poor, ranging from 0–46% of episodes.[23] Even experienced cardiologists, when comparing visual versus computerized analysis of ST-segment analysis on exercise ECGs, demonstrate intraobserver agreement in only 61–85%.[24] These data indicate that a clinician providing MAC anesthesia will fail to diagnose a percentage of myocardial ischemic episodes. Fortunately, modern anesthesia machines incorporate computerized ST-segment analysis. The advent of this technology has increased the accuracy

(when compared with standard Holter recordings) of readings, but there are differences in the proprietary algorithms used by various manufacturers. Leung et al.[25] found the overall average sensitivity and specificity of detection of ischemia to be 74% (range 60–78%) and 73% (range 69–89%), respectively. Anesthesia providers should augment the computerized ST-segment readings with their clinical acumen and risk assessment of the patient's particular likelihood of an ST-segment change representing true ischemia. Additionally, it is vital to realize that the isoelectric and J points are set by computer algorithm, and their accuracy should be manually determined for each individual patient prior to the start of the procedure.

Temperature

ASA standards state that patient temperature should be monitored "when clinically significant changes in body temperature are intended, anticipated, or suspected."[13] Hyperthermia is not a major concern under MAC because triggering agents (e.g., volatile anesthetics and succinylcholine) are not used. Hyperthermia occurring under MAC is most likely iatrogenic in origin, as overzealous application of warming blankets and sheets in combination with a small exposed surgical site can make patients unexpectedly warm and uncomfortable. These conditions are easily correctable if they occur.

A common misperception exists regarding the relationship between MAC or neuraxial anesthesia and hypothermia. Although most clinicians believe that patients can verbalize subjective feelings of coldness, neuraxial anesthesia impairs behavioral thermoregulation and central autonomic thermoregulatory control.[26] Thus, patients cannot always accurately perceive hypothermia. Decreased core temperatures during anesthesia in patients given sedatives preoperatively have been demonstrated, and there is evidence that propofol,[27,28] midazolam,[29,30] and opioids[31,32] reduce vasoconstriction and shivering thresholds when used at doses consistent with MAC anesthesia.

Studies on temperature monitoring and MAC are lacking, but a survey by Frank et al.[33] found that only one third of patients were monitored during neuraxial anesthesia. An ancillary finding was that <15% of those surveyed used core temperature monitoring techniques and instead relied upon skin-surface temperatures [typically 36–39°F (2–4°C) less than the core temperature]. Although manufacturers compensate for this difference by adjusting the offset to the displayed reading, the monitors are inept at both fever screening and malignant hyperthermia detection.[34] Arkilic et al.[35] conducted an observational study on temperature monitoring and neuraxial anesthesia and found that initial postoperative tympanic membrane temperatures in patients having neuraxial anesthesia were <97°F (<36°C) in 77% of patients and <95°F (<35°C) in 22% of patients. Body temperature was monitored intraoperatively in only 27% of patients, and no correlation between the magnitude or duration of surgery and initial postoperative temperatures was observed.

Even mild intraoperative hypothermia [<95°F (35°C)] has been associated with myocardial ischemia and cardiac morbidity in high-risk patients. In addition, hypothermia increases postoperative wound infection and bleeding risk.[36] The morbidity associated with perioperative hypothermia likely is independent of anesthetic technique (e.g., general vs MAC). In most patients, redistribution of heat from the core to the periphery is the major source of intraoperative hypothermia. Cold procedure or operating room suites and unwarmed IV fluids compound the heat loss. Measures to prevent hypothermia should include forced air heaters, radiant heat lamps, fluid warmers, and increasing the ambient temperature where feasible. Because hypothermia appears to be common and unpredictable in patients undergoing MAC, most, if not all, patients should have temperature monitoring. Most measures of core temperature are inconvenient (e.g., pulmonary artery, esophageal) and impractical during MAC cases. Forehead skin surface temperature remains the most common modality despite its limitations. Sessler[34] recommends axillary or intermittent oral temperature readings.

Monitoring Depth of Sedation during MAC

Accurate assessment of sedation depth is important in minimizing the risks of MAC and procedural sedation both inside and outside the operating room. Many patients, particularly the elderly or very ill, may rapidly move from a plane of light sedation to obtundity. Practitioners should have the means to effectively monitor depth of sedation. Clinicians traditionally have relied upon subjective and imprecise measures or autonomic signs of patient responsiveness to judge depth of sedation and analgesia. Unfortunately, this approach has flaws. Because the direct effect of sedatives and hypnotics on the brain cannot be measured, clinicians usually rely on indirect measures of the level of sedation, such as frequent patient stimulation [e.g., Observer's Assessment of Alertness/Sedation Scale (OAA/S), Box 68–2] to measure the depth of sedation. These techniques require persistent patient cooperation and are subject to testing fatigue. Additionally, there are procedures and cases (e.g., MRI) during which periodical patient movement and speech might preclude the successful completion of the procedure. Changes in autonomic signs (e.g., hypertension and tachycardia) do not reliably predict awareness and discomfort during general anesthesia,[37–39] and, for reasons previously stated, would not be helpful even if they accurately preceded patient anxiety or movement.

An objective measure of sedation depth theoretically could decrease the incidence of patient undersedation and oversedation, decrease anesthetic wastage, and shorten recovery and discharge times. Because the brain is the target of anesthetic action, and electrical activity of the cerebral cortex can be measured via the electroencephalogram (EEG), most depth-of-anesthesia monitors have focused on measuring changes in the EEG. The Bispectral Index Scale (BIS) was the first clinically available depth-of-anesthesia monitoring device. BIS is a proprietary algorithm (Aspect Medical Systems, Natick, MA) that generates a linear dimensionless number ranging from 0–100 that decreases in proportion to increased anesthetic depth. The BIS does not correlate with movement, heart rate, or blood pressure. Although BIS has been used more commonly during general anesthesia, it has been evaluated during depth of sedation with propofol,[40,41] midazolam,[39,42] and even sevoflurane.[43] During propofol-induced sedation, BIS was shown to correlate with OAA/S scores,[41,42] loss of response to verbal commands,[40] suppression of learning,[44] and propofol blood concentrations.[44] Gan et al.[45]

BOX 68–2.

Observer's Assessment of Alertness/Sedation Scale

Assessment Categories				
Responsiveness	**Speech**	**Facial Expression**	**Eyes**	**Composite Score Level**
Responds readily to name spoken in normal tone	Normal	Normal	Clear, no ptosis	5
Lethargic response to name spoken in normal tone	Mild slowing or thickening	Mild relaxation	Glazed or mild ptosis (less than half the eye)	4
Responds only after name is called loudly and/or repeatedly	Slurring or prominent slowing	Marked relaxation	Glazed and marked ptosis (half the eye or more)	3
Responds only after mild prodding or shaking	Few recognizable words			2
Does not respond to mild prodding or shaking				1

demonstrated faster recovery times and decreased propofol usage with the addition of the BIS monitor, although formal cost-effectiveness studies during MAC or regional anesthesia have not been done. BIS monitoring accurately and objectively measures patient sedation level during endoscopy[46] and during procedural sedation in the emergency room.[47]

In contrast to the expected BIS readings for patients undergoing general anesthesia (BIS values 40–60), BIS readings of 60–80 are targeted during MAC; BIS values approaching 60 are associated with a low probability of recall.[40,42,48] Recall is impaired at much higher BIS values than is response to command.[49] It is important to realize that BIS measurements are slightly dependent upon the type of anesthetic agents used. Several authors have shown higher BIS values for loss of consciousness when opioids were added to an anesthetic.[43,49,50] This phenomenon, which extends to other agents (e.g., ketamine, nitrous oxide), exists because noncortical structures underrepresented in the EEG contribute to the mechanism of hypnosis and sedation with opioids.[51] Another drug, ketamine, can cause loss of response to verbal command in doses as low as 0.25 mg/kg without altering BIS measurements.[52] It also has been suggested that spinal and epidural anesthesia may affect BIS measurements independent of other anesthetics.[53,54] Morley et al.[53] demonstrated a small but detectable EEG suppression in patients receiving spinal anesthesia without concomitant IV sedation. The mechanism appears to be related to decreased afferent stimulation of the reticular activating system and is independent of block height.

A priori we believe there is a selective subset of patients undergoing MAC in whom BIS monitoring is a valuable *adjunctive* clinical monitor to standard clinical evaluation. As previously implied, BIS monitoring would be particularly beneficial during procedures in which patients should not move or speak, procedures of prolonged duration, or those involving patients of advanced age or ill health. Whenever possible, patients should be monitored via behavioral methods (e.g., continual assessment of response to commands) in addition to BIS. Because both the general public and many nonanesthesiologists have difficulty distinguishing between deep levels of sedation and general anesthesia, it is advisable to discuss patient concerns about "awareness" or "being awake" during the patient's preanesthetic assessment and interview. Patients insisting on guaranteed amnesia and hypnosis for procedures under MAC should be offered general anesthesia if feasible.

PRINCIPLES OF PHARMACOKINETICS AND PHARMACODYNAMICS APPLIED TO MAC

The concentration of drug achieved in a patient is dependent upon the dose administered and the disposition of the drug in the body. The process that describes this disposition is called the drug's *pharmacokinetics.* This dose–concentration relationship, although important, must be considered in conjunction with the response that a drug elicits at a given dose. This relationship between concentration and response is referred to as *pharmacodynamics.* A full discussion of these principles lies elsewhere in this volume (see Chap. 39). Anesthesiologists must be familiar with the principles of both pharmacokinetics and pharmacodynamics in order to effectively and safely sedate patients during MAC. During MAC, the therapeutic window for many drugs is smaller than that for drugs used during general anesthesia. For example, the intubating dose of muscle relaxants used during general anesthesia typically is 2–3 times the ED_{95} median effective dose. One dose fits most people in these instances. However, if this principle were applied to sedation under MAC, the risk of overdose and the accompanying complications of loss of the airway and hypoxia would be unacceptable. Closed claims data discussed earlier in this chapter (see Safety) prove that complications during MAC can arise from excessive or inadequate sedation. Variability in population pharmacokinetics and pharmacodynamics is only one cause of misuse of drugs. Failure to understand and apply these basic principles to MAC is another factor, and it will be useful to review some concepts here.

Pharmacokinetic Applications

Plasma Concentration and Drug Distribution

During MAC, clinicians typically are called upon to administer potent IV drugs in response to changing patient

and surgical needs. IV drugs can be administered via a bolus or via infusion, and typically the therapeutic window for drugs is much smaller than that during general anesthesia. It is dangerously simplistic to consider only the amount of drug administ ered or only the infusion rate when considering the effect on a patient.

An important consideration after the initial bolus of a drug is that there is no homogenous plasma compartment into which a drug equilibrates. As shown in Fig. 68–2, traditional studies assumed that the arterial plasma concentration of a drug decreased monotonically from a peak plasma level (solid line). Studies have indicated not only that arteriovenous differences in peak plasma levels are achieved,[55,56] but that plasma levels oscillate during the first 2 minutes of administration.[57,58]

The distribution phase shows a rapid decline in the plasma concentration. This reflects the fact that drug dosing in man can be estimated by (and therefore based upon) complicated pharmacokinetic modeling. Although it is easier to consider dosing based upon a one-compartment or "bathtub" analogy, virtually none of the drugs used in anesthesia can be described by a one-compartment model.[59] Hence, the relationship between plasma level and half-life, clearance, and elimination becomes more complicated. Extrapolating the abscissa of Fig. 68–2 over a period of hours typically would yield a graph with differing slopes, as indicated in Fig. 68–3. The distribution phase reflects both the rapid movement of the drug from the blood to the vessel-rich tissues and a slower equilibrating compartment composed of less well-perfused tissues, such as muscle and skin. Although the latter compartment is poorly perfused, significant drug accumulation can occur during long infusions, and this compartment can release drug back into the central compartment after administration ceases. This can prolong recovery and change the elimination kinetics of the drug. The elimination phase after a bolus injection is represented by the straight line, and, when drawn on a log scale, the slope or rate is independent of dose.

It should be noted that the "compartments" discussed are not anatomic nor physiologic entities; they are a mathematical concept derived from pharmacokinetic models, which in turn describe drug concentrations over time. A sample three-compartment hydraulic model is shown in Fig. 68–4.[60] Note the different transfer constants or "clearances" among the different compartments.

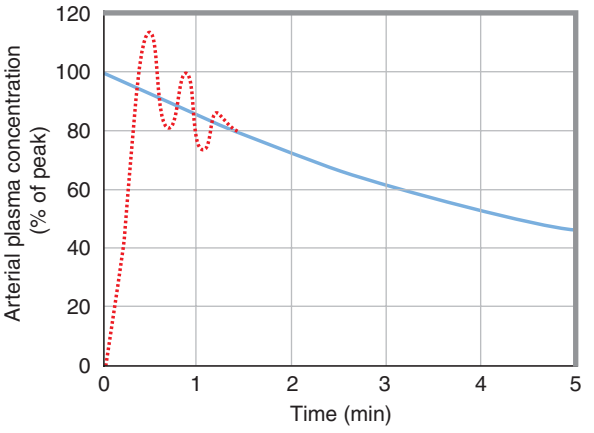

FIGURE 68–2. After bolus drug administration, arterial plasma concentrations were traditionally assumed to decrease monotonically (*solid line*). However, recent studies demonstrate that plasma concentrations may increase during the initial 30–60 seconds, then oscillate (*dashed line*) before decreasing monotonically.[57]

Effect-Site Concentration

For IV anesthetics, the plasma is not the site of action. The effect site or biophase is the site of drug activity. The anatomic site of a drug's biophase may be difficult to identify; even if the biophase is known, the concentration of drug can never be directly measured physically. Despite this limitation, it is important to consider the delay or hysteresis between the peak in plasma concentration and effect-site concentration. By continuously measuring the effect of a drug (e.g., EEG analysis, patient response) and its plasma concentration, it is possible to mathematically compute k_{e0}, the rate of equilibration of the drug concentration between the biophase and the plasma. The $t_{1/2}$ k_{e0} is the time needed for half the equilibration to occur between the biophase and the plasma concentration. The $t_{1/2}$ k_{e0} of some common IV anesthetics are listed in Table 68–5.[61]

The clinical relevance of these data can be seen by using propofol as an example. If a desired effect-site concentration of 4 μg/mL is desired, an

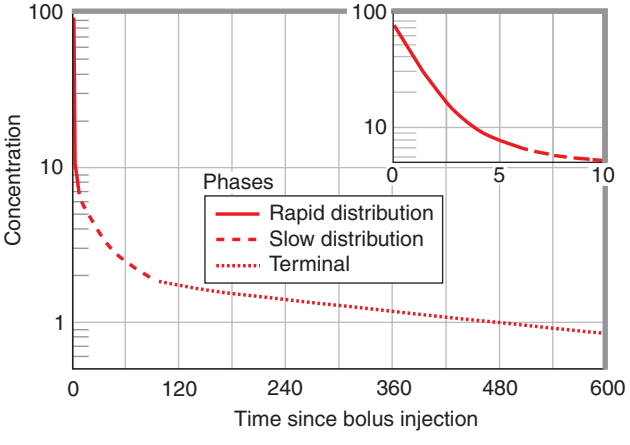

FIGURE 68–3. Three phases of drug distribution following an intravenous bolus. The rapid distribution phase (*solid line*) begins immediately after a bolus injection and is characterized by movement of drug from plasma to rapidly equilibrating tissues. The slow distribution phase (*dashed line*) is bidirectional; drug moves into slower-equilibrating tissues and returns from rapidly equilibrating tissues. During the terminal phase (*dotted line*), drug returns to the plasma from both compartments and is eliminated such that the relative proportion of drug in plasma and peripheral volumes remains constant.

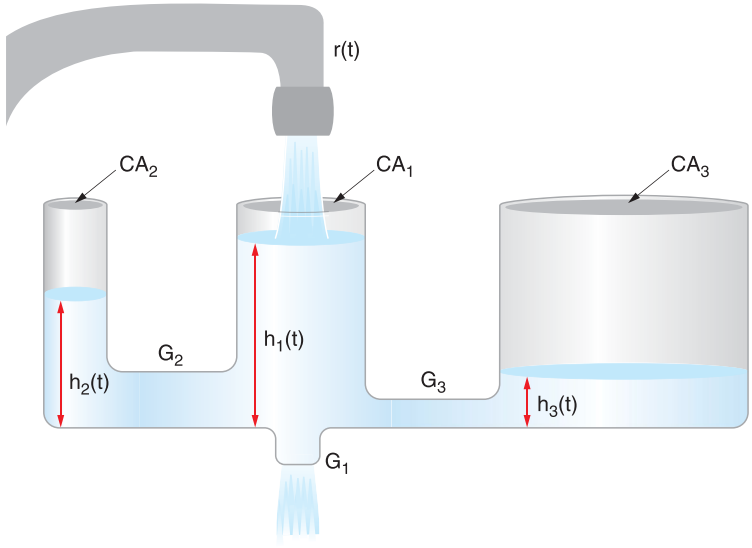

FIGURE 68–4. Hydraulic model analogy to three-compartment pharmacokinetic model. Water enters bucket 1 at the rate of r(t) and leaks irreversibly through G_1. The height of the water level in each bucket is dependent on r(t), the differing cylindrical areas (CA_{1-3}), and the relative conductance levels G_{1-3}.[60]

infusion started in order to obtain a plasma concentration of 4 µg/mL would achieve an effect-site concentration of 2 µg/mL after 2.4 minutes, and four distribution time constants or almost 10 minutes would be required to achieve an effect-site concentration of 4 µg/mL. This dosing scheme is infeasible during MAC cases during which frequent and significant changes in effect-site concentrations are desired. In practical terms, this implies that one either administers a bolus prior to beginning the infusion or starts with a high infusion rate (decreasing the rate with time in order to maintain stable plasma levels). Clinicians must be knowledgeable of the time to peak effect for any drug that will be administered. Additionally, when giving IV drugs by intermittent bolus dosing, the interval between doses needs to be of sufficient duration such that the peak effect after one dose can be observed prior to redosing. Clinically, an example of this would be to compare remifentanil and fentanyl. Remifentanil, which has a much shorter $t_{1/2}\ k_{e0}$ than fentanyl, will have a more rapid onset to peak effect and therefore can be given as an intermittently bolus at shorter intervals. Bolus administration of fentanyl in a similar fashion would be hazardous during MAC because the effect-site concentration would peak only after multiple doses had been given, increasing the likelihood of apnea or hypoventilation. Finally, it is important to consider the time to peak effect of each drug given in a combination, given that most of the drugs in Table 68–5 act in an additive or synergistic interaction.

TABLE 68–5.

$t_{1/2}\ k_{e0}$, Time to Peak Effect Following Bolus Dose, and Volume of Distribution (V_d) Incorporating the Effect Compartment.[61]

Drug	Time to Peak Effect (min)	$t_{1/2}\ k_{e0}$ (min)	V_d (L) incorporating the effect compartment
Dentanyl	3.6	4.7	75
Alfentanil	1.4	0.9	5.9
Sufentanil	5.6	3	89
Remifentanil	1.2	1	
Propofol	2.2	2.4	37
Thiopentone	1.7	1.5	
Midazolam	2.8	4	
Eomidate	2	1.5	

Drug Elimination

The elimination half-time, or the time required for a drug to reach half of its initial concentration (after a bolus or termination of an infusion), used to be the predominant measure of a drug's duration of action. It was thought that dosing intervals and time to reach steady-state concentrations could be predicted from such a value. However, it is relevant only in single-compartment models or during prolonged infusions in which a steady state is reached (which almost never occurs during the course of an anesthetic). Because most drugs are lipophilic and follow a multicompartmental model of distribution and elimination, the elimination of a drug is only one contributor to changing plasma levels; intercompartmental changes frequently are significant as well. The contribution of these compartments depends upon the duration of the infusion (discussed below under Context-Sensitive Half-Time).

Context-Sensitive Half-Time

In 1990, Shafer and Varvel[62] were the first to publish comparative simulations of the pharmacokinetics of three synthetic opioids (alfentanil, fentanyl, and sufentanil). They found that the times required for various decrements in plasma concentration (20%, 50%, and 80%) after discontinuation of drug infusions were dependent upon the duration of administration. They also demonstrated that these decrement times could not be predicted from elimination half-life parameters. The clinical relevance of this can be ascertained from Fig. 68–5.

Although fentanyl has a shorter elimination half-life than sufentanil (475 vs 562 minutes), its 50% decrement time is much greater than that for sufentanil if the infusion duration is >2 hours. Note also from Fig. 68–5 that the decrement times are not linear (50% or 80% decrement time cannot be predicted based upon drug's 20% decrement time).

Following the work of Shafer and Varvel, the term *context-sensitive half-time* was introduced by Hughes et al.[60] in 1992. The context-sensitive half-time is the time required for the plasma concentration of a drug to decrease by 50% after discontinuing a drug infusion. The term is synonymous with the 50% decrement time (Fig. 68–6).

The context-sensitive half-time (or any decrement time) is not specifically

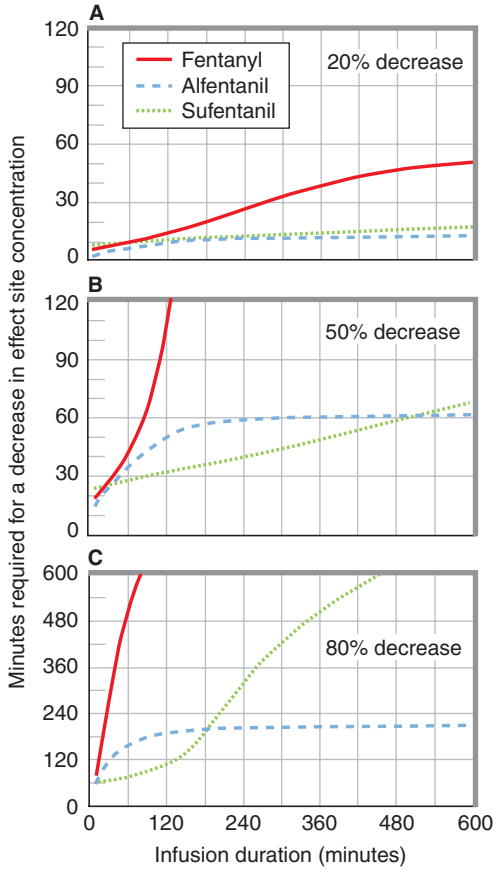

FIGURE 68–5. Overlay of the fentanyl, alfentanil, and sufentanil recovery curves showing the time required for decreases of 20%, 50%, and 80% from the maintained intraoperative effect-site concentration after termination of infusion.[62]

identified with any clinical recovery end point. Thus, although sufentanil has the shortest 50% decrement time after an 8-hour infusion, alfentanil has a much shorter 80% decrement time at the same duration of infusion, and this may be associated with a faster recovery time. This has been suggested by Shafer and Varvel[62] and Youngs and Shafer.[63] Schraag et al.[64] compared two groups of patients (alfentanil/propofol and sufentanil/propofol) and noted no difference in mean extubating times but shorter times to discharge recovery criteria in the alfentanil group after discontinuation of the infusions. The relative decrement values to tracheal extubation were 62% for sufentanil and 48% for alfentanil, compared with 76% and 65% for discharge, respectively. These findings demonstrate that decrement times and their clinical correlates are drug specific. They also bring into question the effect of compounding numerous drugs, as is performed during most anesthetics.

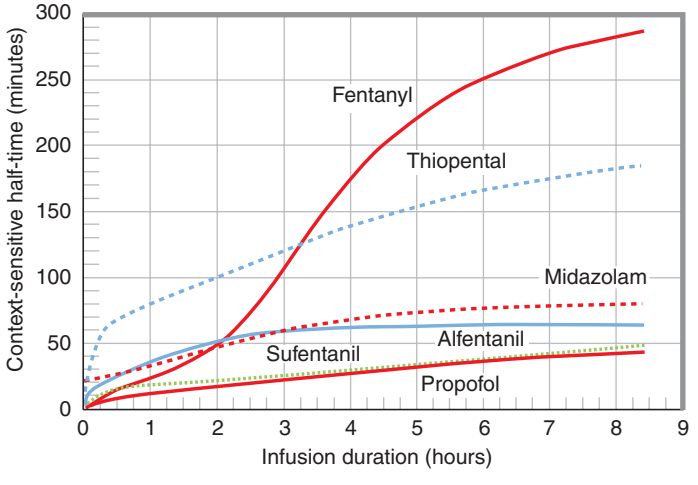

FIGURE 68–6. Context-sensitive half-times as a function of infusion duration for various intravenous anesthetics. Curves are based on simulated pharmacokinetic models. Solid and dashed lines are used only to distinguish overlapping curves.[60]

Pharmacokinetic Concerns in the Obese Patient

Obesity is a common, major health problem throughout the developed world. The prevalence of obesity in middle-aged adults in the United States approaches 25%,[65] and anesthesiologists frequently encounter these patients. The physiologic changes induced by obesity can have marked effects on the distribution and elimination of anesthetics, and adverse events can occur if dosing is based on actual body weight. This is particularly important during MAC cases because concomitant sleep apnea is common in obese patients. Despite these circumstances, studies on which anesthesiologists rely upon to guide drug dosing frequently describe the drug's pharmacokinetics in healthy, nonobese patients.

Scaling Drug Dosages to Lean Body Mass

One strategy for attenuating the risk of drug overdose in the obese patient is to scale the drug dosage to lean body mass (LBM) instead of total body weight (TBW). Scaling drugs for LBM has been recommended for thiopental and methohexital,[66,67] remifentanil,[68] and propofol.[58,69]

LBM can be calculated as follows[70]:

Men: LBM (kg) = 1.1 * TBW (kg) – 120 * [TBW/height (cm)]^2

Women: LBM (kg) = 1.07 * TBW (kg) – 148 * [TBW/height (cm)]^2.

These formulas not only are complex but also fallacious; in cases where TBW significantly exceeds ideal body weight, TBW increasingly overestimates LBM.[66] Bouillon and Shafer[66] have provided a scaled nomogram (Fig. 68–7) that adjusts for both LBM and the fact that recommended doses in package inserts are scaled to TBW.

"Pharmacokinetic Mass"

A second method that can assist the clinician with adjusting drug doses in

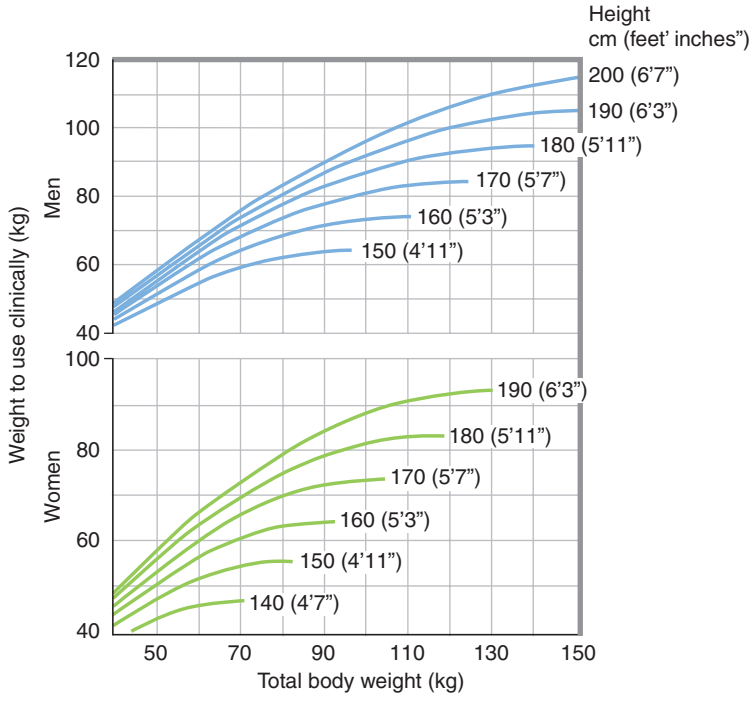

FIGURE 68–7. Scaled nomogram relating total body weight, height, and gender to the body weight that should be used to calculate drug dosages in the obese patient. The clinical weights on the ordinate are calculated from lean body mass and then scaled upward to compensate for the fact that recommended drug doses are similarly scaled to total body weight rather than lean body mass.[66]

the obese patient is use of the concept of "pharmacokinetic mass." Shibutani et al.[71] used this concept to quantify adjustments in fentanyl dosing for obese patients. The pharmacokinetic mass is an appropriate dosing weight derived from TBW and a quantified departure from linearity.[71] It can be seen from Fig. 68–8 that the slope linking TBW and pharmacokinetic mass becomes significantly flatter with increases in TBW; thus, the pharmacokinetic mass may be a particularly helpful concept to consider in the morbidly obese patient. However, the concept was tested for fentanyl exclusively; similar studies on other anesthetics may be forthcoming.

Drug Interactions and Pharmacodynamic Applications

Principles of Drug Interactions

Anesthesia for MAC frequently involves the concomitant administration of multiple drugs. Interactions between these agents can have a pharmacokinetic or pharmacodynamic basis. Despite similar mechanisms of clearance for many anesthetics, pharmacokinetic interactions usually are minor and incidental. In contrast, pharmacodynamic drug interactions often are introduced by design when incorporating multidrug regimens for MAC. Synergistic interactions, produced when two drugs with differing mechanisms of action produce a common effect,[72] can be advantageous because the goals of the anesthetic can be achieved with decreased drug dosages, less toxicity, and faster recovery than when the individual drugs are used alone.

Published evidence demonstrates synergism between benzodiazepines and barbiturates,[73,74] propofol,[75] and opioids.[75,76] Propofol has been shown to act synergistically with opioids.[77,78] It is a gross oversimplification to consider the aforementioned relationships (i.e., synergism) out of context. The clinical end point (amnesia, analgesia, apnea) must be considered, as MAC end points differ from those of general anesthesia. The interaction between two or more drugs can potentially be multidimensional and complex. The interaction also can depend upon the fractions of drugs administered and may not be predictable from the behavior of the individual drugs when used alone. Smith et al.[77] examined the addition of fentanyl to a propofol infusion and the subsequent required change in propofol concentration for loss of consciousness and lack of response to skin incision. They found that with the addition of fentanyl 3 ng/mL, the propofol ED_{50} median effective dose required to inhibit response to verbal command and incision was reduced 40% and 90%, respectively. There was considerable patient-to-patient variation in propofol dose requirements (for both end points), and a ceiling effect was seen at this concentration of fentanyl. Short et al.[75] proposed that when drug combinations are used, "the combination should be regarded as a new drug with individual properties, rather than merely reflecting the known properties of the individual agents." An example of this phe-

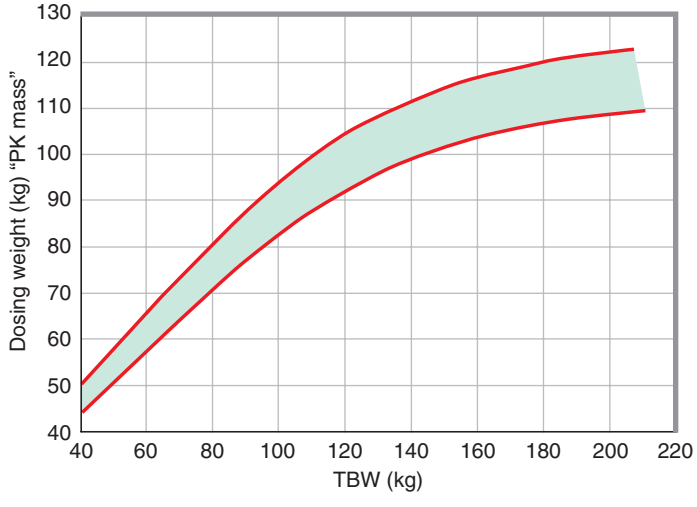

FIGURE 68–8. Nomogram relating appropriate dosing weight or "pharmacokinetic mass" to total body weight for fentanyl. Slope of curve is based upon nonlinear regression analysis of two established pharmacokinetic models (*solid lines*) and actual arterial blood gas samples in both lean and obese patients.[71]

nomenon can be seen with combined sedation using midazolam and fentanyl. Bailey et al.[76] examined the effects of midazolam and fentanyl upon respiration in healthy volunteers. Whereas midazolam alone produced no significant respiratory effects, fentanyl alone produced hypoxemia (oxygen saturation < 90%) in 50% of volunteers. The combination of midazolam 0.05 mg/kg and fentanyl 2.0 μg/kg resulted in hypoxemia in 11 of 12 subjects and apnea in 6 of 12 subjects. The clinical implications of this study are bolstered by the fact that the study examined only healthy volunteers. Elderly patients, patients with preexisting respiratory disease, and patients with obstructive sleep apnea are at greater risk, particularly during MAC anesthesia.

What tools can aid the clinician in elucidating complex pharmacodynamic interactions between anesthetic agents?

Isobolograms

The isobologram provides a convenient graphic display of the respective doses of two drug doses by using rectangular coordinates (a, b) to represent equieffective pairs of doses (isoboles) of drugs A and B, respectively.[79] If two equieffective combinations lie on a straight line, the interaction is additive. Any individual point or combination (a, b) below this line, or a concave-up shaped isobole (Fig. 68–9), represents a synergistic (supra-additive) interaction, as smaller amounts of both drugs are needed to produce the combined drug effect. Conversely, individual points above the line or a concave-down isobole are characteristic of an infra-additive interaction.

The isobologram, although visually appealing, is of limited utility with regard to complex anesthetic interactions. First, it lacks a means for assessing statistical significance. The points of an isobole are pairs of numbers presumably obtained from experimental testing; these are subject to both random and systematic errors.[79] These inherent errors in the dose–effect data are present for both drugs (i.e., both axes). In addition, it is possible that experiments using different fixed-ratio mixtures demonstrate datapoints both above and below the line of additivity. Extrapolating these data to an isobologram requires regression analysis of data from each drug and the mixture. In other words, it is nearly impossible to design an experiment such that each combination point on the isobologram (e.g., ED_{50}, ED_{80}) would be individually investigated. Regression analysis bridges this gap, but the technique is beset with flaws.[72,80] Because drug combinations can be synergistic in certain areas and antagonistic in others, it is more useful to characterize the entire surface response.

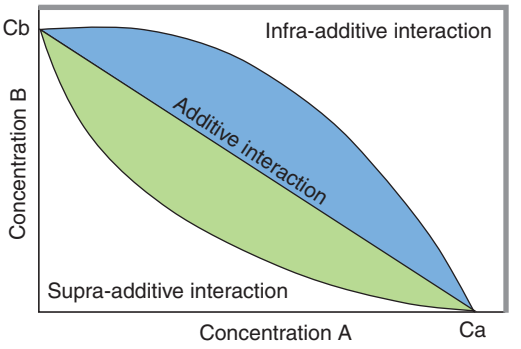

FIGURE 68–9. Isobolographic diagram with the x- and y-axes showing the concentrations of the compounds studied (A and B) and the lines of additivity, infra-additivity, and supra-additivity (synergy). The lines connect concentration combinations of the two drugs that exert a similar effect. Reprinted from, Vuyk J. Pharmacokinetic and pharmacodynamic interactions between opioids and propofol. J Clin Anesth 1997;9:23S–26S, with permission from Elsevier.

Response Surface Methodology

Response surface methodology involves three-dimensional plotting of the doses of two drugs (independent variables) and the effect that results from the combination (dependent variable). The response surface is the graph of the mathematical equation that characterizes the full concentration–response relationship between two drugs. In addition to describing the complex interaction, response surface analysis can assist the clinician in determining where the optimum response occurs. An example of the relationship between a three-dimensional response surface and the conventional two-dimensional isobologram is shown in Fig. 68–10. As illustrated, the isobologram is only a single "slice" at the 50%

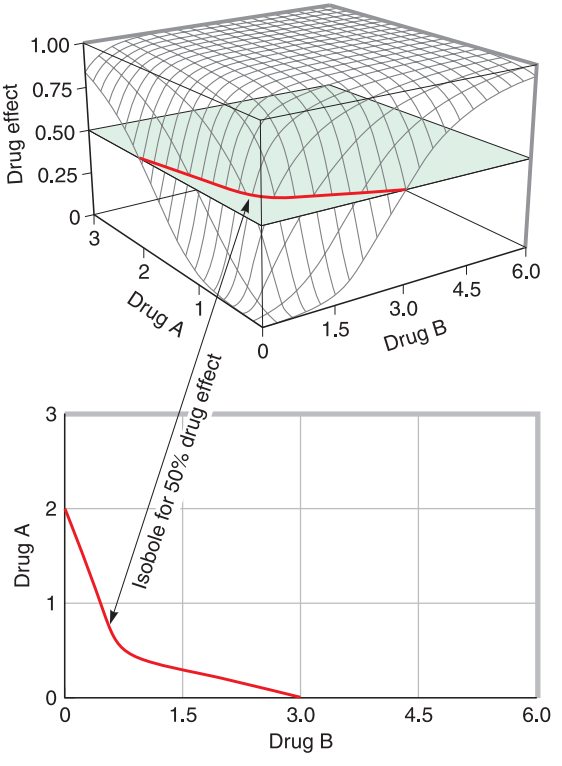

FIGURE 68–10. Relationship between the response surface and an isobologram. The two-dimensional isobologram is generated from a single slice through the three-dimensional surface, generally taken at the 50% response level. Isobolographic analysis fails to capture the full complex surface shape and hence the entire spectrum of interactivity between the two drugs.[80]

response level through the entire complex drug interaction "surface."[80,81]

Because most clinicians will never perform computer simulations to produce response surfaces, what is the importance of such a graphic depiction? Fig. 68–11 illustrates an experiment by Vuyk et al.[82] in which alfentanil and propofol were administered during general anesthesia for lower abdominal surgery. It can be seen from Fig. 68–11 that the shortest recovery time for patients occurred at infusion concentrations of propofol 3.5 μg/mL and alfentanil 85 ng/mL.[83] Interaction models such as these can be used to develop optimal dosing guidelines and can allow the clinician to administer IV anesthetics more rationally.

SEDATION TECHNIQUES AND DRUG DELIVERY SYSTEMS

Bolus Administration

MAC increasingly is involving the use of IV sedatives and evolving techniques for administration. This trend has been driven by the introduction of anesthetic drugs that can be rapidly titrated (e.g., propofol) and by technologically advanced delivery systems that approach the ease and reliability of an agent-specific vaporizer for inhaled anesthetics. The goals of any technique are patient comfort with or without amnesia, improved operative conditions, rapid recovery, and minimal side effects from drug overdose. MAC is provided by an anesthesiologist and the range of sedation and complexity of techniques can be greatly expanded compared to care provided by a nonanesthesiologist during sedation outside the operating room suite. Nonetheless, studies involving minimally invasive procedures such as colonoscopy and dental treatments have examined the role of patient-controlled sedation (PCS) techniques. These techniques are inherently limited by feedback loops that should stop drug administration should patients become oversedated.[84] Despite this safety measure, Campbell et al.[85] found 7 of 20 colonoscopy patients attempting PCS were either undersedated or oversedated. Imperfections in PCS are due to variances in both population pharmacokinetics of drugs and the fact that the technique considers only pharmacokinetics and not pharmacodynamics.

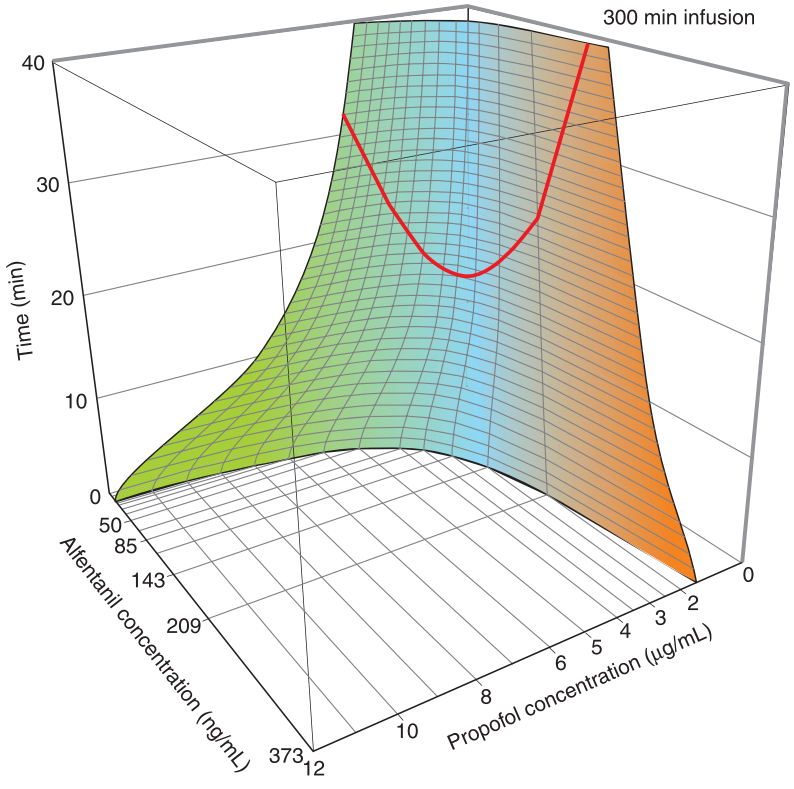

FIGURE 68–11. Computer simulation of the decay in blood propofol and alfentanil concentrations during the first 40 minutes after termination of 300-minute propofol and alfentanil target-controlled infusions of the two drugs to levels associated with a 50% probability of no response to surgical stimuli. Bold line represents the blood propofol and plasma alfentanil concentrations at which 50% of patients regain consciousness postoperatively. The time interval between termination of infusion and regaining of consciousness is shortest after a 300-minute infusion of propofol and alfentanil at concentrations of 3.5 μg/mL and 85 ng/mL, respectively. Reprinted from, Vuyk J. Pharmacokinetic and pharmacodynamic interactions between opioids and propofol. J Clin Anesth 1997;9:23S–26S, with permission from Elsevier.

Continuous Infusions

Classically, IV anesthetics have been administered as a large bolus or by multiple intermittent doses during a procedure. However, clinical studies have demonstrated that IV anesthetics given by variable-rate continuous infusion provide certain advantages over intermittent bolus techniques. They include (1) improved cardiopulmonary stability, (2) more predictable plasma drug concentrations, (3) reduced need for supplemental anesthetics or vasoactive drugs, (4) faster recovery times, and (5) lower total drug doses used.[61,86] The differences in achieving a therapeutic concentration between single or multiple bolus doses and a variable rate continuous infusion are illustrated in Fig. 68–12.

Target-Controlled Infusions

In 1983, Schuttler et al.[87] used a computer-assisted infusion system to administer a constant plasma concentration of alfentanil and etomidate for surgical anesthesia. At the time the concept was novel, because drugs usually were dosed at a constant infusion rate irrespective of expected changes in plasma concentrations over time. Many research groups have since developed their own systems for a variety of anesthetics, and a commercial system for propofol is available outside of the United States (Diprifusor; AstraZeneca, United Kingdom). By delivering a target concentration of drug rather than a target infusion rate, these target-controlled infusion (TCI) systems can effectively and rapidly achieve, maintain, and adapt plasma concentrations of drugs to changing patient and surgical needs.

A TCI device is a computerized infusion pump. As illustrated in Fig. 68–13, the selected drug is administered according to its known therapeutic window, the patient response, and the predicted (via computer modeling) drug concentration. The computer is programmed with a pharmacokinetic model as well as pharmacokinetic data.

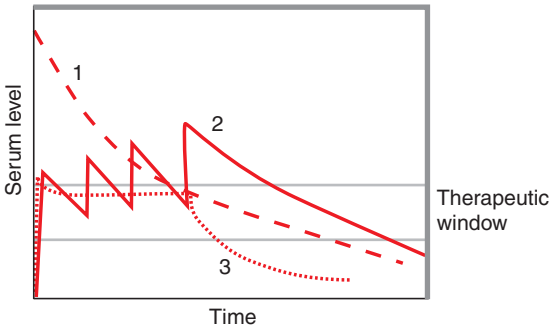

FIGURE 68–12. Resultant serum or blood concentration following intravenous drug administration by a large single bolus (**1**), repeat bolus injections (**2**), or variable-rate continuous infusion (**3**).[61]

The computer automatically controls the infusion pump in order to maintain the target plasma concentration. Target concentrations can be increased or decreased over time based on clinical need.[88]

Pharmacokinetic data used in TCI systems have generally been derived from the literature, and the effectiveness and accuracy of TCI systems are dependent upon such data. Often these pharmacokinetic parameters are derived from small sample sizes of healthy individuals.[89] Larger population studies have been performed. One such study by Schuttler and Ihmsen[56] examined the effects of age and weight on the pharmacokinetics of propofol. They noted that inclusion of age and weight as covariates into the TCI system improved the predictability of the model. As graphically depicted in Fig. 68–14, with propofol used as an example, infusion rates required to maintain steady-state conditions should decrease over time in all population groups.

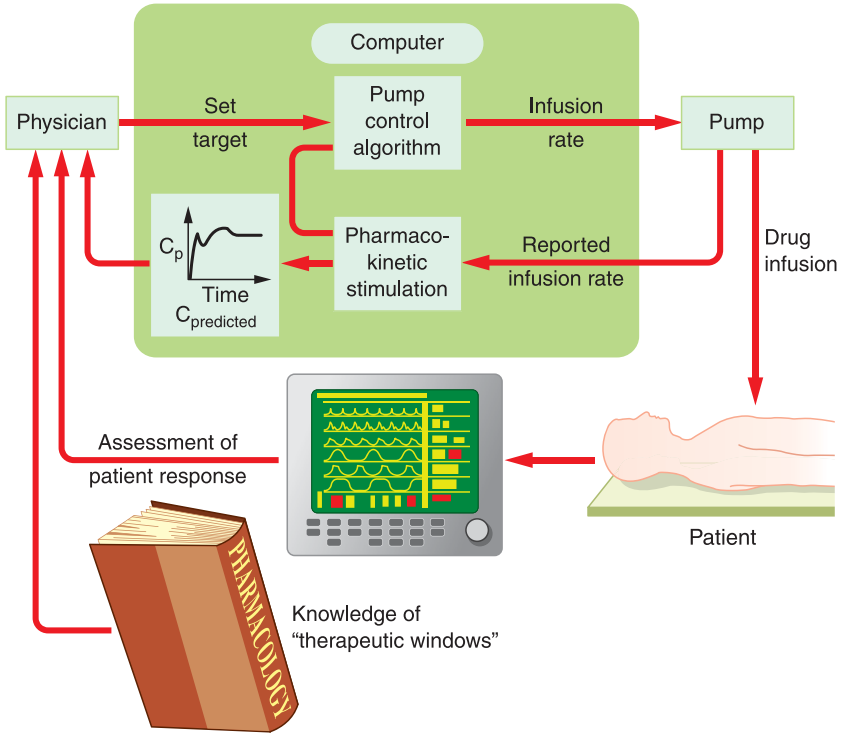

FIGURE 68–13. Schematic representation of a target-controlled infusion system for anesthetic drugs. According to knowledge of therapeutic windows, patient response, and predicted drug concentration, the physician sets the drug concentration target. Using a pharmacokinetic model for the drug, the computer calculates the appropriate infusion rates over time to achieve and maintain the target concentration and directs the infusion pump to administer the appropriate amount of drug. The pump reports to the computer the amount of drug administered so that the computer's pharmacokinetic simulation can be updated.[88]

There is considerable interpatient variability in both pharmacokinetics and pharmacodynamics. The United States Food and Drug Administration (FDA), which classifies TCI systems as a drug and not a device, have not approved the Diprifusor and other TCI systems outside of the research milieu based on concerns regarding safety and the lack of predictability in drug dosing.[90] No evidence in the literature suggests an increased risk of adverse events with TCI systems, and numerous published papers have compared the safety of TCI systems with manual infusions.[88] Because variability in the pharmacodynamic response for all drugs will be greater in routine clinical practice than in healthy volunteers from whom standard parameters (i.e., minimum alveolar concentration for inhaled anesthetics) are derived, it can be argued that TCI devices actually decrease, rather than increase, biologic variability.[91] Compared to standard infusion pumps, TCI systems allow the incorporation of patient covariates (e.g., weight, age, hepatic function, cardiac output) into dosing models that would otherwise be impossible to replicate without TCI systems. Another method by which TCI systems can reduce biologic variability in pharmacokinetics is by programming systems to reflect the multicompartment distribution of drugs. By taking into account uptake and distribution of drug across several compartments and by taking into consideration the time of the infusion, TCI systems can more accurately guide drug administration.

Even if FDA approval of TCI devices were forthcoming, controversies about TCI systems must be addressed prior to widespread adoption of the technology. As mentioned, the TCI system is only as efficacious and accurate as the pharmacokinetic model with which it is programmed. Despite the wealth of literature on the subject, it is evident that models are more accurate for some drugs than for others. Additionally, there is some disagreement over the existence and magnitude of the dysequilibrium between plasma and effect site. Simply stated, the idea that the plasma concentration of drug after a bolus peaks instantaneously and homogenously is an anachronism. Both cardiac output and the peripheral distribution of drugs (multicompartment models) are important determinants of the drug concentration–time rela-

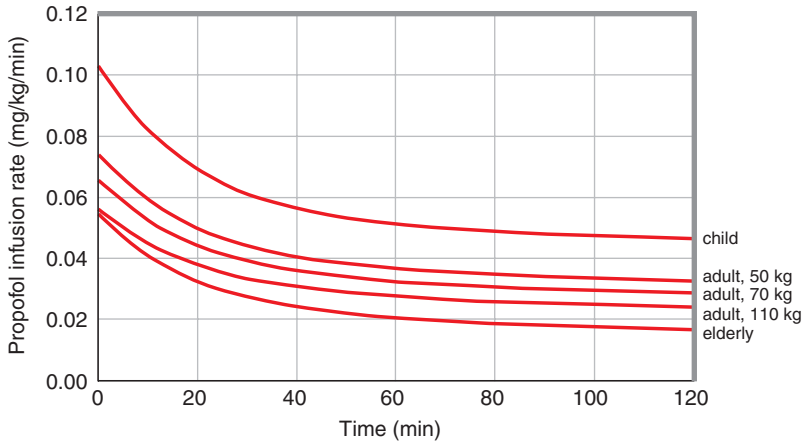

FIGURE 68–14. Propofol infusion rates required to maintain a plasma concentration of 1 µg/mL in a child (body weight 20 kg, age 5 years), a lean adult (50 kg, 30 years), an adult of average weight (70 kg, 30 years), an obese adult (110 kg, 30 years), and an elderly individual (65 kg, 80 years). Infusion rates were calculated from population pharmacokinetic modeling and actual plasma levels from 270 individuals in the study.[56]

tionship, particularly for rapidly acting agents. Avram and Krejcie[92] demonstrated that TCI systems based on such fallacies of early drug distribution kinetics overestimate drug dosages and exceed target concentrations. Newer TCI systems target the effect site or biophase concentration, because this is the site of action and can be clinically measured via patient response or EEG parameters. These models will require rigorous analysis prior to implementation. Fortunately, the effect-site concentration of propofol (the most commonly used anesthetic for TCI) has already been shown to correlate with loss of consciousness or loss of responsiveness[93] and with EEG changes.[39,93,94] A final concern with TCI devices is that the terminology that would define an appropriate IV anesthetic target is either fatuous by nature (e.g., "MAC" for IV agents) or has not been standardized. CP_{50} or the plasma concentration required to produce a 50% probability of some specific event (e.g., loss of consciousness) is frequently used, and values for some anesthetics have been published,[77,96] but frequently the conditions among study protocols (i.e., different OAA/S thresholds to demonstrate loss of consciousness vs patient response) preclude standardization of such values.

DRUGS ADMINISTERED DURING MAC

During MAC, the practitioner frequently administers a variety of anesthetics, including sedative–hypnotics, opioid and nonopioid analgesics, benzodiazepines, barbiturates, and other adjuvants (i.e., α_2-agonists). These drugs often are combined with local anesthetics. As previously mentioned, clinicians must be careful when titrating combinations of drugs. Selecting drugs with regard to concepts as the context-sensitive half-time and effect-site half-times will permit adroit dosing while avoiding hemodynamic and respiratory depression. Generally, agents from numerous classes are combined to achieve maximum patient comfort. It will be useful here to focus on the use of these agents specifically during MAC. Table 68–6 lists common dosing strategies for various agents used during MAC.

Local Anesthetics

Local anesthetics may be administered during MAC by local infiltration, via topical application, via IV regional anesthesia (Bier block), or during peripheral or central neuraxial blockade. Patients usually complain of discomfort during local anesthetic injection, and it can be difficult for patients to lay immobile during prolonged procedures. Additionally, even in the presence of adequate local infiltration, traction on certain structures (i.e., inguinal ligament) can be painful. Finally, many patients express significant anxiety about remaining "awake" during surgery and would otherwise require a general anesthetic. For these reasons, local anesthetics frequently are combined with IV drugs to provide anxiolysis, sedation, and supplemental analgesia.

TABLE 68–6.

Drugs Commonly Used during Monitored Anesthesia Care

Drug Class	Drug	Bolus Dose	Infusion Rate
Sedative anxiolytic	Diazepam	5–10 mg	
	Midazolam	0.5–7.5 mg	1–2 µg/kg/min
	Propofol	10–80 mg	25–100 µg/kg/min
	Methohexital	10–20 mg	20–60 µg/kg/min
	Thiopental	25–150 mg	
Sedative/analgesic	Ketamine	10–50 mg	5–15 µg/kg/min
Analgesic	Fentanyl	25–100 µg	0.01–0.03 µg/kg/min
	Sufentanil	5–30 µg	0.005–0.01 µg/kg/min
	Alfentanil	0.25–0.75 mg	0.25–1 µg/kg/min
	Remifentanil	12.5–25 µg	0.025–0.15 µg/kg/min
Benzodiazepine antagonist	Flumazenil	0.5–1 mg	
Opioid antagonist	Naloxone	20–400 µg	

The choice of local anesthetic depends upon the desired duration of effect. Lidocaine is the most commonly used local anesthetic in the United States.[97] When administered via local infiltration, it will provide anesthesia for 1–2 hours; if administered via peripheral nerve block or with epinephrine, the duration will be slightly longer. Infiltration with bupivacaine will provide sensory anesthesia with a duration of 2–4 hours or greater. Use of bupivacaine for peripheral nerve block will provide anesthesia for up to 10–12 hours, with occasional extended action up to 24 hours. Bupivacaine's utility is limited somewhat by its cardiotoxicity. Almost 20 years ago came the observation that sudden cardiac arrest with bupivacaine (via inadvertent IV injection) was associated with considerable morbidity and mortality. Cardiovascular collapse is caused by the specific accumulation of the drug in the conduction system of the heart, activating reentrant pathways and causing intractable ventricular arrhythmia, including ventricular tachycardia and ventricular fibrillation. These arrhythmias are refractory to conventional treatments. Two newer agents, ropivacaine (a chemical analogue of mepivacaine and bupivacaine) and levobupivacaine (the pure *S*-enantiomer of bupivacaine), have been developed to circumvent the cardiotoxicity of bupivacaine while maintaining the potency and favorable characteristics of bupivacaine. Whether these agents will supplant bupivacaine remains to be seen. Future areas of interest in this field include long-lasting local anesthetics, encapsulated drugs, and continuous-infusion techniques via catheters.[98]

Propofol

Propofol is a rapid, short-acting IV anesthetic that has many of the ideal properties of a sedative–hypnotic for use during MAC. It has a short effect-site equilibration time, and the biophase or effect-site concentration can be ascertained from either clinical signs (i.e., OAA/S) or bispectral analysis.[42,44] Propofol has increasingly become the drug of choice for sedation during MAC, supplanting the previous popular combination of opioids and midazolam.[99] Although midazolam has a short elimination half-life, its context-sensitive half-time is approximately twice as long as that for propofol (Fig. 68–6). Benzodiazepines are frequently associated with prolonged sedation and psychomotor impairment, particularly in the elderly. Opioids alone generally fail to provide adequate sedation, and combining therapy with benzodiazepines can produce profound respiratory depression.

Propofol plasma levels appropriate for sedation (0.5–1.5 μg/mL) or hypnosis (2–6 μg/mL) can be reliably delivered at infusion rates of 25–100 μg/mL/min.[99] Subhypnotic doses of propofol, achieved with median plasma levels of 343 ng/mL, possess antiemetic properties.[100] This level can be rapidly and safely achieved by a 10-mg bolus dose followed by continuous infusion of 10 μg/kg/min.[101] Propofol can be given alone or in combination with a benzodiazepine or opioid, with which it has supra-additive or synergistic effects.[75,102] Additionally, propofol has been shown to alter the pharmacokinetics of alfentanil in healthy volunteers, possibly via changes in cardiovascular function.[103] Smith et al.[104] demonstrated that subhypnotic doses of propofol will not reliably produce amnesia. The same study also noted a poor relationship between plasma propofol levels and the degree of somnolence in individual patients. Premedication with a small dose of midazolam (1–2 mg IV) provides additional sedation, anxiolysis, and amnesia with respect to intraoperative effects.[105] Propofol does not have analgesic properties.[106] The literature on the effect of propofol on pain perception is conflicting; oversedation is a confounding variable in some studies. Frolich et al.[107] assessed the effect of propofol sedation on pain perception and found that propofol caused a dose-dependent increase in pain intensity (Visual Analogue Scale) and unpleasantness (subjective). Patients during MAC often receive supplemental propofol rather than an analgesic for procedure-related discomfort; future research may induce a paradigm shift if the findings of Frolich et al. are confirmed. Propofol-induced injection pain, a separate phenomenon from hyperalgesia, occurs in approximately 70% of patients.[108] Useful interventions include IV lidocaine (as little as 40 mg, preferably as a Bier block with a rubber tourniquet for 30–120 seconds prior to propofol injection), IV opioids (particularly meperidine), and metoclopramide. A systemic review on the subject deemed speed of the injection, size of the IV catheter or the vein, and temperature of the propofol as insignificant.[108]

Although propofol is well suited for long procedures, propofol has favorable qualities that make it a preferred hypnotic for endoscopy,[109] retrobulbar block,[110] and emergency department procedural sedation.[111] It should be noted that the ASA Practice Guidelines for Sedation and Analgesia by Non-Anesthesiologists distinguishes sedation with opioid/benzodiazepine combinations ("moderate sedation") from sedation with propofol ("deep sedation"). The ASA guidelines recommend that, during deep sedation, "a designated individual, other than the practitioner performing the procedure, should be present to monitor the patient…" and that "practitioners administering these drugs should be qualified to rescue patients from any level of sedation, including general anesthesia."[2] Although these recommendations fall short of precluding the use of propofol during procedures in which the patient is not monitored by a separate clinician, they have instigated significant debate and disagreement in the nonanesthesiology literature.[111,112] The potential cost ramifications are significant, because 15 million endoscopic procedures are performed yearly in the United States alone.[109] In our opinion, the ASA practice guidelines are appropriate, and we believe that nonanesthesia personnel should not administer deep sedation.

The growing interest from nonanesthesia providers in using propofol rather than the previously popular benzodiazepine–opioid combinations for sedation is potentially concerning. Any false confidence based upon propofol's short duration of action is mitigated by the potential side effects of the drug. When used in sedative doses, the most common side effect is pain on injection, followed by excitatory phenomena or involuntary movements. Other psychological phenomena, such as euphoria, amorous and disinhibited behavior,[113] and sexual hallucinations,[114] have been described under MAC with propofol. Propofol in subhypnotic doses has been shown to increase pharyngeal motor dysfunction[115] and increase collapsibility of the upper airway.[116] Upper airway collapse is dose dependent and seems to have both central and peripheral components. More serious side effects include alterations in cardiopulmonary and respiratory physiology. Propofol in-

fusions targeted to moderate sedation have been shown to lower sympathetic nerve activity[117] and baroreflex responses to hypotension.[118] Propofol infusion for moderate sedation has been shown to depress the hypoxic ventilatory response.[119] A published gastroenterologist's protocol for "safe and effective administration of propofol during endoscopic examinations" found the incidence of hypotension (>20 mm Hg decline in blood pressure) and hypoxia (oxygen saturation <90%) to be 27% and 9% of 819 patients, respectively.[109] Although all episodes were transient, all subjects were ASA I or II; these findings amplify concerns about propofol use by nonanesthesia personnel, particularly in the seriously ill or elderly.

Ketamine

Ketamine was first used in humans in 1965. It was hoped that it could function as a monoanesthetic drug (i.e., analgesia, amnesia, loss of consciousness, immobility), but because of its psychotropic side effects and the advent of additional IV anesthetics, it fell into disfavor and its role rapidly diminished by the mid 1980s.[120] A 2000 survey of graduating anesthesiology residents found that only 30% of 119 residents had used ketamine for MAC cases >10 times during their training.[121] It has a relatively short distribution and elimination half-life; the α-elimination phase lasts only a few minutes. Ketamine administration leads to a state of dissociation, amnesia, and analgesia, with or without loss of consciousness.

Ketamine can be a useful analgesia adjuvant during MAC. Unlike other IV anesthetics, ketamine has potent analgesic effects at subanesthetic plasma concentrations.[122] Ketamine-induced analgesia can outlast the drug's anesthetic effects, and these effects have been attributed to antagonism at the *N*-methyl-D-aspartate (NMDA) receptor. Animal and human studies have shown that hyperalgesia after tissue injury and opioid tolerance both involve activation of the NMDA receptor.[123] Studies with ketamine have focused on determining whether administration of the drug prior to a noxious stimulus (preemptive analgesia) can reduce subsequent pain. Suzuki et al.[122] demonstrated that a single intraoperative dose of ketamine 50–100 μg/kg given 15 minutes before the end of surgery reduced postoperative morphine requirements by 40%. A systemic review of ketamine and postoperative pain demonstrated a 9–47% reduction in postoperative morphine consumption[124] with intraoperative administration of ketamine (median dose 0.4 mg/kg). The clinical significance of preemptive analgesia with ketamine is controversial.

Other studies have described the use of ketamine in combination with other anesthetics for MAC. The interaction of ketamine and propofol at sedative doses appears to be additive.[125,126] Administration of ketamine 4–18 μg/kg/min in combination with propofol 30–90 μg/kg/min attenuated the respiratory depression produced by propofol/opioid anesthesia, while producing positive mood effects.[127,128] Ketamine maintains protective airway reflexes better in sedative doses than do other IV anesthetics and, through its central sympathetic stimulative effects, diminishes propofol-induced hypotension and decreases inotropic effects.[125]

Ketamine as a sole agent is associated with a dose-dependent incidence of psychic disturbances ranging from 5–30%.[129] Symptoms can vary from alterations in mood state and body image to vivid dreams and hallucinations. Extracorporeal experiences also have been reported. Benzodiazepines and propofol seem to be effective in attenuating the psychomimetic actions of ketamine, as long as they are administered before the drug. Titrating propofol to loss of verbal response and lid reflex prior to ketamine administration has been recommended to significantly attenuate the psychotropic side effects of ketamine.[130] Ketamine can increase oral secretions; we recommend use of glycopyrrolate 0.2 mg IV prior to administration.

Despite the well-founded fear of ketamine's unique side effect profile, ketamine used at doses appropriate for MAC cases and as an adjuvant anesthetic is a safe and efficacious addition to the armamentarium of the anesthesiologist. It should never be used as a sole agent during MAC. Continuing research on preemptive analgesia and NMDA antagonists may increase the utility of ketamine and lead to its widespread use again.

Benzodiazepines

Benzodiazepines remain widely used during MAC. They provide both anxiolysis and dose-dependent anterograde amnesia, but they have no analgesic activity. Diazepam is the prototypic benzodiazepine, but it has a very long elimination half-life (20–50 hours). The active metabolite desmethyldiazepam contributes to the prolonged activity of diazepam, making it unsuitable in the outpatient setting. Its duration of clinical effect ranges from 1–6 hours. Midazolam has replaced diazepam as the most commonly used benzodiazepine during MAC anesthetics and is the most frequent premedication used in the United States.[131] Rapid onset (within 1–2 minutes of IV administration), time to peak effect (3–5 minutes), and short duration of activity (15–80 minutes) make it an attractive adjunct or sole agent during MAC. Midazolam produces more profound amnesia than diazepam. Premedication with midazolam in subhypnotic doses has been shown to decrease the incidence of postoperative nausea and vomiting,[132,133] although the mechanism is poorly understood.

Despite the beneficial effects of benzodiazepines, it appears that they may be best used as an adjunctive sedative for anxiolysis and amnesia in conjunction with a propofol infusion. Benzodiazepines reduce anesthetic requirements (hypnotic effects) for propofol[75,134] and opioids[75,102] in a synergistic fashion. Comparisons between propofol and midazolam infusions as sole agents for MAC have demonstrated superior amnestic properties with midazolam but a more rapid recovery profile with propofol.[135,136] Premedication with midazolam 1–3 mg prior to propofol sedation during MAC has been associated with increased amnesia[137] and patient satisfaction,[132,138] without altering perioperative vital signs or prolonging discharge time from the postanesthesia care unit.[105,132,138]

Benzodiazepines in doses appropriate for MAC are relatively well tolerated; hemodynamic changes are uncommon in healthy patients. Caution should be used in patients with hypoalbuminemia (from hepatic cirrhosis or renal dysfunction), because the unbound fraction of midazolam will increase. The principal active metabolite of midazolam, α-hydroxymidazolam, is cleared by the kidneys and can prolong the drug's action in patients with renal dysfunction.[139,140] The slight hysteresis in the dose–response relationship may lead to oversedation if repeated boluses are administered over a short time interval. Midazolam has a steep dose–response curve and thus must be care-

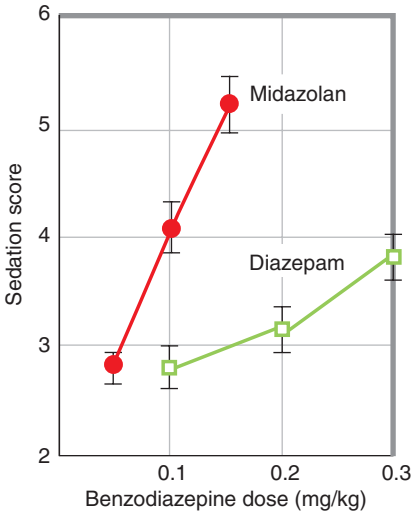

FIGURE 68–15. Relationship between the sedation score (2 = awake/relaxed to 6 = asleep/unarousable) and the initial dose of midazolam or diazepam (in milligrams per kilogram). Values are given as mean ± SEM. The narrower therapeutic dosage range for midazolam should be appreciated and warrants careful titration to avoid excessive sedation or apnea.[141]

fully titrated using small IV boluses or (less commonly) continuous infusion (Fig. 68–15).[141] Aging has been shown to increase the pharmacodynamic sensitivity to midazolam, independent of pharmacokinetic factors.[142] Despite the synergy between opioids and benzodiazepines with respect to hypnosis, sedation, and respiratory depression, the analgesic action of opioids may be *reduced* in the presence of benzodiazepines.[105,143] Interestingly, flumazenil, a benzodiazepine antagonist, has been shown to enhance the postoperative analgesic effects of morphine.[143]

Opioids

Opioid analgesics are frequently administered during MAC for a variety of reasons. They are useful adjuvants during local or regional anesthesia to decrease the pain that frequently accompanies the injection of local anesthetics or central neuraxial blockade. In addition to the obvious indication for treatment of surgical pain, opioids can alleviate discomfort from nonincisional sources, such as uncomfortable positioning or pneumatic tourniquet pain. When administered alone, opioids do not reliably produce sedation in the absence of ventilatory depression.[144] Opioids have little, if any, amnestic activity. Veselis et al.[145] demonstrated that hypnotics such as midazolam and propofol affect memory differently via their sedative effects, and that fentanyl is virtually devoid of amnestic effects at equisedative concentrations of other sedative–hypnotics.[146] Additional reasons for avoiding the use of opioids as sole agents during MAC are dose-dependent increased respiratory depression and postoperative nausea and vomiting.

Opioids are best suited for the analgesic component of a well-balanced MAC anesthetic. The choice of opioid depends upon the desired pharmacokinetic profile; lipophilic opioids such as fentanyl and its analogues (alfentanil and sufentanil) demonstrate rapid blood–brain equilibration and onset of action. Conversely, water-soluble drugs such as morphine have a slower onset of action. For the majority of short procedures, the duration of action for opioids is dependent upon redistribution. Therefore, highly lipid soluble drugs (e.g., fentanyl) will have a shorter duration of action.

Fentanyl

Fentanyl is the opioid most commonly used during MAC. It is administered in 25- to 50-μg increments every 2–3 minutes to a loading dose of 0.5–3 μg/kg. The onset of fentanyl's effects is within 3–5 minutes, but peak effect lags behind peak plasma concentrations. This delay must be appreciated by the clinician in order to avoid excessive respiratory depression during MAC. When fentanyl is administered during MAC, the duration of analgesia of a typical dose of fentanyl is 30–60 minutes. When multiple doses or long infusions of fentanyl are administered, progressive saturation of peripheral tissues can occur, and the duration of action (and side effects) may be prolonged (see Context-Sensitive Half-Time above). The respiratory depressant effects of fentanyl may last longer than the analgesic effects, and even small doses of fentanyl (50 μg) can cause respiratory depression when combined with other sedatives.[76]

Sufentanil

Sufentanil is the most potent synthetic opioid. It is approximately 5–15 times more potent than fentanyl and has a similar onset of effect. Both sufentanil and fentanyl are formulated with the same concentration (50 μg/mL), and an overdose resulting in severe respiratory depression could occur if sufentanil were mistaken for fentanyl. Sufentanil can be given as a bolus (0.1–0.5 μg/kg) or infusion (0.005–0.01 μg /kg/min) during MAC. Bailey et al.[147] compared the effects of sufentanil and fentanyl on volunteers and showed that sufentanil produced longer lasting analgesia but less depression of ventilation than did fentanyl. Despite these findings, few other studies have focused on sufentanil in the setting of MAC, particularly since the advent of alfentanil and remifentanil. One possible reason is unpredictable cardiovascular depression associated with sufentanil use, including bradycardia and hypotension; however, these effects do not appear to be dose dependent.[148]

Alfentanil

Alfentanil, another synthetic analogue of fentanyl, is one fifth to one tenth as potent as the parent compound. Effect-site equilibration with alfentanil is extremely rapid compared with fentanyl (1.4 minutes vs 6.8 minutes for fentanyl). This rapid peak effect of alfentanil is useful during anesthetics in which the response to a brief intense stimulus must be blunted (e.g., retrobulbar block). The rapid onset is due to the drug's low degree of ionization at physiologic pH. Alfentanil is less lipid soluble than fentanyl and sufentanil, a quality that results clinically in a smaller volume of distribution and a *longer* context-sensitive half-time than that of sufentanil for infusions up to 8 hours.[60] Alfentanil can be given via bolus or continuous infusion during MAC. White et al.[149] found that using continuous infusion (vs bolus dosing) of alfentanil reduced perioperative dose requirements by 41% and improved recovery times and postoperative psychomotor function. In the same study, an equianalgesic dose of alfentanil was associated with less respiratory depression than fentanyl. Alfentanil used as a sole agent is associated with an unacceptable incidence of postoperative nausea and vomiting. Pavlin et al.[150] found that alfentanil infusions in healthy volunteers elicited nausea and vomiting rates of 50% and 30%, respectively; administration of a concomitant propofol infusion decreased the rates to 10% (nausea) and 0% (vomiting). Avramov and White[151] found that addition of propofol infusion 50 μg/kg/min to alfentanil 0.3–0.4 μg/kg/min reduced postoperative nausea and vomiting from 33% to 0%.

Both of the aforementioned studies also described an opioid-sparing effect from concomitant administration of propofol, with requirements decreasing 22–50%.

Remifentanil

Remifentanil is an ultrashort-acting opioid that is metabolized by nonspecific tissue esterases. Its clearance is unaffected by cholinesterase deficiency, cholinesterase inhibitors, or hepatorenal dysfunction.[152] Remifentanil has analgesic potency similar to fentanyl but has an effect-site equilibration time (1.0–1.5 minutes) similar to that of alfentanil.[153] Remifentanil has an extremely short (3–4 minutes) context-sensitive half-time that is independent of the dose or duration of infusion (Fig. 68–16).[154,155] More importantly, compared with alfentanil, even the 80% decrement time of remifentanil is unchanged with long infusions.[155] The clinical significance of this observation is that 60–80% decrement times (rather than 50%) may be required to discharge patients following a procedure.

Remifentanil is generally given by continuous infusion during MAC. Bolus or loading doses are not necessary for most cases because a continuous infusion will approach steady-state concentrations within 10 minutes. Current product labeling recommends bolus administration of remifentanil only in patients undergoing general anesthesia. Studies comparing bolus doses of remifentanil to continuous infusions in volunteers[156] and patients undergoing extracorporeal shock wave lithotripsy (ESWL)[157] found that manual bolus doses were as effective and safe as administration via continuous infusion. However, several subjects in these studies experienced respiratory depression at low doses. In addition to respiratory depression and apnea, which occur more frequently than with propofol,[158] other concerns with bolus dosing of remifentanil are chest wall rigidity, hypotension, and bradycardia. These side effects are not seen when remifentanil is administered via continuous infusion in analgesic doses (0.025–0.15 μg/kg/min) during MAC.[156,159] If bolus dosing of remifentanil is deemed necessary, it should be low dose (12.5–50 μg) and slowly administered over 30–60 seconds.

Use of remifentanil as a sole agent during MAC does not produce adequate sedation without an unacceptably high incidence of chest wall rigidity and respiratory depression. When combined with midazolam, adequate sedation and analgesia can be obtained without hemodynamic perturbations, excessive respiratory depression, or prolonged discharge times.[160] Avrimov et al.[160] observed that preoperative administration of midazolam 2–8 mg IV prior to infusion of remifentanil during breast biopsy reduced the dose requirements of remifentanil by up to 50%. A similar study with remifentanil and propofol during ESWL revealed a 37% reduced remifentanil dose with the addition of propofol.[161]

Postoperative nausea and vomiting is a common complication with remifentanil, particularly when it is used as a sole agent. When compared with propofol as adjunctive sedation for regional anesthesia, the nausea and vomiting rates were much higher with remifentanil (60% and 21%, respectively) than with propofol (17%, 6%).[162] When used as an analgesic adjunct during MAC, nausea and vomiting rates are higher with remifentanil alone (42% and 17%, respectively) than with remifentanil/midazolam (21% and 6%) or propofol (27% and 15%).[159] Addition of preoperative midazolam[163] or intraoperative propofol[161,164] to a remifentanil infusion attenuates the risk of nausea and vomiting. Holas et ao.[164] and Joo et al.[161] noted a 0% incidence of postoperative vomiting in patients who received propofol and remifentanil simultaneously and underwent eye surgery and ESWL, respectively.

Remifentanil is supplied as a lyophilized powder and must be reconstituted and diluted before using. Errors in dilution of the drug can easily result in overdosage or underdosage, particularly in awake patients with an unprotected airway. When administered as a continuous infusion during MAC, remifentanil should be titrated to provide analgesia rather than sedation. If bolus dosing is anticipated, it should replace, rather than supplement, a continuous infusion. Remifentanil is a useful adjunct during MAC that is best combined with a hypnotic to minimize respiratory depression and postoperative nausea and vomiting. Because of the risk of apnea and hypoventilation, it is recommended that only clinicians specifically trained in the use of anesthetic drugs and airway management use remifentanil.

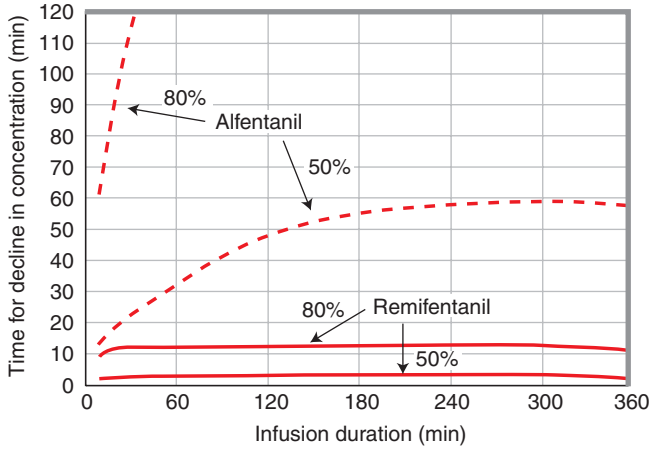

FIGURE 68–16. Time for an 80% decrease in plasma concentration and the context-sensitive half-time of remifentanil and alfentanil for an infusion maintained at a constant plasma concentration for 1–360 minutes.[155]

α_2-Agonists

α_2-Agonists produce sedative, analgesic, and anxiolytic effects by reducing central sympathetic outflow.[165] At low or sedative dosages, they produce sympatholysis (i.e., bradycardia and hypotension). They do not cause respiratory depression at sedative dosages and can attenuate ketamine-induced cardiostimulatory and psychotropic effects.[166] Clonidine, the prototypical α_2-agonist and antihypertensive agent, has been shown to reduce anesthetic and analgesic properties during the perioperative period. Use of clonidine as an anesthetic adjuvant during MAC is limited by its long elimination half-life of 8–12 hours. Dexmedetomidine, a relatively new α_2-agonist, is 8- to 10-fold more potent than clonidine for the α_2 receptor[167] and has an elimination half-life of only 2 hours. The only approved

sedative indication for dexmedetomidine is ICU treatment of postoperative surgical patients for up to 24 hours.[168] Despite the potentially desirable side-effect profile, dexmedetomidine compared with commonly used sedatives is associated with prolonged recovery time[169,170] and significant bradycardia and hypotension.[169,171] A study by Jaakola[171] assessed the efficacy of IV dexmedetomidine 1 μg/kg as a premedication before IV regional anesthesia. Although dexmedetomidine produced opioid-sparing and anxiolytic effects, 20% of patients required atropine for bradycardia (heart rate < 45 beats/min). Jalowiecki et al.[169] evaluated dexmedetomidine for sedation during colonoscopy. The study was interrupted for safety concerns; 3 of 19 patients experienced bradycardia and hypotension of sufficient severity such that they were admitted to the hospital for observation. It is evident that although some properties of α_2-agonists are attractive during MAC, these agents are potentially dangerous and possess unacceptable risk-to-benefit profiles. Other agents discussed in this chapter can be used alone or in tandem to adequately sedate patients during MAC. Clinicians should be mindful that α_2-agonists remain off-label for conscious sedation and MAC.

RECOVERY AND DISCHARGE CRITERIA AFTER MAC

Anesthetics used during MAC should permit rapid recovery with minimal or no residual cognitive or psychomotor impairment. In turn, each patient care facility should develop recovery and discharge criteria that are suitable for its specific patients and procedures. ASA Practice Guidelines for Postanesthetic Care, revised in 2001, consider the recovery and discharge criteria for MAC to be no different from those for general or regional anesthesia.[172] Other requirements are that medial supervision of recovery and discharge is the responsibility of the supervising practitioner, and that an individual trained to monitor patients and recognize complications should be in attendance until all discharge criteria are fulfilled. One of these persons must be qualified to handle complications and trained in airway management. All outpatients should be discharged to a responsible adult who will accompany them home and be able to report complications. Written discharge instructions, including an emergency phone number, should be given to all patients.

Physicians should be able to assess home readiness in a simple, clear, reproducible manner. Medicolegal considerations mandate that physicians have evidence that the patient's discharge criteria were met, and that all discharge instructions have been signed by the patient and documented in the medical record. Patients should be duly informed that home readiness does not confer the ability to drive a car or return to work. Qualitative discharge criteria have guided the assessment of home readiness. The most commonly used method, developed in 1970 by Aldrete and Kroulik[173] (Box 68–3) and still known as the Aldrete Score, assesses activity, respirations, circulation, consciousness, and skin color (since replaced by pulse oximetry in 1995).[174] In 1995, the Modified Aldrete Score added assessment of dressing appearance/surgical bleeding, severity of pain, ability to ambulate, tolerance of oral fluids, and ability to void.[174] Chung et al.[175] developed the Post-Anesthetic Discharge Scoring System in 1995 specifically to assess home readiness after ambulatory surgery (Box 68–4). These scoring systems are beneficial because they encourage continual reevaluation of patients, but they should be tailored to individual patients. For example, a patient undergoing foot or ankle surgery should not be expected to ambulate prior to discharge. After central neuraxial blockade, normal sensory and motor function should be confirmed. Requiring patients to void is prudent because of the risk of urinary retention (which may be asymptomatic) and subsequent bladder damage. After major peripheral nerve block, patients may benefit from long-acting local anesthetics; therefore,

it would be purposeless to await return of sensory and motor function prior to discharge. Patients should be warned of the loss of protective reflexes and sensation in the affected limb.

The ability to void and the ability to tolerate oral fluids prior to discharge are two controversial clinical criteria. ASA Practice Guidelines for Postanesthetic Care state that requirements for voiding and drinking are necessary only for selected patients.[172] The decision to discharge a patient who does not satisfy these criteria should be individualized and based upon factors such as age, medical condition, availability of adult assistance at home, and potential severity of consequences of decreased oral intake or urinary retention. Patients not required to void should be informed of potential signs and symptoms of urinary retention and should be given detailed instructions regarding emergency care if needed.

CHAPTER 69

Anesthesia Care for Diagnostic or Therapeutic Procedures Outside of the Operating Room

Monica Davis, MD

For many years, the realm of choice for most anesthesiologists has been the operating room. We have spent the past few decades painstakingly equipping this environment with the appropriate monitors and machines that will help to ensure the safety of our patients. Many of us have trained almost exclusively in this domain and have gained confidence in the increasing quality of service and skill sets that we provide to our patients. However, because of recent advances in other medical practices, we have seen an exponential growth in the need for anesthesia services outside of the operating room. Each area presents its own unique challenges for the anesthesia care team, from the patient population seen (extremes of age, critically ill) to the very nature of the location itself (presence of bulky equipment, small area, radiation exposure, etc.). The trend to perform interventional procedures outside of the operating room will continue, and the demand for safe and effective anesthesia will undergo tremendous growth. For this reason, the anesthesia care team must become involved not only in the care of the patient but also in the details of the area into which they are called to administer their services. This includes ensuring that the same standards and codes held in the operating room are present in these remote locations prior to administration of an anesthetic.[1] This chapter reviews procedures that often require the expertise of trained anesthesia personnel and the specific challenges faced by the anesthesia care team in these remote areas. The role of the anesthesia provider in designing and developing these nonoperating room locales in accordance with the basic safety standards as set forth by the American Society of Anesthesiologists (ASA) is discussed.

PREANESTHETIC CONSIDERATIONS

Preanesthetic Assessment

Patients who are scheduled to undergo an interventional procedure often are outpatients or same-day admissions. In these circumstances, the anesthesia provider usually sees the patient for the first time on the day of the procedure. It is important that a current history and results of the physical examination be available to the anesthesia provider so that he or she can accurately assess the anesthetic risk of the patient. In many instances, patients undergoing interventional procedures are deemed to be at "high risk" for surgery because of multiple comorbid conditions or a specific life-threatening condition (e.g., primary pulmonary hypertension, recent myocardial infarction). Interviewing this type of patient 10 minutes before an elective procedure without having sufficient information on the nature of the patient's physical status is not ideal. Because many of these procedures either require or have a high probability of requiring general anesthesia in order to be successful, these patients should receive the same level of attention given to patients being prepared for a surgical procedure. In addition, nothing by mouth (NPO) guidelines should be addressed, with patients receiving an anesthetic in the remote setting. To accomplish these goals, many patients require a scheduled visit to a dedicated preoperative clinic prior to any elective procedure.

Airway

First and foremost, a thorough airway examination should be performed during this encounter. Any gross abnormalities as well as any other possible concerns should be documented because they may greatly affect the type of anesthetic given to the patient. Many procedures involve a degree of patient isolation, and the anesthesia provider may not have instant access to the patient's head; this should be taken into consideration when evaluating the airway. For example, if a patient has obvious anatomic irregularities or a known history of a difficult airway, rescue airway equipment [e.g., fiberoptic scope, oral airway device, laryngeal mask airway (LMA)] must be readily available if needed to secure the airway, even if monitored anesthesia care (MAC) or sedation is planned. Other concerns with the airway should be considered for patients with obstructive sleep apnea (OSA), morbid obesity, cervical spine issues, or a history of radiation to the head or neck region. Of particular importance are patients diagnosed with OSA, who present many additional challenges to the anesthesia care team. The ASA has published guidelines on the perioperative management of individuals with OSA. The purpose of these guidelines is to aid in the perioperative care of individuals diagnosed with various degrees of OSA (mild, moderate, and severe) because it affects the anesthesia for the procedure itself as well as the management of the postprocedural course. One of the most important recommendations is the use of general anesthesia with a secured airway, as opposed to deep or moderate sedation for superficial procedures, because these patients often have difficulty maintaining a

KEY POINTS

1. Many patients who present for nonoperating room procedures are considered "high risk" for surgical procedures.
2. The same monitoring and equipment standards used in the operating room apply to remote locations.
3. Preanesthetic assessment should be just as thorough for procedural patients as for surgical patients.
4. Issues such as patient recovery and admission status should be discussed prior to the procedure.
5. Length and type of procedure, patient compliance, and remoteness of location should be considered when choosing the anesthetic technique.
6. Involvement of the anesthesia care team in institutional sedation policy is essential.

patent airway.[2] This possibility must be discussed with the patient and the primary physician, because a general anesthetic in these patients may lead to a longer recovery time or possible postprocedural admission.

Comorbid Conditions

Many patients undergoing interventional procedures are deemed "unsuitable" for more invasive surgery because of the severity of preexisting comorbid illnesses. Many have poorly controlled hypertension or diabetes, uncompensated heart failure, severe chronic obstructive pulmonary disease, or end-stage renal/hepatic failure. These issues should not be taken lightly when preparing for nonoperating room procedures. Appropriate optimization or quantification of these conditions should be attempted prior to the intervention. Electrocardiograms, chest x-ray films, cardiac examinations, or laboratory tests can be performed as indicated by the severity of symptoms, especially if significant blood loss or hemodynamic changes are expected [electroconvulsive therapy (ECT), pulmonary stents/ablations, vessel rupture, etc.] The results of any examinations should be documented and members of the anesthesia and procedural teams made aware of any acute processes. Once the anesthetic risk has been estimated and the physical status of the patient determined, an anesthetic plan can be developed that will help optimize patient safety throughout the procedure.

Requirements for Anesthesia in Remote Locations

Space Allocation and Equipment Needs

Equipment and space considerations often impact anesthetics in an off-site location. These sites can range anywhere from a state-of-the-art interventional radiology suite to a private hospital room. More often than not, these areas initially were developed by the primary service or hospital administration and likely did not consider the needs of the anesthesia team. The presence of large, bulky equipment may greatly limit the space available for carts, monitors, or the providers themselves. The area may lack sufficient lighting or electrical outlets for additional equipment needed. Importantly, the anesthesia providers may find themselves distanced and isolated from other anesthesia personnel. Prior to administering any type of anesthetic, an experienced anesthesia provider should survey the proposed area and determine if anesthesia services can be safely provided. The ASA has published guidelines to assist the anesthesiologist in these matters. The guidelines include the following[3]:

- Availability of a reliable oxygen source and delivery method (nasal cannulas, face masks), along with backup supply of oxygen in the form of a full E cylinder
- Availability of adequate suction
- Ability to scavenge waste gases when inhaled anesthetic agents are required
- Presence of a self-inflating resuscitator bag that can administer at least 90% oxygen and deliver positive-pressure ventilation in the event of respiratory distress
- Adequate anesthetic drugs, monitoring equipment, and supplies for the duration of the case
- Adequate lighting and electrical outlets for proper visualization and operation of anesthesia equipment
- Availability of a sufficient amount of space for the anesthesia provider and any other necessary personnel, as well as unobstructed access to the patient, anesthesia equipment, and emergency supplies
- Emergency cart with a defibrillator and emergency drugs for cardiopulmonary resuscitation
- Observance of all applicable building codes and facility standards
- Availability of adequately trained staff for immediate assistance of the anesthesia provider, as well as reliable two-way communication with which to request additional assistance
- Provision of adequate postanesthesia care, which should include appropriately trained staff and equipment that ensures safe transport of the patient to the designated recovery area

Once these conditions have been met, the anesthesia caregiver can focus on the actual care of the patient undergoing the proposed procedure.

Monitoring Requirements

Any patient receiving an anesthetic, whether in an operating room or a procedural suite, must have basic anesthetic monitoring as described by the ASA. The standards include the presence of qualified anesthesia staff during the conduct of a general/regional anesthetic or MAC and constant evaluation of the patient's oxygenation, circulation, ventilation, and temperature.[4] This is accomplished using standard equipment (pulse oximetry, expired carbon dioxide, electrocardiogram, blood pressure monitors) and by direct observation of the patient by the anesthesia provider. A study by Soto et al.[5] found that a significant percentage of patients undergoing MAC experienced approximately 20 seconds of apnea that was not detected by the anesthesia provider but was detected by capnography and impedance (respiratory rate) monitoring. Although the widespread use of capnography and pulse oximetry has reduced the morbidity associated with anesthesia administered in nonoperating room settings, these monitors should be used as adjuncts to clinical observation. The patient's color and chest excursion should be noted. If the patient is able to respond appropriately, then verbal communication with the patient can be used to continually assess patient status. More invasive monitoring may be necessary, depending on the physical status of the patient and the nature of the procedure. This should be anticipated beforehand because many nonoperating room areas do not provide storage for such equipment. Extenuating circumstances may require modification of these standards, with appropriate adjustments made. In situations where the anesthesia provider may not be able to remain in the procedural area [e.g., during magnetic resonance imaging (MRI), radiation therapy], the patient must be constantly visualized through a window or by video cameras. All machines and monitoring equipment must be tested on a regular basis to protect against untimely malfunction in these remote areas. Personnel assigned to these locations should familiarize themselves with the area and note the most expeditious routes to the operating room or postanesthesia care unit (PACU) should an emergency arise.

Careful attention must be given to the patient's body temperature because hypothermia occurs frequently during many of the lengthy procedures. This is of special concern in the

elderly and pediatric populations and in locations where large equipment must be kept cool. In these situations, monitoring of the patient's temperature, regardless of the type of anesthetic used, should be routine.[6] Forced air warming, if available, is ideal; however, any means of maintaining normothermia (warm blankets, increasing the room temperature, or other skin surface warming techniques) should be instituted during the procedure and in the immediate postprocedural period.

Postanesthesia Concerns

The postprocedural course in some patients can be just as challenging as for operating room surgical patients. For this reason, all postanesthesia recovery areas should exhibit the same standards of care as areas devoted to the care of postsurgical patients. These standards are promulgated by the ASA and are directed to all aspects of postanesthesia care. The guidelines state that the patient who receives an anesthetic must be admitted to a postanesthesia recovery unit for appropriate management, the patient must be continually evaluated and supported during transport, and an appropriate report must be given to the PACU nurse.[7] Under certain circumstances, an individual will meet the discharge criteria soon after completion of the procedure and can be discharged to the care of a responsible individual. In these situations, the anesthesiologist can use his or her best clinical judgment to determine whether or not the patient requires additional monitoring in a postprocedural recovery area. The key is that discharge criteria should remain the same for all postanesthetic patients, regardless of the location of the procedure.

Pharmacologic Agents

The anesthesia provider's choices of pharmacologic agents for nonoperating room procedures are as varied as those for use in the operating room itself. The types of procedures range from imaging studies under MAC to complicated interventional processes that may require general anesthesia with intubation. The majority of nonoperating room anesthetics involve the use of intravenous agents to achieve the level of amnesia and analgesia required to successfully perform these procedures. Among the most commonly used drugs are those in the sedative–hypnotic category. Benzodiazepines are the most widely used by nonanesthesia personnel for minimally invasive procedures. Their properties of anxiolysis and amnesia, as well as the existence of the reversal agent flumazenil, make these drugs (often used in conjunction with a narcotic) an ideal combination for conscious sedation in these circumstances. However, the agent that virtually dominates the landscape of procedural anesthesia is propofol. In the hands of trained individuals, propofol can be easily titrated to produce mild sedation or to induce general anesthesia, in both instances demonstrating rapid recovery and return to baseline mentation.

The quality of amnesia produced by propofol during its administration is a desirable effect in these procedures. A study by Veselis et al.[8] at Memorial Sloan-Kettering investigated the effect of propofol, thiopental, and dexmedetomidine on memory using continuous tasks involving auditory word recognition before and during the administration of the agent. Retention of material into long-term memory, as associated with minimal sedation (which was purported to define drug-induced amnesia), was found to be impaired during propofol administration.

Because of the low analgesic properties associated with propofol, narcotics often are added to the regimen in order to produce a balanced anesthetic technique. For most of these procedures, short-acting opioids are preferred, most notably remifentanil. Despite its brief half-life, remifentanil still produces the same side-effect profile as the other opioid agents, although the effects are short lived. This can be a concern when remifentanil is used with another hypnotic, such as propofol, because their cardiovascular and respiratory depressant effects may be additive. Moerman et al.[9] performed a prospective randomized study to determine if supplementation of a propofol anesthetic with remifentanil had any advantage over the use of propofol alone in patients undergoing colonoscopy. They found that the propofol–remifentanil combination offered no benefit over propofol alone in spontaneously ventilating patients. This finding is in contrast to an earlier study that noted an advantageous relationship of the two drugs when used in patients under controlled ventilation.[10]

Another agent that is gaining popularity for use in the sedation arena is dexmedetomidine. It is a highly selective α_2-adrenoceptor agonist that possesses both sedative and analgesic properties. Its ability to provide profound sedation while preserving respiratory drive makes it a useful anesthetic method in patients with a difficult airway.[11] Additional study is needed to better determine the drug's utility in remote procedural areas.

COMMON PROCEDURAL AREAS

ECT

ECT has long been a treatment modality for patients suffering from some psychiatric illnesses. Conditions include schizophrenia, major depressive disorder, bipolar, and schizoaffective disorders. ECT itself involves the induction of generalized seizure activity by introduction of an electrical stimulus through electrodes strategically placed along the cranium.

In order to be clinically efficacious, the seizure must reach a specific level of intensity duration. The patient typically must undergo several treatments. Because of the nature of the therapy and the associated physiologic responses to generalized seizures, anesthesia is required for the first and all subsequent sessions involving ECT. Many patients have comorbid illnesses in addition to their psychiatric disorders; anesthesiologists must be aware of the physical status of their patients and minimize complications during the course of therapy. Considering the large number of cases performed in the United States, the morbidity and mortality associated with ECT are surprisingly low. These low rates largely result from the use of standard monitors during the course of treatments as well as the recent advances in pharmacologic agents used for anesthetic management and control of hypertensive and cardiac responses to seizure activity. A large retrospective review by Nuttall et al.[12] at the Mayo Clinic reported a low of incidence of complications associated with anesthesia for ECT. The most notable complications associated with ECT were prolonged seizures, which

in this study were successfully treated with benzodiazepines. Anesthetic management for ECT is straightforward, although certain aspects vary among institutions. The goal of the anesthesia provider is to institute adequate airway support, suppress any recall or awareness of the session, and attenuate the physiologic responses to the stimulus. Once the patient is ready to begin the session, the appropriate monitors are placed and oxygen is delivered to the patient via face mask. General anesthesia is induced via an intravenous induction agent. Once the patient loses consciousness, a muscle relaxant, generally succinylcholine, is administered in preparation for the induced seizure. For patients with a pseudocholinesterase deficiency, a suitable nondepolarizing muscle relaxant is used in lieu of succinylcholine. Once general anesthesia has commenced, the patient's airway and breathing are supported via face mask and positive-pressure ventilation.

The anesthesia provider continues to support respiratory function until the return of spontaneous ventilatory effort by the patient. In some instances, other forms of airway intervention may be necessary, such as placement of an LMA. Because the ECT treatment course can last from several days to several weeks, any difficulties with the airway should be duly noted for any subsequent sessions and appropriate arrangements made.

Methohexital has been the most widely used induction agent in recent times. All hypnotic agents cause some reduction in seizure activity, but methohexital affects such activity to a lesser degree than the other agents. However, methohexital alone fails to prevent the resulting tachycardia and hypertension associated with ECT. The increase in systolic blood pressure and heart rate immediately following the stimulus may be as much as 30–40% and 20%, respectively.[13] In patients with known cardiovascular disease or significant risk factors, these responses should be kept to a minimum in order to prevent any untoward cardiac events during the course of treatment. Several studies have been performed to determine which agents or combinations of agent's best suppress this hyperdynamic response to ECT stimulation. A study by Gazdag et al.[14] examined the difference in duration of seizure activity and hemodynamic response to ECT between methohexital and propofol. Although propofol significantly lowered the duration of seizure activity compared to methohexital, the clinical efficacy of the treatment was not diminished, and the resultant lower mean arterial pressure associated with propofol could be beneficial to patients who demonstrate a higher cardiovascular risk profile. Other studies investigated anesthetic regimens that included methohexital with adjuvant therapies. Locala et al.[15] performed a prospective, randomized, double-blind study on the use of methohexital alone and remifentanil supplemented with a dose of methohexital sufficient to suppress recall. Patients who received remifentanil demonstrated a significant reduction in systolic blood pressure and heart rate associated with ECT. In addition to the ability of remifentanil to suppress the sympathetic response to seizure activity, some reports in the literature have indicated that remifentanil may increase the duration of seizure activity, making it an attractive agent in the anesthesia provider's arsenal.[16]

Other means of attenuating the hemodynamic response to ECT in patients with cardiovascular disease include the use of antihypertensive medications, most notably β-blockers. A study by Zhang et al.[17] examined the effect of different doses of nicardipine administered prior to induction of seizure activity. They discovered that a dose of nicardipine 40 μg/kg IV in addition to labetalol 0.15 μg/kg sufficiently blunted the hyperdynamic response without a significant decrease in seizure duration or postprocedural hypotensive effects.

Most patients who present for ECT either are currently taking or have taken antidepressants or other psychiatric agents. Historically, the agents of most concern with regard to anesthesia have been the monoamine oxidase inhibitors (MAOIs). According to previous recommendations, these medications were to be discontinued 2 weeks prior to any elective procedure.[18] However, in a series of case reports presented by Dolenc et al.,[19] patients had no adverse effects from general anesthesia with concurrent use of an MAOI.[19] Furthermore, no difference in hemodynamic response to ECT sessions was noted in patients either currently receiving or not receiving an MAOI. Much debate is ongoing regarding the discontinuance of any psychiatric medication, most notably MAOIs, in preparation for ECT. In the current understanding, ceasing MAOI use prior to the procedure is prudent if the medication is of no benefit to the patient. Avoidance of any known contraindicated drugs (indirect acting sympathomimetics, meperidine) is most important in these instances.

Endoscopy

The number of diagnostic and therapeutic procedures performed in the gastroenterology suite has increased greatly as the benefit of early screening for, and treatment of, both benign and malignant conditions has been well established. The vast majority of cases use some form of anesthesia, either conscious sedation administered by the gastroenterologist or deep sedation/general anesthesia administered by the anesthesia provider. Some cases still are performed without any type of sedation, but they are becoming more infrequent as patients have shown an unwillingness to undergo what may be unpleasant procedures without some form of anxiolysis or anesthesia.[20] The anesthesia team usually becomes involved in the more complicated or emergent cases. To that effect, most patients who present to the anesthesia provider for periprocedural care often are elderly or tend to have multiple comorbid conditions that should be addressed prior to commencement of the anesthetic.

The most common procedures performed in the gastroenterology suite are upper endoscopy, colonoscopy, sigmoidoscopy, and endoscopic retrograde cholangiopancreatography (ERCP). Each of these procedures carries it own unique challenges for the anesthesia provider. Colonoscopy traditionally is performed either without sedation or under conscious sedation administered by the endoscopist. A deeper lever of anesthesia is required in some patients because of their increased apprehension or severe discomfort experienced during the procedure. Important considerations for the anesthesiologist during colonoscopy include hemodynamic instability due to dehydration from a preparatory bowel regimen or uncompensated anemia from severe gastrointestinal (GI) bleeding. Upper endoscopy procedures involve placement of a scope into the esophagus and

stomach (and biliary tract in the case of ERCP) via the oropharynx. Patients usually are placed in the extreme lateral or prone position. The combination of patient positioning and the nature of the procedure itself limits access to the head and, consequently, the airway. Airway obstruction and apnea during sedation may develop, so the endoscopist and the anesthesia provider must have a clear understanding between them that emergency management of the airway supersedes continuation of the procedure until the situation has been safely controlled. Bradycardia or other arrhythmias can result from distension of the GI tract from probe insertion.[21] Other complications include bleeding, perforation, and infection.[22] Because these procedures often cause a great deal of anxiety and initiate a strong gag reflex in patients, most GI physicians use both a topical anesthetic spray and some form of intravenous sedation, usually midazolam and a narcotic (meperidine or fentanyl), to blunt these responses. Some procedures require the use of more potent agents because the procedures are longer and more complex and necessitate a high degree of patient cooperation.[23] Propofol, with its potent amnestic properties and rapid recovery time, has become an ideal choice for these procedures. It can be titrated to produce any level of anesthesia, from anxiolysis to general anesthesia. Its tendency to produce deep sedation with subsequent loss of protective airway reflexes at standard doses should limit its use to anesthesiologists and other individuals trained in airway management.[24] The level of sedation needed to successfully complete endoscopic procedures varies among populations. A study by Kazama et al.[25] found that, in general, elderly patients tolerated these procedures well at propofol concentrations associated with conscious sedation, whereas younger patients typically required larger doses (deep sedation) to suppress the somatic response to endoscopy. Although most GI procedures can be completed successfully under MAC or total intravenous anesthesia (TIVA), general anesthesia with endotracheal intubation may be necessary, for example, in patients who have airway difficulties or are at high risk for aspiration. The need for intubation should be discussed with the endoscopist because the presence of an endotracheal tube (ETT) may make the procedure awkward or difficult to perform.

Cardiopulmonary Suite

One of the main factors responsible for the phenomenal growth in nonoperating room procedures has been the need for interventional therapy in what traditionally have been considered nonsurgical candidates. This trend is definitely evident in the area of cardiopulmonary medicine. Many of these patients do not qualify for surgical intervention because of their poor physical status or the extent of their disease. Other patients simply refuse to undergo a surgical procedure that carries a high risk of mortality. The most common procedures requiring anesthesia generally involve patients diagnosed with some type of pulmonary malignancy. The interventions used in this population of patients range from rigid bronchoscopy to laser ablation; each intervention has its associated risks and complications. Most cardiac procedures are performed in the cardiac laboratory and involve treatment of arrhythmia via cardioversion or an implantable device.

Pulmonary Suite

Various techniques have been used for treatment of airway obstruction. One of the earlier treatment modalities involved use of the neodymium:yttrium-aluminum-garnet (Nd:YAG) laser. This procedure initially was used for treatment of endobronchial lesions. It consisted of coagulation of the tumor by the laser and subsequent coring and removal of the tumor by forceps or the tip of the bronchoscope. The Nd:YAG laser can be used with either a rigid or a flexible bronchoscope. The preferred method is rigid bronchoscopy because it lends itself to simultaneous use of the laser and suction.[26] Possible complications of laser therapy include hemorrhage, pneumothorax, airway perforation, arrhythmia, and myocardial infarction.[27–30] Airway fire is a rare complication, but high concentrations of oxygen should be avoided during the laser portion of the procedure.

Electrocautery is a more recent technique used for treatment of central airway lesions. Its use is gaining in popularity because if its wide availability, cost effectiveness, and ability to use either a rigid or a flexible bronchoscope.[31] Sutedja et al.[32] reported rapid relief of symptoms and ease of the technique when the procedure was performed on several patients with central airway obstruction.

Although the aforementioned techniques can successfully relieve symptoms caused by intrinsic obstruction, airway stents are the only devices that can provide relief and structural support for airway compression caused by extrinsic tumors or stenosis. The most common conditions that require stenting are tracheomalacia, polychondritis, tracheal stricture secondary to prolonged intubation, and bronchial stenosis after lung transplantation. The two main types of stents currently in use are silicone and metallic. Both have advantages and disadvantages. Metallic stents are considered permanent and normally are used to treat obstruction caused by malignancy. They are flexible and expandable, and they allow for normal ciliary movement once they are in place. These stents can be placed using a flexible bronchoscope with or without the use of general anesthesia. The major disadvantage of metallic stents is the difficulty in removing or repositioning them once they are deployed. Silicone stents can be removed or displaced with relative ease, and they are generally used to treat more acute processes, such as infection and inflammation.[33] However, these stents are much more rigid than their metallic counterparts and require prior airway dilation before deployment. This is accomplished using rigid bronchoscopy and subsequently requires the use of a general anesthetic.

Thorough preoperative evaluation of all patients undergoing interventional pulmonary procedures should be performed. In many cases, large masses are compressing vital airway structures, and the extent of compromise must be determined prior to the procedure. Pulmonary function tests with flow–volume loops are pivotal in differentiating between fixed and variable obstructions. Imaging studies include chest radiography or computed tomographic (CT) scan to determine the extent of obstruction. In emergent situations, the anesthesia provider may not have the luxury of extensive testing and will need to rely on physical symptomatology to determine the type of lesion present. Inspiratory stridor is indicative of an extrathoracic obstruction, whereas expiratory stridor is associated with intrathoracic

obstruction. For anesthetic management of these cases, the anesthesia provider must be prepared for airway emergencies. Several ETTs of various sizes as well as LMAs should be readily available. The provider should be prepared for emergency rigid bronchoscopy or tracheostomy.[34] Patients should be well oxygenated, and spontaneous ventilation should be maintained, especially in patients with severe obstruction or large mediastinal masses, until the airway is secured. Additional management includes the use of topical agents to anesthetize the airway prior to induction (through a nebulizer or spray) and careful titration of intravenous agents to achieve a satisfactory level of sedation. When general anesthesia is necessary, a small dose of succinylcholine usually is sufficient to facilitate placement of a rigid bronchoscope or ETT in patients in whom muscle relaxation is not contraindicated. Once the airway is secure, the anesthetic agents (including paralytics) can be titrated to prevent excessive movement and coughing during the procedure. Infusions of propofol and remifentanil are commonly used for TIVA in these instances.[35] Because of leak caused by rigid bronchoscopy, manual intermittent positive-pressure ventilation through the side port of the bronchoscope or swivel connector is normally used as opposed to mechanical ventilation. Hyperventilation with 100% oxygen (when not contraindicated) also is necessary to compensate for prolonged periods of apnea. Postoperatively, these patients should be transported with the appropriate monitors to the PACU, where they can be closely monitored for any sign of airway compromise and a chest x-ray film can be obtained to search for evidence of barotrauma.

Cardiac Laboratory

An increasing number of patients are undergoing invasive cardiology procedures that require the presence of trained anesthesia providers. In the past, certain procedures, such as placement of pacemakers/defibrillators, were performed in the operating room by a cardiovascular surgeon with a cardiac anesthesiologist in attendance.[36] Recently, however, implantation of these devices is being performed by the interventional cardiologist in the cardiac/evoked potentials laboratory with the assistance of a noncardiac anesthesiologist. The physiologic status of patients presenting for placement of implantable cardioverter-defibrillators vary from young, otherwise healthy individuals with supraventricular dysrhythmias (Wolff-Parkinson-White syndrome) to elderly patients with significant coronary artery disease/congestive heart failure who have survived a life-threatening arrhythmia (ventricular tachycardia, ventricular fibrillation). Many have severe ventricular dysfunction (ejection fraction 10–35%) and are taking antiarrhythmic or cardiac medications. The extent of their cardiac disease should be assessed preoperatively by the anesthesia care team and appropriate consultations obtained from the cardiologist involved in the patient's care. Anesthetic management for these cases ranges from sedation to general anesthesia with an ETT. Once the device is implanted, ventricular tachycardia or ventricular fibrillation is induced in the patient and a corresponding shock is delivered. This process can be quite uncomfortable to the patient, especially if multiple cycles are necessary. In circumstances where sedation is used, the anesthesia provider must be prepared for a brief period of general anesthesia to allow for device testing.[37] Antiarrhythmic drugs and an external defibrillator should be present at all times should the device fail to restore normal sinus rhythm. Standard monitors usually are sufficient for these cases, with more invasive monitoring reserved for patients in a more tenuous physical status. A postprocedural chest radiograph should be obtained to rule out pneumothorax or pericardial effusion and to confirm lead placement. Patients may recover in either the cardiac catheterization laboratory or the PACU, if necessary.

Electrical cardioversion is used to convert patients to normal sinus rhythm. The usual indications are atrial fibrillation, atrial flutter, supraventricular tachycardia, or other ventricular arrhythmias. Cardioversion can be performed either emergently (unstable arrhythmias) or electively (failed medical therapy). Because of the physical discomfort and psychological distress caused by the procedure, electrical cardioversions are performed either under deep sedation or with general anesthesia. For emergent cases, patients should be treated as having "full stomachs" and appropriate aspiration precautions taken. In elective cases, deep sedation is adequate, accompanied by a brief period of general anesthesia for the actual delivery of the stimulus. Gradual induction of anesthesia can be accomplished with careful titration of either etomidate or propofol, depending on the patient's hemodynamic status.[38] Respiratory assistance during this time is provided by mask ventilation; however, patients with airway difficulties may require an LMA or ETT for ventilatory management during the procedure. The postprocedural recovery time is generally brief, and outpatients may be discharged home as soon as 1–2 hours after cardioversion. In some patients, particularly those with hemodynamic instability, recall of the procedure may be an issue. This possibility should be discussed with the patient and the appropriate support and information concerning recall should be made available by the anesthesia provider.

Interventional Radiology

As a result of rapid advances in the areas of medical and computer technology as well as biophysics, the field of interventional radiology currently is exhibiting unprecedented growth. From state-of–the-art imaging studies to placement of vascular stents, the procedural possibilities in this specialty appear nearly infinite. As interventional radiologists continue to expand their scope of practice to the limits of modern medicine, the role of the anesthesiologist in this medical odyssey has become increasingly prominent. Initially, the majority of interventional procedures were performed with local anesthesia and minimal sedation administered by the radiologist. However, as the nature of the procedures became increasingly complex and the need for total patient compliance became necessary, the level of sedation required to successfully perform these interventions gradually began to increase. The frequent need for deeper sedation coupled with the increasing number of high-risk patients presenting for these "minimally invasive" procedures has led to the growing involvement of trained anesthesia personnel in perioperative management in the radiology suite. The radiology community generally believes that the presence of a separate anesthesia provider responsible for pain control and continuous resuscitation during technical-

ly challenging procedures, especially in the critically ill, should be mandatory.[39] A wide variety of cases are performed in the radiology suite, many of which involve the services of the anesthesiologist. For this discussion, we focus on the most common and technically demanding procedures and their complications as they relate to the anesthetic management.

Radiofrequency Ablation

Radiofrequency ablation (RFA) is widely used as a noninvasive treatment of primary and metastatic tumors and painful bone and neural lesions. A limitation to this form of therapy has been the relatively small area of tumor destruction achieved in a single treatment. Recent technologic advances in this modality have allowed for destruction of larger lesions (>5 cm in diameter) during a given session.[40] This has led to the expanded use of RFA in the treatment of many malignant tumors, including pulmonary, hepatic, bone, and renal cancers.

The technique of RFA involves placement of either a single electrode or multiple electrodes that are contained in a single needle into the lesion targeted for ablation. Once in place, tissue coagulation is induced through an electromagnetic source within the electrode.[41] Correct positioning of the electrode into the lesion of interest is accomplished through guidance from various imaging techniques, which include ultrasonography, CT, CT with fluoroscopy, or MRI. The choice of imaging depends on the availability of the technology at that center and the technical expertise of the interventionalist performing the procedure. A study by Ahrar et al.[42] at MD Anderson Cancer Center investigated the success of treating renal cell carcinoma through RFA. Image guidance using CT or CT fluoroscopy was the modality of choice because it allowed for accurate visualization of the tumor and surrounding structures and the image was not obscured by bleeding or vaporization of surrounding tissue, as is the case with ultrasonography. MRI has the advantage of clear delineation of the tumor and surrounding structures in addition to its capability of real-time multiplanar imaging and temperature monitoring.[43] However, its limited availability in most centers prevents its widespread use in this arena.

Anesthetic management of RFA depends on the size and location of the tumor. For most cases, MAC is sufficient and is generally well tolerated by patients. For larger lesions or lesions near vascular structures, general anesthesia with placement of ETT may be required to prevent patient movement during critical portions of the procedure. Complications of RFA include hemorrhage, pneumothorax, hemothorax, thermal injury, electrical shock, and hyperthermia, as the patient may exhibit significant increases in body temperature in response to direct heating of large masses.[44] Patients can be taken to the PACU or kept in the recovery area of the interventional suite, if appropriate, for postoperative monitoring and pain control.

Interventional Neuroradiology

Perhaps one of the most challenging and exciting fields of interventional medicine is the area of interventional neuroradiology. Noninvasive treatment of neurovascular disease has evolved significantly, and it seems that no vessel is unreachable with today's arsenal of catheters and imaging techniques. The most common treatments are embolization or sclerotherapy of tumors and arteriovenous malformations (AVMs), angioplasty for cerebral vasospasm, and coil embolization of cerebral aneurysms. In most of these cases, general anesthesia is the preferred method of anesthetic management because patients are often required to remain motionless for extended periods. Each of these procedures carries its own patient and risk profiles that the anesthesia provider should consider in formulating a management plan. Common complications of interventional neuroradiologic procedures include cerebral ischemia, hemorrhage, catheter displacement, and pulmonary embolism.[45] The goals of perioperative management in these procedures are no different than those set for any neurosurgical case: maintenance of hemodynamic stability, preservation of cerebral blood flow and cerebral perfusion pressure, respectively, and rapid emergence following completion of the procedure to assess the patient's neurologic status.[46]

AVMs are vascular structures in which one or more aberrant arteries feed into a nidus that then is drained by coexisting aberrant veins. In the past, embolization of AVMs was performed prior to surgical resection of the abnormality. However, many of these lesions now are being treated by embolization alone given the presence of experienced neuroradiologists.[47] Embolization can be accomplished by deployment of thrombosing coils or permanent balloons or by injection of sclerosing agents, glues, or particulate material. Complications following embolization include cerebral hemorrhage or edema resulting from sudden reperfusion into areas that previously were underperfused.[48]

Careful management of arterial blood pressure and, thus, cerebral perfusion pressure is important. This is best accomplished under general anesthetic with use of muscle relaxation to avoid the sudden increase in blood pressure and intracranial pressure associated with coughing or involuntary paroxysmal movement. Some patients may require preoperative and intraoperative pharmacologic agents to assist in controlling blood pressure during the procedure. Propanolol, in addition to its known hemodynamic effects, has been shown to possibly reduce cerebral metabolic rate and cerebral blood flow without significant impairment of metabolism–flow coupling.[49] Invasive blood pressure monitoring is recommended for patients in whom deliberate hypotension is planned. Placement of other invasive monitors will depend on the current physical status of the patient and the need for postprocedural hemodynamic monitoring.

Although surgical clipping remains the treatment of choice for ruptured cerebral aneurysms, the endovascular approach via coil placement is gaining popularity in the treatment of unruptured aneurysms.[50] The basic goal of this approach is obliteration of the aneurysm sac through the placement of coils.[51] Possible complications associated with coil embolization include hemorrhage, thromboembolism, and vasospasm, which is most notably problematic in the case of aneurysm rupture. Nimodipine still is considered the agent of choice for prevention or continued treatment of vasospasm. Patients who undergo these procedures are taken to the ICU for monitoring of their neurologic status.

Transjugular Intrahepatic Portosystemic Shunting

Transjugular intrahepatic portosystemic shunting (TIPS) is a technique that involves the creation of a shunt through the liver between one of the

hepatic veins and either the right or left portal vein.[52] TIPS traditionally has been used to treat esophageal varices, but its utilization has been expanded to include the treatment of several other hepatic conditions, such as portal vein thrombosis and Budd-Chiari syndrome. TIPS can be performed under MAC or general anesthesia, depending on the patient's physical status and the practitioner's comfort level with the technique. Patients who present for TIPS may have a large number of ascites or other complications of hepatic disease (pleural effusions, intrapulmonary shunting) that can restrict ventilatory effort and decrease oxygenation.[53] Patients who have a significant amount of ascites or a recent episode of GI bleeding are at increased risk for aspiration. The procedure itself may take several hours to perform, which requires a cooperative and stable patient. All of these factors must be taken into consideration when choosing an appropriate anesthetic method. Standard monitors usually are sufficient, but more invasive techniques may be required in emergent cases or in hemodynamically unstable patients (active bleeding, severe cardiomyopathy, acid–base disturbances). Adequate IV access in the form of a large-bore catheter should be established, because one of the complications of the procedure is hemorrhage and the patient may experience hemodynamic instability. Recovery usually takes place in the PACU or ICU setting, as many seriously ill patients fail to improve in the immediate postprocedural period.

Diagnostic Imaging

In the previous section, we discussed therapies in the radiology suite that involve some type of invasive technique. For many of these procedures, the need for sedation or anesthesia is self-explanatory. However, the services of the anesthesia provider may be required for various noninvasive diagnostic modalities. For these imaging studies, total patient cooperation is needed in order for the studies to have optimal diagnostic value. This section discusses the most frequently performed examinations: MRI and CT scan.

MRI

MRI is a diagnostic imaging tool that uses both static and gradient magnetic fields with the addition of radiofrequency pulses to provide clear and anatomically correct body images. The strength of the magnetic field used in MRI ranges from 0.15–3.0 T, with stronger fields producing a higher quality image. Although MRI does not use ionizing radiation (as in CT) and is not known to produce any harmful physiologic effects, the scan involves certain risks of which all personnel in the area should be aware. The most important are those involving ferromagnetic objects or equipment near the magnetic field. Many of the reports of injury or fatality are related to these objects, which become projectiles when exposed to the strong magnetic field. In addition, patients who have any indwelling metallic device, such as a pacemaker, implantable cardioverter-defibrillator, aneurysm clip, or infusion pump, are generally contraindicated for MRI.[54]

Because of the need for absolute immobility and the length of some types of scans, some patients, most notably pediatric patients, require deep sedation or anesthesia for successful completion of the study. In the adult population, claustrophobia and movement disorders are the most common reasons for the involvement of anesthesia services. Studies have shown that a fairly large percentage of adults (14–20%) require some anesthesia in order to tolerate MRI.[55] In these cases, anesthetic techniques range from conscious sedation for adults with mild claustrophobia or anxiety to general anesthesia for patients in whom airway issues are expected (e.g., patients with OSA). One of the more effective and popular techniques is TIVA with propofol as the drug of choice. Whatever the preferred method, the presence of MRI-compatible airway equipment is a must during any anesthetic in this location. Ideally, an MRI-compatible anesthesia machine and monitors also should be available. In the event such availability is not feasible, the area can be adapted with extra long tubing for the monitors and an extended breathing circuit for the machine that is stationed outside of the scanning room. Additional anesthetic considerations for MRI include limited access to the patient and decreased visibility.[56] Most institutions have a window or video equipment with which to view the patient throughout the examination, as well as an intercom with which to talk to the patient who is mildly sedated. The technicians or other personnel in the area should clearly understand that the scan should be halted if any issue arises. If designated space is available, patients may recover in the radiology area.

CT Scans

CT scans are generally of shorter duration than MRI scans and rarely require the presence of an anesthesia provider. Most young children still require some form of anxiolysis, which can be accomplished in most centers by a specially trained sedation nurse. In instances where a longer scan is needed or oral contrast is required, general anesthesia is used. Sargent et al.[57] performed an interesting study that examined CT scans of the chest in children receiving sedation versus general anesthesia with ETT. They discovered that patients who received general anesthesia displayed areas of atelectasis large enough to obscure possible metastases. Subsequent study found that adding 5 cm H_2O positive end-expiratory pressure was sufficient to prevent this degree of atelectasis.[58] As with MRI, access to the patient undergoing a CT scan is limited because of the ionizing radiation being used to produce the required images. However, use of specialized anesthesia equipment is not necessary, and the patient is much more visible to the anesthesia provider because the patient is not completely enclosed in a cylinder. Propofol is the drug of choice, because the procedures often are short, and lingering sedative effects are undesirable. Patients who receive oral contrast should be intubated and the contents of their GI tract suctioned prior to extubation. Recovery time usually is short, depending on the agent used. Many patients can bypass the PACU and recover on site, if stable.

PEDIATRIC PATIENTS

In order to successfully diagnose and treat the myriad of disease processes that we see in medicine today, patients must sometimes experience a rather grueling process of multiple diagnostic studies and procedures. Pediatric patients are no exception. Adult patients can endure many of these processes without the use of anesthetic intervention. However, children

often lack the emotional maturity and mental resolve to cooperate with many of these basic procedures. Because their treatment plan should be no less comprehensive than that of their adult counterparts, the services of a qualified anesthetic provider often are elicited in order to complete the pediatric treatment course. In this section, we focus on the current standards for anesthetic management in the more common nonoperating room procedures performed in the pediatric population.

History of Pediatric Sedation

Prior to the 1980s, the involvement of the anesthesiologist in pediatric sedation was sporadic. However, with increasing reports of pediatric morbidity and mortality in settings where sedation was used in the absence of individuals trained in resuscitative techniques, the need for monitoring guidelines was clear. The first of these guidelines was developed in cooperation with the American Academy of Pediatric Dentistry and the ASA. The guidelines addressed issues such as informed consent, fasting requirements, availability of appropriately sized equipment, standard physiologic monitoring, frequent documentation of vital signs, and proper recovery and discharge protocols.[59] The establishment of these guidelines greatly improved the safety of children undergoing anesthesia in these remote locations but still left room for improvement. With the introduction of pulse oximetry and more comprehensive discussion of the various levels of sedation by the ASA, the guidelines have undergone revisions over the years, most recently in 2002.[60] This last compilation has eliminated the term *conscious sedation* with regard to the pediatric population (because this state was rarely achieved in children) and stressed the use of the new terminology of *minimal, moderate,* and *deep sedation,* in keeping with the language of the ASA and the Joint Commission on Accreditation of Healthcare Organizations.[61]

Current Practice

Although the ASA was actively involved in providing the necessary sedation guidelines, the majority of sedation in pediatric patients still was performed by nonanesthesia providers (dentists, nursing personnel). Although mortality associated with sedation in remote locations decreased, the problems of prolonged recovery from comparatively short procedures and failure to complete a study because of inadequate sedation were common. These problems largely were related to the fact that the majority of agents used for sedation by nonanesthesia providers in the procedural areas (pentobarbital, ketamine, midazolam, methohexital) were used for general anesthesia in the operating room setting.[62] It comes as no surprise that many of these "sedations" often drift into the realm of a general anesthetic, which may necessitate more aggressive airway management.

With the more stringent guidelines for sedation in nonoperating room locations and the growing number of treatment modalities and studies available for the pediatric population, increasingly more departments have been eliciting the services of the anesthesia provider for their rising case load.[63] The advent of propofol and the use of TIVA greatly decreased the procedure failure rate and increased patient satisfaction, as patients had the dual benefit of deep sedation/general anesthesia for uncomfortable procedures and short recovery times.

Oncology Procedures and Imaging Studies

This combination is particularly beneficial to pediatric oncology patients, who often must undergo multiple painful procedures or numerous radiation therapy sessions during a potentially lengthy treatment process.[64] A study by Glaisyer and Sury[65] compared the technique of TIVA using propofol and remifentanil versus propofol and inhalational agents in pediatric patients undergoing lumbar punctures and bone marrow aspiration. They found that the propofol–remifentanil method allowed for quick induction, adequate anesthesia and analgesia, and shorter recovery times than the inhalational method.

In addition to the more invasive oncology procedures, many pediatric patients require anesthesia for diagnostic imaging studies. Many of these procedures require a lengthy period of immobility in an area resonant with strange sounds and ominous appearing equipment. Many small children cannot be compliant with instructions in this situation, and light-to-moderate sedation may be inadequate. In these instances, deep sedation often is required. Depending on the institution, the pediatric department may or may not provide specific procedural instruction (e.g., NPO instruction) or IV access for the patient. For this reason, the patient should undergo the same preanesthetic assessment and preparation required for patients scheduled for more complex procedures. The same anesthetic concerns apply for both adults and children in these remote imaging locations. The appropriate monitors and equipment should be available, and the anesthesia provider should have an unobstructed view of the patient, either through a window or via video surveillance equipment. In most circumstances the presence of a pediatric trained anesthesiologist is not required, but the providers who are present should be comfortable with straightforward procedures on pediatric patients and be familiar with the strengths and deficiencies of that particular location.

CONCLUSION

The role of the anesthesiologist has greatly expanded outside of the arena of the operating room. Our services are being requested constantly as the area of interventional medicine continues its phenomenal growth. As a result, we must leave the protective auspices of the operating theater and venture into the unfamiliar territory of hospital policy and procedures to ensure that our nonoperating room patients receive the same level of care that would be available to them in the operating room. Our specialized training and thorough knowledge of the physiologic effects of anesthetic agents in various disease processes give us a distinct advantage over many of the personnel who currently provide sedation services in these remote areas. Although an increasing amount of literature regarding our role and current practices in nonoperating room locations is available, still more needs to be done to enable us to further increase our efficiency in this field and accommodate the growing number of patients and specialists requiring our services.

CHAPTER 70

Anesthesia for Trauma Patients

John K. Stene, MD, PhD, and Christopher M. Grande, MD, MPH

Many anesthesia practitioners encounter trauma patients at odd hours, such as nights and weekends, when they are practicing alone or have limited access to colleagues. Thus, they must be prepared to handle challenging patients based on a firm understanding of the pathophysiology and consequences of trauma and the approaches to modifying these processes to assure best outcomes. Although trauma can be viewed as a disease entity per se, injured patients present as a nonhomogeneous collection of surgical patients. Furthermore, trauma care is not limited to the immediate care phase; anesthesiologists are as likely to anesthetize trauma patients for scheduled post trauma reconstructive surgery as for emergency lifesaving procedures. These patients have a wide variety of preexisting chronic medical conditions that interact with the traumatic injury and alter their physiologic responses. Typical preexisting medical problems include ethanol abuse, cigarette smoking, drug abuse, heart disease, chronic obstructive pulmonary disease, and a variety of mobility issues in elderly patients injured in falls. In fact, a large part of the anesthesiologist's effort is directed toward counteracting the "normal" response typically mounted by a person in reaction to an injury (i.e., the "flight or fight" response). Although tachycardia and hypotension noted as part of the primary survey signify significant blood loss and the potential need for emergency surgery, preexisting disease states will modify these responses. For example, very fit athletes often present with heart rates in the normal range after significant blood loss, an effect that also can be present in patients taking β-adrenergic blocking drugs for heart disease. Cocaine intoxication leads to tachycardia and hypertension, and alcohol intoxi-

KEY POINTS

1. Early involvement of the anesthesia provider in the perioperative care of the trauma patient will benefit the patient. A full understanding of the mechanisms of injury, preexisting medical conditions, requirements for airway management, fluid and blood resuscitation, and medications will be gained, and likely pitfalls in management will be avoided.
2. The anesthesia caregiver should carefully consider all background medical conditions of the trauma patient and factor these issues into the perioperative care plan.
3. Evaluation of the airway in trauma patients includes asking patients to speak and assessing whether the larynx and/or trachea have been injured.
4. The anesthesia care team must understand the necessity of evaluating the patient's cervical spine and the exact meaning of clinical and radiologic "clearing" of the cervical spine. The anesthesia care team must understand how to obtain and maintain a patent airway in a patient whose cervical spine has not yet been "cleared."
5. Direct laryngoscopy can be performed in the presence of cervical spine injury, provided proper "manual inline axial stabilization" is maintained. It is not mandatory to move immediately to fiberoptic intubation, blind nasal intubation, or surgical airway. However, it is mandatory to have a series of contingency plans ready to be executed in every patient should the initial airway management strategy fail or not be fully satisfactory.
6. Caregivers who often deal with emergency trauma patients must be facile with the full range of airway management techniques, including "surgical options," and should be familiar with the concepts and techniques of both "classic" and "modified" rapid sequence induction and the implications of each in the setting of acute trauma management.
7. Every trauma patient should be considered to have a full stomach, regardless of when he or she had the last meal.
8. Caregivers should be thoroughly familiar with the complications of massive transfusion, which include hypothermia, impaired oxygen release, coagulopathies, electrolyte and acid–base abnormalities, and citrate intoxication.
9. Anesthesia providers should have a solid plan for preoperatively assessing the volume status of any traumatized patient. Assuming that a "tilt test" can be performed or that it will provide adequate assessment of volume status in a patient with an uncertain volume status is an invitation for disaster.
10. The benefits, risks, and complications associated with succinylcholine use should be thoroughly understood in patients who may present with massive trauma, spinal cord injury, burns, eye injury, or similar conditions. Hyperkalemia after succinylcholine administration can occur on the first day in cases involving crush or degloving injuries, burns, trauma, and abdominal sepsis. The so-called *safe period* for succinylcholine should be viewed with skepticism.
11. Intraoperative awareness is a definite possibility in hemodynamically unstable trauma patients during anesthesia and surgery. The primary goal is patient safety, but with adequate analgesia and hypnosis to prevent awareness. Use of "cardiostable" anesthetics, analgesics, and neuromuscular blockers usually achieves an adequate compromise.
12. Intravenous fluid administration should not be restricted in patients with head injury and elevated intracranial pressure if there is evidence of hypovolemia. The goal is to ensure normovolemia and adequate arterial and cerebral perfusion pressures.
13. Prevention of renal failure is especially important in trauma patients. Simply administering diuretics to achieve urine output will not suffice. Adequately assessing volume status and replacing and maintaining circulating blood volume are key.
14. Standard coagulation tests are temperature corrected to 99°F (37°C) and may not reflect hypothermia-induced coagulopathy. Hypothermia impairs coagulation because of slowed enzymatic rates and reduced platelet function. Treatment of hypothermia-induced coagulopathy consists of rewarming the patient, not administration of fresh-frozen plasma or platelets.

Continued

Key Points—continued

15. Preventing hypothermia is a high priority during trauma resuscitation and surgery. The anesthesia provider should be thoroughly aware of the complications resulting from hypothermia and the advantages and disadvantages of the various modalities used to prevent and treat hypothermia.
16. The effects of pain and the related stress response almost always are detrimental to the trauma patient. Methods of pain relief range from simple continuous or on-demand IV opioids to more sophisticated techniques such as regional or neuraxial blocks. Use of adjuvant drugs, such as dexmedetomidine, gabapentin, or celecoxib, may decrease opioid dose and improve analgesia.
17. Hyperventilating head-injured patients may cause regional or global cerebral ischemia as a result of hypocapnia-induced cerebral vasoconstriction and has been shown to worsen outcome after head trauma. Measurements of intracranial pressure, in conjunction with monitoring of jugular venous oxygen saturation, may help guide therapy aimed at improving cerebral perfusion.
18. The anesthesia provider should consider early placement of invasive monitors in severely injured trauma patients to measure and manage cardiovascular, respiratory, and metabolic parameters. Patients who attain supranormal values of cardiac index, oxygen delivery, and oxygen consumption may have enhanced survival and decreased organ failure, perhaps because of the ability to meet the increased metabolic requirements of trauma and to repay a previous "oxygen debt."

cation is associated with a biphasic blood pressure response—initial hypotension followed by hypertension. The diagnosis of head injury is further complicated by ingestion of mind-altering substances.

Multiple injury patterns cause a wide variety of direct organ damage that interacts with the patient's physiologic response. These injury patterns are broadly classified into penetrating trauma, blunt trauma, or a combination of blunt and penetrating trauma (Table 70–1). Other injury classifications include burns, inhalation injury, and a range of environmental exposures. These various categories have some prognostic value to the anesthesiologist in understanding potential organ injuries. Examples of the prognostic value to the anesthesiologist of knowing the mechanism of injury are penetrating trauma to the trunk, which may cause serious hemorrhage along a knife or bullet track, and high-energy blunt trauma (e.g., pedestrian struck by car), which is associated with long bone and pelvic fractures, closed head injury, rib fractures and pulmonary contusions, and intraabdominal solid organ injuries. Thus, the anesthesiologist should be ready to immediately transport the patient to the operating room to explore the wound track and stop hemorrhage associated with penetrating trauma to the trunk; prepare a patient for prolonged mechanical ventilation, prolonged shock resuscitation, and hypothermia; and deal with significant issues associated with posttraumatic analgesia in the patient with high-energy blunt trauma.

Despite the nonhomogeneous nature of traumatic injury, all trauma patients exhibit some effects of cellular hypoxia and shock. These effects normally are accompanied by varied degrees of characteristic neurohumoral responses to trauma, which frequently initiate a self-destructive cascade of other phenomena (Table 70–2).[1] For example, profound vasoconstriction induced by large amounts of epinephrine and norepinephrine released in response to hemorrhagic shock leads to organ ischemia and increased anaerobic metabolism. This in turn causes metabolic acidosis, which can be confused with diabetic ketoacidosis when accompanied by hyperglycemia caused by decreased insulin secretion and elevated glucagon secretion. The treatment is restoration of the patient's hydration, blood volume, and cardiac output, not insulin injection.

TABLE 70–1.

Mechanism of Injury vs. Common Injury Patterns

Injury Pattern	Typical Etiology	Characteristics
Blunt trama	Motor vehicle crashes Falls	Multiple fractures Closed head injuries Widespread microvascular hemorrhage
Penetrating trauma	Knife wounds Gunshot wounds	Localized tearing of tissues along wound track Major blood vessel hemorrhage
Blunt and penetrating trauma	Blast injury with shrapnel	Hemorrhage along penetrating wound tracks Disruption of air filled organs
Burns	Thermal burns Electrical burns	Deep partial thickness of skin burn Full-thickness skin burn Muscle coagulation (electrical)
Inhalation injury	Smoke inhalation Poison gas	Respiratory distress
Environmental exposure	Extreme cold	Hypothermia Frost bite

TRAUMATIC SHOCK

Shock, defined as a sudden physical or mental disturbance,[2] describes the appearance of a patient with cardiovascular collapse as if he or she suffering from a great blow or sudden mental trauma. Although the origins of the term *shock* are incorporated in this definition, the understanding of what constitutes shock has changed in response to pathophysiologic research after the term was coined centuries ago. Our current understanding of shock involves inadequate cellular oxygenation from hemorrhage (hemorrhagic shock), cardiac failure (cardiogenic shock), and massive vasodi-

latation (neurogenic shock), although no precise pathophysiologic definition exists.

Traumatic hemorrhage causes shock principally through loss of circulating blood volume. Early physiologists described the tachycardia, hypotension, ashen complexion, and cool moist skin of the injured patient suffering from hemorrhagic shock.[3] Walter Cannon, who served as an army surgeon in World War I before becoming a Professor of Physiology at Harvard, recognized that loss of blood reduced cardiac output and caused traumatic shock.[3] Cannon[4] proposed that the term *shock* be replaced by the term *exemia* to emphasize that blood loss was the cause of shock following wounding. A mechanical model developed by Henderson[5] advanced the understanding of the role of blood loss in hemorrhagic shock. Arthur Guyton refined this concept with the venous return curve, which was severely depressed following hemorrhage with a reduction in the mean filling pressure of the circulation, thus limiting maximum cardiac output (Fig. 70–1).[6] The majority of a person's blood volume resides in the venules as the "unstressed volume" (blood that fills the anatomic space of the veins and venules without stretching the vascular structures and, therefore, does not generate pressure; Fig. 70–2).[7] A trauma patient can lose as much as 25–30% of his or her blood volume before developing systolic hypotension, as the available vascular space contracts to reduce the unstressed volume (Box 70–1).

In addition to hypotension, loss of a significant portion of the unstressed blood volume will result in decreased cardiac output and thereby restrict oxygen delivery to various organs. This in turn causes anaerobic metabolism and metabolic acidosis and eventually triggers a series of characteristic neurohumoral responses to the insult.[1,8,9] These neurohumoral responses range from increases in circulating levels of epinephrine, norepinephrine, growth hormone, glucagon, adrenocorticotropic hormone, and cortisol (and a reduction in insulin) to activation of various cytokines and white blood cells, modulation of coagulation, and more. Tachycardia, hyperglycemia, increased white blood cell count, and hypokalemia all result from these neurohumoral responses to trauma.

Decreased tissue blood flow following hemorrhage causes decreased oxy-

TABLE 70–2.

Neurohumoral Response to Trauma

Humoral Response	Metabolic Effect
Epinephrine increase	Tachycardia, vasoconstriction, hyperglycemia, hypokalemia
Norepinephrine increase	Tachycardia, vasoconstriction
Adrenocorticotropic hormone increase	Cortisol increase
Cortisol increase	Hyperglycemia, hypertension, fluid retention
Insulin decrease	Hyperglycemia, hyperkalemia
Glucagon increase	Hyperglycemia
Acute phase response	Cytokine release: Tumor necrosis factor-α, IL-1, IL-2, IL-6, and interferon; prostaglandins (regulate inflammatory response); increase C-reactive protein, fibrinogen, complement C3, haptoglobin

IL, interleukin.

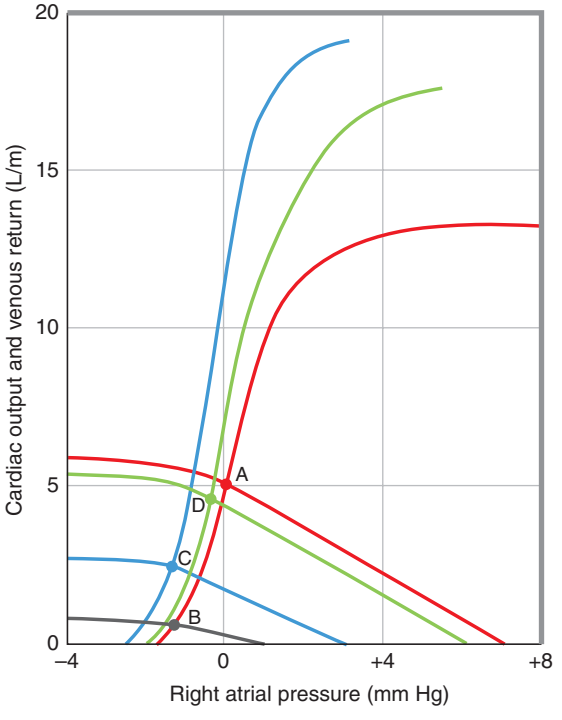

FIGURE 70–1. Effects of hemorrhagic shock on control of cardiac output. Graphic intersection of the cardiac function curve (sigmoid shaped line) shows increase in cardiac output as right atrial pressure increases (Starling curve), and linear negatively sloped venous return curve shows venous return to the heart decreases with increasing right atrial pressure until venous return ceases when right atrial pressure equals mean vascular filling pressure. Venous return limits maximal cardiac output independent of the cardiac inotropic state, and the intersection of the two curves sets the cardiac output and right atrial pressure. Point A represents right atrial pressure and cardiac output under normal conditions. Point B represents the effects of acute hemorrhage, which reduces mean vascular filling pressure of the circulatory system, and severely depressed venous return. Point C represents sympathetic nervous compensation for reduced cardiac output with mobilization of unstressed blood volume, which increases mean vascular filling pressure and venous return, and increased inotropic stimulation of the heart shifts the cardiac function curve to the left (increased cardiac output for any given right atrial pressure). Point D represents the state of the circulatory system after transcapillary refill of interstitial water and/or intravenous fluid replacement with increased mean vascular filling pressure, increased venous return, and somewhat relaxed inotropic state of the heart. FIGURE 70–2. Bathtub representing the concept of unstressed volume. **Top:** drain in the bottom removes all the water. Flow through the drain is determined by the water level in the tub at any time. **Bottom:** drain in the side—water drains only to the level of the hole. Flow through the hole is determined by the level above the hole, and the volume below the hole is necessary to get the water to that level but does not affect flow. (From Magder and De Varennes[7] with permission.)

BOX 70–1.

Pathophysiology of Shock

- Loss of circulating blood volume causes decreases in venous return and cardiac output.
- Arterial pressure decreases.
- Sympathetic nervous system is activated by reduced cardiac output and reduced arterial pressure at aortic and carotid baroreceptors.
- Catecholamines are released from the adrenal medulla.
- Heart rate increases in response to circulating and intramyocardial catecholamines.
- Stroke volume decreases in response to decreased venous return and increased heart rate.
- Available blood volume stores are mobilized from unstressed blood volume because of arterial inflow diverted by vasoconstriction from vascular beds with large venous capacitance such as cutaneous and splanchnic vascular beds.
- Clinical picture consists of increasing heart rate and decreasing pulse pressure; diastolic pressure rises before further hemorrhage causes systolic pressure to fall. Renal vasoconstriction and secretion of antidiuretic hormone decrease urinary output.
- Increasing hemorrhage leads to progressive increases in heart rate. Heart rates >140 beats/min are common with ≤40% loss of blood volume.
- Loss of >30% blood volume is required to consistently cause systolic hypotension in the supine position.
- Mental status changes to confusion and then lethargy with >30% loss of blood volume.
- Urinary output decreases with increasing blood loss and becomes negligible with 40% loss of blood volume.

gen delivery to the cells and mitochondria.[10,11] As the mitochondria become starved for oxygen, aerobic production of adenosine triphosphate (ATP) ceases, and cells become dependent on their small stores of ATP and phosphocreatine for energy. Anaerobic glycolysis replaces some of the lost ATP as long as an adequate supply of glucose can be maintained by the reduced blood flow. Initial changes in cellular structure and function occur when the cells no longer have the energy stores to maintain transmembrane ion gradients. Under optimum conditions, these changes are reversible for up to 1 hour and then the cells proceed to irreversible changes and cell death, thus the origins of the concept of the "golden hour." Inability to restore adequate circulating supplies of oxygen and glucose within a relatively short time leads to massive cell death and irreversible shock, followed by death of the patient.

Cell death in response to traumatic hemorrhagic shock is primarily necrosis, not apoptosis. Necrosis, which occurs when a cell is deprived of an essential nutrient for a critical time period (the golden hour), results in fluid swelling of the mitochondria, loss of high-energy phosphate compounds, disintegration of the cell membrane, and rupture of the cell and cellular organelles. In a review on cell death, Sedlak likens this process to murder of the cell compared to cellular suicide or apoptosis.[12,13] Apoptosis, which is not an important response to shock, is characterized by maintenance of cellular membrane architecture, albeit in a highly permeable state, condensed nuclear chromatin, disintegration of the nucleus, and finally the death of the cell. Other differences between apoptosis and necrosis are that apoptosis requires cellular energy whereas necrosis occurs in the absence of cellular energy, and necrosis triggers an inflammatory response whereas apoptosis does not.

Reactive oxygen species, the final common pathway for cell death, are triggered by many insults, including tissue ischemia and inflammation, both of which are associated with trauma. High levels of oxidants released from mitochondria are associated with necrosis, whereas low levels can lead to apoptosis in susceptible cells. Interestingly, bilirubin is a potent cytoprotective antioxidant whose effects are comparable to those of glutathione.[13]

Treatment of Shock

An appreciation of the relationships among these issues is important for the anesthesiologist who must manage an injured patient, because restoration of circulating blood volume is critical to restoring tissue oxygen delivery. Restoration of tissue oxygenation is required to first arrest and then reverse impending organ death. World War I era surgeons realized that blood loss reduced venous return, cardiac filling, and ultimately cardiac output, but it was not until the seminal work during the 1950s of replacing interstitial and intracellular fluid losses that intravenous fluids were routinely administered to restore circulating blood volume. Cellular dehydration following traumatic blood loss was a significant issue, and administration of excess electrolyte solutions after traumatic hemorrhage was required to restore interstitial and cellular hydration.[14] Rapid replenishment of shed blood volume restored sufficient tissue oxygen delivery and improved organ function.[15–17] The concept of a "golden

hour," which seeks to establish a limited time frame in which to restore hemodynamic and metabolic homeostasis to prevent irreversible shock, promoted a concerted improvement in trauma resuscitation and survival.

Delayed Fluid Resuscitation

Careful observation of the injured patient's response to resuscitation gave rise to the concept of "delayed fluid resuscitation," which emphasized the notion that overzealous fluid administration to a traumatized patient often can worsen outcome by disrupting natural hemostasis with clot dilution and generate high-pressure gradients for blood loss.[18,19]

In some ways, this concept is intuitive and actually represents a renaissance or rediscovery of a similar idea presented almost a century ago. Thus, current dogma is that, based upon the mechanisms of injury, rapid replacement of some of the shed blood volume (within the golden hour) is critical to assuring survival of an injured patient with hemorrhagic shock. However, fluid resuscitation must be used judiciously prior to surgical hemostasis to minimize ongoing hemorrhage and avoid compounding the adverse development of dilutional coagulopathy with anemia, hypothermia, and other iatrogenic sequelae.[20–22]

Although both laboratory and clinical trials have shown that modulating fluid resuscitation until surgical hemostasis is underway decreases the extent of hemorrhage and its sequelae, there is concern that prolonged hypotension may compromise renal function and compound the "secondary injury" effects on head injury.[23–25] Because of the concerns about prolonged hypotension, delayed fluid resuscitation is most successfully applied in locations where emergency medical systems (EMS) transport distances and times are short. This concern limits the universal applicability of strict delayed fluid resuscitation. However, patients with extensive blunt trauma in rural settings benefit from limited fluid resuscitation in the EMS phase of care. For example, administering very large volumes of crystalloid fluids in an attempt to achieve an arterial pressure of 140/90 mm Hg is no longer acceptable.

Small Volume Resuscitation

Another theme developed to achieve rapid restoration of blood volume without fluid overload and dilution of hemostatic elements is so-called *small volume resuscitation.*

Hypertonic saline (3–7%) has the ability to draw interstitial free water into the circulation and thereby rapidly restore perfusing volume and pressure. The hypertonic solution can be combined with colloidal solution to prolong the effect, helping to retain intravascular volume despite diffusive forces that promote capillary leaks.

Small volume resuscitation with 4 mL/kg of 7.5% NaCl in 6% dextran 40 or hydroxyethyl starch has achieved clinical success in several emergency medical programs. RescueFlow (6% dextran 70 dissolved in 7.5% NaCl; BioPhausia, Stockholm, Sweden) is a commercial product available in many countries outside of the United States that provides a convenient source of small volume resuscitation.[26–28] This resuscitation regimen is especially useful for patients with head injuries in whom hypertonic and/or hyperoncotic fluid helps reduce the development of brain edema.

Following on the issues related to delayed resuscitation discussed earlier, there is some concern that the hypertonic/hyperosmotic fluid may restore blood pressure and tissue flow too quickly in patients with penetrating trauma, thereby causing increased hemorrhage. Patients with crush injuries (in whom toxic products of rhabdomyolysis and reperfusion are circulating throughout their systems) may benefit from small volume hypertonic resuscitation, but administration of saline, bicarbonate, and mannitol may be just as effective.[24–28]

Other Shock Therapy

Blood gas analysis of the "typical" major trauma patient in shock admitted to the emergency department reveals a metabolic acidosis (the extent of which often correlates with the amount of blood loss), a mild degree of hypocarbia, and a moderate hypoxic state. Because of decreased tissue oxygen delivery, respiratory muscles perform very poorly during shock. Moreover, there are myriad reasons for compromise of the entire respiratory system, ranging from mechanical (e.g., rib fracture, flail chest) to central drive (e.g., head injury, narcotics) to parenchymal (e.g., pulmonary contusion) to physiologic (i.e., ventilation–perfusion $\dot{V}/\dot{Q}$ mismatching due to lung and/or heart trauma).

Characteristically the injured patient with hemorrhage develops a marked increase in pulmonary dead space and must mount an increased minute ventilation to effectively excrete additional carbon dioxide (CO_2) produced. Further influencing the patient's "optimum minute ventilation" is the need to buffer the metabolic acidosis with hypocarbia. The poorly perfused ventilatory muscles soon fatigue and further contribute to a feedback situation that compounds ventilatory failure, with worsening hypoxia and eventually death.

Therefore, for a variety of reasons, it is prudent that the anesthesiologist view traumatic hemorrhagic shock as an indication for urgent endotracheal intubation and mechanical ventilation. Mechanical ventilation supports the patient's gas exchange needs while "unloading" the ventilatory muscles and not diverting precious supplies of blood from other vital organs.

Hemostasis is critical for survival from traumatic injury; however, patients who lose large volumes of blood exhibit coagulopathy.[29] Part of the neurohumoral response to trauma may lead to disseminated intravascular coagulopathy, which is a combination of blood hypercoagulability causing clot formation that leads to depletion of fibrin and coagulopathy from clot lysis in the small arteries. Thus, trauma patients may exhibit the paradoxic state of systemic anticoagulation but local thrombus formation, possibly causing a variety of thromboembolic phenomena. Hypothermia adds to the coagulopathic component because the various clotting factors have temperature-dependent kinetics.[30] Therefore, the goals for management of the trauma patient during both resuscitation and emergency surgery include restoration and/or maintenance of normothermia as well as replacement of depleted coagulation factors.[31,32]

A number of strategies for rewarming hypothermic trauma patients in order to restore or maintain normothermia have been studied. Arteriovenous perfusion through a hot water heat exchanger has been used successfully to rewarm cold trauma patients.[31] The less invasive technique of applying a vacuum to dilate cutaneous veins of a limb surrounded by a hot water heat exchanger has worked well in experimental settings but has not yet achieved clinical application, partially

because of the lack of commercial practicality.[32]

The classic therapy for posttraumatic coagulopathy has been monitoring of prothrombin time, international normalized ratio, partial thromboplastin time, and platelet count. Replacement therapy with fresh-frozen plasma, platelet concentrates, and/or cryoprecipitate is used in an attempt to restore normal coagulation states.

Some trauma anesthesiologists have used activated factor VII to rapidly improve hemostasis without using large volumes of replacement factors.[33] Although activated factor VII theoretically accelerates thrombus formation at sites of hemorrhage and initiation of coagulation, its use in traumatic injury is controversial. There is concern that thrombus formation stimulated by activated factor VII may not be confined to the injured hemorrhaging blood vessels and may cause venous and/or arterial thromboembolic disease. A large, randomized, prospective clinical trial would be useful in determining the utility of this expensive therapy but, like all research in acute trauma, would be difficult to organize and implement, thus the dearth of evidence-based medicine in this practice area.

Although activated factor VII is most active at the location of disrupted blood vessel endothelium and triggers coagulation at sites of posttraumatic bleeding, it can place the patient at risk for thrombus at a distant site, especially in light of the general inflammatory, hypercoagulable state following injury.[33] Both arterial and venous thromboembolic disease are potential complications of uncontrolled use of activated factor VII.

Patients Taking Anticoagulants

In highly industrialized nations such as the United States, the median age of the trauma population has been growing older as the number of elderly people has been increasing. Because of the increase in the geriatric trauma population, the number of patients taking warfarin (Coumadin) for anticoagulation prior to injury is increasing. These patients require an especially intensive effort to restore the coagulation cascade, including the use of intravenous vitamin K therapy and fresh-frozen plasma. When these formerly anticoagulated patients arrive in the ICU following resuscitation of traumatic injuries, they require continued frequent monitoring and control of coagulation status, not only to correct the initial coagulopathy but often to reestablish anticoagulation for chronic conditions such as atrial fibrillation, cardiac valve replacement, or previous venous thromboembolism, which led to anticoagulation prior to the acute traumatic injury.

Blood Glucose Control

The neurohumoral response to trauma frequently leads to hyperglycemia when insulin secretion decreases and glucagon and epinephrine, which increase blood glucose, are secreted in great excess. Although posttraumatic hyperglycemia was ignored historically, recent evidence indicates that controlling blood sugar levels improves outcomes of critical care patients and cardiac surgical patients.[34,35] Therefore, it seems prudent for the anesthesiologist to monitor blood glucose levels when anesthetizing a trauma patient. Continuous intravenous infusions of regular insulin, adjusted by hourly glucose measurements, are an effective method for maintaining euglycemia, which is defined as a blood glucose level from 80–120 mg/dL. Hourly glucose measurements allow the anesthesiologist to identify and treat hypoglycemia before the patient suffers significant sequelae. Thus, the fear that insulin infusions might lead to undiagnosed hypoglycemia during anesthesia is more than balanced by the potential improvement in outcome resulting from hyperglycemia control.

Monitoring

At a minimum, trauma patients undergoing anesthesia require the standard monitoring recommended by the American Society of Anesthesiologists, including blood pressure, heart rate, single-lead electrocardiography, pulse oximetry, core temperature, and capnography. These basic monitors will provide a "first-level profile" of the trauma patient's physiologic response to injury and therapy. However, it is crucial that the anesthesiologist maintain a low threshold for intensifying the range and extent of specialized monitoring systems to more intensively and accurately follow cardiopulmonary and metabolic changes (Table 70–3).

Jugular bulb oxygenation

Invasive hemodynamic monitoring provides opportunities for more frequent assessment of blood pressure, and measurement of cardiac output and cardiac filling pressures allows assessment of myocardial performance. Additionally, vascular access provides a route for blood sampling of biochemical markers of shock and cellular ischemia or hypoxia. Intraarterial catheters ("a-lines") are the most basic invasive hemodynamic monitors and should be used liberally in seriously injured trauma patients. As always, the choice of monitors should be guided by an informed appreciation of the mechanisms of injury, extent of injury and/or blood loss, and subsequent response to shock and tissue injury.[36]

In unstable multiple-injured patients, the directly measured arterial pressure is more accurate than the indirectly measured arterial pressure, which is estimated by cuff and oscillometric device. Intraarterial pressure can be followed from beat to beat to track the results of resuscitation more closely than indirect arterial pressure measured episodically. An indwelling catheter facilitates frequent blood analysis and likely causes less patient discomfort and arterial trauma than do repeated multiple arterial punctures for blood sampling, particularly during extended stays in the ICU.[37]

Arterial blood gases are essential to monitor the patient's acid–base balance and ventilatory status. Restoration of the arterial base deficit to zero is one of the more sensitive indicators of adequate shock resuscitation and a practical therapeutic goal when evaluating the efficacy of shock resuscitation.[38–42] Because base deficit changes

rapidly in response to hemorrhage and resuscitation, it is a very useful parameter to follow during shock resuscitation. The base deficit usually is quite negative when shock resuscitation starts and approaches zero when the patient's blood volume is restored.[39–41] Although trauma patients with significant blood loss and hypoperfusion frequently have base deficits lower than –10 mEq/L, the correct treatment is replacement of blood and fluid losses, not administration of sodium bicarbonate. Buffers such as bicarbonate are reserved for patients with high plasma myoglobin or free hemoglobin levels who need alkalinized urine. More recently, a number of commercially available devices have become available that either invasively (by being mated to an indwelling arterial line system) or noninvasively measure pH and/or oxygen (O_2) and CO_2 gas tensions.

Large-bore central venous catheters should be placed in patients admitted with significant shock following injury. Central venous pressure (CVP) and pulmonary arterial pressure (PAP) monitoring also are indicated in certain trauma resuscitations, especially those in which there is a question of cardiac performance. Tracking cardiac output and left ventricular filling pressures is useful if cardiac function is compromised by preexisting heart failure, myocardial contusion, or aortic injury requiring cross-clamping of the thoracic aorta. CVP varies with blood volume, and measurement of this parameter supplements other estimates of blood volume restoration.[37]

Large-bore catheters placed into the large central veins (subclavian, internal jugular, or femoral) provide excellent venous access for high-volume fluid resuscitation with or without venous pressure monitoring. However, placement of such catheters is not without complication, especially in hypovolemic patients. Complications include catheterization of the subclavian or carotid artery and pneumothorax. For this reason, the femoral route has been most recently suggested by the Advanced Trauma Life Support (ATLS) protocols.

More specifically, pulmonary artery catheters can be introduced through a large-bore sheath in a central vein (usually subclavian or internal jugular) to monitor cardiac output as well as pressures in the superior vena cava (CVP) and pulmonary artery (PAP). When the pulmonary artery is occluded by wedging the catheter balloon tip (i.e., wedge pressure), PAP reflects the pressure in the left atrium and ventricle at diastole. Therefore, the filling pressures of both the right heart (CVP) and the left heart (wedge P) can be compared to cardiac output for evaluation of cardiac performance.[43] Blood gases sampled from the distal (PAP) lumen of the pulmonary artery catheter provide a measure of mixed venous oxygen and CO_2 and can be compared to simultaneous arterial samples to determine the efficiency of pulmonary gas exchange (Box 70–2). Mixed venous oxygen tension provides a monitor of the adequacy of oxygen delivery to the tissues relative to oxygen demand and reflects issues such as oxygen consumption and the efficiency of oxygen delivery to the periphery.[44–46] For example, normal mixed venous oxygen tension is approximately 40 mm Hg but decreases significantly if oxygen extraction is increased due to decreased oxygen delivery associated with hypovolemia.

Body temperature monitoring is a simple clinical measurement that has a significant impact on outcome in trauma patients. Hypothermia is extremely common in trauma victims with serious injuries. Although shock reduces blood flow to the skin and thus should decrease heat loss, thermogenesis is significantly decreased by hypoperfusion of skeletal muscle and abdominal viscera. In addition to having prognostic value, hypothermia causes significant physiologic changes. Coagulopathy induced by hypothermia increases uncontrolled hemorrhage during traumatic shock resuscitation and is considered part of the "triad of death" (hypothermia, acidosis, and coagulopathy).[29,30] The combination of these three responses to trauma is associated with a high mortality rate.

Because the coagulation cascade is composed of interacting enzymes, its effectiveness decreases significantly at temperatures $<91^\circ F$ ($33^\circ C$). Therefore, rewarming a patient's core temperature improves blood coagulability and helps control hemorrhage.[30] Rewarming is performed by a variety of techniques. Infusing the patient with warm intravenous fluids (limited to $108^\circ F$ [$42^\circ C$]) is important in preventing and treating hypothermia. A variety of fluid warmers are available, and the anesthesiologist must select from several having the capacity to warm at flow rates typical for trauma resuscitation. Excess capacity may counter intuitively allow fluids infused at lower rates to cool before they reach the patient's vein. Convective warming also is important and is achieved by keeping the emergency department and operating room warm and/or using a hot air convective warming blanket.

BOX 70–2.

Use of Pulmonary Artery Catheter

Useful Equations

Oxygen Delivery: $Q_T \times CaO_2$

Oxygen Consumption: $Q_T (CaO_2 - CvO_2)$

Pulmonary Shunt: $Q_s/Q_T = \frac{C_AO_2 - CaO_2}{C_AO_2 - CvO_2}$

Extraction Ratio: $O_{2FR} = (CaO_2 - CVO_2)/CaO_2$

Oxygen Content Calculated By:

Oxygen Content = (O_2 saturation/100 × Hemoglobin × 1.39) + $PO_2 \times 0.003$

Use: Arterial PO_2 and saturation for CaO_2

Pulmonary artery PO_2 and saturation for CvO_2

Calculated alveolar PO_2 and saturation (usually 100%) for C_AO_2

CaO_2, arterial O_2 content; C_AO_2, pulmonary capillary O_2 content; CvO_2, mixed venous O_2 content; Q_s, pulmonary shunt flow; Q_T, total cardiac output.

Anesthetic Drugs of Choice

Anesthesia induction in the trauma patient is similar in concept to anesthesia induction of other surgical patients but often is complicated by the presence of a full stomach, associated head, neck, thoracic, or abdominal injuries, and hypovolemia. The resultant scenario poses significant issues for the well-being of the patient and the practice of the clinician. The more hemodynamically unstable the trauma patient, the more careful the anesthesiologist must be with titrating the induction drugs to effect (Table 70–4). Occasionally in the past, some investigators implied that the combination of only oxygen and a neuromuscular blocking drug was adequate for the severely hypovolemic trauma patient, but that viewpoint has been replaced by the judicious use of intravenous anesthetics because of the high inci-

TABLE 70–4.

Anesthetic Drug for Trauma Patient

Function	Drugs	Trauma Dose (mg/kg)
Hypnosis (induction of anesthesia)	Etomidate	0.1–0.2
	Thiopental	0.5–2.0
	Propofol	0.5–1.0
	Ketamine	0.5–1.0
Analgesia	Fentanyl	0.001–0.003
	Morphine	0.05–0.1
	Sufentanil	0.1–0.5 μg/kg
Muscle relaxation	Vecuronium	0.15–0.3
	Rocuronium	0.9–1.2
	Succinylcholine	1.0–1.5
	Cisatracurium	0.10
Anesthesia maintenance	Isoflurane	Titrate to blood pressure
	Total intravenous anesthesia (propofol, fentanyl, dexmedetomidine)	50–100 μg/kg/min, 1–2 μg/kg/h, 0.5 μg/kg/h
	Ketamine, propofol	50–100 μg/kg/min propofol, 10–20 μg/kg/min ketamine

dence of unpleasant recall of perioperative events (and concomitant risk of punitive malpractice actions).

Ketamine has been recommended because of its perceived property of stimulating or at least stabilizing the sympathetic nervous system. Although ketamine usually causes hypertension and tachycardia secondary to increased sympathetic nervous system activity in unstressed patients, it can cause hypotension by direct myocardial depression in patients with maximally stimulated sympathetic responses secondary to shock. Thus, even ketamine must be used in small, preferably titrated, doses.

Etomidate similarly should be titrated to effect. Many clinicians believe that etomidate does not cause hypotension, but we have observed that etomidate may decrease blood pressure when administered to hypovolemic and maximally sympathetically stressed patients, similar to the clinical scenario noted with ketamine.

Thiopental or propofol can be titrated to effect without causing excessive hypotension. Often the doses needed to induce anesthesia in the patient with reduced blood volume and cardiac output (and possibly other abnormal pharmacodynamic and pharmacokinetic derangements) are so small that profound hypotension can be avoided. Overall, the operating principle should be small titrated doses of whatever induction agent is selected. Given the state of current evidence, this is perhaps more important than the specific choice of drug.

The combination of ketamine and propofol (i.e., "ketafol") is gaining popularity for induction of trauma anesthesia and as an intravenous infusion to supplement regional anesthesia for repair of traumatic injury. Typically, 200 mg of propofol is mixed with 40–100 mg of ketamine in the same syringe (the drugs are compatible). In practice, the mixture is carefully injected intravenously until the patient is in the desired state of sedation or until anesthesia is induced, depending on the desired end point (Table 70–4). Ketamine and propofol appear to be somewhat synergistic in inducing anesthesia, and the sympathetic stimulation associated with ketamine is thought to counteract the cardiovascular depression associated with propofol.[47]

Careful attention to both adequacy of ventilation and protection of the airway is required when inducing anesthesia in the trauma patient, especially when incremental doses are administered while "titrating" to effect, an approach that minimizes the potential cardiovascular instability that commonly results with use of typical doses of induction agents. The patient's gas exchange should be supplemented by hand ventilation through a face mask while an assistant administers effective cricoid pressure. Cricoid pressure (i.e., Sellick maneuver) has been used for many years to prevent both insufflation of ventilatory gases into the stomach during mask ventilation and regurgitation and aspiration of gastric contents from the hypopharynx.[48,49] Control of ventilation while titrating induction drugs to effect will result in unconsciousness of the patient at the lowest efficacious dose, with less drug-induced hypotension. An additional benefit is an increase in alveolar oxygen and decrease in alveolar CO_2 immediately preceding the obligatory apneic period during intubation of the trachea. Some of the disadvantages of "classic" rapid sequence induction include the hypoxia hypercarbia that may occur during the 60- to 90-second apneic interval associated with endotracheal intubation. This often is further complicated in trauma patients by poor visualization (e.g., blood in the hypopharynx) or the need for special protection of the cervical spine in patients with head or neck injuries. Modified rapid sequence induction using cricoid pressure and sustained mask ventilation avoids this substantial insult.

The choice of muscle relaxant remains controversial. Proponents of succinylcholine tout its rapid onset, whereas those who favor nondepolarizing neuromuscular blocking drugs cite the undesirable side effects of succinylcholine, such as hyperkalemia, cardiac arrest ("black box" warning in package insert), and malignant hyperthermia. Because many trauma patients present for anesthesia without a complete medical/anesthetic history, the side effects of succinylcholine must be taken seriously and balanced against the benefits of that drug.

The possibility that a patient who cannot be ventilated or intubated would recover to spontaneous ventilation prior to sustaining brain damage secondary to cerebral hypoxia probably is not one of the benefits of succinylcholine. The 1–1.5 mg/kg dose of succinylcholine needed to achieve relatively rapid onset will require at least 5 minutes before recovery to meaningful spontaneous ventilation. In the trauma patient in shock who has increased pulmonary shunt, dead space, and all the other hemodynamic and metabolic issues noted above, this interval is long enough to result in profound hypoxia. Rapid onset of neuromuscular blockade can be achieved with nondepolarizing

relaxants by increasing the dose administered to multiples of the ED_{95}. The most commonly used nondepolarizing neuromuscular blockers are vecuronium (noted for its cardiovascular stability), rocuronium, and cisatracurium.

Opioid analgesics are an important component of trauma anesthesia practice, not only for critically injured patients who require immediate anesthesia induction for a variety of urgent imaging studies and/or surgery but also for less critically injured patients who need only analgesia, sedation, and monitoring of vital signs but require appropriate opioid analgesics for pain management. Fentanyl is an opioid useful for trauma care because its high lipophilicity, potency, and rapid redistribution make it easy to titrate to effect without causing hemodynamic deterioration. Morphine has a long history of use in trauma care, but its relatively slow onset makes it difficult to titrate and avoid subsequent overdose. Hydromorphone may be a more attractive option.

Regional Anesthesia

Although opioids reduce afferent stimulation in the neurohumoral response to trauma and thus reduce some of the proinflammatory stress responses, regional anesthesia may be even more effective for blunting these responses. Regional anesthesia can be an important adjunct to the total anesthetic management of the trauma patient, especially for its ability to reduce inflammatory triggers from the site of injury. Epidural anesthesia has been documented to reduce systemic stress from surgery, but it must be used especially carefully in trauma patients. Because many trauma patients have direct thoracic or lung injury and/or shock-induced pulmonary dysfunction ($\dot{V}/\dot{Q}$ mismatch, etc.), they often benefit greatly from mechanical ventilation. They may be hypovolemic as well, and sympathectomy accompanying neuraxial anesthesia can result in significant hypotension; if used, it must be initiated with small incremental doses of local anesthetic while frequently monitoring arterial pressure (and perhaps CVP). Furthermore, a generalized posttraumatic anticoagulated state will put some trauma patients at risk for epidural hematoma formation and thus be a relative contraindication for an epidural as a component of their anesthetic and critical care management. Thus, the decision to use epidural anesthesia depends on a variety of considerations, but it can be particularly helpful for the postoperative care of patients who suffer multiple rib fractures and/or flail chest.

However, peripheral nerve blocks that deafferent an injured limb can be safely applied to supplement general anesthesia for most trauma patients, except those who arrive in extremis. Peripheral nerve blocks will reduce the need for systemic opioids in the postoperative phase and in many instances allow earlier extubation of the trauma patient with painful injuries. Indwelling catheters can be placed at peripheral nerve block sites to provide continuous analgesia for postoperative pain management. Electrodes implanted in stimulating catheters allow the use of nerve stimulation to accurately place these catheters near major nerves (femoral nerve, brachial plexus, etc.) (Arrow International Inc., Reading, PA).

Some uses of regional anesthesia to enhance the anesthetic care of trauma patients are summarized in Table 70–5. Patients with isolated limb injuries often can be managed with peripheral nerve blocks as their sole anesthetic. This is especially useful in austere conditions where backup help for airway management problems may not be available or where the full gamut of anesthetic equipment and agents might not be available (e.g., fiberoptic intubation devices, etc.). Isolated peripheral nerve blocks have less propensity than neuraxial blocks (spinal and epidural) to cause hypotension and thus are less likely to cause cardiovascular problems with anesthesia administered for trauma surgery.[50]

However, patients who suffer severe injuries to the chest or abdomen will require intubation and ventilatory support. These patients will need airway support to provide a route for the requisite general anesthesia and to protect the airway from soilage.

SPECIFIC INJURY PATTERNS

Damage Control Surgery

Patients with profound hemodynamic instability and intraabdominal hemorrhage benefit from "damage control surgery," an operative strategy designed to rapidly achieve hemostasis without attempting definitive repair of solid organ injury.[51] For example, a patient with a grade 5 liver laceration (involving hepatic veins) would undergo an exploratory celiotomy for repair of the hepatic venous laceration and packing of the liver wound for hemostasis. The patient then would be transferred to the ICU. After rewarming the patient and completing hemodynamic resuscitation in the ICU, the trauma team returns the patient to the operating room 24–48 hours later for a "second look." During the second look, packs are removed and the wound in the liver is judiciously débrided. The patient may require several more trips to the operating room to complete repairs of all the intraabdominal injuries.

This approach to resuscitating the injured patient with major intraabdominal hemorrhage is consistent with the ATLS philosophy of delivering simultaneous emergency lifesaving treatment with definitive diagnosis of injuries. Thus, uncontrolled hemorrhage is contained, and the patient is allowed to stabilize and return to the operating room for definitive correction of major injuries when he or she is sufficiently stable to undergo lengthy surgical re-

TABLE 70–5.

Regional Anesthesia

Type of Regional Anesthesia	Purpose of Block
Pure regional anesthesia	Useful for isolated injuries, e.g., hand injury, ankle fractures
Combination regional/general anesthesia	Reduced brain response to injury stimulation plus controlled ventilation
Continuous regional blocks	Supplement general anesthesia to reduce neurohumoral response to injury plus postoperative pain
Peripheral nerve blocks (single-dose and continuous catheter nerve blocks)	Alternative to neuraxial block, less risk in coagulopathic/anticoagulated patient

pair. This avoids the often fatal triad of ongoing massive transfusion—hypothermia, coagulopathy, and persistent metabolic acidosis—while the surgeon struggles to débride and repair massive liver lacerations or other extensive intraabdominal organ injury during the initial operation.[29,51]

The anesthesia team must continually monitor fluid replacement and the effectiveness of resuscitation efforts by tracking the status of metabolic acidosis during damage control surgery. General anesthesia, including neuromuscular blockade to facilitate surgery, and judicious use of analgesic and hypnotic drugs (either inhalation or intravenous), as tolerated by the patient, are required for damage control surgery. These patients require controlled ventilation, large-bore intravenous access (infusion into both the superior and inferior vena cavae systems is recommended), and direct monitoring and control of blood pressure (with an intraarterial catheter used also for blood sampling), core temperature, and urinary output. Maintenance of body temperature and/or rewarming requires keeping the room temperature >72°F (>22°C), as well as use of hot air convective body warmers and fluid warming devices. Following initial damage control surgery, these patients will be managed with heavy sedation and/or neuromuscular blockade in the postoperative ICU phase. Therefore, the anesthetic plan should incorporate transportation from operating room to ICU, with the patient remaining intubated and fully monitored during transport.

Head and Spinal Cord Injuries

Head injuries lead to increased mortality and morbidity in victims of both blunt and penetrating trauma. Therapeutic goals for patients with central nervous system (CNS) injuries are designed to minimize the amount of injured tissue, prevent secondary CNS injury, and facilitate rehabilitation and recovery. The critical points in head injury resuscitation are maintaining adequate perfusion pressure and preventing hypoxia and hyperglycemia. Cerebral perfusion pressure (CPP), which is the mean arterial pressure minus the intracranial pressure (ICP), is recognized as a more important parameter to monitor than ICP alone.[52] This is because an increased ICP is deleterious to trauma victims by reducing nutrient blood flow perfusing the brain. As the high ICP obstructs cerebral perfusion, ischemia develops, and regions of the brain may suffer necrosis.[53,54] Maintaining CPP >70 mm Hg provides sufficient pressure for perfusion through arteries partially obstructed by elevated ICP and prevents ischemia. Evidence indicates that even CPP >60 mm Hg may be adequate to prevent secondary brain injury. Loss of adequate CPP, usually resulting from arterial hypotension, is one of the more ominous events in the early treatment of head injury. Thus, anesthesia induction should be planned and implemented to minimize hypotension. Ketamine, an antagonist of the *N*-methyl-D-aspartate (NMDA) receptors associated with secondary brain injury, is being investigated as a potential neuroprotective anesthetic for head injury.[55] Some investigations have shown that the *S*-isomer has neuroregenerative properties,[56] although this form remains unavailable for clinical use in the United States. Ketamine tends to elevate ICP in normovolemic patients, but this effect is unlikely in those who are hypovolemic (studies in animals confirm this concept). Thus, ketamine is being reevaluated as an induction agent for patients with traumatic brain injury. The combination of NMDA antagonism produced by ketamine and γ-aminobutyric acid agonism produced by propofol is particularly appealing from a theoretical viewpoint in the anesthetic management of traumatic brain injury.

Hypoxia is deleterious to all organs and tissues, although the brain is relatively resistant to arterial hypoxia if perfusion is well maintained to clear the toxic byproducts of anaerobic metabolism from the brain.[57] The patient with traumatic brain injury and multisystem trauma may become hypoxic because of chest trauma or $\dot{V}/\dot{Q}$ mismatch; therefore, it is imperative to prevent hypotension and maintain CPP to allow the brain to tolerate the period of hypoxia. Hypotension is treated with pressors and fluid loading because hypovolemia rapidly leads to hypotension and loss of adequate CPP, leaving the injured brain starved for blood flow. Although the past dogma for treating traumatic brain injury emphasized induced dehydration through aggressive diuresis in an attempt to extract water from edematous regions of the injured brain, little was achieved except a vicious circle of positive feedback with cerebral ischemia leading to higher ICP and further diuresis to dehydrate the patient, which in turn caused worsening ischemia and further increases in ICP and so on until brain death occurred.

The concept of reducing ICP as another method of enhancing cerebral perfusion remains viable. Reduction of ICP usually involves draining cerebrospinal fluid through a ventriculostomy catheter. Other methods for reducing ICP, such as diuretics, barbiturates, or extreme hyperventilation to reduce intracerebral blood volume, may be poorly tolerated in trauma patients and must be used with caution. Mannitol has a long tradition as an emergency drug used to reduce ICP and is well tolerated in moderate doses. Drugs that increase mean arterial pressure will help restore perfusion to the noninjured brain and possibly help reduce the size of the injury. The future will see the development of anesthesia strategies for reducing secondary brain injury from excitatory neurotransmitters; the earlier discussion regarding ketamine and propofol is an example of these potential strategies.

Spinal Cord Injuries

The general principles of anesthetic management described for patients with traumatic brain injury also apply to the care of patients with spinal cord injury. However, in addition there are significant concerns about mechanical injury from movement of the cervical, thoracic, or lumbar spine, depending on the site of injury. Stabilizing the spine is critical to preventing additional injury to the spinal cord and to fostering potential healing of spinal cord lesions. A short (48-hour) course of steroids usually is administered to patients with "incomplete" spinal cord injuries to reduce peri-injury edema and in theory to promote reperfusion and healing of injured spinal cord tissue.

Anesthesia management of patients with potential spinal cord injury can be challenging because of the critical need to prevent motion of the spine. It is during airway management when the anesthesiologist has perhaps the highest probability of extending the injury. Most maneuvers used to secure a patent airway with either an oral airway or an endotracheal tube are associated with some motion of the cervical vertebrae.[58] There are

several recommendations for stabilizing the cervical spine during anesthesia induction and endotracheal intubation. These maneuvers vary from awake fiberoptic intubation to direct laryngoscopy controlled by manual inline axial stabilization (Fig. 70–3 and Box 70–3). The anesthesiologist's decision on the technique to use depends on the stability of the fracture and the urgency of airway management.[58] (Details of airway management are presented in Chapter 35 the guiding principles that apply to patients with head or spine injuries are discussed here.)

Unstable fractures with disruption of both anterior and posterior elements of the spine require more caution in choice of intubation method, especially in patients with fracture but no spinal cord injury or in those with incomplete injury. A flexible fiberoptic bronchoscope can be used to direct the endotracheal tube through the larynx with minimal movement of the cervical spine. However, the fiberoptic bronchoscope is vulnerable to blood or secretions that obscure the operator's vision and render intubation very difficult. Direct laryngoscopy provides better vision in patients with copious bloody secretions but frequently causes an obligatory extension of the upper cervical vertebrae, even with application of manual inline axial stabilization. Indirect fiberoptic laryngoscopes (e.g., Bullard, Wu, or Upsher scope) often can expose the larynx with little to no motion of the cervical vertebrae. Other techniques, such as intubating laryngeal mask airway and transtracheal retrograde wire technique, have been used with generally good results.

Although blind nasal intubation once was the technique of choice for injured patients with cervical spine fracture, it has several drawbacks in patients with acute trauma. Achievement of blind nasal intubation requires a spontaneously breathing patient, and adequate sedation for this procedure is difficult to achieve without depressing respiration and thus adding to the potential for hypoxemia or hypotension. In contrast, inadequate sedation or analgesia may result in excess cervical motion in a patient who actively resists the painful procedure. Acute head injury associated with blunt trauma presents additional risks for blind nasal intubation, with the potential for introduction of a foreign body (endotracheal tube) through a basilar skull fracture that extends into the nasopharynx as well as increased risks of a serious sinus infection that may spread into meningitis. For these reasons, nasal tracheal intubation is reserved for patients who require intraoral surgery and postoperative intramaxillary fixation. In these cases, a controlled nasotracheal intubation guided by a fiberoptic bronchoscope is preferable to a blind nasal intubation. The patient with maxillofacial fractures and traumatic brain injury who will require prolonged ventilatory support will be best served by preoperative controlled tracheostomy for ongoing airway management.

Anesthetic drugs that aid awake/sedated intubation include midazolam, fentanyl, ketamine, lidocaine (topical and nerve blocks), and dexmedetomidine. Blocks of the superior laryngeal nerve and/or transtracheal injection of local anesthetic render the patient's upper airway insensate and reduces the need for systemic sedation. Generous amounts of 5% lidocaine ointment

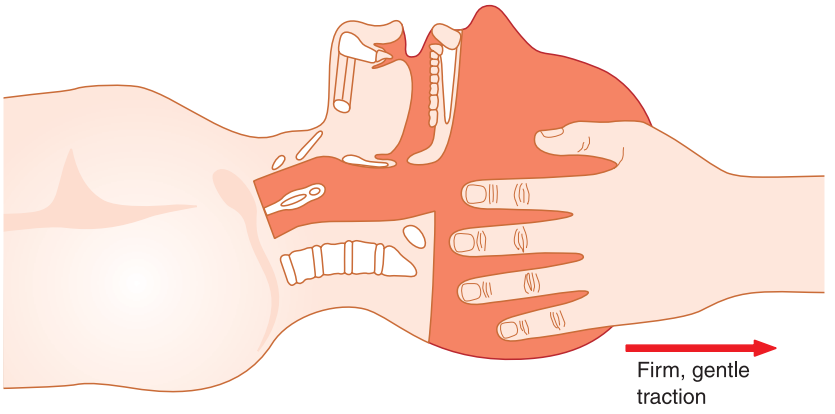

FIGURE 70–3. Manual inline axial stabilization (MIAS) applied for immobilization of the cervical spine during endotracheal intubation. (From Grande CM, Smith CE, Stene JK. Trauma anesthesia. BOX 70–3.

Modified Rapid Sequence Induction and Intubation for Trauma Patients

1. Be familiar with evaluation of the difficult airway and the American Society of Anesthesiologists practice guidelines for management of the difficult airway.
2. Be familiar with noninvasive and invasive techniques of airway management.
3. Evaluate the airway and be prepared to execute multiple contingency plans.
4. Preoxygenate the patient with 100% O_2 by face mask.
5. Remove anterior portion of the cervical spine collar and apply manual inline axial stabilization of the head and neck if suspected cervical spine injury.
6. Give appropriate medications IV, as indicated by the clinical setting and hemodynamic status:
   - Lidocaine 1.5 mg/kg if suspected head injury
   - Sedative–hypnotics (see Table 70–4)
   - Muscle relaxants (see Table 70–4)
7. Apply cricoid pressure until intubation is completed.
8. Manually ventilate the patients' lungs with 100% O_2 using inflation pressures <20 cm H_2O to prevent (or treat) hypoxemia and hypercarbia before (or between) intubation attempt(s). Continue cricoid pressure during bag-mask ventilation.
9. Confirm correct position of endotracheal tube by visualizing tube passing through cords, sustained presence of end-tidal CO_2, auscultation of breath sounds, and self-inflating bulb
10. After successful intubation, administer additional increments of sedative–hypnotics and analgesics or begin a potent volatile agent, as dictated by clinical need. Consider using a longer-acting relaxant once the effects of succinylcholine, if used, have worn off.

coating an oral airway has been used successfully to provide topical anesthesia to the pharynx and upper airway, as has aerosolized lidocaine breathed by the patient for several minutes prior to initiation of the intubation procedure. Benzocaine sprays also have been used to topically numb the upper airway but are associated with the risk of methemoglobinemia.

Dexmedetomidine, an α_2-agonist, provides sedation and analgesia without respiratory depression and is an attractive choice for sedation prior to awake intubation. However, it has a relatively long half-life and requires some infusion time to achieve steady-state blood levels. Boluses have been used to shorten the time to adequate sedation but are associated with an increased risk of bradycardia, hypotension, and/or hypertension. Dexmedetomidine is especially useful for patients who will undergo neuromonitoring with evoked potentials because a continuous infusion will potentiate propofol and opioids but will not affect the quality of the electroencephalographic response. Thus, a dexmedetomidine infusion used for sedation during intubation can be continued through the entire anesthetic.

After anesthesia induction, the fractured spine must be carefully immobilized during other patient movements, such as transfer to the operating table. Patients who must be placed in the prone position need special care to prevent flexing or extending the spine during turning, and a neurosurgeon or orthopedic surgeon should supervise this procedure. Following stabilization surgery, patients are less vulnerable to spine motion when being transferred out of the operating room. However, they still will require external stabilization during patient movements throughout the period of bone fracture healing.

Airway Injuries

The true incidence of airway injury is unknown because many patients with such injuries presumably die at the accident scene or during transport, but airway injuries present one of the greatest of challenges for trauma anesthesia care. Airway injuries may dramatically complicate the preoperative preparation and anesthetic induction of trauma patients. These injuries often require extreme measures of ingenuity and innovation on the part of the anesthesiologist to safely manage a patient with an airway injury for emergency surgery; the situation represents a continuous high risk until the airway is secured. Although in most cases intubation via the mouth or nose is recommended, upper airway injuries associated with disruption of laryngeal cartilage may be best treated with primary tracheostomy. However, in truly emergent situations of ventilatory distress, translaryngeal intubation with a small endotracheal tube can be lifesaving and support the patient's ventilation during subsequent tracheostomy.

An initial triage assessment that assigns patients with airway injuries into relative categories of "stable" or "unstable" is important because it facilitates subsequent evaluation and management planning. In patients who are stable, obtaining imaging studies that elucidate the site (i.e., tracheobronchial level) and extent of injury to the airway will allow more comprehensive anesthetic management and formulation of a treatment plan in concert with surgical colleagues.

In urgent situations that include suspected injuries to the trachea, intubation with a fiberoptic bronchoscope may allow inspection of tracheal integrity as well as assist in guiding an endotracheal tube into position. A majority (approximately 80%) of blunt tracheobronchial lacerations occur within 1 cm of the carina, and fiberoptic bronchoscopy can easily view most of these lacerations. Clinical signs of tracheal or bronchial lacerations include pneumomediastinum, subcutaneous emphysema, pneumothorax, and persistent air leak.

In less urgent presentations, serious consideration should be given to full bronchoscopic examination of the tracheal bronchial tree of patients who suffered blunt chest trauma and have a persistent air leak.

Although chest trauma potentially compromises a patient's ventilation and hemodynamic status, the vast majority of chest injuries are managed outside of the operating room. However, the anesthesiologist must be familiar with devices used for chest tube drainage and management, because many patients with chest trauma and hemothorax or pneumothorax require operative care of other injuries.

Long Bone and Pelvic Fractures

Fat embolism is a potential cause of respiratory compromise in patients with major lower extremity or pelvic fractures. The full fat embolism syndrome starts with respiratory failure and then proceeds to a diffuse distribution of petechia and neurologic dysfunction. Release of bone marrow contents from long bone and pelvic fractures first affects pulmonary gas exchange and then leads to systemic manifestations, multiple cutaneous hemorrhages, and cerebral dysfunction. Fat globules can be found in the urine and observed in retinal blood vessels. Early fracture fixation with hardware combined with intubation and mechanical ventilation prevents continued leaching of marrow fat into the venous and pulmonary circulation and reverses pulmonary dysfunction from fat emboli before the full syndrome develops.[59] Fat released into the venous circulation from fractures through the marrow compartments of long bones also releases mediators that react with pulmonary blood vessels, leading to $\dot{V}/\dot{Q}$ mismatching and hypoxia. These injuries, especially pelvic fractures, cause major hemorrhage and ongoing blood loss. Although closed fractures can be stabilized and treated with bed rest, open fractures require prompt operative intervention, preferably within 6 hours of injury. Patients with blunt trauma often will require multiple trips to the operating room for debriding of contaminated open fractures as well as operative stabilization of complex highly comminuted fractures, so their management commonly involves multiple frequent anesthetics.

Patients with blunt trauma and multiple systems injuries have improved outcomes with early operative fixation of fractures. Prolonged bed rest with femur traction is associated with increased risk of both pneumonia and venous thromboembolic disease. Additionally, stabilizing long bone fractures seems to reduce the risk of fat embolization by minimizing motion of the fracture site. Although the incidence of fat embolism varies based on multiple considerations (location, extent of injury, comorbidities, medications, etc.), mortality from fat embolism remains high and is a serious threat that must be guarded against and managed aggressively.

Arterial blood gases of patients with long bone fractures should be measured following hospital admission. Patients with hypoxia (low Pao_2/FiO_2

ratio) should be intubated and mechanically ventilated. These patients should be monitored with an arterial catheter ("a-line") during anesthesia and surgery to facilitate measurements of blood gases. Patients with a low Pao_2/FiO_2 ratio should remain intubated and ventilated in the ICU postoperatively.

Abdominal Compartment Syndrome

Critical care observation has demonstrated the importance of increased intraabdominal pressure in the genesis of multiorgan failure, including acute respiratory distress syndrome.[60] Intraabdominal pressure is monitored by measuring the pressure in the urinary bladder after instillation of 50 mL of saline. Classically, intraabdominal pressure >40 mm Hg has been called *abdominal compartment syndrome.* This syndrome is associated with increased ventilatory pressure to expand the lungs adequately and with oliguria, as the high pressure compresses the renal veins (thus decreasing renal perfusion) and possibly the ureters as well. Evidence indicates that intraabdominal pressures as low as 20 mm Hg may be associated with the systemic inflammatory response syndrome and multiorgan failure. Left unchecked, high intraabdominal pressure is associated with release of inflammatory mediators from the relatively ischemic intestines and subsequent development of multiple organ failure.

Patients with abdominal compartment syndrome require urgent surgical decompression to relieve the tension and to allow improved parenchymal blood flow and restoration of renal function. Continuous neuromuscular blockade can relax the abdominal wall and reduce mild increases in intraabdominal pressure. More persistent and serious increases will require surgical intervention. Relief of increased intraabdominal pressure also allows improved ventilation because motion of the diaphragm is no longer impeded.

CONCLUSION

Trauma patients present the anesthesiologist with many clinical challenges because of the varied nature of traumatic injury. Although no two injuries are exactly alike, traumatic injury causes a characteristic physiologic and metabolic response usually recognized as hemorrhagic shock. Without resuscitation within the "golden hour," posttraumatic hemorrhagic shock leads to cellular hypoxia and irreversible organ ischemia. Although excess fluid administration prior to surgical hemostasis can lead to further uncontrolled hemorrhage, administering some fluid resuscitation in the "golden hour" is critical. Head-injured patients require somewhat higher blood pressure than do patients who are not head injured. Because CPP of 60 mm Hg may be adequate to maintain perfusion following head injuries, a target mean arterial pressure of 80 mm Hg prior to surgical hemostasis should provide adequate cerebral perfusion, assuming an ICP of 20 mm Hg.

Airway management presents special challenges in trauma patients, especially in those with potential cervical spine injury and/or airway injury. Modified rapid sequence intubation with cricoid pressure, gentle mask ventilation before oral intubation, and manual inline spine stabilization is the technique of choice for most trauma patients.

Metabolic management of the trauma patient includes aggressive rewarming and maintenance of normothermia, maintenance of a euglycemic state, and prevention of base deficit.

CHAPTER 71

Anesthetic Management of the Burned Patient

Edward A. Bittner, MD, PhD, Loreta Grecu, MD, and J.A. Jeevendra Martyn, MD, FCCM

Major burn injury results in pathophysiologic changes in most organ systems. The perioperative care of burn patients requires knowledge of these changes from the initial injury until wounds have been covered and healed. Patients suffering from burn injuries often require surgical treatment for years following their initial injury.

PREOPERATIVE EVALUATION

Patients are often brought to the operating room in the early phase of burn injury, when they are undergoing significant fluid shifts, with cardiovascular instability and/or respiratory insufficiency. The most frequently performed surgical procedure is excision and grafting of the burned area. Other procedures that may be required during their hospital stay include escharotomies, tracheostomy, and exploratory procedures related to accompanying trauma. During this time, the postburn physiology is not optimal for maintenance of normal homeostasis. Nevertheless, attempt should be made to optimize organ function. The physiologic and psychological changes resulting from burn injury must be taken into account in addition to the usual considerations for a patient undergoing anesthesia and surgery. Useful and important preoperative information include the time and extent of burn injury, coexisting medical problems, medications, drug allergies, problems with anesthetics and family anesthetic history and NPO status (Table 71–1). In addition, the anesthesiologist must be cognizant of the problems unique to burn patients including altered responses to anesthetics and muscle relaxants, difficulties with airway management, altered ventilatory status, difficult intravascular access and monitoring, positioning, potentially significant transfusion requirements and methods of safe transport to and from the operating room.

KEY POINTS

1. Major burn injury results in pathophysiologic changes in virtually all organ systems. The perioperative care of burn patients requires knowledge of these changes from the initial period of injury through the period until wounds have been covered and healed.
2. In patients with severe burn injury, massive heat loss can occur through the open wounds, making the maintenance of normothermia challenging. Multiple strategies are used to maintain body temperature in the operating room, including use of warming blankets, radiant warmers, blood/fluid warmers, and wrapping the head and extremities with plastic or thermal insulation.
3. Securing the endotracheal tube in a patient with facial burns can be difficult. It is essential to secure the endotracheal tube with a carefully secured tie harness to avoid the potential catastrophe of accidental extubation.
4. Use of cuffed endotracheal tubes in pediatric patients with significant burn injury is not unusual. Considerable fluctuations in airway diameter can occur throughout the patient's hospital course. With fluctuations in airway diameter, the endotracheal tubecuff should be adjusted to facilitate mechanical ventilation without a leak.
5. Because of their hypermetabolic state, oxygen consumption and CO_2 production can be significantly increased in patients with major burns. Consequently, the minute ventilation can exceed 20 L/min in an adult patient with a large burn. This large minute volume may exceed the capacity of some anesthesia machine ventilators; an ICU ventilator may be needed in the operating room.
6. Transport of a burn patient to and from the operating room can be a time of high risk. A systematic approach to maintenance of the patient's respiratory, hemodynamic, and general support helps insure patient safety. The need for continual observation by the anesthesia team during patient transport cannot be overemphasized.
7. Burn patients develop tolerance to most narcotics and sedatives thus requiring higher doses than for patients without thermal injury. Sedatives and narcotics should be titrated to effect while the patient is carefully monitored.
8. In burn patients, exposure to succinylcholine can result in an exaggerated hyperkalemic response that can induce cardiac arrest. The general recommendation is to avoid succinylcholine administration in patients 24 hours after burn injury. The duration of this dangerous response to succinylcholine is unknown.
9. Blood loss during burn wound excision can be deceptively large. It is not difficult for the surgical team to remove eschar so rapidly that the patient becomes hypovolemic and unstable. Good communication between the surgical and anesthesia teams as well as limiting the operative duration and extent of excision can prevent such problems.
10. Burn injury leads to increased susceptibility to infection through multiple mechanisms including loss of the physical barrier of intact skin, damage to lining of respiratory tract from inhalation, altered gut permeability and function. Maintaining strict aseptic technique both in the operating room and during transport is essential.
11. Nearly every aspect of treatment of burn injury is associated with pain. Poorly controlled pain and anxiety can have significant adverse physiologic and psychological effects. Standardized pain and anxiety guidelines have been used successfully to provide appropriate, consistent patient comfort.

PATHOPHYSIOLOGY OF BURNS

Effects on Cardiopulmonary Function

Hemodynamic function in the early burn period is characterized by a reduc-

tion in cardiac output, and an increase in systemic and pulmonary vascular resistance, possibly with pulmonary edema (see Chap. 77). These effects are the result of hypovolemia caused by increased vascular permeability, reduced cardiac contractility from reduced responsiveness to circulating catecholamines, and circulating myocardial depressant factors. Increased circulating catecholamines, histamine, serotonin, and thromboxane lead to increased vascular resistance. Early and adequate fluid resuscitation is the hallmark of successful early burn management. Approximately 3–5 days after major burn injury, a hyperdynamic and hypermetabolic state occurs, with tachycardia, increased stroke volume, hyperthermia, and increased protein catabolism.

Pulmonary dysfunction after burn injury can be caused by increased pulmonary vascular permeability, and increased airway reactivity. Inhalational injury may lead to upper airway swelling, toxicity from carbon monoxide (CO) and other combustion products, and direct injury to the lower respiratory tract from inhaled chemicals. Pulmonary function may further worsen days later as a consequence of sloughing of bronchial mucosa, impaired clearance of secretions, and development of pneumonia.[1]

Effects on Renal Function

The incidence of acute renal failure (ARF) in burn patients has been reported to range from 1–30% with mortality exceeding 70% in the presence of renal failure.[2,3] Acute renal failure in burn patients can be categorized as early (within first few days of injury) or late. The early stage of ARF is related to hypovolemia, low cardiac output, and systemic vasoconstrictive effects and/or myoglobinuria. Elevated stress hormones, catecholamines, angiotensin, aldosterone, and vasopressin have also been implicated in the pathogenesis of ARF. Early, appropriate fluid resuscitation has decreased the incidence of early ARF. Patients with large, deep burns and those with electrical injury are at increased risk. Late ARF has a more complicated pathogenesis and is usually related to sepsis, multisystem organ failure, or the effects of nephrotoxic drugs. It is reported more frequently in patients with inhalational injury.

Factors associated with decreased incidence of ARF include early adequate fluid resuscitation, early wound excision, and prevention and treatment of infection.[4] Assessing renal function in burn patients is essential to the development of a comprehensive anesthetic plan. During the hyperdynamic period, renal blood flow and glomerular filtration rate increase, both of which are related to the increased cardiac output in response to the hypermetabolic phase (Table 71–2).

THERMOREGULATION

In addition to conductive and convective heat loss, considerable evaporative heat loss can occur through the open wounds, making maintenance of normothermia challenging. This is especially true during transport to and from the operating room. Patients should be covered with warm blankets during transport. Children have greater surface-area-to-body-weight ratios, resulting in more rapid heat loss. Temperature of the environment should be maintained at above-normal levels.

Burn patients, if given a thermostat, will set their environmental temperature higher than normal.[5] Multiple strategies are used to maintain body temperature in the operating room, including use of warming blankets, radiant warmers, blood/fluid warmers, and wrapping the head and extremities with plastic or thermal insulation. Temperature in the operating room is commonly maintained at 90–100°F (32.2–37.8°C), depending on the age and severity of the burn. Although a hot operating room can be uncomfortable for the medical staff, maintaining the patient's temperature is essential to minimize metabolic demand, maintain normal coagulation, and prevent shivering on emergence. The latter issue has the potential to dislodge recently placed grafts.

SURGICAL MANAGEMENT

Early excision of dead tissue and closure of burn wounds are the greatest advance in management of patients with severe burns during the last two decades. Early excision and closure results in decreased metabolic rate, incidence of sepsis, and pain. In addition, early surgical therapy before extensive bacterial colonization, may decrease operative bleeding and transfusion requirements.[6]

At present, most full-thickness burn wounds are best closed with split-thickness autografts. Nonetheless, the split-thickness autograft is an imperfect replacement for full-thickness skin, and harvesting of normal skin is associated with pain and donor-site morbidity.[7] Consequently skin substitutes, either temporary or permanent may be needed. Temporary skin substitutes provide transient physiologic wound closure providing protection from mechanical trauma, minimizing evaporative water and heat losses, and acting as a physical barrier to bacteria. These skin substitutes can also be used as a dressing on donor sites to decrease pain, enhance epithelialization, and to provide temporary closure while awaiting healing of underlying, widely meshed autografts. These skin substitutes can also be used as a "test" graft in questionable wound beds. No ideal permanent skin substitute exists at present, although a number of techniques are in use, including cultured epithelial cells and dermal analogues.[7,8]

ANESTHETIC MANAGEMENT

Airway Management

If injuries allow standard airway management (mask fit, mouth opening, neck extension), direct laryngoscopy and intubation can be performed. Gastric emptying may or may not be delayed in burn patients.[9]

If bowel sounds are present and there is no ileus, rapid sequence induction may not be necessary. Infection/sepsis, edema, and opioids may slow

TABLE 71–2.

Systemic Effects of Burn Injury

System	Early	Late
Cardiovascular	Hypovolemia Impaired cardiac contractility Decreased cardiac output	Increased cardiac output Hypertension
Pulmonary	Upper/lower airway obstruction Bronchospasm Decreased pulmonary/chest wall compliance Complications of resuscitation (pulmonary edema)	Complications of ventilation (pneumonia, barotrauma) Tracheal stenosis
Renal	Decreased renal blood flow/function Myoglobinuria	Increased renal blood flow
Hepatic	Impaired function as a result of decreased circulation, blood volume, hypoxia, hepatotoxins	Altered function as a result of hypermetabolism, increased cardiac output, enzyme induction Hepatic steatosis
Hematologic	Hemoconcentration Hemolysis Activation of fibrinolytic and thrombotic systems	Anemia Low platelets or clotting factors
Neurologic	Encephalopathy Seizures Acute pain	Encephalopathy ICU psychosis Chronic pain
Metabolic	Increased metabolic rate Impaired thermoregulation Hypocalcemia	Increased O_2 consumption and CO_2 production
Skin	Increased heat and fluid losses	Contractures, scar formation
Gastrointestinal	Stress ulceration (Curling ulcers) Impaired intestinal barrier function	
Pharmacologic	Altered volume of distribution Altered protein binding Altered pharmacokinetics and pharmacodynamics	Increased tolerance to sedatives, narcotics Enzyme induction, alteration of receptors Drug interactions

gastric emptying, which can result in increased risk of aspiration. Laryngeal mask airways (LMAs) have been used successfully in burn patients.[10] Use of the LMA for airway management may help avoid further laryngeal injury associated with tracheal intubation. It can also serve as an aid to fiberoptic intubation.

Securing the endotracheal tube in a patient with facial burns can be difficult. Tape or ties crossing burned areas can irritate the wound or cause graft injury. It is essential to secure the endotracheal tube with a carefully secured tie harness (Fig. 71–1) to avoid unintentional extubation. Placement of a circumferential tie around the patient's head, using wire to secure the tube to a tooth, or use of arch bars can provide safe fixation.[11,12]

Use of cuffed endotracheal tubes in pediatric patients with significant burn injury is not unusual. Use of cuffed endotracheal tubes (ETTs) in the pediatric population, both in the operating room and in the intensive care unit, is

FIGURE 71–1. Photo of secured endotracheal tube. It is essential to secure the endotracheal tube with a carefully secured tie harness to avoid accidental extubation.

safe.[13,14] In the younger age group, considerable fluctuations in airway diameter can occur throughout the patient's hospital course, with narrowing of the airway during the acute resuscitation phase because of laryngeal and bronchial tissue edema. With fluctuations in airway diameter, the ETT cuff should be adjusted to facilitate mechanical ventilation without a leak. The proper timing and indication of tracheostomy in burn patients remains controversial. Early studies of tracheostomy reported complications to be more frequent and severe in burn patients.[15–19] Several factors contribute to the complications, particularly when tracheostomies are performed through burned tissue or in the presence of edema. The tracheal stoma allows the passage of secretions from the wound areas to the lungs leading to pneumonia. Tracheostomy however, can be helpful particularly when weaning from mechanical ventilation is difficult or when thick secretions require frequent pulmonary toilet. Ideally, the tracheostomy is performed under controlled conditions with the patient adequately anesthetized and positioned. Resolution of neck edema and absence of burns over the planned tracheostomy site are preferable. Recent reports examining the use of tracheostomy in severely burned children indicate that tracheostomy is appropriate.[20,21] Palmieri et al., in a case series of 38 severely burned pediatric patients undergoing early tracheostomy, found no tracheal site infections, tracheostomy-related deaths, or tracheal stenoses.[22]

Vascular Access

Managing vascular access in burn patients can be difficult. In the setting of acute burn injury, patients can be hypovolemic, making venous access technically difficult. In addition, the typical vascular access sites can be involved in the burn injury. In pediatric patients, the task can be even more difficult. Central venous access is usually necessary in patients with large burn injuries. Because burn patients undergo multiple surgical procedures during their hospitalization, access is required multiple times. Furthermore, frequent catheter changes are often performed to minimize the risk of catheter-related sepsis. The sites of these lines can be rotated. Localization of vessels using ultrasonography guidance can be useful in placing peripheral and central catheters in patients when access is difficult.[23] For excision and grafting procedures, securing adequate vascular access before the surgical procedure begins is necessary as blood loss can be rapid and substantial.

Ventilatory Management

Respiratory failure is common after serious burns caused by inhalation injury, inflammatory mediators from the burn, effects of fluid resuscitation, and infection. In providing mechanical ventilation, care must be exercised to provide adequate oxygenation and ventilation without inducing further morbidity from oxygen toxicity, hemodynamic compromise, barotrauma or alveolar overdistension. A growing appreciation of the effects of ventilator-related morbidity has triggered a search for the optimum strategy for mechanical ventilation for critically ill patients with respiratory failure. The ARDS Net trial was the first large randomized study demonstrating a reduction in mortality with the use of lower tidal volumes in patients with acute respiratory distress syndrome (ARDS).[24] The strength of their findings has changed ventilatory strategies and is becoming the standard of care for burn patients with acute lung injury. The empiric use of a tidal volume of 6 mL/kg ideal body weight and plateau airway pressure below 30 cm H_2O are recommended in all patients with acute lung injury. Furthermore, lower tidal volume ventilation may decrease the incidence of the development of acute lung injury that develops after the initiation of mechanical ventilation.[25] In the ARDS Network trial, positive end-expiratory pressure (PEEP) was assigned on the basis of the requirement for inspired oxygen concentration (FiO_2); in the low-tidal-volume group, the average PEEP was 9 cm H_2O. Although the assessment of optimal PEEP is still a topic of ongoing investigation, in patients with refractory hypoxemia, trial of high PEEP may be useful.

Permissive hypercapnia is a common consequence of low-tidal-volume ventilation because of decreased minute ventilation and an increased dead-space-to-tidal-volume ratio. Permissive hypercapnia is an acceptable side effect of lung-protective ventilation and is associated with excellent outcomes in burn patients.[26] Contraindications to permissive hypercapnia include predisposition to increased intracranial pressure and hemodynamic instability.

Because of their hypermetabolic state, oxygen consumption and CO_2 production can be significantly increased in patients with major burns. Consequently, the minute ventilation can exceed 20 L/min in an adult patient with a large burn. This large minute volume may exceed the capacity of some anesthesia machine ventilators; an ICU ventilator may be needed in the operating room.

Extensive excision and grafting procedures may cause such a physiologic change that postoperative mechanical ventilation is needed. The decision to wean from mechanical ventilation and extubate after burn surgery is based on the same considerations as in the non-burn patient. Weaning is not performed in the presence of hemodynamic instability, significant metabolic derangement, hypothermia, sepsis or worsening pulmonary function. In addition, in these patients assessment of the status of airway edema is essential.

High-frequency percussive ventilation is a newer ventilatory strategy that combines features of conventional ventilation with jet ventilation. Standard pressure-controlled breaths (10–30 breaths/min) are superimposed on high-frequency delivery of breaths (200–600 breaths/min) adding a percussive element to conventional pressure control ventilation.[27] Theoretical advantages include better mobilization of airway secretions and provision of gas exchange at lower airway pressures. Studies show improvements in oxygenation and rate of pneumonia with decreased work of breathing and lower airway pressures. This method seems particularly effective in patients with inhalational injury.[28–31]

Monitoring

As with any patient suffering from multiorgan system dysfunction, monitoring of a burn patient depends on the patient's physiologic status and extent of planned surgery.

Difficulty may be encountered in adherence of standard electrocardiogram (ECG) electrodes to the skin of burn patients as a result of exudation of fluid from the injured sites or of the presence of topical antibiotic ointment. Use of needle electrodes or surgical staples over skin to fix the electrodes can be effective. Alternatively, placing the electrodes on the

back or dependent sites may hold them in place.

Application of pulse oximetry probes can also be difficult when standard sites are burned or within the surgical field. Alternative sites, such as the ear, nose, or tongue, can be used in such circumstances. Reflectance oximetry has been suggested as an alternative if skin sites for monitoring are limited.[32]

In an extensively burned patient, a blood pressure cuff may have to be placed directly over injured or recently grafted tissue. In these cases, great care should be taken to protect the underlying area and the cuff should be sterile before application. If blood loss is expected to be rapid and extensive, an arterial line should be placed for continuous and direct measurement of blood pressure and blood sampling. An arterial catheter provides easy access for repeated measurements of blood gases, electrolytes, and hemoglobin. In addition, the arterial pressure waveform and its alterations in relation to respiration provide continuous hemodynamic information about preload and cardiac output and can be used to guide volume and vasoactive therapy.[33] Insertion of invasive monitors through burned tissue is sometimes necessary. Temperature monitoring is important as burned patients are quite prone to hypothermia, which carries its own morbidity.

Neuromuscular function monitoring in patients receiving neuromuscular blocking drugs is required as dose requirements can be significantly altered in burn patients.

In patients with more severe burns, a central venous catheter may be helpful for administration of blood and fluid, vasoactive medications, and monitoring. Although blood sampled from a central venous catheter provides central venous and not mixed venous oxygen content, this value may be helpful in assessing adequacy of tissue perfusion. Furthermore, central venous pressure may provide additional information on the status of intravascular volume. Central pressures should be interpreted carefully as PEEP, pleural, or pericardial fluid and abdominal distension can effect measured pressures. More recently esophageal Doppler monitoring (Cardio Q™, Deltex Medical Ltd., Chichester, UK) has been used to monitor cardiac output in burn patients undergoing early burn wound excision.[34] However its use is not routine.

Patient Transport

Transport of a burn patient to and from the operating room can be a time of increased risk. A systematic approach to maintenance of the patient's respiratory, hemodynamic, and general support will optimize patient safety. Continual observation by the anesthesia team during patient transport is required. In patients with major burns who require mechanical ventilation, at least two anesthesia personnel are required to manage ventilation, observe the monitors, and administer medications during transport.

Providing adequate sedation and analgesia is essential before moving patients to or from the bed or operating room. Intravenous narcotics and benzodiazepines are often used in combination to provide analgesia and sedation. Burn patients develop tolerance to most narcotics and sedatives thus requiring higher doses than for patients without thermal injury. Sedatives and narcotics should be titrated to effect while the patient is monitored.

PHARMACOLOGIC CONSIDERATIONS

Clinical Pharmacology

Burn injury causes pathophysiologic changes in the cardiovascular, pulmonary, renal, and hepatic systems, as well as concentrations of circulating plasma proteins. These changes result in altered pharmacokinetic and pharmacodynamic responses to drugs. Consequently changes in the usual dosages of drugs may be necessary to ensure efficacy or avoid toxicity.

There are two distinct phases of metabolic response to burn injury that affect pharmacokinetics in different ways. During the acute injury phase (0–72 hours) there is rapid loss of fluid from the intravascular space, resulting in decreased cardiac output and blood flow to organs and tissues. Fluid resuscitation during this phase dilutes plasma proteins and expands the intravascular volume. Despite adequate resuscitation, patients may continue to have decreased cardiac output. Decreased renal and hepatic blood flow reduces drug elimination by these organs. Following the resuscitation phase, the hypermetabolic, hyperdynamic phase begins, which is characterized by increased cardiac output, oxygen consumption, and temperature. Because increased blood flow to the kidneys and liver may increase drug clearance, drug doses may have to be adjusted.

Plasma protein concentrations are altered in the resuscitation and hypermetabolic phases of burn injury. The two major drug-binding proteins, albumin and α_1-acid glycoprotein (AAG), have different responses to burn injury. Albumin binds to mostly acidic and neutral drugs and is decreased in burn injury.[35] AAG is an acute-phase reactant and its concentration may double after an acute burn. Cationic drugs (lidocaine, propranolol, muscle relaxants, and some opioids) bind to AAG, resulting in decreases in free fraction.

Hepatic clearance of drugs highly extracted by the liver depends primarily on hepatic blood flow and is relatively insensitive to alterations in protein binding. Clearance of these drugs may decrease during the early postburn phase as a result of hypoperfusion from hypovolemia and hypotension. Similarly, clearance of these drugs may increase during the hyperdynamic phase when hepatic blood flow increases (e.g., fentanyl).[36] In contrast, clearance of drugs that have a low hepatic extraction coefficient is unaffected by changes in hepatic blood flow, but is sensitive to alterations in plasma protein levels as it is the unbound fraction of drug that is metabolized. Hepatic clearance of drugs with low extraction coefficients is also sensitive to alterations in hepatic enzyme activity. Hepatic enzyme activity appears to be altered in patients with burns.[37] Phase I reactions, which include oxidation, reduction, hydroxylation, and demethylation, are impaired in burn patients. Phase II reactions involve conjugation and seem to be relatively unaffected.[38] Other excretion pathways may result in altered drug clearance. Thus some antibiotics and H_2-receptor antagonists will have enhanced clearance because of increased renal blood flow and glomerular filtration rate.[39,40] Additionally, systemically administered drugs may leach out through the burn wound and blood loss during surgery can potentially exaggerate the elimination of drugs from the skin.

Muscle Relaxants

Muscle relaxant pharmacology is significantly altered after burn injury.[41]

In burn patients, exposure to succinylcholine can result in an exaggerated

hyperkalemic response, which can induce cardiac arrest. The general recommendation is to avoid succinylcholine administration in patients 24 hours after burn injury.[42,43] An increase in the number of extrajunctional acetylcholine receptors has been suggested as the mechanism for increased hyperkalemia after succinylcholine administration and decreased sensitivity to the effects of nondepolarizing muscle relaxants. The duration of this response to succinylcholine is unknown. However resistance to nondepolarizing relaxants was reported in a pediatric patient 463 days after burn injury, suggesting that the hyperkalemic response to succinylcholine could also persist for more than a year.[44] Although a hyperkalemic response to succinylcholine may be seen, whether lethal levels would be reached is unknown. Consequently, even in the treatment of laryngospasm, succinylcholine should be avoided. Whether extremely small doses (0.1 mg/kg) of succinylcholine will result in less hyperkalemia has been inadequately studied. Martyn and Ritchfield have reviewed this subject.[45] Nondepolarizing muscle relaxants are the relaxants of choice in burn patients.

Rocuronium or high doses of other nondepolarizing muscle relaxants can be used if rapid intubation is needed and one is confident that the patient can be ventilated. It must be remembered, however, that even with a dose of 1.2 mg/kg of rocuronium, the onset time to effective paralysis approximates 90 seconds in burn patients compared with < 60 seconds in nonburned patients.[46]

The dose of nondepolarizing muscle relaxant necessary to achieve paralysis in burn patients can be substantially elevated in a patient with burn injury. Studies with nondepolarizing muscle relaxants have demonstrated that resistance to the muscle relaxants is highly correlated with the magnitude of the burn (Figure 71–2). One study demonstrated the dose of *d*-tubocurarine and the serum concentration necessary to achieve a given degree of twitch depression was 3–5 times greater in patients with burn injury than in nonburn patients.[47] Studies with intermediate- and short-acting muscle relaxants have shown resistance to the neuromuscular effects of the drugs, but less pronounced than with long-acting relaxants. Pharmacologic reversal of neuromuscular blockade poses no special problems in patients with burn injury. Recovery of neuromuscular blockade has been observed at serum concentrations that would cause 100% twitch depression in nonburned patients.[47]

Anesthetic Agents

Many aesthetic agents have been used successfully for the induction and maintenance of anesthesia in burn patients. Choice of agent should be based on the patient's hemodynamic and pulmonary status and potential difficulty in securing the patient's airway. Because of its rapid onset and lack of pungency, sevoflurane offers advantages for smooth inhalational induction in children or adults with abnormal airways. The choice of volatile aesthetic does not appear to influence outcome in burn patients. All anesthetics cause dose-dependent depression of cardiac output.

Ketamine has many potential advantages for induction and maintenance of anesthesia in burn patients and is used by some centers as the primary anesthetic. Ketamine often is associated with hemodynamic stability, preserving hypoxic and hypercapnic responses, and decreasing airway resistance. Ketamine occasionally causes a hypotensive response, particularly in patients with major burns who have desensitized adrenocepters.[48] Ketamine may be the agent of choice if one wishes to avoid manipulation of the airway (e.g., after placement of fresh facial grafts, for brief procedures such as dressing changes or for patients with toxic epidermal necrolysis syndrome).[49] Ketamine can also be used as supplement to other anesthetics because of its effects as an analgesic acting via the *N*-methyl-D-aspartate (NMDA) receptor.[50] The major disadvantage of ketamine is production of dysphoria. The addition of benzodiazepines is often recommended to reduce the incidence of dysphoria. Because of the increased secretions associated with ketamine, glycopyrrolate is frequently coadministered.[50]

Regional anesthesia may have a role in burn surgery, either alone or in combination with general anesthesia, but is usually limited to patients with small burns. An epidural catheter offers the advantage of prolonged postoperative analgesia. Lumbar paravertebral blocks have been used successfully to manage postoperative pain from skin donor sites.[52] Patients with major burns may have multiple areas of injury or donor sites that cannot be easily blocked by a regional technique.

METABOLIC AND NUTRITIONAL MANAGEMENT

Severe burn injury results in a hypermetabolic response with profound

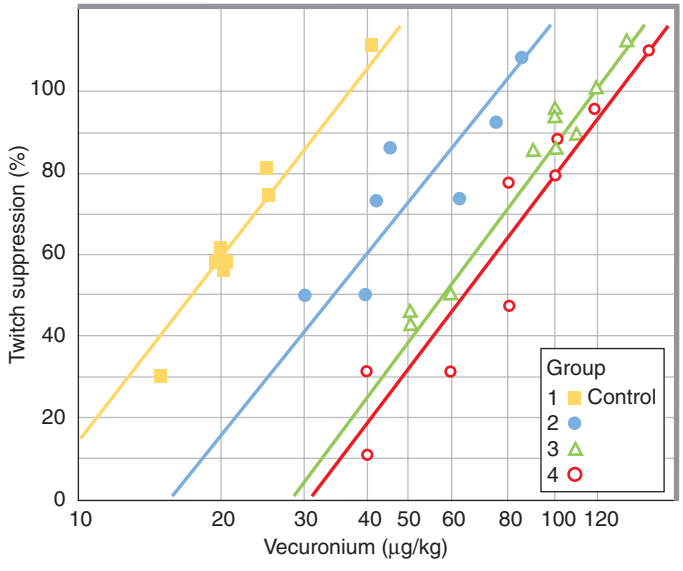

FIGURE 71–2. Dose–response curves for vecuronium in normal and burned children. Logarithm of dose versus twitch suppression for vecuronium in control subjects and burned children. With acute injury, the vecuronium effective dose values increased with increasing burn size. *Solid squares*, children without burn injury; *solid circles*, children with ‹40% burn injury; *open triangle*, children with 40–60% burn injury; *open circles*, children with ›60% burn injury. (Reproduced with permission from Mills AK, Martyn JAJ. Neuromuscular blockade with vecuronium in paediatric patients with burn injury. Br J Clin Pharmacol 1989;28:155–159.)

wasting of lean body mass that can last for more than a year after injury.[53] A number of strategies are employed to minimize this catabolic response, including early wound excision and grafting, prompt treatment of sepsis, maintenance of high environmental temperature, early institution of feeding, and exercise programs.[54]

Early excision and grafting is the treatment that has the greatest impact on decreasing the hypermetabolic response to burn injury. If a large burn (>50%) is excised and covered within 2–3 days of injury, the metabolic rate is decreased by 40% compared with a burn that is not covered until 1 week postinjury.[55]

Sepsis in burn patients can be difficult to diagnose because even in the absence of sepsis, patients are hypermetabolic with hyperdynamic physiology. Septic patients can have an additional 40% increase in metabolic rate and catabolism compared to nonseptic patients.[55] Therefore prevention, early diagnosis, and treatment of infection are essential to reducing hypermetabolism.

Burn patients can have substantial water loss (4000 mL H_2O/m^2 total body surface area [TBSA] per day in adults) from unhealed wounds.[56] The hypermetabolic response is further increased by the body's effort to generate heat to offset the inevitable temperature loss that occurs with evaporation. Consequently, maintaining environmental temperature with high humidity is important to minimize the hypermetabolism.

Continuous enteral or parenteral nutrition partially abates the hypermetabolic response to burns and maintains total body weight. A high-carbohydrate, high-protein diet (82% carbohydrate, 15% protein, 3% fat) stimulates protein synthesis, increases endogenous insulin production, and improves lean body mass.[57] Enteral feeding is preferable to parenteral feeding as it maintains GI motility and reduces bacterial translocation and sepsis. Parenteral feeding is associated with impaired liver function, hepatic steatosis, reduced immune function, and increased mortality.[58,59] Consequently parenteral nutrition is reserved for patients with intolerance for enteral feeding or prolonged ileus.

Children have higher energy needs per unit body weight than adults and tolerate periods of inadequate nutrition poorly. Consequently, early nutritional support is essential.

Because metabolic rate rises significantly with pain or anxiety, optimal use of analgesics and anxiolytics, together with psychological support during burn care, are of great importance. A number of pharmacologic adjuncts have been proposed to minimize loss of lean body mass after burn injury, including administration of anabolic agents, recombinant human growth hormone, insulin, oxandrolone, and propranolol.[60,61]

FLUID MANAGEMENT AND BLOOD LOSS DURING BURN WOUND EXCISION

The goal of surgical management is to remove layers of burned eschar until bleeding dermis is reached. Blood loss during burn wound excision can be deceptively large. It is not uncommon for the surgical team to remove eschar so rapidly that the patient becomes hypovolemic and unstable. Children have thinner skin than adults, making burns relatively deeper. This may result in relatively greater bleeding during excision and grafting procedures. Correction of intravascular volume before induction of anesthesia is essential. Good communication between the surgical and anesthesia teams, as well as limiting the operative duration and extent of excision, can prevent such problems. Blood should be readily available before extensive burn excision is initiated. Published estimates of the amount of blood loss during burn excision operations are in the range of 3.5–5% of the blood volume for every 1% TBSA excised.[62,63] This amount of blood loss results because diffuse bleeding is used as an end point for excision, informing the surgeon that the tissue is viable. However diffuse bleeding is not the only sign of tissue viability. The experienced surgeon can identify viability with other signs, including the presence of moist yellow fat, patent small blood vessels, and absence of extravascular hemoglobin.[64] Blood loss during these procedures can be minimized by the use of an intraoperative tourniquet for limb surgery, injection of dilute epinephrine, and brisk operative pace. Injection of higher-than-usual doses of epinephrine is permissible because the adrenoreceptors in burn patients are desensitized.[48] The dose limitation of epinephrine in normal patients is approximately 15–20 μg/kg. In burn patients, even with twice this dose, no arrhythmias and a mild rise (15%) in blood pressure have been observed with this technique. If blood loss appears significant, it is prudent to assess the patient's hematologic status regularly.

CALCIUM HOMEOSTASIS

Depression in ionized calcium levels is common with acute burn injury and abnormalities in calcium metabolism may persist for several weeks after injury, depending on the burn size.[65] These levels can be further diminished by the administration of citrate containing blood products that bind calcium. Normal calcium levels are necessary for optimal myocardial and smooth muscle contraction. Severe hypocalcemia can lead to dysrhythmias, hypotension, and/or electromechanical dissociation. Consequently the administration of supplemental calcium is important in the management of severely burned patients, particularly during rapid administration of (citrated) fresh-frozen plasma or albumin, both of which bind calcium.[66]

TEMPERATURE MANAGEMENT

Intraoperative consequences of hypothermia include decrease in cardiac output, arrhythmias, including ventricular fibrillation if severe enough, abolition of hypoxic pulmonary vasoconstriction, left shift of the hemoglobin dissociation curve, release of catabolic hormones, interference with the normal blood clotting mechanism, and reduction of hepatic and renal function. Postoperative consequences include shivering, impairment of drug clearance, and masking of hypovolemia.[67] Furthermore, shivering can dislodge grafts and increase O_2 consumption by 400–500%, resulting in increased stress to the cardiopulmonary system which already has increased demands.[68]

INFECTION CONTROL

Infection in burn patients is a leading cause of morbidity and mortality. The patients are immunocompromised and therefore susceptible to colonization

and infection from organisms in the environment. Sources of organisms that can cause infection include the patient's own (endogenous) flora, exogenous environmental sources, and transmission by healthcare personnel. Burn injury leads to increased susceptibility to infection through multiple mechanisms, including loss of the physical barrier of intact skin, damage to lining of respiratory tract from inhalation, and altered gut permeability and function. Invasive devices, including endotracheal tubes, intravascular catheters, and urinary catheters, bypass the body's normal defense mechanisms.

Central line-related infection may be associated with significant morbidity and mortality in burn patients. One large study of 1183 burn patients and 1346 central venous catheters reported an incidence of catheter-related infection of 19.5% and mortality of 14%.[69] The American Society of Anesthesiologists and the Centers for Disease Control have published guidelines for preventing catheter-related infections.[70,71] These guidelines recommend strict sterile technique during placement, use of single-lumen catheters, and placement in the subclavian site when possible. Despite this recommendation, it is not unusual to place multiport catheters in patients with burn injury, because of the need for simultaneous administraion of fluid, sedatives/narcotics, parenteral nutrition and other drugs. Both groups recommend against routine changing of central lines as a method to prevent catheter infection.

Microorganisms causing infection in burn patients include gram-positive and gram-negative bacteria, as well as yeast and fungi. The typical burn wound is colonized early on with gram-positive organisms, which are fairly rapidly replaced by antibiotic-susceptible gram-negative organisms. With persistence of open wounds, these flora are replaced by resistant bacteria, yeast, and fungi. Strategies to prevent infection include strict aseptic techniques, including use of sterile gloves and dressings, wearing masks, and spacial separation of patients.[72,73] Maintaining sterile technique both in the operating room and during transport is essential.

BURN WOUND MANAGEMENT

Considerations of Topical Agents

Microorganisms grow rapidly in burn wounds as a result of damage to the normal skin barrier, as well as from impaired immunologic function. Because burn eschar is often distant from patent microvasculature, systemically administered antimicrobial agents may be ineffective in the prevention of colonization or treating infection at the wound surface. Topical antimicrobials, however, provide high concentrations of drug at the wound surface and penetrate the eschar to varying degrees, depending on the agent. Topical antimicrobials delay the interval between injury and colonization and reduce levels of wound flora. Considerations in choice of topical agents include antimicrobial spectrum, degree of eschar penetration, patient comfort and toxicity.[74] Topical agents commonly used in the treatment of major burns are mafenide acetate (Sulfamylon), silver nitrate, and silver sulfadiazine (Silvadene) (Table 71–3).

Methemoglobinemia

Some strains of gram negative bacteria can reduce nitrates from silver nitrate to nitrites. These nitrites can diffuse into the bloodstream, converting hemoglobin to methemoglobin.[75] Methemoglobin decreases the oxygen carrying capacity of hemoglobin and shifts the oxyhemoglobin dissociation curve to the left, resulting in decreased oxygen delivery to the tissues. Therefore, methemoglobin should be

TABLE 71–3.

Topical Antimicrobial Agents and Their Toxicities

	Effectiveness	Side Effects	Ease of Use	Pain
Silver nitrate ($AgNO_3$) 0.5% aqueous solution	Broad spectrum Inhibits cell wall growth Penetrates 2–4 mm into wound	Hypoallergenic Leeches plasma electrolytes	0.5-inch-thick wet dressings Change daily and soak q2h to keep damp Stains tissue and environment black	Stings briefly
Mafenide acetate (Sulfamylon aqueous solution)	Broad spectrum Effective for resistant organisms (i.e., *Pseudomonas*)	Causes dose-related metabolic acidosis as a result of HCO_3 wasting Sensitivity rash	0.5-inch-thick wet dressings Change daily and soak q6h to keep damp	Stings briefly
Silver sulfadiazine (Silvadene 1% cream)	Broad spectrum Chemical debriding agent	Dose-related neutropenia Contains sulfur Sensitivity rash	Change daily To prevent buildup, remove residue with each dressing change	Stings briefly
Bacitracin ointment	Broad spectrum antibiotic ointment for partial-thickness wounds	Hypoallergenic (does not contain sulfur compounds)	Daily dressing change Apply and cover with dressing	No pain

considered in the differential diagnosis of cyanosis in this setting. Blood that contains more than 10% methemoglobin usually appears dark red or brown despite high Pao_2. Pulse oximetry, although showing a decreased saturation, will be falsely elevated. Treatment of methemoglobinemia consists of removing the silver nitrate, delivery of additional oxygen, and administration of methylene blue (2 mg/kg).[76]

Postoperative Care

A phone call to the burn unit should be made at least 30 minutes before completion of the procedure in the operating room to allow the care team adequate time to warm the room and to obtain necessary supplies and equipment (e.g., infusions, ventilator) that will be needed on the patient's arrival to the burn unit.

Ensuring adequate sedation and analgesia is essential in the immediate postoperative period. The presence of newly excised tissue and harvested donor sites can be very painful, requiring higher doses of analgesics and sedatives. As indicated previously, it is common for burn patients to become quite tolerant of sedatives over time and thus doses substantially larger than normal may be required.

Patients should be recovered in a prewarmed room as considerable heat loss can develop during transport. Radiant heaters, fluid warmers, and warming blankets are useful in maintaining normothermia.

Pain Management

Nearly every aspect of treatment of burn injury (e.g., dressing changes, excision and grafting procedures, physical therapy) is associated with pain. Pain results from direct treatment itself and is exacerbated by anxiety from patient anticipation. Poorly controlled pain and anxiety can have significant adverse physiologic and psychological effects. Posttraumatic stress disorder has been reported to occur in up to 30% of patients with severe burn injury, often developing in the setting of inadequate treatment of anxiety and pain.[77,78] The amount of pain associated with burn injury has been reported to be directly proportional to the size of the thermal injury. Early concerns over fear of addiction to opioids were unwarranted. No studies of pediatric patients have documented addiction and the addiction rate in adult patients is very low.[79] Patient-controlled analgesia has been shown to be a safe and effective method of opioid delivery for acute or procedure related pain in both children and adults with burn injury.[80–82]

In the early stages of burn injury there may be an increased potency of analgesic medications, but over time marked increases in analgesic requirements occur. Continuous administration of analgesics by itself can result in opioid-induced hyperalgesia. This will accentuate the need for higher opioid levels.[83]

To provide appropriate, consistent patient comfort, standardized pain and anxiety guidelines are used in many burn centers. The ideal characteristics of such a guideline include (a) safety and efficacy over a broad range of ages and burn injury severities, (b) explicit recommendations for drug selection, dosing, and increases in dosing, (c) a limited formulary to promote staff familiarity with drugs used, and (d) regular assessment of pain and anxiety levels with guidance for intervention through adjusted drug dosing.[84] Table 71–4 gives one example of a pain treatment guideline. Adjustments to treatment of opioid tolerance include switching of opioids (morphine-> fentanyl-> methadone) and coadministration of drugs acting on nonopioid receptors (ketamine–NMDA antagonist, dexmedetomidine–α_2-agonist).

Acetaminophen is a useful first line analgesic for minor burns. Nonsteroidal antiinflammatory drugs (NSAIDs) and benzodiazepines are commonly combined with opioids to relieve procedural pain. Pain is exacerbated by anxiety which may be reduced by benzodiazepines. Antidepressants appear to enhance opiate-induced analgesia, especially in patients with chronic (neuropathic) pain. Antidepressants have potential cardiovascular effects and for this reason are contraindicated in the early stages of burn treatment. Anticonvulsants may be useful in the pain following burns. Clonidine, an α_2-agonist, may be a useful adjunct in reducing pain without causing pruritus or respiratory depression. However, it can cause hypotension in higher doses and therefore should not be given to hemodynamically unstable patients.[85] Dexmedetomidine has been used to provide sedation–analgesia for burned patients and to decrease opioid requirements.[86,87] Its usefulness and side effects in burn patients have not been thoroughly studied.

As a patient recovers, the painful stimuli decrease and opioid dosing is gradually reduced. Prompt, definitive wound closure is the most effective treatment for minimizing pain and narcotic requirements. When a patient is being weaned, opioid and benzodiazepine dosages are decreased to allow adequate sensorium for airway protection yet still allowing adequate analge-

TABLE 71–4.

Pain Treatment Guidelines

Stage of Injury	Background Anxiety	Background Pain	Procedural Anxiety	Procedural Pain
Acute burn mechanically ventilated	Midazolam infusion Dexmedetomidine	Morphine infusion	Midazolam bolus	Morphine bolus Ketamine
Acute burn not mechanically ventilated	Scheduled lorazepam PO or IV	Scheduled morphine PO or IV	Lorazepam PO or IV	Morphine PO or IV Ketamine
Chronic acute burn	Scheduled lorazepam PO	Scheduled morphine or methadone PO	Lorazepam PO	Morphine PO
Reconstructive burn surgery	Scheduled lorazepam PO	Scheduled morphine PO	Lorazepam PO	Morphine PO

sia and anxiolysis. Patients may be safely extubated while still receiving opioid infusions.[88]

Pruritus is a common problem during the healing process. The causes of pruritus are multifactorial, often being triggered or worsened by heat, physical activity, and stress. Pruritus usually diminishes gradually with time but sometimes persists even after complete wound healing. A variety of approaches can control itching including systemic antihistamines, moisturizing lotions, and wearing loose-fitting clothing.

Children have unique developmental and psychosocial needs that should be considered. Pain and anxiety may be more difficult to assess but should be anticipated and treated. Support and involvement of parents and family members are important adjuncts to care and recovery.

SUMMARY

The anesthetic and intensive care management of burn patients requires detailed knowledge of the pathophysiologic effects of burn injury on multiple organ systems. Optimal treatment of the burn patient requires the cooperation and care from anesthesiologists, surgeons, nurses, psychiatrists, and family members. Awareness of the alterations in pharmacokinetics and pharmacodynamics in patients with burn injury is essential. Safe care can be provided by understanding, appreciating, and anticipating the unique preoperative, intraoperative, and postoperative issues and problems of the burn patient.

PART 5

POSTOPERATIVE CARE OF THE ANESTHESIA PATIENT

CHAPTER 72

Recovery of the Healthy Patient

Loreta Grecu, MD,
Edward A. Bittner, MD, PhD,
and Edward George, MD, PhD

Recovery of patients after procedures requiring anesthesia or sedation is most commonly performed in a postanesthesia care unit (PACU) or recovery room. These specialized areas are designed for the observation, treatment, and discharge of postoperative patients. The PACU optimally is located near the operating room, thereby minimizing transport time for the patient and affording rapid access to anesthesiologists and surgeons. The PACU is staffed by nurses trained in the care of patients in the immediate postoperative period. Under the supervision of an anesthesiologist, the PACU provides care to a broad cross-section of postprocedural patients, with the majority subsequently transferred in a timely manner from the PACU to a general care floor of the hospital or, in the case of an ambulatory care facility, discharged home. The diversity of patients and surgical procedures admitted to the PACU is quite varied. Many are healthy and have an uneventful hospital course, whereas some experience a more complex perioperative course influenced by their preexisting medical history and/or a complicated intraoperative course.

Patients are admitted into the PACU at the conclusion of procedures requiring anesthesia or sedation. With some exceptions, such as healthy patients receiving only local anesthetics or carefully selected patients capable of bypassing the PACU (see PACU Discharge), most patients undergoing surgical procedures do experience a period of postprocedural observation. Patients are admitted after surgical procedures in the operating room, but interventions under anesthesia also may take place outside of the operating room in other departments, such as radiology, cardiology, or gastroenterology. These patients may be cared for in areas removed from the hospital's main recovery areas. Personnel trained and experienced in the recovery of these patients should be present to oversee the recovery phase and must be able to obtain immediate help in the event of an urgent or acute change in a patient's condition.[1]

Given the wide range of patients undergoing recovery in the PACU, the potential issues also are quite varied. Being able to anticipate common issues in advance may facilitate the initiation of appropriate action(s) in a timely manner and help prevent the complications associated with more urgent interventions.

Healthy patients may undergo procedures as either inpatients or outpatients, depending upon the severity of the surgical intervention. Some complex surgical procedures, even in an otherwise healthy subject, may require prolonged postoperative care in the hospital. In such cases, the planned length of the hospital stay is influenced by the period required for functional recovery, as well as possible postoperative complications. An uncomplicated recovery in the PACU is generally anticipated for most patients. However, patients often present to the PACU with comorbid conditions that may influence their postoperative course, both in the PACU and during their subsequent hospital stay. Although patients with multiple medical conditions are routinely discharged home on the same day as surgery, comorbidities often are a major factor in the decision to admit patients to the hospital after surgery. This chapter reviews the clinical scenarios most commonly encountered during routine postoperative recovery of surgical patients.[2] Less common and often more clinically demanding issues associated with the recovery of the postoperative patient are discussed in Chapter 73. The recovery of pediatric patients is discussed in Chapter 63.

ORGANIZATION OF THE PACU

The PACU is staffed by anesthesiologists, specially trained recovery room nursing staff,[3] and support personnel. General principles summarizing recovery criteria are listed in Table 72–1. In addition to providing the ability to appropriately monitor patients and administer routine postoperative care, the PACU affords the capability for mechanical ventilation and invasive monitoring, as well as the emergency equipment and skilled personnel able to conduct emergency resuscitation and provide advanced care.

The staff assigned to the PACU must have a thorough understanding of the procedures performed and be familiar with potential complications[4] associated with both the anesthetic provided and the surgical procedure, as well as the patient's pertinent past medical and surgical history. The American Society of Anesthesiology's (ASA) standards for postanesthesia care specifically identify five principles of care intended to encourage quality patient care (Table 72–2). Standards for PACU operations were established in 1988 by the ASA's House of Delegates and amended in 2002.[5] Standards include guidelines for admission, patient transport and transfer of care from the operating room team to the PACU

KEY POINTS

1. Postanesthesia care units (PACUs) require specially trained personnel to recognize and respond to clinical issues associated with the patient in the immediate postoperative period.
2. The PACU should be located in reasonable proximity to the operating rooms for access to key personnel in a timely manner.
3. The majority of patients admitted to the PACU experience an unremarkable recovery and are discharged from the PACU without incident.
4. Prophylaxis for postoperative nausea and vomiting is far more effective than rescue therapy.
5. Effective postoperative analgesia should be initiated during the surgical procedure.
6. Hypoxia most often is the result of residual effects of anesthetic agents.
7. Hypotension unresponsive to fluid resuscitation in the postoperative patient most often is due to hemorrhage until proven otherwise.

TABLE 72–1.

General Principles of Recovery

- Medical supervision of recovery and discharge is the responsibility of the supervising physician.
- The recovery area should be equipped with appropriate monitoring and resuscitation equipment.
- Patients should be monitored until appropriate discharge criteria are satisfied.
- Level of consciousness, vital signs, and oxygenation (when indicated) should be recorded at regular intervals.
- A nurse or other individual trained to monitor patients and recognize complications should be in attendance until discharge criteria are fulfilled.
- An individual capable of managing complications should be immediately available until discharge criteria are met.

General principles of recovery provide a structure upon which an institution may develop a system to manage the recovery of the immediate postoperative patient. Capable of modification to best serve the clinical requirements of the specific patient population and nature of surgery, these principles should be used as a framework that can be integrated with a formalized system for recovery and discharge of the patient.[5]

team, patient care in the PACU, and discharge guidelines and procedures.

Specialized nurses, certified by the American Society of Peri-Anesthesia Nurses (ASPAN), are essential to providing care for postoperative patients. Nursing standards for recovery established by ASPAN[6] are similar to those developed by the ASA for physicians. These standards are designed to optimize the care of postoperative patients. The similarity between the ASA and ASPAN standards for patient care represents a significant convergence for physicians and nurses in providing optimum care to the patient in the immediate postoperative period.

Standard monitors capable of displaying vital signs are used for all patients arriving in the PACU. An oxygen supply and a method for providing suction are required. Adequate supplies used for patient care (dressings, intravenous [IV] fluids, drains, etc.) and medications must be available. A method for providing emergency positive-pressure ventilation (i.e., self-inflating bag valve mask or Ambu bag) must be present at each bed station. Importantly, emergency equipment and personnel trained in emergency resuscitation must be immediately available.

PACU OPERATIONS

Patients receiving general anesthesia, deep or moderate sedation, or regional anesthesia should be admitted into the PACU at the completion of their procedure. Patients, monitored in the PACU until free from the effects of the administered anesthetic and who are clinically stable, usually are transferred to a general care floor in the hospital or are discharged to home. Patients undergoing surgical procedures without sedation (i.e., local anesthetics) may not require admission to the PACU as dictated by institutional policy.

In many institutions, recovery may be conducted in varied facilities: a main PACU for inpatients, a separate facility for children, and an ambulatory PACU specifically designed for patients not requiring postoperative admission to the hospital. The focus of these units may differ, but there is a large degree of overlap of characteristics. This is particularly important because patients from the various groups may be recovered in multiple sites, depending upon the characteristics of the case, operational tempo, and institutional procedures.

Early recovery (phase I) takes place in the PACU, lasting from the time of admission to the PACU until protective airway reflexes and motor functions have recovered. Phase I mirrors the immediate postemergence phase of recovery conducted in the operating room by the team providing the intraoperative anesthetic. The patients is always monitored during this stage, and acute treatment of clinical issues such as nausea and vomiting, pain, respiratory compromise, and hemodynamic liability may be required. Phase II of the recovery of ambulatory patients consists of patient education and preparation for home discharge. Ambulatory patients may be recovered in the PACU (phase I) or may bypass the PACU and go directly to a phase II recovery facility (see Fast-Tracking below). Phase II recovery of the patient who is being admitted to the hospital constitutes a period during which the patient's vital signs remain stable, with adequate pain control, control of nausea and vomiting, and a return to an appropriate level of consciousness.

Fast-tracking refers to the recovery of patients in areas other than a formal PACU, for example, by direct transfer from the operating room to a postrecovery lounge.[7] This system can be used for patients undergoing ambulatory anesthesia. With the increase in surgical procedures being performed on an outpatient basis, fast-tracking is being used more commonly. The process can offer faster recovery without direct involvement of the PACU. This

TABLE 72–2.

Standards for Postanesthesia Care

I. All patients who have received general anesthesia, regional anesthesia, or monitored anesthesia care shall receive appropriate postanesthesia management.

II. A patient transported to the PACU shall be accompanied by a member of the anesthesia care team who is knowledgeable about the patient's condition. The patient shall be continually evaluated and treated during transport with monitoring and support appropriate to the patient's condition.

III. Upon arrival in the PACU, the patient shall be reevaluated and a verbal report provided to the responsible PACU nurse by a member of the anesthesia team who accompanies the patient.

IV. The patient's condition shall be evaluated continuously in the PACU.

V. A physician is responsible for the discharge of the patient from the PACU.

PACU, Postanesthesia care unit.
These standards apply to postanesthesia care in all locations. The standards may be exceeded based on the judgement of the responsible anesthesiologist. They are intended to encourage enhanced quality of patient care but cannot guarantee a specific patient outcome. They are subject to revision from time to time as warranted by the evolution of technology and practice. Under extenuating circumstances the responsible anesthesiologist may waive requirements, but it should be so stated and a note to that effect placed in the patient's medical record.[5]
Excerpted and adapted from http://www.asahq.org/publicationsAndServices/standards/36.pdf

results in the safe and appropriate recovery of the postoperative patient in an efficient and resource-sensitive manner.[8] For a detailed discussion of fast-tracking of the postoperative patient, see Chapter 67.

The personnel resources used in the various phases of recovery may differ based on the acuity of illness of patients after surgery and are defined by standards established by ASPAN. In phase I recovery, the staffing may range from one nurse per two patients to two nurses for one unstable or complex recovering patient. In phase II of recovery, the staffing ratio can similarly vary. Phase III recovery is designated for patients requiring continued observation in preparation for discharge from the hospital or transfer to a general care ward. Normally a ratio of one nurse per three to five patients is used in this final stage of recovery prior to discharge.

ADMISSION TO THE PACU

Transfer to the PACU

Transport from the operating room is carried out under the direct supervision of an anesthetist. If possible, the head of the bed is elevated or the patient is placed in the lateral decubitus position to maximize airway patency and minimize aspiration risk. Oxygen delivered via a face mask or nasal cannula is indicated for most patients to prevent hypoxemia due to hypoventilation. Unstable patients, such as those receiving vasoactive medications, will require monitoring of vitals signs during the transport. In transporting unstable patients, additional resources are required, including airway devices and a self-inflating bag valve mask (Ambu bag), emergency drugs, and appropriate means for monitoring oxygen saturation, heart rate, blood pressure, and respiratory rate. The anesthesiologist accompanying the patient to the PACU must provide care until a set of vital signs is obtained, the patient is deemed stable for the PACU to assume care, and a full handoff report is given to the PACU staff. The anesthetist should remain in charge of the care of the patient until the PACU team is ready to assume full responsibility for his/her care. This level of monitoring and transport can be similar to that required by a critically ill patient and is discussed in detail in Chapter 80.

Reporting to the PACU Staff

The verbal report (handoff) is most often provided directly to the nurse in the PACU, who will then assume responsibility for providing supervised care to the patient. Ideally the report should not be interrupted, and the provider and receiver of the report should be able to concentrate on transferring this important information. Depending upon institutional guidelines, the PACU nurse may accept responsibility for care of the patient on behalf of the physician overseeing the PACU or as a representative of the surgical care team. In the event of an intraoperative complication or in the setting of a complex procedure, the report should be provided directly to the physician in charge of the PACU. The report to the PACU staff may include, but is not limited to, the guidelines listed in Table 72–3. This table is a suggested template for the transfer of information components and can be modified as dictated by institutional practice. Upon arrival in the PACU, vital signs are recorded by the staff, and the anesthetist provides a complete report to the PACU team. At the Massachusetts General Hospital, a member of the surgical team also accompanies the patient from the operating room and provides pertinent details of the surgical procedure to the PACU staff.

The formal face-to-face report is a vital component of the process of transferring the responsibility of care for the patient from the team in the operating room to the team in the PACU. This report often may be the sole formal account of the intraoperative events between the team providing care in the operating team and the personnel who will provide the immediate postoperative care.[9]

Report should include the following:

1. Two forms of patient identification,[10] age, surgical procedure, diagnosis, a summary of prior medical history, medications, allergies, and preoperative vital signs. When present, specific features such as deafness, poor vision, psychiatric issues, language barriers, or precautions for infection control also should be mentioned.
2. Location and size of intravascular catheters.
3. Premedication, antibiotics, anesthetic drugs given for induction and maintenance, opioids, muscle relaxants, and reversal agents. Vasoactive drugs, bronchodilators, and other relevant drugs administered

TABLE 72–3.

Guidelines for Report to the PACU Staff

Significant Preoperative Issues	Intraoperative Issues
Patient's demographics	Access and invasive monitoring
Diagnosis	Special catheters (epidural, cooling)
Surgical procedure/urgency	Airway management issues
Past medical history	Induction and maintenance medications
Allergies and medications	Paralytics and reversal agents
Social history	Vasoactive agents
Past medical history relevant to anesthetic	Anticoagulants
Complications (personal or familial)	Antibiotics
Last meal	Analgesics/anxiolytics
Preoperative medications	Ventilatory parameters
Anxiolytics	Events of note
Antibiotics	Cardiopulmonary instability/hemorrhage
Analgesics	Emergence (pain, consciousness level)
	Estimated blood loss and urine output
	Fluids and blood products
	Tubes, lines, and drains
	Infectious precautions

A concise report must be provided to the postanesthetic care unit (PACU) team accepting responsibility for the care of the patient. The suggested information should be used as a framework to report pertinent information. The nature and extent of the information provided will be influenced by multiple factors, including the patient's overall medical condition, the surgical procedure, and any intraoperative factors that could influence postoperative recovery.

should be listed and the reasons for their use described.

4. Exact nature of the surgical procedure. If relevant surgical issues exist (e.g., adequacy of hemostasis, care of drains, restrictions on positioning, etc.), the PACU staff should be informed.
5. Anesthetic course, with emphasis on problems that may impact on the immediate postoperative course, including laboratory values, difficult IV access, difficult airway management, intraoperative or postoperative hemodynamic instability, electrocardiographic (ECG) changes, etc.
6. Fluid balance, including amount, type, and rationale of fluid replacement, urine output, and estimated fluid and blood loss.

Complex Patients

As dictated by the clinical situation, the accompanying anesthetist may elect to speak directly to the anesthesiologist in charge of the PACU or to a consultant regarding issues of particular importance for the patient. Issues commonly communicated directly to the anesthesiologist responsible for the patients in the PACU or a consultant can include intraoperative instability, pertinent comorbidities, excessive blood loss, or airway difficulties, as well as persistent paralysis and other indications for continued mechanical ventilation.[11] The surgical team should be informed on admission to the PACU of any potential clinical issues that may impact the postoperative course of the patient.

Monitoring in the PACU

The ASA recommends that during the emergence and recovery phases of care, periodic assessments be made of multiple parameters, including monitoring of respiratory and cardiovascular function, neuromuscular function, mental status, temperature, pain, nausea and vomiting, drainage and bleeding, and urine output. The frequency and duration of monitoring is dictated by the clinical status of the patient.[5]

COMMON POSTOPERATIVE ISSUES

Clinical situations encountered in the postoperative patient may range from common events, such as inadequate analgesia, to less frequently experienced clinical issues, such as negative pressure pulmonary edema. This chapter addresses the more commonly experienced postoperative clinical events. For detailed discussion of less frequently encountered issues, see Chapter 73.

Postoperative Nausea and Vomiting

One of the most common complications of general anesthesia—postoperative nausea and vomiting (PONV)—is less of an issue with regional anesthetic techniques.[12] Afpel et al.[13] showed that the overall incidence of PONV is approximately 34% in patients receiving a general anesthetic without preoperative antiemetic therapy, with reductions of postoperative PONV risk by 26% with prophylactic administration of ondansetron, dexamethasone, or droperidol. Prevention of PONV is much more effective than treatment administered after symptoms occur.[13,14]

Patients are commonly stratified preoperatively (see Chapter 4) with regard to their risk of PONV; the incidence of PONV is greater in women, nonsmokers, and patients with a history of PONV or motion sickness.[15,16] Additional risk factors involve the use of narcotics, nitrous oxide, volatile anesthetics, and neostigmine as components of the anesthetic.[17] Certain types of surgery, such as abdominal, breast, ear nose and throat (ENT), neurosurgery, and correction of strabismus, may also increase the risk for PONV. Prolonged surgery is associated with an increased incidence of PONV. Apfel et al.[18] showed that, after administration of an anesthetic consisting of a volatile anesthetic, nitrous oxide, and fentanyl without prophylactic antiemetics, the incidence of PONV was as high as 59%. In contrast, anesthetic techniques not using nitrous oxide but using propofol, remifentanil, ondansetron, dexamethasone, and droperidol reduced the incidence of PONV to 17%.

If PONV occurs in the untreated patient in the PACU, therapy should be initiated with an IV serotonin antagonist and supplemented, if necessary, with medications from other classes of drugs (Table 72–4). In patients who have received prophylaxis, PONV rescue therapy should consist of drugs given from classes other than those previously administered.[19] Administration of drugs from the same class within the first 6 hours after surgery has not been found to be effective in the treatment of PONV. Tramer et al.[20] suggests that treatment of nausea and vomiting may be more cost-effective than prophylaxis. This view is based, in part, on the poor results associated with prophylaxis using a single agent.[21] Com-

TABLE 72–4.

Antiemetic Treatment for Patients with PONV Who Did Not Receive Prophylaxis or in Whom Prophylaxis Failed–Exclude Inciting Medication or Mechanical Causes of PONV

Initial Therapy	Failed Prophylaxis
No prophylaxis or dexamethasone	Small does of SA
SA plus second agent	Use drug from a different class
Triple therapy with SA plus two other agents when PONV occurs <6 h after surgery	Do not repeat initial therapy
	Use drug from different class or…
	Propofol 20 mg as needed in the PACU
Triple therapy with SA plus two other agents when PONV occurs >6 h after surgery	Repeat SA and droperidol (not dexamethasone or transdermal scopolamine)
	Use drug from a different class

SA, Serotonin antagonist.

Table describes a sequential approach to the treatment of patients experiencing postoperative nausea and vomiting (PONV) with the level of supporting evidence based on original student design as noted by Gan et al.[71] Patients may be naïve to antiemetic therapy on arrival to the postanesthesia care unit (PACU; initial therapy) or may have failed preoperative use of antiemetic agents (failed prophylaxis) based upon preoperative risk stratification for PONV. Escalation of antiemetic therapy, as required, is based on the introduction of additional agents from categories of medications (described in the text) not previously administered. Repeated dosing of a previously ineffective agent will yield little success in the treatment of PONV. Inciting medication and mechanical causes may include the use of morphine patient-controlled analgesia, blood draining down the back of the throat, and/or abdominal distension.

mon categories of agents used for treatment of PONV[2] include the following:

1. *Serotonin antagonists* are efficient as prophylactic antiemetics when administered prior to the use of narcotics or before the completion of surgery. About one fourth of the dose used for prophylaxis can be given for rescue therapy.
2. *Phenothiazines* (Compazine) have been given both for prevention and treatment of PONV. This class of antiemetics can be associated with significant sedation.
3. *Dexamethasone* is most effective for prophylaxis if administered before the induction of anesthesia. It also can be given as a rescue drug.
4. *Droperidol* is no longer used as a first-line drug for the prevention and treatment of PONV. A "black box" warning was issued in 2001 by the FDA, associating droperidol with QT-segment prolongation and torsade de pointes in some patients.[22] When droperidol is given, documentation of a normal QT segment before administration and continuous ECG monitoring for 2–3 hours after administration is currently recommended. Droperidol now is used for treatment of PONV that has been refractory to other drugs. Charbit et al.[23] demonstrated that patients with PONV have a high incidence for a prolonged QTc interval because of a variety of factors associated with anesthesia, even before administration of an antiemetic such as droperidol or ondansetron. Both of these agents may increase the QTc interval after administration for treatment of PONV. Given this concern about cardiac arrhythmias, clinicians have sought alternatives to droperidol and have given *haloperidol* in lower dosages than used for antipsychotic therapy. In a meta-analysis, Buttner et al.[24] demonstrated that low-dose IV haloperidol is an effective drug for treatment of PONV with minimal side effects.

Respiratory and Airway Complications

Most surgical patients arrive in the PACU following tracheal extubation in the operating room, with supplemental oxygen provided. Supplemental oxygen delivered by nasal cannulas or a face mask during transport of the patient from the operating room is generally well tolerated by the patient. Most patients wean from the supplementary oxygen soon after arrival in the PACU. However, some patients have a continued requirement for supplemental inspired oxygen in the PACU and may require more aggressive respiratory therapy, such as a high-flow oxygen (O_2) mask, noninvasive mechanical ventilation, or even reintubation. For treatment of hypoxemia not responsive to oxygen therapy and for management of the intubated patient, see Chapters 73 and 83.

Respiratory and airway complications are some of the most common perioperative complications occurring in the immediate postoperative period. The predominant issues include inadequate oxygenation and/or ventilation, upper airway obstruction, laryngospasm, and aspiration.[25]

General anesthesia inhibits hypoxic and hypercapnic ventilatory drive and reduces the lung's functional residual capacity (FRC). These changes may persist for variable periods of time postoperatively and predispose the patient to hypoventilation and hypoxemia. In the immediate postoperative period, hypoxia may be primarily explained by the presence of residual anesthetic agents. After sufficient time for recovery from anesthetic effects, hypoxia may be caused by the side effects of other depressant medications prescribed for the patient. Analgesia and the degree of respiratory depression can differ based upon the route of analgesic administration. The effects may range from a slight decrease in oxygen saturation (SpO_2) requiring supplemental oxygen, to severe hypoventilation requiring treatment with the opioid antagonist naloxone, to reverse respiratory depression. Using decreased oxygen saturation as an indicator, the incidence of respiratory depression is less (11.5%) for patient-controlled analgesia (PCA) compared to epidural analgesia (15.1%).[26] The standard of care suggests that all patients receive supplemental oxygen in the immediate postoperative period.[5] However, although supplemental oxygen may mask and delay the detection of hypoventilation by pulse oximetry,[27] evidence also suggests that use of supplemental oxygen in the immediate postoperative period may be associated with a reduced rate of wound infection.[28–30]

Clinical signs of hypoxemia include dyspnea, cyanosis, altered mental status, agitation, obtundation, tachycardia, hypertension, and arrhythmias. Causes of hypoxemia include the following:

1. *Atelectasis,* with a subsequent increase of right-to-left intrapulmonary shunting, is a predictable effect of the decreased FRC caused by general anesthesia. A reduction of FRC occurs frequently in obese patients and after thoracic or upper abdominal procedures because these patients are prone to develop atelectasis in the postoperative period. Patients undergoing procedures with epidural anesthesia but without general anesthesia have minimal atelectasis formation as a function of the level of neuromuscular blockade.[31] Deep breathing and incentive spirometry are equally effective in reexpanding small regions of alveolar collapse. Noninvasive ventilation has been used to reduce atelectasis and augment oxygenation in postoperative patients.[32] Occasionally, in patients with profuse secretions and a poor cough reflex, hypoxemia may persist and chest radiography may reveal a segmental or lobar collapse. Chest physiotherapy or fiberoptic bronchoscopy may be required to facilitate the expansion of the atelectatic segment.
2. *Hypoventilation* due to inappropriately low minute ventilation causes hypoxemia by promoting alveolar collapse and increases the carbon dioxide (CO_2) partial pressure in arterial blood, resulting in hypercapnia and acute respiratory acidosis. Hypoventilation, when severe, can produce hypoxemia, CO_2 narcosis, and ultimately apnea. Supplemental oxygen may mask the early detection of hypoventilation and, by reducing alveolar nitrogen concentration, can augment atelectasis. A decline in oxygen saturation (SpO_2), as a sign of hypoventilation, has been found to be useful only in patients breathing air.[27] Therefore, monitoring the ventilatory status of postoperative patients should not rely solely on pulse oximetry.

Etiologies of postoperative hypoventilation can be divided into two groups:

1. *Decreased ventilatory drive,* as a result of medications and agents ad-

ministered during the intraoperative and postoperative course, normally is short lived and resolves shortly after the patient's arrival in the PACU.

Pulmonary and respiratory muscle insufficiency or compromise due to conditions such as chronic obstructive pulmonary disease, obesity, or surgical manipulation can limit the patient's ventilatory capability in the postoperative setting. Additionally, the effect of inadequately reversed neuromuscular blockade can markedly inhibit the patient's respiratory efforts in the immediate postoperative setting.

2. *Upper airway obstruction* is most often caused by inadequate recovery of the airway reflexes and muscle tone. Principal signs are lack of adequate air movement, intercostal and suprasternal retractions, and discoordinate abdominal and chest wall motion during inspiration. Complete upper airway obstruction is silent, whereas partial obstruction often is accompanied by snoring (if the obstruction is above the larynx) or inspiratory stridor (if perilaryngeal). Obstruction is more commonly seen in patients with obstructive sleep apnea, obesity, or nasal obstruction due to tonsillar or adenoidal hypertrophy.[33] To treat obstruction, 100% O_2 is given by mask, and rapid airway management is required. A chin lift, with or without jaw thrust, often resolves the obstruction; however, some patients (e.g., patients with obstructive sleep apnea) may benefit from continuous positive airway pressure. This is most common in patients already using such therapy at home. Additional conditions with the potential to impact respiratory function in postoperative patients include laryngospasm, bronchospasm, pulmonary edema, and aspiration of gastric contents. For a detailed discussion of specific complications that can compromise respiratory function in the postoperative patient, see Chapter 73.

Hypotension

The differential diagnosis of hypotension is aided by a review of the patient's history and intraoperative management. Preoperative dehydration in the setting of an aggressive bowel preparation or intraoperative fluid restriction during a thoracic resection are often the causes of hypotension in the immediate postoperative patient. As such, the patient's intraoperative course may offer insights into postoperative signs/symptoms, and discussion with patient's anesthetist may yield insights into the pathogenesis of postoperative hypotension. Common causes of postoperative hypotension include the following:

1. *Hypovolemia* is the most common cause of hypotension in the PACU, and hemorrhage must be considered as the cause until proven otherwise. Inadequate fluid replacement, osmotic polyuria, and fluid sequestration (intestinal obstruction, ascites) are common causes of hypovolemia in the postoperative patient. Nonspecific signs of insufficient fluid resuscitation include hypotension, tachycardia, tachypnea, decreased skin turgor, dry mucous membranes, oliguria, and thirst. An IV volume challenge (250–1000 mL of crystalloid or an equivalent volume of a colloid) should be considered therapeutic in the setting of a patient suspected of underresuscitation during surgery. Persistent hypotension following seemingly adequate volume replacement mandates further assessment, to include placement of a urinary catheter and, if persistent, invasive hemodynamic monitoring.
2. *Impaired venous return* occurs when mechanical forces decrease venous return to the heart. Common causes include positive-pressure ventilation and increased intraabdominal compartment pressure due to edema or a fluid collection. Signs of obstruction to venous return may be differentiated from those of true hypovolemia by the presence of jugular vein distension in the setting of decreased breath sounds and heart tones. Volume administration is the mainstay of symptomatic therapy, but treatment of the cause is the ultimate intervention.
3. *Vasodilatation.* Neuraxial anesthesia, residual inhalation agents, rewarming after hypothermia, transfusion reactions, adrenal insufficiency, anaphylaxis, systemic inflammation, sepsis syndrome, hepatic failure, and administration of vasodilatory agents all can cause hypotension due to systemic vasodilatation. Hypovolemia accentuates the hypotension caused by vasodilatation, and volume replacement alone may not fully restore the systemic blood pressure. Pharmacologic treatment can include α-adrenergic receptor agonists such as phenylephrine or norepinephrine. Use of these IV agents mandates close monitoring of the blood pressure. Diagnosis and treatment of the specific etiology of vasodilatation must be concurrent with symptomatic treatment.
4. Additional causes of hypotension are cardiac dysfunction, sepsis, and chronic antihypertensive therapy. For a detailed discussion of many of the causes of postoperative hypotension, see Chapter 73.

Cardiac Dysrhythmia

An enormous number of stimuli, including increased sympathetic or vagal nervous outflow, hypoxemia, hypercarbia, electrolyte and acid–base imbalance, myocardial ischemia, elevated intracranial pressure (ICP), drug toxicity, thyrotoxicosis, and malignant hyperthermia, are possible etiologies of perioperative dysrhythmias. Premature atrial contractions and unifocal premature ventricular contractions generally do not require treatment.[34] Assessment and definitive therapies are discussed in Chapters 73 and 84.

Commonly occurring cardiac dysrhythmias seen in the immediate postoperative setting include the following:

1. *Supraventricular dysrhythmias*
   A. *Sinus tachycardia* may be secondary to pain, agitation, hypovolemia, fever, hyperthermia, hypoxemia, hypercarbia, congestive heart failure, and pulmonary embolism. Pharmacologic treatment of tachycardia with β-blockers or calcium channel blockers should be instituted only after the underlying etiology is addressed. However, the hazard of myocardial ischemia may dictate early therapeutic intervention.
   B. *Sinus bradycardia* may result from high-level neuraxial anesthetic blockade, opioid administration (except meperidine), vagal stimulation, β-adrenergic blockade, and increased ICP. Symptomatic treatment with anticholinergic muscarinic agents is indicated when hypotension is present or bradycardia is marked with compromising cardiac output.

2. *Stable ventricular dysrhythmias.* Premature ventricular contractions and stable nonsustained ventricular tachycardia do not routinely require intervention. However, reversible causes of dysrhythmia, such as hypoxemia, myocardial ischemia, acidosis, hypokalemia, hypomagnesemia, and ventricular irritation caused by the stimulation of a central venous catheter, should be treated immediately. For further discussion and therapy, see Chapters 73 and 84.

Other Cardiac-Related Events

Myocardial ischemia and infarction may be observed in the PACU as the patient is recovering after an anesthetic. Postoperative pain, respiratory distress, hypovolemia, and anemia are common clinical conditions that may result in excess cardiovascular stress and can result in ischemia or a myocardial infarction. Changes in the ECG may provide an early indication of cardiac compromise. Common findings on the ECG include the following:

1. *T-wave changes* (inversion, flattening, pseudonormalization) may be associated with myocardial ischemia and infarction, electrolyte imbalance, hypothermia, surgical manipulation of the mediastinum, or incorrect lead placement. Isolated T-wave changes must be considered within the clinical context of each patient, as such changes may be benign in the postoperative setting. It is essential that postoperative changes in the ECG be compared to a recent preoperative ECG.[35]
2. *ST-segment elevation or depression* generally indicates myocardial infarction or ischemia, respectively. ST-segment elevation can be a normal variant or may occur in other conditions, such as left ventricular hypertrophy, left bundle-branch block, or hyperkalemia.[36] Unlike myocardial infarctions occurring in the nonsurgical setting, most myocardial infarctions occurring in the postoperative period are associated with ST depression and have a non–Q-wave pattern. Supplemental oxygen should be administered and a 12-lead ECG obtained, and any potential precipitating factors for the ST-segment changes must be reviewed and corrected. Common etiologies of these ECG changes include hypoxemia, anemia, tachycardia, hypotension, and hypertension. Cardiac enzyme levels should be monitored sequentially in patients with persistent ECG changes. If clinically appropriate, β-blockade and IV nitroglycerin should be considered. Consultation with a cardiologist is indicated in the setting of hemodynamic instability, and transfer to an intensive care unit (ICU) may be required for prolonged monitoring and therapy. Ongoing myocardial ischemia mandates the institution of invasive monitoring and/or specialized treatments (thrombolysis, percutaneous angioplasty, etc.).
3. In patients at high risk for adverse cardiac events (patients with ischemic heart disease, cerebrovascular disease, renal insufficiency, diabetes mellitus, or patients undergoing intrathoracic, intraperitoneal, or suprainguinal vascular surgical procedures), β-blockade has been found to decrease the risk of adverse cardiac events.[37–39] An institutional perioperative β-blockade protocol may be useful to standardize care for these patients.[40,41] For patients receiving vasoactive agents for hemodynamic support in the setting of hypotension, the addition of β-blockade should be considered in the context of the clinical situation.
4. The patient with a *permanent pacemaker* or *implantable cardioverter-defibrillator* (ICD) requires special consideration in the perioperative setting.[42] Information regarding the patient's pacemaker dependency state and the specialized features of the particular device must be obtained from the operating room team or the patient's cardiologist. Continuous ECG monitoring is essential, with particular attention to the patient's rhythm, rate, and hemodynamic status. Electrocautery used during the surgery can electrically reset the pacemaker, with older models likely more susceptible (see Chapter 27). Placement of a magnet over the permanent pacemaker or ICD during surgery can temporarily or permanently deactivate or reset the device, depending upon the age and specific nature of the device. Newer pacemakers may have rate-adaptive capabilities requiring a selective intervention by the electrophysiology service prior to surgery. Given the potential for inadvertent program modification in the perioperative setting, interrogation of the device and communication with the electrophysiology service both before and after surgery is generally recommended. Reprogramming of the device to the original parameters may be required in the PACU. For a more detailed discussion of patients with cardiac pacemakers and ICDs, see Chapter 51.

Hypertension

Commonly observed in patients not receiving scheduled antihypertensives preoperatively, systemic hypertension is often seen in patients having undergone vascular surgery (carotid endarterectomy) or intrathoracic procedures. Additional postoperative etiologies for hypertension include pain, bladder distension, fluid overload, hypoxemia, hypercarbia, hypothermia, increased ICP, or excessive administration of vasoconstrictor agents. Hypertension usually is asymptomatic but may present as headache, visual disturbances, dyspnea, restlessness, and chest pain. The initial physician's assessment should include a review of the patient's history and operative course and verification of the accuracy of blood pressure measurement (e.g., comparing both arms). Management of systemic hypertension usually is targeted to restoring blood pressure to within 20% of the patient's baseline. Strict postoperative blood pressure control often is required following intracranial aneurysm surgery, creation of vascularized muscular flaps, or microvascular surgery, and in patients with severe vascular disease. When appropriate, resumption of the patient's chronic antihypertensive oral drug therapy is ideal. If necessary, the therapy can be supplemented or substituted with parenteral medication. Commonly used medications include the following:

1. β-adrenergic antagonists: *Labetalol* (an α- and a β-blocker), esmolol, metoprolol, and propranolol are effective in controlling heart rate and systemic blood pressure.
2. *Calcium-channel blockers.* Verapamil or diltiazem can be given as either a bolus or an infusion; nicardipine can be administered enterally. Sublingual nifedipine is no longer recommended because it can be associated with rapid and

severe hypotension resulting in myocardial ischemia.

3. *Hydralazine* is a potent vasodilator that may induce reflex tachycardia.
4. *Nitrates.* Nitroglycerin is primarily a venodilator at low infused doses and is quite useful in patients with known myocardial ischemia. Sodium nitroprusside is a potent vasodilator and requires invasive blood pressure monitoring.
5. *Fenoldopam,* a selective peripheral dopaminergic receptor agonist, can be administered as an IV infusion. Side effects include tachycardia, headache, and increased intraocular pressure.
6. *Enalaprilat,* administered parenterally, is useful in patients routinely treated with angiotensin-converting enzyme inhibitors or angiotensin receptor blockers in the postoperative setting where oral medications are not possible.

Neurologic Complications

1. *Delayed awakening* is most often due to the persistent effects of anesthetic agents.[43] Metabolic causes of delayed awakening include hypothermia, sepsis, preexisting encephalopathies, hypoglycemia, and electrolyte or acid–base derangements. Additional causes of delayed awakening or obtundation include decreased cerebral perfusion, during or after surgery, which may cause diffuse or localized injury to the brain. In patients with cerebrovascular disease, brief periods of hypotension may cause a critical reduction of cerebral perfusion and brain damage. If such an event is suspected, a neurologic consultation should be obtained as soon as possible, with specific tests (e.g., computed tomography [CT], magnetic resonance imaging [MRI], or angiography) considered. If cerebral edema is suspected, treatment should begin immediately (see Chapter 50).
2. Neurologic damage may be the result of a *stroke* or may be due to peripheral nerve injury. Strokes have an incidence of 0.08–2.9% in the perioperative period and may be either ischemic or hemorrhagic.[44] Early diagnosis of a stroke may be difficult because symptoms and signs, such as slurred speech, visual changes, dizziness, agitation, confusion, psychosis, numbness, and muscular weakness or paralysis, may overlap with the manifestations of residual anesthetic agents. Ischemic strokes are more common in patients with cerebrovascular disease, hypercoagulable states, atrial fibrillation, and they may be associated with intraoperative hypotension. Fat embolism secondary to long bone fractures can lead to strokes. Hemorrhagic strokes are more common in patients with coagulopathies, uncontrolled hypertension, cerebral aneurysms or arteriovenous malformations, and head trauma. Strokes are more frequent following intracranial surgery, carotid endarterectomy, cardiac surgery, or major traumatic injury. Neurologic consultation in conjunction with appropriate imaging studies is mandatory to guide the possible choice of treatment options.
3. *Emergence delirium* is characterized by excitement alternating with lethargy, disorientation, and inappropriate behavior. Delirium may occur in any patient but is more frequent in the elderly and patients with a history of drug or alcohol dependency, dementia, Alzheimer disease, or other psychiatric disorders. Many pharmacologic agents used commonly in the perioperative period, such as ketamine, opioids, benzodiazepines, metoclopramide, anticholinergics (atropine or scopolamine), and droperidol, may precipitate delirium. Delirium may be a symptom of many intercurrent complicating clinical and metabolic conditions, such as hypoxemia, acidemia, hyponatremia, hypoglycemia, intracranial injury, sepsis, severe pain, and alcohol or drug withdrawal and, as such, mandates investigation to exclude each of these causes.[45] Treatment usually is symptomatic by providing supplemental oxygen, fluid and electrolyte replacement, and adequate analgesia. Antipsychotic medications such as haloperidol can be given to patients refractory to symptomatic treatment. Physostigmine administration may reverse delirium due to anticholinergic agents.
4. *Peripheral neurologic lesions* may result from improper intraoperative positioning or direct surgical damage, or it may be a complication of regional anesthetic techniques. In the ASA closed claim analysis, ulnar nerve injury accounted for approximately one third of the cases of nerve injury, followed by damage to the brachial plexus and the common peroneal nerve. Risk factors for nerve injury after surgery include slender body habitus and history of neuropathy, smoking, or diabetes. Additional sites of potential nerve damage are discussed in Chapter 26.
5. *Intraoperative awareness and recall* are uncommon complications of general anesthesia (0.13% incidence in a large multicenter trial) that initially may be detected in the PACU.[46,47] Awareness and recall are most commonly associated with trauma and with cardiac and obstetric surgery.[48] Risk factors include young age, history of substance abuse, ASA physical status III–V, and use of muscular relaxants. A modified Brice Questionnaire (Table 72–5) can be used as a screening tool in the PACU to identify patients at risk for intraoperative recall. Patients with evidence of recall should receive reassurance and sympathetic care. They may require referral for psychological counseling, as required.[49]

Principles of Pain Management

Adequate analgesia usually begins in the operating room and continues in

TABLE 72–5.

Modified Brice Questionnaire to Screen for Intraoperative Awareness

What is the last thing you remember before going to sleep for the operation?
What is the first thing you remember upon waking after the operation?
Do you remember anything between going to sleep and waking up?
Did you have any dreams?
What was the most unpleasant thing you remember from the operation and anesthesia?

The Brice questionnaire can be used in the immediate postoperative period to explore issues that suggest the possibility of intraoperative awareness. Although the first indications that intraoperative recall may have occurred can be noted in the postanesthesia care unit, it is important to ensure that the patient has recovered adequately from the effects of anesthesia and is able to appropriately cooperate with the examiner.[71]

the PACU.[50] Apfelbaum et al.[51] reported that most patients experience pain in the recovery room; approximately 20% describe the pain as severe, suggesting that pain often is inadequately treated before arrival in the PACU. In the postoperative period, incisional pain is the most common discomfort experienced by patients.[52,53] A detailed discussion of the management of postoperative pain is given in Chapter 74. A brief overview of some of the most common therapeutic modalities is given here.

1. *Opioids* (IV or epidural) are the mainstay of postoperative analgesia. Fentanyl, a potent synthetic opioid with rapid onset of action, is commonly administered in the operative setting. However, small parenteral doses can be titrated postoperatively to establish rapid analgesia. Morphine, hydromorphone and meperidine are effective as longer-acting agents. Meperidine must be avoided in patients taking monoamine oxidase inhibitors.
2. *Nonsteroidal antiinflammatory drugs* (NSAIDs) and *acetaminophen* can be effective complements to opioids, with ketorolac providing potent postoperative analgesia. Potential toxicities of all NSAIDs include decreased platelet aggregation, gastrointestinal bleeding, and nephrotoxicity.[54] Regional and peripheral sensory blockade (see Chapter 48) can be effective postoperatively and offers flexibility for patients in whom opioids may be contraindicated.
3. *IV patient-controlled analgesia* (IV-PCA) has been shown to be superior in patient satisfaction compared with intermittent analgesia administered by the medical staff. Continuous epidural analgesia should be continued postoperatively or promptly initiated in the PACU when indicated.[55]

Temperature Control

1. *Hypothermia* is a common occurrence in the PACU as a result of the cool environment of the operating room combined with temporary pharmacologic impairment of effective thermoregulation. A core body temperature between 34°C and 36°C will be perceived as uncomfortable by a conscious patient. Additional side effects associated with hypothermia include shivering,[56] increased duration of muscle relaxation, coagulopathy, cardiac dysrhythmias, and increased duration of postanesthetic recovery.[57] Treatment with warmed blankets or with forced-air warming systems is generally effective.[58] In the setting of major parenteral fluid administration, one must ensure that a fluid warming system is used to prevent cooling the patient.
2. *Hyperthermia* is less common than hypothermia in the immediate postoperative period. Fever in the PACU can be associated with postoperative atelectasis and is responsive to incentive spirometry. However, the presence of an elevated temperature in the immediate postoperative patient can be associated with conditions such as sepsis or reactions to medications and requires appropriate investigation. Although extremely rare, hypermetabolic states such as malignant hyperthermia or thyrotoxicosis may be first noted as a fever in the PACU. Hypothermia and hyperthermia are discussed further in Chapter 89.

Fluid Administration and Hemorrhage

All patients in the PACU must be evaluated for the adequacy of intraoperative fluid resuscitation. Parameters indicating that the patient requires additional fluid administration include hypotension, tachycardia, and low urine output. Hypovolemia is the most common cause of postoperative hypotension, and, until proven otherwise, hemorrhage must be a primary concern in postoperative hypotension. Gan et al.[59] demonstrated that intraoperative goal-directed fluid administration can decrease postoperative complications and is associated with earlier return of gastrointestinal function and shorter length of hospital stay.

There is significant debate in the literature regarding the nature of the appropriate fluid for resuscitation of postoperative patients. A possible advantage to using colloid solutions for resuscitation is that they ensure rapid and effective expansion of intravascular volume and do not instantly cross capillary membranes into the interstitial space. However, investigators in a Saline versus Albumin Fluid Evaluation (SAFE) trial demonstrated that albumin and saline both are safe and clinically equivalent, rendering the same 28-day outcome for resuscitation of critically ill patients in the ICU.[60]

Blood transfusion carries specific risks, which include but are not limited to viral infections, contamination with bacteria, parasites, and prions, hemolytic transfusion reactions, alloimmunization, autoimmunization, immunosuppression, transfusion-related lung injury, and errors associated with the processing and administration of blood products. Hebert et al.[61] showed that critically ill patients who undergo a restrictive approach to blood transfusion have a better outcome than do patients who receive liberal blood transfusions, thereby driving a trend to lower the transfusion hemoglobin threshold and ultimately reducing the number of blood transfusions in critically ill patients. Clinicians must consider the risks and benefits to the individual patient of using a volume replacement strategy that may involve blood component therapy.[62]

Unrecognized or ongoing hemorrhage, although uncommon in the immediate postoperative patient, is an emergency requiring immediate treatment and can tax the resources of any PACU. Coordination with the blood bank, the surgery and anesthesia teams, and the operating room staff must be performed in a timely manner. Personnel assigned to the PACU should have a clear plan established to address the requirements of the hemorrhaging postoperative patient.

Hemorrhage may present in an obvious manner, such as rapid saturation of a dressing or an increase in chest tube drainage. However, the presentation may be subtle, as in the case of increased abdominal tension, hypotension, decreased urine output, or downward trend of hematocrit or hemoglobin values.

In laparoscopic procedures involving the abdomen and thorax, signs of internal bleeding may not be obvious initially and may be identified only later in the PACU.[63] Bleeding of a delayed nature may be associated with any procedure requiring the insertion of trocars.[64]

Patients receiving chronic anticoagulation therapy with warfarin (Coumadin) may be at greater risk for postoperative bleeding complications. In a study of 600 surgical patients chronically anticoagulated with warfarin, wherein anticoagulation was either discontinued pre-

operatively or reversed, Torn et al.[65] demonstrated an increased incidence of hemorrhage-related complications, especially in surgical procedures involving the thorax. A detailed discussion regarding the management of fluid and blood component replacement therapy is given in Chapters 34 and 85.

PACU DISCHARGE

As described in the ASA's Standard's for Postoperative Care, a physician should be responsible for the discharge of each patient from the PACU.[5] In the absence of a physician present in the PACU, a nurse may determine that the patient meets the institutionally established discharge criteria and can discharge the patient, noting the physician responsible and appropriate instructions for the patient upon discharge from the hospital.

A variety of discharge criteria and systems for evaluation of a patient prior to discharge from the PACU are used and must be approved by the anesthesia department and the medical staff of each institution. Table 72–6 gives generalized principles summarizing PACU discharge criteria. These criteria may require modification to address the specifics of a discharge. For example, criteria for a patient being discharged to a surgical ward will vary from criteria for a patient to be discharged from the hospital.[66]

Discharge criteria may be based on length of stay in the PACU (time based) or may be based on a clinical scoring system. A variety of parameters are included in PACU discharge scoring systems, such as vital signs, adequate control of pain, nausea, and return to baseline level of consciousness. Each can be evaluated and assigned a score to set minimum values for discharge eligibility. Although no set of criteria or scoring system has been shown to be better than another, evidence suggests that a clinical-based scoring system may reduce overall length of stay in the PACU, without adding risk to the patient's course. Predictors of an increased length of stay in the PACU include length of the surgical procedure, use of opioids, tracheal intubation, and administration of antiemetics. Of note, age, gender, ASA classification, and urgency of surgery did not predict a longer PACU stay.[67] In the 1970s, a scoring system was developed to assess the appropriateness of discharge to an ambulatory unit or to phase II recovery. Later modified to condense discharge criteria into a more effective scoring system, use of the Aldrete recovery score (Table 72–7) appears to decrease the PACU length of stay.[67,68]

TABLE 72–6.

General Guidelines for PACU Discharge

- Patients should be alert and oriented. Patients whose mental status initially was abnormal should have returned to their baseline.
- Vital signs should be stable and within acceptable limits.
- Discharge should occur after the patients have met specified criteria. Use of a composite scoring system may assist in documentation of fitness for discharge and shorten PACU length of stay.
- Outpatients should be discharged to a responsible adult who will accompany them home and be able to report any postprocedural complications.
- Outpatients should be provided with written instructions regarding postprocedural diet, medications, activities, and a physician phone number to be called in case of emergency.

PACU, Postanesthesia care unit.
General guidelines for discharge describe some of the basic principles that might be incorporated into a formalized system to aid in the evaluation of the patient for discharge. The criteria that are developed should be designed to minimize the risks of central nervous system and cardiorespiratory depression after discharge.[5]

TABLE 72–7.

Postanesthesia Recovery (PAR) Scoring Criteria: Modified Aldrete Recovery Score

PAR Score		Admission	15 min	30 min	60 min	Discharge
Activity						
Able to move voluntarily						
4 extremities	2					
2 extremities	1					
0 extremities	0					
Respiration						
Breathes deeply, coughs freely	2					
Dyspnea, shallow or limited respirations	1					
Apnea	0					
Circulation						
BP ± 20% of preop	2					
BP ± 20–49% of preop	1					
BP ± 50% of preop	0					
Consciousness						
Fully awake	2					
Arousable with minimal stimulation	1					
Not responding to noxious stimulus	0					
O_2 Saturation						
>92% on room air	2					
Needs O_2 to maintain >90%	1					
<90% even with O_2	0					
Total	0–10					

BP, Blood pressure; preop, preoperative value.
The primary shortfall of the Aldrete scoring system is that it does not consider pain, or nausea or vomiting, both common occurrences in the postanesthesia care unit (PACU).[66] Institutions may create individual systems, with similar parameters for evaluation. The goal of any system is to reliably define the time when a patient can be safely transferred from observation in the PACU, either for transfer to a hospital ward or for accompaniment home. A minimum composite score of 8 is required for discharge.[67]
Reprinted from Aldrete J. The post-anesthesia recovery score revisited. J Clin Anesth 1995;7:89, with permission from Elsevier.

The decision to admit a PACU patient to the hospital for additional care or to discharge the patient to home is based upon a number of factors, including the nature of the surgical procedure, complications encountered, the patient's comorbidities, and the home care situation. In our hospital, patients who will be admitted to the ICU after a surgical procedure are transferred directly to that unit from the operating room, thereby avoiding an extra handoff. However, these patients can be initially transferred to the PACU while awaiting postoperative radiographic testing, such as CT or MRI. Occasionally patients require a period of close observation of airway issues, which is best carried out in the PACU.

Given the ever-increasing pressure of throughput in hospitals, there is often a shortage of beds in the ICU. Consequently, doctors often will use the PACU as a short-term ICU for patients who are expected to recover within a 24- to 36-hour period to permit safe care on a hospital ward.[69,70]

CHAPTER 73

Postoperative Complications

Edward A. Bittner, MD, PhD,
Loreta Grecu, MD, and
Edward George, MD

Complications in the postanesthesia care unit (PACU) are common. In a study of 18,473 patients entering the PACU at a university teaching hospital, Hines et al.[1] reported a complication rate of 23%, with nausea and vomiting (9.8%), need for upper airway support (6.9%), and hypotension (2.7%) the most frequently encountered problems (Fig. 73–1). Despite pharmacologic and medical advances over the last 10 years, the incidence of postoperative complications appears largely unchanged.[2] Even minor postoperative complications are important to patients (Table 73–1), and greater efforts at preventing and treating complications should lead to improved postoperative recovery and patient satisfaction.[3,4]

This chapter focuses on postoperative complications commonly encountered in the PACU setting, with emphasis on early diagnosis and treatment. Naturally there is some overlap with events that occur during routine recovery (see Chapter 72). Many of the specific details

KEY POINTS

1. Complications in the postanesthesia care unit (PACU) are common. Despite pharmacologic and medical advances over the last 10 years, the incidence of postoperative complications appears largely unchanged. Even minor postoperative complications are important to patients, and greater efforts at preventing and treating such complications should lead to improved postoperative recovery and patient satisfaction.
2. Knowledge of the expected postoperative course for a given operation is essential to identifying and managing problems when they occur. Awareness of the temporal patterns of complications is important to anticipating periods of increased perioperative risk.
3. Airway obstruction is common in the postoperative period. Upper airway obstruction arises in the pharynx (posterior tongue displacement, soft tissue collapse), larynx (laryngeal edema, laryngospasm, vocal cord paralysis), or trachea due to extrinsic compression. Anesthetics, and even minimal residual neuromuscular blockade, may lead to upper airway obstruction.
4. Hypoxemia is common in postoperative patients not receiving supplemental oxygen.

   Following general anesthesia or sedation all patients should receive supplemental oxygen (O_2) during their transport from the operating room and during their initial PACU stay. Continuous monitoring of oxygen saturation with pulse oximetry is essential for early detection of hypoxemia.
5. Several conditions may necessitate continued intubation after surgery. They include delayed emergence from general anesthesia, inadequate reversal of neuromuscular blockade, potential for airway obstruction, inadequate gas exchange, and hemodynamic instability.
6. Hypotension is a common postoperative complication that results from hypovolemia (most common), decreased vascular tone, and/or reduced cardiac output. Causes of hypovolemia in the PACU include inadequate fluid replacement, ongoing hemorrhage, and fluid sequestration ("third spacing"). Clinical evaluation of a patient's intravascular volume status requires consideration of preoperative status, type and duration of surgery, estimated blood loss, fluid replacement, and evidence of hemostasis.
7. Cardiac dysrhythmias are common during the perioperative period, and most dysrhythmias are benign. The precipitating factor is usually a transient imbalance such as hypoxia, ischemia, increased catecholamines, altered acid–base status, or electrolyte abnormalities. The management strategy for a new dysrhythmia is focused on stabilizing hemodynamics and treating the underlying problem.
8. Hypertension is a very common problem in the postoperative period. Sympathetic nervous system activation resulting from noxious stimuli, such as pain, anxiety, bladder distension, fluid overload, hypoxemia, hypercarbia, and hypothermia, are common precipitants. The decision to treat hypertension should take into consideration the patient's baseline blood pressure, coexisting diseases, and perceived risk of complications.
9. Urinary retention and oliguria are common problems in the PACU. Oliguria is most commonly caused by hypovolemia (prerenal) in the immediate postoperative period, but postrenal and intrinsic renal causes also should be considered.
10. Patients who develop bleeding postoperatively require rapid evaluation to differentiate poor surgical hemostasis (perhaps requiring immediate reoperation) from a diffuse coagulopathy. It is important to appreciate that surgical and nonsurgical bleeding often coexist. If there is evidence of significant bleeding, diagnosis and treatment usually occur simultaneously. Adequate IV access should be established, availability of appropriate blood products ensured, and a diagnostic evaluation performed.
11. Hypothermia remains a common PACU problem. Even mild hypothermia (core temperature between 34°C and 36°C) has been associated with adverse outcomes, including myocardial ischemia, arrhythmias, coagulopathy, wound infection, decreased drug metabolism, and poor patient satisfaction.
12. The major causes of delayed awakening after general anesthesia can be divided into three groups: (1) prolonged pharmacologic effects, (2) metabolic abnormalities, and (3) neurologic injury.
13. Awareness with recall of intraoperative events is an infrequent but recognized complication of general anesthesia that can result in significant distress to patients and long-term psychological sequelae. In cases of possible awareness, the patient should be offered counseling and psychological support.

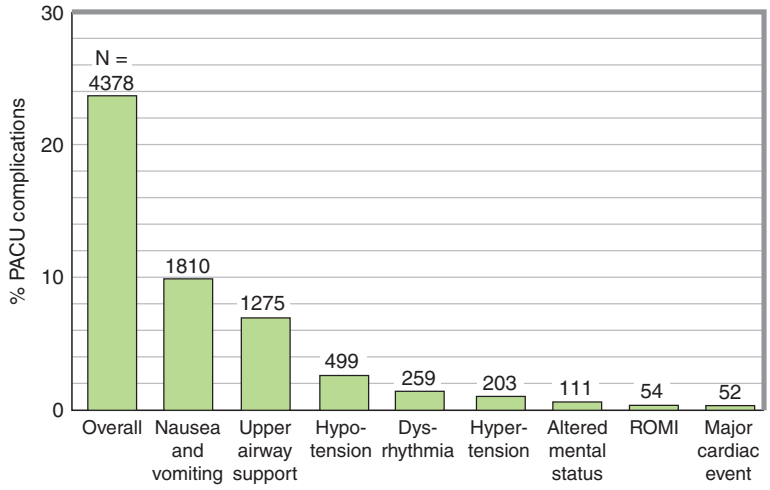

FIGURE 73–1. Major postanesthesia care unit complications by percentage of occurrence from a prospective study of 18,473 patients. From Hines R et al.[1] with permission.

of diagnosis and management are covered in other chapters of this book and will not be repeated here.

As with intraoperative anesthetic care, knowledge of the expected postoperative course for a given operation is essential to identifying and managing problems when they occur. Awareness of the temporal patterns of complications is important to anticipating periods of increased perioperative risk (Table 73–2).[5] When complications do occur, early communication with the surgical team is essential.

TABLE 73–1.

Temporal Patterns of Postoperative Complications

Complications	Time/Interval of Greatest Risk
Hypotension Myocardial infarction Respiratory depression	Day 1
Congestive heart failure Pulmonary embolism Respiratory failure	Days 1–3
Pneumonia	Days 4–7
Cerebrovascular accident Sepsis	Days 8–30
Renal failure	Days 1–3, 8–30

Results of 1021 patients undergoing intra-abdominal operations in Veterans Administration (VA) medical centers. Data from Thompson JS et al.[5] Temporal patterns of postoperative complications. Arch Surg 2003;138:596–603.

AIRWAY COMPLICATIONS

Upper Airway Obstruction

Upper airway obstruction can arise in the pharynx (posterior tongue displacement, soft tissue collapse), larynx (laryngeal edema, laryngospasm, vocal cord paralysis), or large airways due to extrinsic compression. Anesthetics, and even minimal residual neuromuscular blockade, may lead to upper airway obstruction.[6] Principal signs are lack of adequate air movement, intercostal and suprasternal retractions, and discoordinate abdominal and chest wall movements during inspiration.

Pharyngeal Obstruction

Simple maneuvers such as a chin lift, jaw thrust, and lateral decubitus positioning, as well as decreasing the level of sedation usually are successful in relieving pharyngeal obstruction. Oropharyngeal or nasopharyngeal airways are useful adjuncts. Nasopharyngeal airways are better tolerated than oral airways at light levels of sedation because of less tendency to provoke a gag reflex. Careful insertion of nasal airways is necessary to avoid creating a nosebleed.

Laryngeal Obstruction

Laryngeal Edema Laryngeal or subglottic edema can create airway obstruction, especially in children because of their smaller airway diameter and in patients recovering from neck surgery. Treatment of partial airway obstruction resulting from airway edema includes head-up positioning to promote venous drainage and administering nebulized epinephrine and steroids. Treatment of severe airway edema may require emergency reintubation or tracheostomy.

Prolonged surgery in a head-down position can result in significant airway swelling. The common practice of listening for an air leak after a positive pressure breath (with the endotracheal cuff deflated) is a reliable way to determine that extubation likely will be successful if a leak is present.[7] However, a failed leak test does not preclude uneventful extubation.[8] Patients at risk for significant swelling should be evaluated (using direct or fiberoptic laryngoscopy) prior to extubation because they are at risk for complete airway obstruction. Patients with significant obstruction should remain intubated until airway edema resolves.

Laryngospasm Laryngospasm is a reflex resulting from prolonged glottic closure. Although the cords are adducted, the primary obstruction is caused by tonic contraction of the laryngeal muscles and descent of the epiglottis over the laryngeal inlet. Laryngospasm may be precipitated by light anesthesia and the presence of an airway irritant such as secretions, blood, or a foreign body. It also can be caused by stimulation from an elongated uvula, may be sleep related, or may be stimulated by distal esoph-

TABLE 73–2.

Ranking of Patient's Preferences for Postoperative Anesthesia Outcomes

Outcome	Rank (Mean)[a]
Vomiting	2.56
Gagging on endotracheal tube	2.97
Pain	3.46
Nausea	4.02
Recall without pain	4.85
Residual weakness	5.34
Shivering	5.36
Sore throat	8.02
Somnolence	8.28

[a]Outcomes are ranked in relation to each other on a scale from 1 (most undesirable) to 10 (most desirable).
Modified from Macario et al.[3] with permission.

ageal afferents.[9] Partial laryngospasm allows for some air movement and may be difficult to distinguish from other causes of upper airway obstruction. Complete laryngospasm prevents all air movement and is a prominent cause of negative pressure pulmonary edema (see Pulmonary Edema below). Management of laryngospasm consists of jaw thrust, positive-pressure ventilation, and possibly administration of intravenous propofol or a small dose of succinylcholine (0.1 mg/kg).

Vocal Cord Paralysis Vocal cord paralysis can be due to nerve injury or mechanical injury and may be unilateral or bilateral. Injury to the recurrent laryngeal nerve prevents abduction of the ipsilateral vocal cord, which becomes fixed in a paramedian position because of the unopposed action of the cricothyroid muscle. An inflated endotracheal tube cuff in the subglottic larynx can compress the anterior branch of the recurrent laryngeal nerve as it enters between the cricoid and thyroid cartilage, resulting in nerve injury. Recurrent laryngeal nerve injury may occur after operations such as a rigid bronchoscopy, thyroid and parathyroid surgery, or laryngeal and thoracic surgery. Arytenoid avulsion can result in vocal cord immobility.[10]

Hoarseness usually is noted immediately after extubation. Healthy patients generally tolerate the resulting increased airway resistance, but it may become a problem in patients with preexisting pulmonary compromise. Bilateral recurrent laryngeal nerve injuries result in inadequate glottic opening and require emergent reintubation or tracheostomy. Vocal cord paralysis usually is associated with spontaneous recovery, but this may take a period of days to months. Otolaryngologic evaluation in the acute setting is generally warranted.

Extrinsic Airway Compression

Acute extrinsic neck compression from an expanding neck hematoma can be life threatening. Neck hematomas can develop after carotid endarterectomy, thyroid or parathyroid surgery, or other neck surgery. Although many neck hematomas can be treated conservatively, they should be closely monitored for progression and signs of airway compromise. A rapidly expanding hematoma can cause marked tracheal deviation and make emergency reintubation extremely difficult. If possible, a subcutaneous clot should be decompressed by removing surgical sutures. Definitive treatment usually requires returning to the operating room for hematoma evacuation and exploration.

PULMONARY DYSFUNCTION

General anesthesia inhibits hypoxic and hypercapnic ventilatory drive and reduces the lung's functional residual capacity. These changes may persist for variable periods of time postoperatively and predispose to hypoventilation and hypoxemia. Additional causes of hypoxemia and hypercapnia that are encountered in the PACU include aspiration, pulmonary edema, pulmonary embolism (PE), and pneumothorax.

Hypoxemia

Hypoxemia is common in postoperative patients not receiving supplemental oxygen. In a study of patients undergoing transfer from the operating room to the PACU, Tyler et al.[11] found that 30% of patients had oxygen saturations (SpO_2) < 90% while breathing air. The most common causes of hypoxemia in the early postoperative period include hypoventilation and atelectasis. Patients with preexisting lung disease or obesity and those recovering from thoracic and upper abdominal surgery are at increased risk (Fig. 73–2).[12]

Following general anesthesia or sedation, all patients should receive supplemental oxygen (O_2) during transport from the operating room and during their initial PACU stay. Continuous monitoring of oxygen saturation with pulse oximetry is essential to early detection of hypoxemia. It is important to remember that supplemental oxygen can prolong the time to desaturation, which may delay the detection of hypoventilation. Hypoxemia is treated by increasing the inspired oxygen concentration, elevating the head of the bed, performing lung expansion maneuvers, and eliminating other reversible causes (e.g., bronchospasm, secretions, and mucous plugs). Continuous positive airway pressure may be effective in treating more severe hypoxemia in some patients and decrease the need for endotracheal intubation (Fig. 73–3).[13,14]

Hypoventilation

Hypoventilation is characterized by an inappropriately low minute ventila-

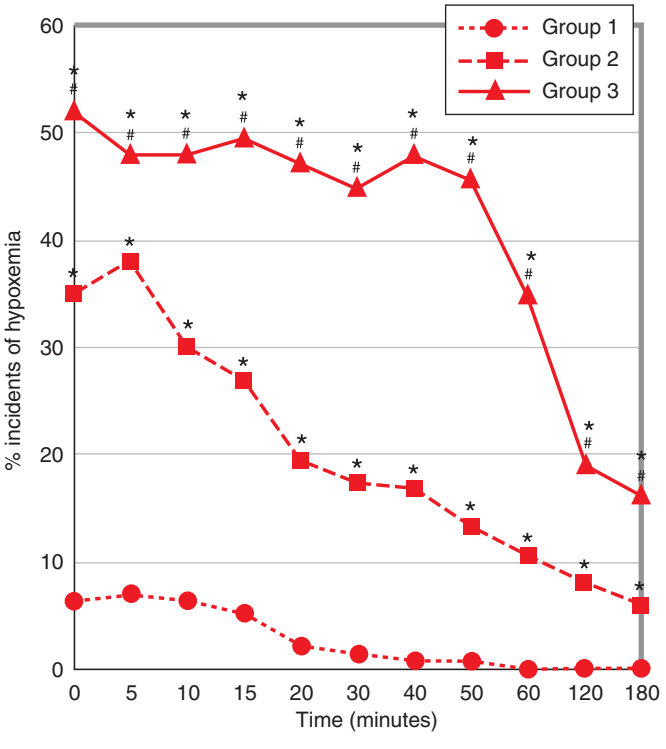

FIGURE 73–2. Incidence of hypoxemia in the first 180 minutes after surgery while patients were breathing room air. Group 1, Superficial plastic surgery; group 2, upper abdominal surgery; group 3, thoracoabdominal surgery. Points are incidence of hypoxemia (SpO_2 85–90%). *P <.01 vs group 1. #P <.05 vs group 2. FIGURE 73–3. Intubation rates: continuous positive airway pressure + oxygen (CPAP) versus oxygen alone (control) for treatment of postoperative hypoxemia. The CPAP group had a significantly lower intubation rate ($P = .005$, log rank test) than did the group treated with oxygen alone. From Squadrone V et al.[13] with permission.

tion with resulting hypercapnia and respiratory acidosis. Severe hypoventilation results in hypoxemia, carbon dioxide (CO_2) narcosis, and ultimately apnea. Causes of postoperative hypoventilation include decreased ventilatory drive, respiratory muscle insufficiency, increased CO_2 production, and acute or chronic lung disease.

Decreased Ventilatory Drive

The typical combination of inhaled anesthetics, opioids, and benzodiazepines can depress both the hypercarbic and hypoxic drive, resulting in hypoventilation. Development of postoperative hypercarbia can be deceptive, as patients may appear awake and even complain of pain while experiencing significant hypoventilation. Ventilatory depression from opioids and sedatives will become significantly worse, however, if the patient falls asleep (see Chapter 41). A balance must be achieved between adequate analgesia and an acceptable level of respiratory depression. Opioid-induced hypoventilation can be reversed by small incremental doses of naloxone (0.04–0.08 mg) while preserving some analgesia. Reversal usually occurs within 1–2 minutes and lasts for 30–60 minutes. Caution should be exercised as the duration of action of naloxone is shorter than that of most opioids, and repeated doses of naloxone or an infusion may be required. Flumazenil can reverse the sedative effects of benzodiazepines, but it does not reverse the depression of hypoxic drive (see Chapter 40). Flumazenil does not reverse opioid-induced depression.

Respiratory Muscle Insufficiency

Incomplete reversal of neuromuscular blockade can result in airway obstruction and hypoventilation. The patient may exhibit discoordinated movements, generalized weakness, hypoxemia, or shallow breathing. Residual block is more common in patients who receive long-acting muscle relaxants such as pancuronium and those not treated with reversal agents (Fig. 73–4).[15,16]

Limited chest expansion may be caused by pain (splinting) after thoracic and upper abdominal surgery, resulting in atelectasis and consequently right-to-left shunting. Better analgesia (particularly that produced by neuraxial and intercostal blocks) facilitates deep breathing and significantly reduces hypercapnia and hypoxemia.

Many factors increase the work of breathing for postoperative patients. For example, the functional residual capacity can be reduced by airway closure and collapse, and significant muscular effort then is required for lung reexpansion. Other intrathoracic factors, such as pulmonary edema, pneumothorax, restrictive lung diseases, and skeletal abnormalities, can reduce lung compliance and increase energy expenditure for breathing. Obesity, gastric distension, and restrictive dressings on the chest or abdomen are extrathoracic factors that result in increased work of breathing and the potential for inadequate ventilation. Incentive spirometry, chest physiotherapy, upright positioning, and continuous positive airway pressure may be effective therapeutic maneuvers for these patients.

Acute or Chronic Lung Disease

Preexisting pulmonary disease is an important risk factor for developing postoperative pulmonary complications.[17] Respiratory diseases usually are categorized according to the manner in which they alter pulmonary mechanics, producing either a limitation of expiratory airflow (obstructive disease) or a limitation of lung expansion (restrictive disease). Exacerbations of obstructive diseases, such as asthma and chronic obstructive pulmonary disease (COPD), are frequently accompanied by increasing hypercapnia and worsening hypoxemia. The key management issues are similar in both acute asthma and COPD exacerbations. They include treating bronchospasm and airway inflammation, correcting hypoxemia and respiratory acidosis, clearing secretions, and removing/treating pre-

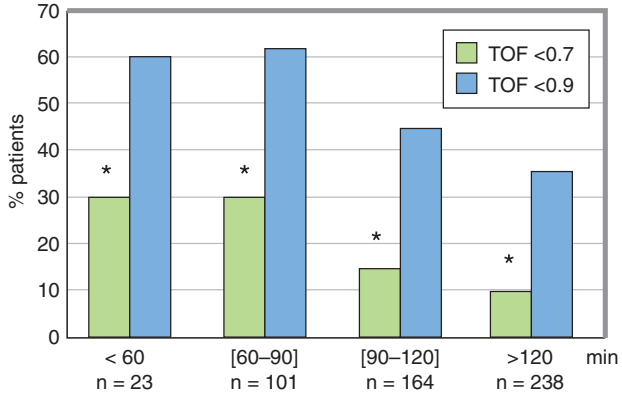

FIGURE 73–4. Residual paralysis rate. Partial paralysis rate (percent) according to delay between administration of an intermediate-duration muscle relaxant (atracurium, vecuronium, rocuronium) and arrival in the postanesthesia care unit. Train-of-four (TOF) ratios ‹0.7 and ‹0.9 were examined as criteria for partial paralysis. Neuromuscular blockade was not reversed at the end of the procedure. From Bebaene B et al.[16] with permission.

cipitating factors. The concerns for CO_2 retention and respiratory depression resulting from administration of supplemental oxygen to patients with COPD have been overemphasized.[18] In all cases, correction of hypoxemia should take precedence over concerns for carbon dioxide retention.

Restrictive pulmonary disorders are characterized by decreased lung compliance resulting from intrinsic disease of the lungs (e.g., pulmonary fibrosis, pulmonary edema) or extrinsic disorders (e.g., pleural effusions, obesity, scoliosis, abdominal distension, massive ascites) that impair normal lung expansion. Management is directed at treating the underlying disease process (e.g., steroids for pulmonary fibrosis, draining the pleural space, etc.) and supportive respiratory care.

Aspiration

General anesthesia and surgery depress airway protective reflexes and predispose patients to aspiration. Gastric contents or objects such as dislodged teeth can enter the trachea during induction or emergence, and even after PACU admission. Perioperative pulmonary aspiration is an infrequent event (1: 2000–3000 general anesthetics), but it can result in severe morbidity and mortality.[19] Signs of significant aspiration include bronchospasm, hypoxemia, atelectasis, tachypnea, tachycardia, and hypotension. Radiographic evidence of aspiration (usually infiltrates in the upper lobes of supine patients) may take some time to appear.

The severity of symptoms depends on the type and volume of material aspirated. *Aspiration pneumonitis* (Mendelson syndrome) is a chemical injury to the lungs that is caused by inhalation of sterile acidic gastric contents, whereas *aspiration pneumonia* refers to inhalation of contents that are colonized by pathogenic bacteria.[20] Initial treatment of a significant aspiration consists of oropharyngeal suctioning, administration of bronchodilators for bronchospasm, and supplemental oxygen. Plans should be made for transfer of the patient to an intensive care unit (ICU). Bronchoscopy may be beneficial to remove particulate matter from the tracheobronchial tree, but pulmonary lavage with large volumes of saline is generally believed to be detrimental. Mechanical ventilatory support with positive end-expiratory pressure may be necessary if hypoxemia is severe. Administration of empiric antibiotics for aspiration is not recommended unless the material aspirated has a high bacterial load, as with a small bowel obstruction. Steroids are not beneficial for treatment if administered after an aspiration has occurred. In cases of mild or uncertain aspiration, close postoperative observation should be undertaken with continuous pulse oximetry monitoring and chest radiography. Patients with clinical evidence of aspiration who do not develop signs or symptoms (cough, wheeze, hypoxia on room air, or radiologic abnormalities) within 2 hours of aspiration are unlikely to develop pulmonary complications (Fig. 73–5).[21,22]

Pulmonary Edema

Pulmonary edema is the accumulation of fluid in the interstitium and alveoli of the lungs that can hinder gas exchange. Cardiac pulmonary edema results from increased pulmonary capillary pressure secondary to elevated left atrial pressure that may be precipitated by fluid overload, left ventricular dysfunction, or mitral valve disease. A careful physical examination, chest x–ray film, electrocardiography (ECG), and arterial blood gas analysis are useful for diagnosis. Evaluation by a cardiologist may be indicated when myocardial ischemia or acute valvular disease is considered to be the cause of the pulmonary edema. Noncardiac pulmonary edema usually is due to increased pulmonary capillary permeability. Mainstays of treatment include supplemental oxygen, diuretics, vasodilators, and mechanical ventilatory support with positive end-expiratory pressure.

Pulmonary edema can occur in the operating room or PACU secondary to acute upper airway obstruction (*negative-pressure pulmonary edema*). During upper airway obstruction, forceful inspiratory efforts against a closed glottis can result in large negative intrathoracic pressures with an increased left ventricular preload and afterload. In addition, hypoxia and increased circulating catecholamine levels may elevate pulmonary and systemic vascular resistance, shift the intraventricular septum to the left, and cause left ventricular diastolic dysfunction. These result in negative-pressure pulmonary edema, a rapid onset of copious pink fluid with bubbles due to acute fluid filtration into the lung, and capillary failure resulting in alveolar hemorrhage and hemoptysis.[23,24]

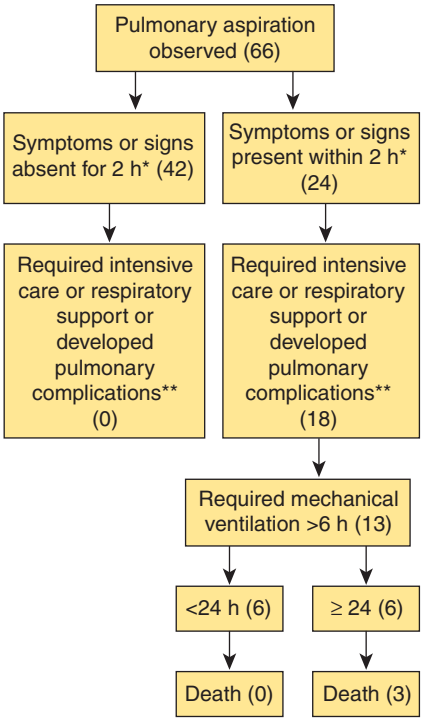

FIGURE 73–5. Relationship of symptoms or signs of perioperative pulmonary aspiration that develop within 2 hours of aspiration to pulmonary outcomes. *Symptoms or signs of pulmonary aspiration include development of a new cough or wheeze, decrease in SpO_2 while breathing room air ≥10% preoperative value, alveolar–arterial oxygen tension ≥300 mmHg, and radiologic evidence of pulmonary aspiration. **Pulmonary complications included development of radiologic evidence of acute respiratory distress syndrome, pneumonitis, or pneumonia. From Warner MA et al.[21] with permission.

Pulmonary Embolism

PE contributes to 50,000–200,000 deaths annually.[25] The mortality rate exceeds 15% in the first 3 months after the diagnosis is made, and in nearly 25% of patients with PE, the initial clinical sign is sudden death.[26] Under pathologic conditions, thrombi escape the normal fibrinolytic system, propagate in the deep veins of the lower extremities and pelvis, and then dislodge and embolize blocking pulmonary vessels. Thrombosis is triggered by venous stasis, hypercoagulability, and vessel wall inflammation (Virchow's triad). The diagnosis of PE can be challenging because the clinical presentation can vary substantially. Dyspnea is the most frequent symptom, although patients may be asymptomatic. A patient with a massive PE may present with hypotension, severe

hypoxemia, cardiogenic shock, or cardiac arrest. ECG may reveal signs of right ventricular strain but may be entirely normal in previously healthy patients, and the chest x-ray film is often normal. Chest CT has become the primary diagnostic imaging modality to evaluate suspected PE. Alternate imaging modalities include a ventilation–perfusion lung scan, magnetic resonance angiography, echocardiography, and pulmonary angiography. Treatment of PE is supportive (volume infusion, vasopressors, and mechanical ventilation) because anticoagulation or thrombolytic therapy often is not an option in the immediate postoperative period. Inhaled nitric oxide has been given experimentally to reverse pulmonary vasospasm. Insertion of an inferior vena cava filter may be beneficial to prevent further embolism in patients in whom anticoagulation is contraindicated. In patients with severe hypoxemia and/or hypotension, emergency pulmonary embolectomy may be required.

Pneumothorax

Pneumothorax is the accumulation of gas within the pleural space. It can result from surgical entrance into the pleural space during thoracic, upper abdominal, or retroperitoneal surgery, tracheostomy, or surgery on the chest wall or neck. Other causes include blunt or penetrating trauma, rupture of blebs or bulla, barotrauma from positive-pressure ventilation, and as a complication of procedures such as central line placement, thoracentesis, or upper extremity neural blockade.

A *tension pneumothorax* occurs when the site of pulmonary air leak forms a one-way valve, allowing airflow into the pleural space during inspiration but preventing its elimination during expiration. The rapid unilateral increase in intrathoracic pressure can be life threatening because it can produce a contralateral mediastinal shift with a rapid deterioration in gas exchange, diminished cardiac output, and marked hemodynamic instability. Diminished or absent chest sounds on auscultation may be present over one hemithorax. If a tension pneumothorax is suspected and hemodynamic or respiratory status is compromised, then decompression should be performed immediately, without waiting for confirmation of the diagnosis by chest radiography. A 14-gauge angiocath can be placed through the chest wall in the second intercostal space at the midclavicular line or the fourth intercostal space at the midaxillary line. The needle is removed, and the catheter is held securely in position until a tube thoracostomy can be performed. A rush of released air and immediate improvement in respiratory and hemodynamic status should occur when decompression is successful.

A disposable one-piece suction device (e.g., Pleurovac) is commonly used for chest tube drainage. The underlying principle of drainage is the same as the original "three-bottle" system, but the apparatus is more compact with fewer connections. The proximal compartment collects drainage, the middle prevents flow of air back into the thorax by forming a water seal, and the distal compartment regulates the amount of suction that is applied to the pleural cavity (Fig. 73–6). Generally, the chest tube initially is given active suction of 20 cm H_2O. If no bubbles are observed in the water seal (i.e., no air leak is detected), active suction may not be necessary.

Chest tubes should be monitored continuously to ensure that they are functioning properly and achieving the desired therapeutic effect. The position of the chest tube, lung expansion, and fluid content of the pleural space should be evaluated by chest radiography.

Prolonged Intubation

Several conditions may necessitate continued intubation after surgery. They include delayed emergence from general anesthesia, inadequate reversal of neuromuscular blockade, potential for airway obstruction, inadequate gas exchange, and hemodynamic instability.

Delayed emergence from general anesthesia due to volatile or IV agents

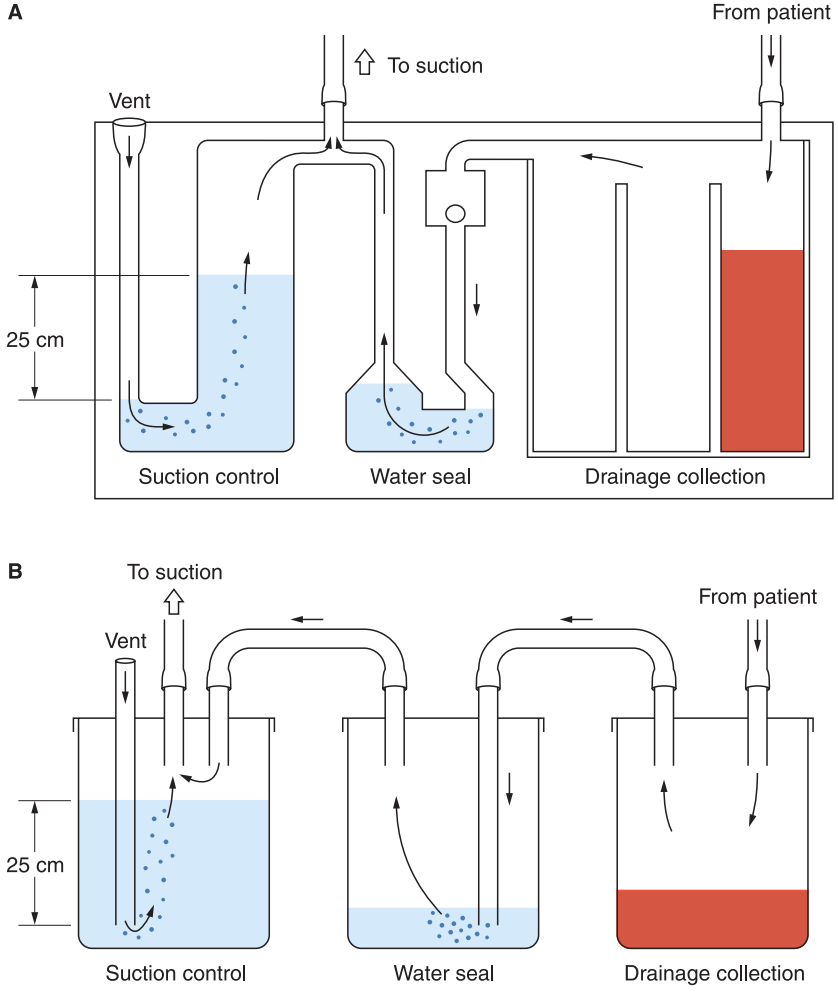

FIGURE 73–6. Chest tube drainage system. **A.** Commercial apparatus. The proximal chamber is for pleural drainage, the middle chamber (water seal) prevents air of fluid from being driven in to the thorax, and the distal chamber regulates the level of suction. **B.** Traditional "three-bottle" system for comparison. From Davignon et al.[86] with permission.

is an indication to delay extubation (see Delayed Awakening below). Reversal may be facilitated pharmacologically, but generally it is prudent to provide support with controlled or assisted ventilation until the patient spontaneously emerges. Spontaneous ventilation of the intubated patient through a "T-piece" may be sufficient when prolonged emergence is not foreseen. The presence of a full stomach mandates that laryngeal reflexes and consciousness be fully recovered before extubation to avoid aspiration.

The potential for airway obstruction is highest after head and neck procedures, drainage of pharyngeal abscesses, or when the jaws are wired closed following facial trauma. As stated previously, obstruction from glottic edema can occur after prolonged surgery, especially in the prone or head-down position. Hemodynamic instability, when severe, may be associated with a variable degree of impaired gas exchange or impaired consciousness that requires continuation of mechanical ventilation. A cardiovascular system that is stressed by hypovolemia, hypothermia, or myocardial ischemia may not be able to compensate for marginal oxygenation or ventilation. Early admission to an ICU should be considered for patients who are not anticipated to improve after a few hours in the PACU.

CARDIOVASCULAR DYSFUNCTION

Hypotension

Hypotension is a common postoperative complication that can result from hypovolemia, decreased systemic vascular tone, and/or reduced cardiac output. Hypotension can result in myocardial ischemia or infarction, stroke, acute renal failure (ARF), and bowel ischemia. During hypotension, the body attempts to redirect blood flow toward the brain, heart, and kidneys, so signs of hypoperfusion of these organs suggest that compensatory mechanisms have failed. Hypotension may be defined as a >20% decline of blood pressure from baseline or evidence of end-organ hypoperfusion.

Accurate measurement of blood pressure is essential to making a correct diagnosis of hypotension. An inappropriately large blood pressure cuff or an arterial transducer that is improperly zeroed, positioned, or dampened can lead to falsely low blood pressure readings.

Hypovolemia

Causes of hypovolemia in the PACU include inadequate fluid replacement, ongoing hemorrhage, and fluid sequestration ("third spacing"). Clinical evaluation of a patient's intravascular volume status requires consideration of preoperative status and comorbid conditions, type and duration of surgery, estimated blood loss, fluid replacement, and evidence of hemostasis. Signs of hypovolemia include hypotension, tachycardia, orthostasis, decreased skin turgor, oliguria, and dry mucus membranes. Administration of a fluid bolus during the initial assessment is generally a safe maneuver. Persistent hypotension despite seemingly adequate fluid replacement requires further assessment and may require monitoring of central venous and pulmonary artery pressures or echocardiography.

Systemic Vasodilatation

Neuraxial anesthesia, residual inhalation agents, administration of vasodilators, rewarming after hypothermia, transfusion reactions, systemic inflammation, and sepsis can cause hypotension by decreasing systemic vascular resistance and impairing venous return. Hypovolemia increases systemic hypotension due to vasodilatation, but fluid resuscitation often does not fully restore the blood pressure. Pharmacologic treatment includes administration of a peripheral vasoconstrictor. A pure α_1-agonist, such as phenylephrine, often is chosen because it is unlikely to cause dysrhythmias and can be administered through a peripheral intravenous line. Administering powerful pressor agonists, such as norepinephrine, usually requires a central venous line for administration. Diagnosis and treatment of the specific etiology of the vasodilatation should be concurrent with symptomatic treatment.

Myocardial Ischemia and Infarction

A variety of factors in the perioperative period may alter the balance between myocardial oxygen supply and demand. The body's physiologic response to surgery is an increase in circulating catecholamines that increases myocardial demand by increasing heart rate, myocardial contractility, and peripheral vascular resistance. Myocardial oxygen supply may be decreased by perioperative factors such as hypoxemia and hypotension. Patients with coronary artery disease or those at risk for coronary disease have significantly higher rates of perioperative myocardial ischemia, infarction, and cardiac death.[27] Mangano et al.[28] reported that the incidence and severity of perioperative myocardial ischemia were greatest during the first 48 hours after surgery. Badner et al.[29] reported that the peak incidence of perioperative myocardial infarction (MI) occurred during the first 24 hours following surgery.

The diagnosis of perioperative ischemia can be difficult because the condition often is silent. Postoperative chest pain may be masked by residual anesthesia or analgesics, and pain perception may be altered by the competing stimulus of incisional pain. The patient at high risk for perioperative myocardial ischemia and MI should be assessed by ECG preoperatively, immediately after surgery, and daily for the first 2 postoperative days.[30] In patients with suspicion of a silent perioperative MI, serial markers of myocardial injury (troponin, creatine phosphokinase) should be followed. Therapy for perioperative ischemia or MI is similar to that for other medical patients with MI and includes aggressive pain control, β-blockade, aspirin, and nitrates.

Dysrhythmias

Cardiac dysrhythmias are common during the perioperative period; transient dysrhythmias reportedly occur in 62–84% of patients.[31] Most perioperative dysrhythmias are benign. They are most likely to occur in patients with underlying structural heart disease; however, the precipitating factor is usually a transient imbalance such as hypoxia, ischemia, increased circulating catecholamine levels, altered acid–base status, or electrolyte abnormalities. The clinical significance of a dysrhythmia depends on the patient's underlying cardiac function. Bradycardia may cause a clinically significant reduction in cardiac output in a patient with relatively fixed stroke volume. Tachycardia may reduce cardiac output by decreasing diastolic filling time and increasing myocardial oxygen consumption, resulting in myocardial ischemia. Loss of atrial contrac-

tion in atrial fibrillation may decrease cardiac output by decreasing diastolic filling. The management strategy for a new dysrhythmia is focused on stabilizing hemodynamics and treating the underlying problem. Significant hemodynamic instability resulting from a dysrhythmia is an indication for emergent cardioversion.

Specific antiarrhythmic therapy in the postoperative setting is similar to that in the nonoperative setting, but it will generally not be effective unless the precipitants are identified and treated.

Tachycardia

Tachyarrhythmias usually are classified according to their anatomic origin as either supraventricular or ventricular. Supraventricular arrhythmias include sinus tachycardia, atrial fibrillation and flutter, ectopic atrial tachycardia, multifocal atrial tachycardia, junctional tachycardia, atrioventricular nodal reentrant tachycardia, and accessory pathway reciprocating tachycardias. Ventricular arrhythmias consist of ventricular premature beats, ventricular tachycardia, and ventricular fibrillation. For a comprehensive discussion of cardiac arrhythmias, see Chapters 43 and 51.

Sinus tachycardia is the most common dysrhythmia in the immediate postoperative period. Increased sympathetic discharge resulting from pain, hypovolemia, anemia, anxiety, hypoxia, and hypercarbia are common causes. Sinus tachycardia usually is benign; however, it may precipitate myocardial ischemia in a patient with coronary artery disease. Treating the underlying cause(s) (e.g., with analgesics for pain, intravenous fluids for hypovolemia, sedatives for anxiety) usually is adequate for resolution. In patients at risk for myocardial ischemia, β-blockade usually is effective in reducing the heart rate.

Supraventricular tachyarrhythmias are more common after thoracic surgery, than after other types of noncardiac surgery with a reported incidence ≥ 15%.[32] In these patients, prophylaxis with calcium channel blockers or β-blockers has been shown to significantly reduce the occurrence of atrial fibrillation.[32]

Atrial fibrillation is the most common supraventricular dysrhythmia after both cardiac and noncardiac surgery and has the greatest potential for serious consequences.[33] For unstable patients with atrial fibrillation and a rapid ventricular rate, urgent cardioversion is indicated. In hemodynamically stable patients, β-blockers, calcium channel blockers, or amiodarone are alternatives for rate control. In most patients, atrial fibrillation will resolve within 36–48 hours. New-onset atrial fibrillation raises risks for embolism, but anticoagulation may not be possible in a postoperative patient at risk for bleeding.

Bradycardia

Bradycardia usually is associated with sinus node or atrioventricular node dysfunction. The various possible presentations are sinus bradycardia, sinus pause, sinoatrial block, sinus arrest, junctional rhythms, and varying degrees of heart block. At sufficiently slow heart rates, ventricular escape beats may be seen. In the postoperative setting, bradycardia is often due to increased vagal tone as a result of hypoxemia, pain, nausea, drugs (e.g., neostigmine, β-blockers, or opioids), or the effects of neuraxial anesthesia. Sinus bradycardia can be a normal rhythm in a young healthy patient. Bradycardia without hypotension usually is benign, and no treatment is needed. If the bradycardia is associated with hemodynamic compromise (hypotension, low cardiac output) then treatment with antimuscarinic agents (glycopyrrolate or atropine) or β-agonists (ephedrine) can restore normal sinus rhythm.

Development of complete heart block can occur in patients with preexisting conduction disease, and the resulting idioventricular bradycardia often will compromise systemic hemodynamics. Atropine may improve atrioventricular nodal conduction to allow supraventricular impulse transmission. Epinephrine, isoproterenol, and ventricular pacing will increase the ventricular rate. In the setting of complete heart block, the need to provide either external or internal pacing must be anticipated. Consultation with a cardiologist in anticipation of pacing requirements is recommended.

Ectopy

Ectopic beats, whether atrial or ventricular, are common and by themselves do not necessarily imply underlying cardiac disease. In the postoperative period, ectopic beats often are associated with electrolyte imbalances, hypoxia, acid–base abnormalities, and hypertension. They may result from drug therapy (e.g., digitalis toxicity) or cardiac irritation from central venous catheters. Hypokalemia and hypomagnesemia are the most common electrolyte abnormalities associated with ectopy. Care should be taken when correcting these abnormalities because rapid administration of large quantities of either potassium or magnesium can cause greater problems than the original ectopy.

Frequent premature atrial contractions usually are of minor hemodynamic significance but may be harbingers of supraventricular tachycardia or atrial fibrillation. Medical therapy is generally not needed, but the patient should be monitored closely.

Similarly, premature ventricular contractions in an asymptomatic patient generally do not require treatment. Ventricular ectopy that was present preoperatively usually reappears postoperatively and does not predict an adverse outcome.[34]

Postoperative ECG Changes

ECG changes are common after anesthesia and surgery. Changes in P- or T-wave morphology, intraventricular conduction, or ST segments may occur in the absence of a cardiac abnormality or ischemia. These changes result from the cardiac effects of anesthetics and other administered drugs, increased sympathetic tone, hypothermia, and electrolyte imbalances. Breslow et al.[35] reported an 18% incidence of T-wave changes in a postoperative population. These changes occurred with equal frequency in all age groups and were not more common in patients with preexisting coronary artery disease. During postoperative followup, these patients did not show any evidence of myocardial ischemia or injury, and most of the ECG changes resolved with 24 hours. Of course, when there is a suspicion of perioperative ischemia, T-wave changes should be treated as a potential MI, adding therapeutic control of heart rate and blood pressure, obtaining serial ECGs and cardiac enzyme levels, as well as a cardiology consultation.

Hypertension

Hypertension is a very common problem in the postoperative period. It typically has an early onset (usually within 2 hours after surgery) and requires treatment for 6 hours or less. It

occurs most commonly after vascular, head and neck, and neurosurgical procedures (Table 73–3).[36] Patients with preexisting hypertensive disease are more likely to develop postoperative hypertension, especially if antihypertensive medications were withheld preoperatively. Sympathetic nervous system activation resulting from noxious stimuli, such as pain, anxiety, bladder distension, fluid overload, hypoxemia, hypercarbia, and hypothermia, are other common precipitants. Complications of severe postoperative hypertension include myocardial ischemia/infarction, dysrhythmias, congestive heart failure, stroke, and increased surgical bleeding. For some of these complications, whether systemic hypertension was the cause or the consequence is unclear.

The decision to treat hypertension should take into consideration the patient's baseline blood pressure, coexisting diseases, and perceived risk of complications. Systolic or diastolic blood pressure >20% above baseline, signs or symptoms of complications such as chest pain or dysrhythmias, or a perceived increased risk of complications are indications for treatment. Reversible causes of hypertension (e.g., pain, anxiety, bladder distension) should be ruled out before antihypertensive therapy is initiated. For patients with preexisting hypertension, resumption of chronic antihypertensive therapy is a sensible option. Short-term control of blood pressure in the PACU is best accomplished with drugs that have a rapid onset and possess a short-to-intermediate duration of action. Intravenous agents such as labetalol, esmolol, propranolol, and hydralazine are commonly used for short-term blood pressure control. For persistent or refractory hypertension, continuous infusions of vasodilators such as nitroprusside, nitroglycerin, or fenoldopam may be needed.

URINARY AND RENAL DYSFUNCTION

Postoperative bladder distension with associated urinary retention may induce pain, restlessness, and delirium and may delay PACU discharge. Furthermore, severe or prolonged bladder distension may cause permanent damage to the detrusor muscle. The prevalence of postoperative bladder distension, which ranges from 1% to >50% of patients, depends upon the population, type of surgery, and method of estimating bladder distension.[37] A study of predictive factors for early postoperative urinary retention in the PACU found older age (≥ 50 years), bladder volume on entry to PACU (≥ 270 mL), and quantity of intraoperative fluids administered (> 750 mL) each independently increased the risk of urinary retention.[38] Based on these results, it was suggested that regular evaluation of bladder volume with ultrasound should occur in the PACU, especially in patients with the enumerated risk factors.

Oliguria, defined as a urine output <0.5 mL/kg/h, is a frequent postoperative occurrence. Oliguria may be a sign of ARF, a condition associated with a markedly increased morbidity and mortality in the postoperative patient.

- Prerenal ARF is caused by decreased renal perfusion due to a decreased effective circulating blood volume or impaired renal hemodynamics. Hypovolemia is the most common prerenal cause of oliguria in this setting. Administration of a 250- to 500-mL IV fluid bolus helps to rule out hypovolemia. Maintenance of adequate systemic blood pressure (based on preoperative values) is essential to allow sufficient renal perfusion. If urine output does not improve despite what appears to be an adequate fluid resuscitation and blood pressure, then a more extensive investigation is warranted. Central monitoring and/or echocardiography may provide better assessment of intravascular filling and cardiac function.
- Postrenal ARF is caused by obstruction of urinary flow. In patients without a bladder catheter, it is important to determine the time since last voiding. Placement of a urinary catheter helps to differentiate insufficient urine production from the inability to void. Assessing the urinary catheter for kinking, obstruction (by irrigation), or migration is important to exclude common postrenal causes of oliguria.
- Intrinsic ARF is divided into tubular (acute tubular necrosis [ATN]), interstitial, glomerular, and vascular etiologies. Analysis of urine electrolytes, osmolality, and cast formation may be helpful in this assessment. Diuretics should be given sparingly because they may worsen preexisting renal injury, and forced diuresis does not improve the prognosis of ARF. Intraoperative events that could result in ARF (e.g., extended aortic cross-clamping, prolonged systemic hypotension, possible ureteral ligature, or trauma) should be investigated. Imaging studies such as ultrasonography, CT, angiography, or radionuclide scanning may be indicated to clarify renal status and exclude reversible causes of injury. Early consultation with a nephrologist is indicated.

TABLE 73–3.

Frequency of Acute Postoperative Hypertension by Surgical Procedure

Procedure	Frequency
Carotid endarterectomy	9–64%
Cardiac surgery	22–54%
Abdominal aortic surgery	33–75%
Radical neck dissection	10–20%
Intracranial surgery	57–91%
Elective general surgery	3–20%
Flexion contracture release	46%

Entrance of irrigation fluid into the intravascular space during cystoscopy may lead to substantial fluid and electrolyte shifts. This is best described for the setting of *transurethral resection of the prostate (TURP) syndrome*.[39] A similar syndrome has been described in women undergoing transcervical endometrial ablation. In both cases, irrigation is performed with solutions of glycine that are nonconductive and permit use of electrocautery. Signs and symptoms result from acute changes in intravascular volume, increases in levels of plasma glycine, and rapid decreases in plasma sodium concentration. At the extreme, hyponatremia may produce convulsions, coma, and death. Cardiovascular findings can include hypertension (from hypervolemia) or hypotension (from congestive heart failure), dysrhythmias, pulmonary edema, and cardiac arrest. The diagnosis is confirmed by measuring plasma sodium and osmolality. Management involves providing supportive care, including diuretics for

volume overload and administration of isotonic saline. Hypertonic saline therapy may be warranted when the plasma sodium level falls to < 120 mmol/L or when acute neurologic deterioration occurs.[40] Caution should be exercised when infusing hypertonic saline because overly rapid correction has been linked to central pontine myelinolysis.

CNS DYSFUNCTION

Delirium

Delirium is a transient, fluctuating disturbance of consciousness, attention, cognition, and perception. Postoperative delirium is a common problem in the PACU, with a reported incidence of 3–5% in adults.[41,42] The delirious patient often is hypertensive and tachycardic, and the accompanying agitation can have serious consequences, including trauma, disruption of suture lines or surgical repairs, and accidental removal of catheters, tubes, and drains. Healthcare providers are also at risk for injury. Postoperative delirium is more common in the elderly, in whom it may delay recovery and prolong hospital stay.[43,44] Other preoperative risk factors include organic brain disease, alcohol and sedative withdrawal, anxiety, and depression. Intraoperative risk factors include specific types of surgery (e.g., cardiac, orthopedic, ophthalmologic) and administration of certain drugs (e.g., anticholinergics, barbiturates, benzodiazepines). Perioperative hypoxemia, hypotension, and sepsis are believed to be risk factors. There appears to be no difference in the incidence of postoperative delirium with either neuraxial or general anesthesia.[45]

The first priority in management of postoperative delirium is to rule out physiologic causes, including hypoxemia, hypotension, and acidemia. Postoperative pain often plays a significant role and should be treated adequately.[46] Other causes include hypoglycemia, electrolyte disturbances, sepsis, and sensory overload. Bladder or gastric distension, or other nonsurgical pain sources (e.g., corneal abrasion, infiltrated IV, poor positioning) should be excluded. Delirium should be treated supportively with verbal reassurance that the surgery is over and that the patient is doing well. Symptomatic medications may be indicated in some circumstances. Physostigmine is helpful when delirium is believed to be the result of central anticholinergic drugs such as scopolamine. Although haloperidol does not improve the disordered thinking, the catatonia that it produces may protect the patient from physical harm.

Delayed Awakening

The major causes of delayed awakening after general anesthesia can be divided into three groups: (1) prolonged pharmacologic effects, (2) metabolic abnormalities, and (3) neurologic injury. The residual effects of anesthetic drugs are the most common cause of delayed awakening. It is important to obtain information on the patient's preoperative level of arousal, the timing and dosage of sedatives and opioids administered, and use of volatile anesthetics and muscle relaxants. Volatile anesthetics, especially those with high solubility, are more likely to result in delayed awakening after longer procedures or in obese patients. If residual sedative effects of opioids or benzodiazepines are suspected, then pharmacologic reversal with naloxone or flumazenil, respectively, can be used for evaluation. Administration of physostigmine (1.25 mg IV) nonspecifically reverses the anesthetic effects of some sedative and inhalational agents. The effects of profound neuromuscular blockade can mimic unconsciousness by preventing a motor response to stimuli. In this situation, spontaneous ventilation and movement will be absent, although autonomic responses may remain present. Possible causes of prolonged paralysis include an overdosage of neuromuscular blocking agents, their impaired clearance, a drug interaction (e.g., with certain antibiotics), or a failure to reverse. The possibility that the patient has pseudocholinesterase abnormality or an unrecognized neuromuscular disease also be should considered. Evaluation with a train-of-four nerve stimulator is straightforward.

Metabolic causes of delayed awakening include hypoxemia, hypercapnia, hepatic, renal or endocrine dysfunction, and glucose and electrolyte abnormalities. Hypoglycemia should be considered early, and 50% dextrose should be administered immediately if hypoglycemia is suspected. Hyperglycemia, resulting in hyperosmolar coma or diabetic ketoacidosis, also can be a cause. Obtaining arterial blood gas and plasma chemistries are the first steps in identifying metabolic etiologies.

Sleep deprivation and disruption of normal sleeping patterns in children can result in difficulty with arousal (see Chapter 63). Profound hypothermia (< 33°C) can cause unconsciousness and increase the sedative effects of medications. Extreme hypothermia can cause fixed dilated pupils and areflexia. Overdosage with local anesthetics or inadvertent subarachnoid injection during retrobulbar block can cause unconsciousness.

If the diagnosis remains uncertain, then neurologic consultation should be sought. Urgent radiologic imaging (e.g., CT, MRI) can be performed to rule out a structural abnormality or hypoxic injury. Trauma patients may be found to have unrecognized intracranial injury. Cerebral vascular accidents, although uncommon after general surgery, can occur in the perioperative period.[47,49] Subclinical generalized seizures are an uncommon cause of postoperative unconsciousness. Patients often are slow to awaken after long intracranial procedures; however, consideration should be given to the occurrence of complications such as intracranial hemorrhage or increased intracranial pressure. Rarely, psychiatric causes can result in impaired consciousness.[48]

Stroke

The incidence of perioperative stroke varies with the type and complexity of the surgical procedure, with the reported incidence ranging from as low as 0.08% after general surgical procedures to > 9% in complicated cardiac and vascular surgery.[49] Perioperative strokes are predominately embolic and ischemic. Approximately half of perioperative strokes are identified within the first postoperative day.[49] These early strokes generally result from emboli from manipulations of the heart or the aorta or from particulate matter emanating from cardiopulmonary bypass. Strokes occurring after the first postoperative day generally are caused by emboli resulting from atrial fibrillation, MI resulting in cerebral hypoperfusion, and coagulopathy. Surgery-induced hypercoagulopathy, general anesthesia, dehydration, bedrest, and perioperative withholding of antiplatelet and anticoagulant medications are factors contributing to thrombogenic events such as stroke. Early diagnosis and management is essential to improving outcome after stroke. However, diagnosis may

be difficult because symptoms such as somnolence, slurred speech, visual changes, agitation, confusion, numbness, and muscular weakness or paralysis may overlap with the effects of residual anesthetics. Neurologic consultation in conjunction with radiologic imaging is mandatory to guide therapy. Administration of intravenous thrombolytics may be contraindicated in patients who have recently undergone major surgery. However, intraarterial administration of tissue plasminogen activator and endovascular mechanical clot disruption are potentially safer options in the postoperative period.[50,51]

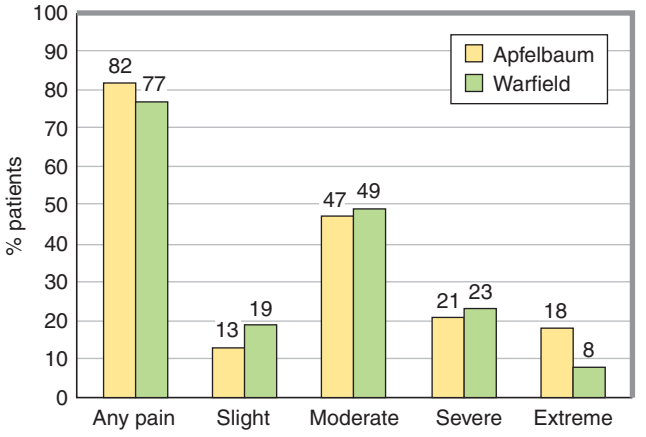

FIGURE 73–7. Severity of postoperative rain. Results from a national survey of patients who had recently undergone surgical procedures. Patients reported intense pain after surgery, and the incidence of reported pain did not decrease compared with a similar survey reported 8 years earlier. From Apfelbaum et al.[55] with permission.

INTRAOPERATIVE AWARENESS

Awareness with recall of intraoperative events is an infrequent but recognized complication of general anesthesia, with a reported incidence of 0.1–0.2%.[52] Awareness can result in significant distress to patients and long-term psychological sequelae, including symptoms associated with posttraumatic stress disorder. Certain patient characteristics (e.g., younger age, higher American Society of Anesthesiologists [ASA] physical status, history of alcohol or drug tolerance, history of difficult intubation), types of procedures (e.g., cesarean section, cardiac surgery, trauma surgery), and anesthetic techniques (e.g., rapid sequence induction, reduced anesthetic doses) are associated with an increased risk of intraoperative awareness.[53] A questionnaire such as that proposed by Brice et al.[54] is a useful way to screen for intraoperative awareness in the PACU and during the postoperative visit.

For the patient indicating possible awareness, the clinician should speak with the patient to obtain specific details of the event and to learn possible reasons for its occurrence. The patient should be offered counseling and psychological support.

COMPLICATED ACUTE PAIN MANAGEMENT

Despite increased knowledge of the mechanisms of acute pain and increased emphasis on pain management programs, postoperative pain continues to be undermanaged (Fig. 73–7).[55,56] Inadequate pain relief may have harmful physiologic and psychologic consequences resulting in increased postoperative morbidity. In addition, inadequate pain control delays PACU recovery and discharge home, and it may result in development of a chronic pain syndrome, all of which increase resource use and healthcare costs.[57,58]

In order for patients to function well postoperatively, it is important that they have adequate pain relief at rest and with movement. Multimodal analgesic approaches that combine regional techniques, nonsteroidal antiinflammatory drug (NSAID), and opioid therapies are recommended to provide pain relief during movement while producing a low incidence of side effects.[59] Procedure-specific guidelines for pain therapy may be helpful because pain intensity, as well as the risks and benefits of different analgesics, clearly are procedure related.[60,61] A thorough discussion of acute postoperative pain management is given in Chapter 83.

Patients who are opioid tolerant (either from substance abuse or legitimate medical therapy) often present a management challenge in the immediate postoperative period. These patients may be receiving large doses of long-acting oral opioid agonists or even high doses of the opioid partial agonist buprenorphine (see Chapters 23 and 41). When possible, regional anesthetic techniques and nonopioid adjuncts (e.g., NSAIDs, clonidine) should be used to provide multimodal therapy. If a regional technique is used as the primary anesthetic in a patient known to be physically dependent upon opioids, it is important to provide a supplemental opioid to prevent the symptoms of withdrawal.

Sometimes opioid-tolerant patients require parenteral opioids as a primary mode of analgesia after surgery. Tolerant and nontolerant patients are at similar risk for opioid-induced respiratory depression if comparable levels of pain relief are achieved (see Chapter 48). Unfortunately, assessing pain relief in opioid-tolerant patients can be difficult and sometimes inaccurate. Relying on a "pain score" as an analgesic end point may be unwise, because these individuals report higher pain scores even when quite sedated.[62] For this reason, patients requiring very large doses of opioids should undergo careful monitoring of oxygen saturation and respiratory rate for signs of respiratory depression. Patients with coexisting respiratory diseases such as sleep apnea may be best managed in an ICU during the early postoperative period.[63] In addition, consultation with a specialist in addiction medicine may assist with acute management as well as followup during or after patient hospitalization.

HEMORRHAGE

Patients who develop bleeding postoperatively require rapid evaluation to differentiate poor surgical hemostasis (perhaps requiring immediate reoperation) from a diffuse coagulopathy. It is important to appreciate that surgical and nonsurgical bleeding often coexist. Visible bleeding from wounds or drains makes the diagnosis simpler, whereas bleeding into the chest, pelvis, thigh, or retroperitoneum can be difficult to detect. Drains can become

blocked, kinked, or malpositioned, resulting in a false sense of security.

The patient should be examined for tachycardia, diminished urine output, and delayed capillary refill. Blood pressure may be preserved, especially in the young patient, despite loss of up to 40% of total blood volume.[64] Orthostatic hypotension and tachycardia may provide an early indication of intravascular volume depletion. Hemoglobin levels may remain stable for a time, and initial declines may be attributed to hemodilution despite significant hemorrhage.

If there is evidence of significant bleeding, diagnosis and treatment usually occur simultaneously. Adequate IV access should be established and the availability of appropriate blood products ensured. Diagnostic studies that should be considered early include measurement of filling pressures (i.e., central venous pressure or pulmonary capillary wedge pressure) and imaging techniques (ultrasound, CT). Angiography eventually may be required for definitive diagnosis, localization, and therapy.

The diagnosis of a coagulopathy in the surgical setting commonly occurs with a dilutional thrombocytopenia and loss of clotting factors. Coagulation tests should be guided by a knowledge of preexisting medical illnesses (e.g., hepatic disease, bone marrow suppression) or specific surgical factors (e.g., sepsis leading to disseminated intravascular coagulation). Hypothermia should be corrected because it can cause platelet dysfunction, and urine and blood should be checked for signs of hemolysis, possibly indicating a transfusion reaction. Laboratory test results can change rapidly, and serial measurements are often required.

TEMPERATURE ABNORMALITIES

Hypothermia

Hypothermia remains a common postoperative problem despite the ASA requirement for the "availability" of intraoperative temperature monitoring and the improved technology for patient warming in the operating room. Multiple sources of heat loss, decreased heat production, and impairment of thermoregulatory control all contribute to intraoperative hypothermia. Even mild hypothermia (core temperature between 34°C and 36°C) has been associated with adverse outcomes, including myocardial ischemia, arrhythmias, coagulopathy, wound infection, and decreased drug metabolism.[65] Furthermore, hypothermia can result in substantial discomfort, rated by some patients as worse than their surgical pain. Mild hypothermia may increase the duration of PACU stay by 40 minutes or more.[66] Violent shivering may increase the risk of trauma or subcutaneous bleeding. It also may dislodge medical devices and interfere with ECG and pulse oximetry monitoring.

Restoration of normothermia is an important goal during the postoperative period. For patients with mild hypothermia, warm blankets and verbal reassurance usually are adequate treatment. Forced-air warming devices are more efficient, if available. Shivering can be rapidly suppressed with small doses of meperidine, which acts by stimulating α2B receptors (see Chapter 41). This will decrease heat production but will make the patient more comfortable. Clonidine, dexmedetomidine, and doxapram also have been used successfully to treat shivering.[67]

Hyperthermia

Although fever is common during the first few days after surgery, significant hyperthermia is relatively uncommon in the PACU. Most early postoperative fever is caused by cytokine release in response to surgery, and it resolves spontaneously. A 1.4°C average increase of the core temperature setpoint occurs in patients undergoing major surgical procedures (Fig. 73–8).[68] Brief periods of hyperthermia also can occur when patients are closely draped and aggressive warming techniques are used in the operating room. Infection is always a concern but is less likely in the PACU unless the patient had a preexisting infection or bacteremia was provoked by the surgical procedure. Another possibility to consider is a febrile reaction to a medication or blood product given during surgery. Less common etiologies include hyperthyroidism, malignant hyperthermia, and the neuroleptic malignant syndrome. Fever can be associated with other adverse events, including PE, adrenal insufficiency, and ethanol withdrawal.

Evaluation of fever in the early postoperative period begins with a careful history and physical examination. Did the patient have a fever or leukocytosis preoperatively? What preoperative and intraoperative medications were given? Did surgery involve drainage of an abscess, cause

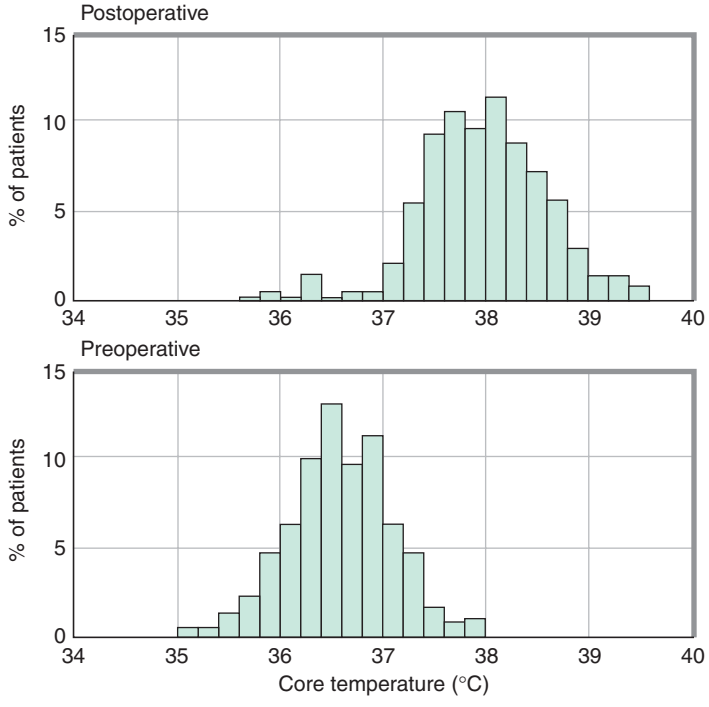

FIGURE 73–8. Histograms illustrating preoperative and maximum postoperative core temperature in the first 24 hours after surgery in 271 patients. Data indicate a postoperative shift in the setpoint to a higher core temperature. From Frank et al.[68] with permission.

fecal spillage, etc.? Routine use of blood and urine cultures, urinalysis, and chest radiography is costly, and these tests should be ordered only when indicated by the history and physical examination. The decision to administer additional antibiotics depends upon the perceived urgency of treatment and the level of clinical suspicion of infection. Symptomatic treatment with rectal or oral acetaminophen is useful for patient comfort and to minimize the increased metabolic demands of fever.

HYPERGLYCEMIA

Increasing evidence indicates that close perioperative glycemic control can improve patient outcome, including reduced rates of surgical site infections and decreased mortality of critically ill patients.[69] The American College of Endocrinology and the American Diabetes Association have published goals for glycemic control in hospitalized patients that can be applied postoperatively.[70,71] These guidelines include maintenance of blood glucose levels <180 mg/dL for all patients and between 80 and 110 mg/dL in ICU patients; avoiding oral hypoglycemic agents when not on a regular diet; providing basal insulin doses for patients who are insulin deficient; and implementing a program to prevent and manage hypoglycemia. These issues are covered more completely in Chapters 12 and 59.

INJURIES

Ocular

Visual changes after anesthesia for nonocular surgery are relatively infrequent, with an incidence of 0.0008% after all noncardiac surgery and 0.2% following spine surgery.[72,73] Severity ranges from transient blurring of vision to irreversible blindness. Transient blurring of vision can be due to cycloplegia from anticholinergic medications, use of ocular lubricants, excessive corneal drying, or a corneal abrasion.[74] Corneal abrasion is suggested by symptoms of tearing, miosis, photophobia, and the sensation of a foreign body in the eye. The diagnosis is confirmed by fluorescein staining of the cornea. Ophthalmologic consultation is recommended, and management usually consists of patching and administration of topical antibiotics, anesthetics, and cycloplegics.

Prolonged or permanent visual loss is a recognized complication after head/neck, neurovascular, cardiopulmonary bypass, and spine surgery. Impairment of retinal perfusion may result from direct ocular compression, but it also is associated with acute anemia, hypotension, emboli, and large-volume crystalloid administration in the absence of direct compression. The risk is higher in patients with preexisting vascular disease and in those receiving long anesthetics and surgery in the prone position.[75]

If there is a postoperative concern regarding potential visual loss, urgent ophthalmologic consultation should be obtained to determine its cause. Optimizing hemodynamics, hemoglobin levels, and arterial oxygenation may improve recovery, but this has not been confirmed prospectively. MRI may be needed to detect intracranial causes of vision loss.[76]

Oropharyngeal

Sore throat, hoarseness, and dysphagia are common postoperative complaints following tracheal intubation and laryngeal mask airway (LMA) insertion. In most cases, the laryngeal or pharyngeal trauma is minor, and symptoms resolve without treatment. Gargling with viscous lidocaine may provide symptomatic relief but increases the risk of aspiration during recovery. Severe or persistent pain, dysphagia, or hoarseness may suggest more significant pathology warranting otolaryngologic consultation. Pathologic changes from laryngoscopy and intubation include epithelial loss, glottic hematoma and edema, submucosal tears, and granuloma formation. Oropharyngeal injuries resulting from LMA insertion include pharyngeal abrasion, nerve palsy, arytenoid dislocation, epiglottitis, and uvular bruising.[77]

Dental

Perioperative dental injury has a reported incidence of 1:4500 general anesthetics.[78] Risk factors include preexisting poor dentition and a difficult laryngoscopy/intubation.[79,80] The upper incisors are most often involved. Damage to teeth should be carefully documented and a dental consultation obtained. If a tooth is missing and cannot be found, a chest x-ray film should be obtained to rule out a pulmonary aspiration.

Nerve

Sixteen percent of claims in the ASA closed claims project database were for anesthesia-related nerve injuries.[81] Nerve injury may result from improper intraoperative positioning, direct surgical damage, or as a complication of needles and drugs used in regional anesthesia. Preexisting nerve abnormalities also may play a role. Many perioperative neuropathies have no identifiable cause. Examination of the patient in the PACU may lead to earlier recognition of a peripheral neuropathy.[82] The patient should be positioned in a manner to prevent further compression or stretch of the involved nerve. Evaluation for potentially treatable sources of injury, such as constrictive dressings or improperly applied casts, is important. Prompt neurologic consultation should be obtained when a new deficit is identified in order to document the patient's status, arrange additional testing or intervention, and provide followup. Neurophysiologic assessment, such as nerve conduction studies, evoked potentials, and electromyography, may be helpful in localizing the injury and establishing the diagnosis and prognosis. This information may be helpful in directing a treatment plan.

Major neurologic complications after spinal or epidural anesthesia are rare but can be devastating. The etiology may be traumatic injury to the spinal cord or nerve roots during needle or catheter placement, spinal hematoma or abscess, or a direct toxic effect of injected medications or contaminants.[83] Several of these possibilities require urgent MRI and neurologic evaluation. Lack of recovery from spinal or epidural anesthesia may indicate spinal cord compression from a hematoma. Persistent motor blockade after recovery of sensory anesthesia may be due to spinal artery occlusion or spasm. In both cases, prompt diagnosis with MRI and early intervention greatly increase the likelihood of a successful outcome.

Hearing

Hearing loss has been reported after general and neuraxial anesthesia, but it is often subclinical and goes unnoticed unless audiometry is performed. Hearing loss after spinal anesthesia or

lumbar puncture is reported most frequently, with 10–50% of patients experiencing an audiometrically measurable low-frequency hearing loss.[84] The etiology appears to be related to cerebrospinal fluid leak, so impairment is increased with use of larger-gauge and cutting-tip needles. Hearing loss after dural puncture generally resolves completely within days to weeks. In severe cases, an epidural blood patch may hasten recovery.

Hearing loss after general anesthesia has been reported after both cardiac and noncardiac surgery. The etiology often is unclear but may be related to changes in middle ear pressure, injury to the inner ear microcirculation, embolism, or the effects of ototoxic drugs. Some patients who received nitrous oxide may actually have hyperacusis (increased sensitivity to sound), presumably from changes in middle ear pressure.

Extravasation Injury

Extravasation injury can result from unintentional injection or leakage of intravenous fluids or medications into the perivascular or subcutaneous space. The amount of injury depends on the specific drug and concentration, the site of injury, the infusion pressure, and the duration of tissue exposure.[85] Extravasation of vasoconstrictors, alkaline solutions such as thiopental, and hyperosmolar or concentrated electrolyte solutions may cause significant tissue necrosis. Pain, swelling, and local hyperthermia are not reliable predictors of the degree of tissue damage. The intravenous infusion should be stopped immediately. Conservative measures such as elevating the involved extremity or applying heat or cold have not been shown to be beneficial, although early aspiration of the intravenous cannula and flushing with saline may be useful. In the case of extravasation of vasopressors, early infiltration with phentolamine may be effective. Surgical consultation and radiologic imaging (e.g., MRI) may be helpful if there is concern regarding tissue damage (Fig. 73–9).

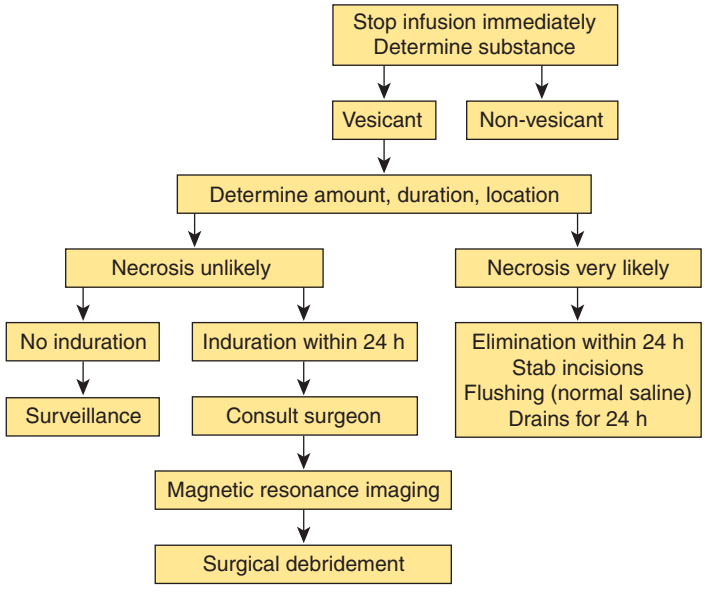

FIGURE 73–9. Algorithm for managing extravasation injury in the perioperative setting. Vesicants refer to drugs that can cause tissue destruction. Common vesicants used in the perioperative setting include vasoconstrictors (e.g., epinephrine, dopamine, norepinephrine), concentrated electrolyte solutions (e.g., calcium chloride, potassium chloride, sodium bicarbonate), and hyperosmolar solutions (e.g., glucose 20%, mannitol, phenytoin [Dilantin]). From Schummer W et al.[85] with permission.

CHAPTER 74

Management of Acute Postoperative Pain

Jane C. Ballantyne, MD, FRCA

After the first public demonstration of ether anesthesia at the Massachusetts General Hospital in 1846, the news that "We have conquered pain" spread around the world. What was not understood at the time is that the potent hypnotics merely suspend pain perception, but do little to change pain transmission. The addition of neural blockade or strong analgesics (notably opioids) is needed to halt the pain processes that excite the nervous system, trigger neuroendocrine stress responses, and produce pain once it can be perceived. The provision of analgesia, during and after surgery, is now considered a vital and integral part of anesthesia and its central goal to reduce the stress and derangements of surgery. Anesthesiologists apply their knowledge of pharmacology, anatomy, physiology, pathophysiology, surgery, and medicine toward optimizing pain relief. Whether by means of an informal relationship with surgical colleagues, or a more structured service—an acute pain service—they play a key role in managing postoperative pain.[1] As experts, they help educate others in the tools of pain management, and teach the importance of pain control in terms of postoperative recovery.

BACKGROUND

Institutional Considerations

The Role of the Acute Pain Service

The idea of the acute pain service arose during the 1980s when "walking" epidurals made epidural analgesia suddenly more feasible for postoperative patients, and when the microchip made patient-controlled analgesia (PCA) pumps small enough to have wide applicability. Initially, pain services ran both these modalities, developed treatment protocols, and taught nurses and others how to manage these new therapies. Soon surgeons and nurses became familiar with the use of PCA, so that this component of postoperative management, at least for routine cases, largely has been taken over by them. Epidurals and other continuous perineural techniques remain the province of anesthesiologists, and the core function of most acute pain services is to manage postoperative epidural analgesia. The acute pain service is also available to help with complex cases, notably cases that cannot be managed using routine measures. Naturally, each institution will structure its pain service differently, according to institutional and local factors—smaller hospitals and ambulatory facilities may not have a service as such.

Acute pain services are usually staffed by a mixture of attending physicians (sometimes pain trained and commonly anesthesiologists), nurses, and pain fellows in academic centers, and anesthesia residents. Rotation to the acute pain service is a valuable component of residency training, as this is likely the only point during training that anesthesia residents have the opportunity to daily follow patients postoperatively. The allocation of roles on the service will depend to a large extent on factors such as reimbursement, hospital policies, the relationship between anesthesia and surgery departments, and the expectations and support of both the hospital and the department of surgery. For example, funding for nursing on the service will vary according to institution, and the provision of nonbillable services, such as daily followup of PCA, may only be feasible if nurses are available and funded. Epidural management remains the most favorably reimbursed of acute pain services. Unfortunately, as pain management becomes increasingly challenging because of rising numbers of opioid-tolerant patients (both substance abusers and opioid-treated chronic pain patients), and because of mandated pain management, reimbursement often fails to cover the realistic costs of ideal pain management.

Joint Commission on Accreditation of Healthcare Organizations and Pain Management

The Joint Commission on Accreditation of Healthcare Organizations (JCAHO) evaluates and accredits more than 19,000 healthcare organizations in the United States and its status as an accreditation body is such that it serves as an alterative to state and federal inspection mechanisms. Because of its wide reach, it was chosen for collaboration when various bodies seeking to improve pain management—including the American Pain Society, the Agency for Healthcare Policy and Research (now the Agency for Healthcare Research and Quality), and the University of Wisconsin Medical School (supported by a grant from the Robert Wood Johnson Foundation)—determined that the accreditation body could potentially improve pain care visibility by mandating the development of processes that increase provider accountability for the assessment and treatment of pain. Five elements were established that were considered essential for establishing institutional responsibility for making pain management a priority[2]:

KEY POINTS

1. Analgesia, as distinct from hypnosis, is a vital and integral component of anesthesia.
2. Anesthesiologists must plan for the continuum of intra- and postoperative pain.
3. The principles of "opioid-sparing" or "multimodal analgesia" are central to the goal of rapid recovery as opioid side effects delay recovery.
4. Patient-controlled analgesia has greatly facilitated acute pain management at both provider and institutional levels.
5. Epidural analgesia continues to play an important role in the treatment of pain after major intraabdominal and thoracic surgery, although the benefit versus risk should be reexamined in an era of potent thrombosis prophylaxis.
6. Chronic opioid use and abuse are emerging as prominent challenges during acute pain treatment.

1. Pain must be recognized and treated promptly.
2. Information about analgesics should be readily available to clinicians in a way that facilitates order writing and interpretation of orders.
3. Patients must be assured of attentive pain care.
4. Explicit policies should be developed for the use of advanced analgesic technologies.
5. Processes and outcomes should be examined for continued improvement.

The idea was to make pain management a priority in the healthcare system and to establish systems to support, reinforce, and reward good pain management practice. The standards were approved in 1999 and formally introduced into the accreditation process in 2001.[3] Perhaps the most obvious manifestation of the mandate, was the introduction of "pain as a fifth vital sign," part of the effort to "make pain visible." Many hospitals have now introduced a requirement to record a pain score on the vital signs chart. Although it was never the intention of JCAHO or the pain advocates that this should become the focus of the pain mandate, and indeed there is no written requirement for the "fifth vital sign" in current JCAHO standards, nevertheless it has become the hallmark of the JCAHO mandate. Of course, the recording of a pain score does nothing to advance pain management unless the pain score is acted on, but at least it raises general awareness of pain and gives patients the opportunity to express pain complaints. The question that naturally follows is this: Has the mandate succeeded in improving patients' access to adequate pain care?

There has been a great deal of concern expressed by dissenters that the mandate represents an unreasonable intrusion into clinical practice, an excessive burden on healthcare facilities that will ultimately drive up the cost of healthcare, and an encouragement to patients that they have a "right" to the elusive goal of pain abolishment or to opioid treatment. Surveys to date show a high rate of compliance with the JCAHO mandate, meaning there are demonstrable improvements in pain assessment. However, it is less easy to determine if the standards have resulted in improvements in pain relief. With the support of the American Medical Association, and the continued support of pain advocates, JCAHO continues to work with hospitals and specialty organizations to clarify and update the standards and strongly encourages improvements in undergraduate medical education and evidence-based performance measurement for pain management.

Preparation

Patient Education

Patients who are informed about their likely postoperative experience are much better able to cope with pain and the other discomforts of the postoperative state than those who enter the experience uninformed.[4] Whether it is the surgeon, the anesthesiologist, or the nurse who talks to the patient about the postoperative course, the message should always be that the team will use all methods available to make the experience tolerable, but that a goal of total pain abolition is unrealistic. This approach makes patients less fearful when they find that pain has not been completely removed. Anxious and fearful patients do not handle pain well, patients become fearful very quickly if they experience unexpected pain, and telling patients that the methods we have available are good enough to remove all pain is unhelpful. How often do we hear enthusiastic residents or nurses tell patients that if they accept an epidural, they will not have any pain?

Patients should be informed of their options with regard to pain management, preferably early in the preoperative course. The use of brochures or pamphlets describing analgesic options is helpful. A description of risks as well as benefits is necessary. Some patients expect to be informed and to take an active role in decisions regarding their care; others prefer that decisions are made by their medical team. In either case, informed patients are better prepared psychologically than those who are not informed.

The preoperative visit is also an opportunity to teach patients how to communicate their pain. For example, if they are likely to be asked to relate pain using a verbal pain score, they should be taught about this. They should be encouraged to express pain and not try to be stoical. They should learn that uncontrolled pain may have undesirable consequences such as splinting of the diaphragm, atelectasis and possible chest infection. They should learn how to use a PCA pump if they are likely to receive one. In particular, they should be aware that early on, they will need supplementary analgesia and should not expect that pressing the button will necessarily remove the severe pain that can occur in the immediate postoperative period. They should also be aware of the inherent safety of PCA, and that overdose is unlikely.

Anesthesia Planning

Anesthesiologists can have a significant impact on patients' postoperative pain experience, even if they are only involved in intraoperative care. This is not only by means of sustainable analgesia (epidurals and other catheter treatments), but also by careful anesthesia planning that results in a pain-free or near pain-free emergence from anesthesia. The importance of a pain-free emergence cannot be overemphasized; patients who wake from anesthesia in severe pain, especially those who are not expecting pain, are already disadvantaged in terms of being able to control their pain—again, fear and anxiety intervene to make pain control difficult.

Every anesthetic plan should incorporate planning for postoperative analgesia. The first question is whether a nerve block, a spinal, an epidural, or a plexus catheter treatment would help. This decision must also involve whether these treatments can additionally be used intraoperatively to provide analgesia or even anesthesia. How does the risk weigh against the benefit of these procedures when considering their role for both intraoperative and postoperative use? When one of these techniques is chosen, it becomes necessary to plan the exact injection regime. Will a nerve block last into the postoperative period or need to be supplemented by systemic analgesics? Can spinal analgesia be prolonged by using an opioid in the injectate? How will an epidural or other catheter treatment be used so that both its intra- and postoperative effects are optimized?

Despite the usefulness of neural blockade and catheter treatments, the vast majority of cases will be managed without these. Planning for intraoperative and postoperative analgesia remains important. The basic principles of opioid-sparing and preemptive analgesia, described in the following sections, are incorporated into the analge-

sia plan. Opioids are the only strong analgesics capable of controlling severe pain with systemic use, and are the mainstay of both intra- and postoperative pain relief. Opioids can be used liberally during anesthesia, but less liberally postoperatively because of side effects. Individual practices vary, but the goal of a pain-free emergence should always be incorporated into the plan. Provided they are not contraindicated, nonsteroidal antiinflammatory drugs (NSAIDs), including injectable ketorolac, or other adjuncts, can be used when predicted pain is mild or as an adjunct to opioids for moderate to severe pain.

Pain Assessment

Pain is a complex, multidimensional symptom resulting from a combination of tissue damage and nociception, previous pain experience, personal beliefs, culture and mood. This explains why patients with the same degree of tissue damage can differ widely in their pain reports. Because there is no objective measure of pain, we must trust that patients' report of pain reflects their pain experience or distress. Acute pain is relatively straightforward to assess as, unlike chronic pain, it generally bears a predictable relationship to obvious tissue damage. Because the level of postoperative pain tends to change rapidly throughout the postoperative course, especially early after surgery, a policy of regular assessment of pain using simple measurement tools is the best way to ensure that pain treatment can be appropriately titrated. Side effects and recovery milestones are also measured so as to optimize analgesia and recovery.

Many institutions record pain as a "fifth vital sign" on the vital signs chart, especially since the introduction of the JCAHO mandate; others have a policy of recording a pain level in the medical record. Wherever it is documented, the recorded level is useful for communication between medical professionals, and for assessing trends in an individual's pain level.

Verbal numeric rating scales are most commonly chosen to measure acute pain. The patient is asked to rate pain on a numeric scale, usually 0–10, where 0 is no pain and 10 is the worst pain imaginable. Verbal descriptive scales could also be used, but are difficult for postoperative patients to cope with. Examples would be "mild, moderate, or severe" or "mild, discomforting, distressing, horrible, or excruciating." Visual analog scales are used in research, and unlike verbal numeric rating scales, are validated for this purpose. The patient marks on a measured line labeled "no pain" at one end and "worst pain imaginable" at the other. Visual analog scales are rarely used in clinical practice, again because compliance is difficult for postoperative patients. Although the use of pain scales is necessary for documentation purposes, the clinical assessment of pain should always include asking patients to describe their pain and their pain experience since the last assessment. This is likely to reveal more information than the simple level. At the same time, the clinician should assess pain location, radiation, quality, and etiology. It is always important to expand the assessment to identify or exclude sources of pain not accounted for by the primary and expected source.

Assessment of pain in children, especially young children, is much more difficult. Although developmentally normal children older than 6–7 years of age will respond to adult assessment tools, children younger than this need a different approach. Infants, neonates, and very young children (0–4 years of age) are the most challenging. Children as young as 3 years old may be able to express pain, and point to a painful area, but are unlikely to be able to rate their pain. Children younger than this are unable to express pain other than by crying or screaming, posturing, grimacing, palmar sweating, and respiratory and heart rate changes—signs that are not specific to pain. Older children (4–7 years of age) are usually able to rate their pain, but it is helpful to use a scale designed for children, such as the Wong-Baker FACES Pain Rating Scale (Fig. 74–1). Parents are usually better able to recognize the presence of pain in their children than are any of the other caregivers, and they should always be asked to contribute to the assessment process.

Basic Principles

Two important principles influence our choice of drug, dose, route of delivery, and timing for the treatment of acute pain. These are the principles of preemptive analgesia and opioid sparing.

Preemptive Analgesia

Preemptive analgesia is described by Igor Kissin as "an antinociceptive therapy that prevents establishment of altered processing of afferent input, which amplifies postoperative pain."[6] In simpler terms, a preemptive analgesic intervention is one that stops or alters pain transmission so that pain will not become amplified by the nervous system. Kissin's definition embraces the fundamental principles necessary for understanding the concept of preemptive analgesia: (a) that the central nervous system is capable of changing so that pain becomes either improved and worsened via central processes such as desensitization and sensitization, and (b) that alterations in sensory and pain transmission can effect such changes. The idea that pain treated early in its course is easier to control than established pain is not new; in fact it is a truism passed down through generations. The new idea is that in addition to psychological factors, which remain important, especially in humans, a central process—central sensitization—can be altered by altering afferent input using analgesic drugs or neural

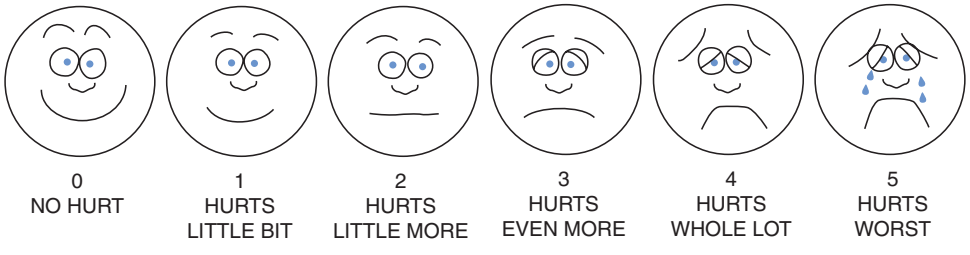

FIGURE 74–1. Wong-Baker FACES Pain Rating Scale. (From Hockenberry MJ, Wilson D, Winkelstein ML, eds. Wong's Essentials of Pediatric Nursing. 7th ed. St. Louis: Mosby, 2005. Used with permission. Copyright, Mosby.)

blockade. Animal studies show strong and convincing effects after preemptive interventions including nerve blocks and systemic analgesics.[7] Human studies are less convincing.[8,9] But the idea that our interventions, before, during, and after surgery, could attenuate pain responses, is too attractive to lay to rest. Studies are still being conducted, and the clinical role of preemptive analgesia is still uncertain and much debated.

A systematic review published by Moiniche et al. in 2002[8] found no support for preemptive analgesia when 80 trials assessing preemptive administration of epidural analgesia, systemic opioids, NSAIDs, local infiltration, and *N*-methyl-D-aspartate (NMDA) antagonists were grouped and analyzed, finding no overall benefit to any of the preemptive treatments. (The last intervention may have a special effect in that central sensitization is mediated by NMDA receptor activity).[10,11] In all 80 trials selected here, preincision treatment was compared with postincision treatment. Despite this disappointing result, Ong et al. went on to conduct a new meta-analysis, which included 10 newly published randomized controlled trials (RCTs).[9] Their methods differed from those of Moiniche et al. in several respects: They included trials that compared the preemptive intervention with no intervention as well as the comparison with postincision interventions;[12] they used a different approach for analyzing pain scores; and they used different exclusion criteria (fewer studies met the inclusion criteria). And in this case, several preemptive treatments—epidural analgesia, NSAIDs and wound infiltration—were strongly effective. Preemptive opioid and NMDA antagonists were ineffective.

The preemptive analgesia concept may seem simple—stop central sensitization and pain will improve. But it is far from simple: central sensitization itself is a complex process; NMDA antagonists may alter central sensitization but not necessarily because they are given prior to, versus after, an incision; opioids may actually cause central sensitization under some circumstances;[13–15] and neural blockade does not always succeed in preventing all afferent input from a surgical process.[6,12] It is no surprise, then, that study results seem conflicting and meta-analyses do not provide clear answers to the question of whether preemptive analgesia has an important clinical role. We have a lot to learn about how preemptive analgesia studies should be designed and how to combine them rationally in meta-analyses. Until we have better answers, we should be guided by preliminary data that suggest that there is little to lose, and possibly much to gain, from early use of neural blockade and NSAIDs.

Opioid-Sparing and Multimodal Analgesia

Opioid drugs mimic endogenous analgesic responses so it is not surprising that they are our most powerful analgesics. Centuries of opioid (opium) use have provided humans with relief from pain and suffering. Yet, throughout this long history, there have been concerns about the opioids' toxic effects—particularly their addictive effects, and the potentially fatal side effect respiratory depression. The extent to which opioids have been used for the relief of pain has fluctuated, not only throughout history, but also between cultures. In the United States and other industrialized nations, opioid use for severe pain has been strongly encouraged, especially since the 1980s when it was recognized that antidrug regulations had severely inhibited opioid use, to the detriment of pain control. Current teaching states that good pain relief during and after surgery, using opioids whenever necessary, can improve surgical recovery.[16] Pain relief is an important component of accelerated recovery programs that aim to achieve early return of mobility, coughing, and bowel and bladder function, and to restore normal physiologic functioning as rapidly as possible, thereby reducing complication rates.[17,18] Yet herein lies a paradox: although opioids are our most effective analgesics, they can delay recovery because of their sedative effects, their nauseating effects, and, most importantly, by slowing bowel activity. Opioid-sparing interventions reduce opioid requirements, and in some cases obviate the use of opioids altogether. Such interventions include the use of adjunctive medications, epidurals, and other nerve blocks, as well as nondrug interventions. The concept of "multimodal analgesia"[19]—using several analgesic modes together—is similar to the concept of opioid sparing.

TREATMENT OPTIONS

Systemic Treatments

Opioids

Opioids remain the mainstay of acute pain treatment, despite concerns about their side effects. Systemic opioids are used alone or in combination with other analgesics. Generally, higher doses of parenteral opioids are given during the first 24–48 hours after surgery, when pain tends to be severe and patients are unable to tolerate oral medications. The intravenous (IV) route is the preferred parenteral route, as most hospitalized patients already have intravenous catheters in place. Later, oral opioids, often in combination preparations such as Percocet (oxycodone with acetaminophen) replace the parenteral opioid. Side effects may limit opioid use, but there are few absolute contraindications, and true allergy to opioids is rare. Meperidine should not be used with monoamine oxidase inhibitors (MAOIs).

Choice of Opioid *Morphine* is the main constituent of opium, it was the first opioid alkaloid to be identified, and it is the standard opioid to which other opioids are often compared. Codeine is the only other naturally occurring opioid in common usage. The other familiar opioids are *semisynthetic*, derived from opium constituents (hydromorphone, hydrocodone, and oxycodone) or *synthetic*, synthesized de novo (meperidine, methadone, fentanyl, and fentanyl derivatives). These drugs are all opioid agonists, chiefly at the μ opioid receptor. Other opioids are mixed agonists–antagonists or partial agonists (buprenorphine, butorphanol, pentazocine, nalbuphine), and are generally used for treating chronic rather than acute pain (or addiction), at least in the United States. They are not described in detail here. Naloxone is a pure opioid antagonist and can be useful to treat opioid overdose. Table 74–1 lists the commonly used opioid agonists with recommended doses; Table 74–2 summarizes opioid effects. The opioids described below are μ agonists with essentially similar effects. Choice of opioid depends as much on the familiarity and preference of the treating physician as on the generally subtle differences in pharmacology between these drugs.

Morphine is the standard, most widely used of the opioids, and in

TABLE 74–1.

Standard Doses of Commonly Used Opioids

		Equianalgeic Doses		Typical First Dose	
Generic Name	**Trade Name**	**Oral**	**Parenteral**	**Oral**	**Parenteral**
Codeine		200 mg	120 mg	30 mg q3–4h	10 mg q3–4h
Fentanyl patch	Duragesic	N/A	N/A	N/A	25 μg/h patch q72h[a]
Fentanyl Oralet	Actiq	N/A	N/A	N/A	200 μg[b]
Hydrocodone	Vicodin,[c] Lorcet,[c] Lortab,[c] Norco[c]	N/A	N/A	10 mg q3–4h	N/A
Hydromorphone	Dilaudid	7.5 mg	1.5 mg	2–4 mg q3–4h	1.5 mg q3–4h
Levorphanol	Levo-Dromoran	4 mg	2 mg	4 mg q6–8h	2 mg q6–8h
Meperidine	Demerol	300 mg	100 mg	100 mg q3h	100 mg q3h
Methadone[d]	Dolophine	2–4 mg	10 mg (acute) 2–4 mg (chronic)	5 mg q8–12h	5 mg q8–12h
Morphine		30 mg	10 mg	15 mg q3–4h	10 mg q3–4h
Morphine SR	MS Contin	N/A	N/A	15 mg q8–12h	N/A
Oxycodone	Percocet,[c] Percodan[c]	N/A	N/A	5 mg q3–4h	N/A
Oxycodone CR	OxyContin	N/A	N/A	10 mg q8–12h	N/A

[a]Lowest available does. Risk of overdoes in opioids-naïve patients. 24 μg/h patch = 50–75 mg oral morphine per 24-hour period. Conversions should be made conservatively (consult product literature) and titrated slowly.
[b]Lowest available does. Contraindicated in opioids-naïve patients, especially children. Not for use in children <10 kg. 200 μg Oralet = 2 mg IV morphine. 800 μg Oralet = 10 mg IV morphine.
[c]Combination formulations, with either acetaminophen or aspirin.
[d]The equianalgesic conversion does for methadone decreases significantly with increasing does of pervious opioids. Caution guided by experience is mandatory.

some countries, it is the only available opioid. It is the least lipophilic opioid (Table 74–3), which delays its peak effect (occurs at 20 minutes after IV injection) but makes it a good choice for epidural administration when a widespread effect is desirable. Morphine is highly metabolized, and has at least two active metabolites (morphine-6-glucuronide and morphine-3-glucuronide), which can delay normalization after morphine administration, especially during renal compromise and continuous administration. (Morphine metabolites may also contribute to morphine toxicity and morphine-induced hyperalgesia in the special circumstance of sustained use.) Morphine induces histamine release and rapid bolus injection may produce local erythema, hypotension, or, rarely, bronchospasm. The normal duration of a standard dose (10 mg) is 3–4 hours. Morphine has poor oral bioavailability, and the oral dose is 3 times the parenteral dose. Morphine may cause biliary and urinary tract spasm, and a different opioid is often substituted (meperidine or fentanyl) during treatment for gallstones and renal stones, or during biliary tract and urinary tract surgery, although recent studies suggest that the effect is an opioid effect, not specifically a morphine effect.[21,22]

TABLE 74–2.

Opioid Effects

Analgesia
Respiratory depression
Nausea and vomiting
Sedation
Direct bowel effects
Dizziness
Pruritus
Meiosis
Euphoria
Dysphoria
(Biliary spasm—typically morphine)
(Urinary retention—uncertain)

TABLE 74–3.

Opioid Lipophilicities

Opioid	**Coefficients**	**Coefficient (cm/min × 10^{-3})**	**MEAC[a] (ng/mL)**
Morphine	1	0.6	30
Meperidine	525	NA	455
Hydromorphone	525	NA	4
Fentanyl	955	0.9	0.6
Sufentanil	1737	0.75	0.04
Alfentanil	129	2.3	41
Bupivacaine	560	1.6	NAp

MEAC, minimum effective analgesia concentration; NA, not available; NAp, not applicable.
[a]MEAC represents a range of plasma levels, not a specific value. MEAC plasma levels may vary up to 5-fold between different patients and with time and activity in specific patients.

Codeine is less potent, although more constipating, than morphine. Constipation limits the recommended dose to 30 mg, which has only mild analgesic (and respiratory depressant) effects. Codeine is available for oral use only, and is commonly found in combination analgesics such as Tylenol No. 3 (acetaminophen with codeine). In many countries, codeine is available over the counter, as it is considered to have low abuse potential and a good safety record. Its main usage is for pain of moderate severity, especially for children.

Hydromorphone (Dilaudid) is a useful alternative to morphine. For ill-defined reasons, many patients seem to prefer hydromorphone and claim they feel more clear headed, less dizzy, and less nauseated. At present, these can only be considered anecdotal observations. There are no active metabolites, therefore hydromorphone is a good choice for continuous administration, especially in patients with renal compromise.

Hydrocodone is used for mild to moderate pain, most commonly in the oral combination formulation Vicodin (hydrocodone with acetaminophen).

Oxycodone is not available for parenteral use in the United States, although it is elsewhere. It is a familiar opioid in the United States in the form of Percocet (oxycodone with acetaminophen), and is widely used for the treatment of moderately severe acute pain, including home treatment. More recently, oxycodone was formulated as a long-acting preparation (OxyContin), and this became a useful alternative to morphine and MS Contin (long-acting morphine) for the treatment of cancer and selected chronic pain. OxyContin and other long-acting oxycodone preparations have also been used for the treatment of acute pain, to aid sleep at night and function during the day. OxyContin availability has been limited by constraints associated with its popularity as a drug of abuse.

Meperidine (Demerol) was widely used for sedation and analgesia during procedural treatments, particularly in the office setting, as well as for hospital treatment of intra- and postoperative pain, until in the early 1980s several problems with the drug became clear. The first was normeperidine toxicity, normeperidine being a toxic metabolite capable of inducing central nervous system excitation and seizures, and liable to accumulate in the elderly and those with impaired renal function. The second was the propensity of meperidine to cause addiction—probably related to its lipophilicity and rapid onset of both analgesia and euphoria. Published guidelines began to state that meperidine should not be used routinely,[23,24] and many hospitals withdrew it from their formularies. When it is available, meperidine remains a useful drug; its ability to produce fast onset analgesia and euphoria is its great advantage, especially during the treatment of postoperative pain. It also has an idiosyncratic and little understood advantage for treating postoperative shivering. It must, however, be used cautiously, being particularly mindful of normeperidine toxicity, which can occur with repeated or continuous use. Meperidine has mild anticholinergic, antihistaminic and local anesthetic effects. There may be a dangerous interaction (serotonin syndrome) with MAOIs, producing seizures, coma, and possibly death, even after a single meperidine dose.

Methadone is a complex drug, rarely used for acute pain, except in patients already treated with this drug. Important considerations are its multiple interactions with other drugs, especially with antibiotics and antifungals, and its propensity to prolong the QT interval, especially at high doses.[25,26] The reader should refer to more detailed texts if faced with a patient requiring high-dose methadone, or receiving methadone as part of a complex drug treatment regime.

Fentanyl use in the postoperative setting is largely confined to PCA and epidurals, where its high lipophilicity and short duration can be used to advantage.

Tramadol (Ultram) is an interesting drug with weak opioid activity and additional norepinephrine and serotonin reuptake inhibition. It has low abuse potential and is not a controlled substance. It is widely used in Europe to treat acute and postoperative pain, but is less favored in the United States, where it is only available for oral use. Its use for severe pain is limited by the fact that it has a ceiling effect, but it may be useful for mild to moderate pain, particularly in patients who refuse opioids or tolerate them badly.

Adverse Effects Respiratory depression is the most feared of the opioid side effects, and rightly so, as this is a potentially fatal side effect. The possibility of respiratory depression occurring produces a real conflict when trying to balance effective analgesia with safety. A key issue is to understand the likelihood of the event, and therefore the risk, and to provide adequate monitoring in high-risk situations. The immediate postoperative period is a period of high risk: the patient is often opioid-naïve, has been given multiple sedating drugs during surgery, may be weak, and may have high analgesic requirements. Neonates and infants are always at increased risk because of their immature nervous systems, propensity to apnea, and poor ability to metabolize opioid drugs. The elderly are at similar risks. Patients established on a stable opioid regime are at lower risk. The level of monitoring required is a matter of judgment, whether this consists of frequent checks by a nurse, or the application of a monitor such as an apnea monitor or pulse oximeter.

Other side effects are less catastrophic, but can significantly compromise the success of opioid therapy. Patients may prefer to be in pain rather than feel disorientated, dizzy, or nauseated; physicians may undertreat pain rather than delay hospital discharge because of ileus or nausea. Secondary treatments such as antiemetics may help, but it is the principles of opioid sparing that play a key role in minimizing opioid side effects and optimizing pain control.

Tolerance, Dependence, and Addiction It is important to understand tolerance, dependence, and addiction, and the differences between these three phenomena. Drug *tolerance* arises when an increase in dose is required to achieve the effect of a prior dose. Opioid tolerance arises through a combination of receptor desensitization (nonassociative tolerance) and psychological factors (associative tolerance).[27,28] Apparent tolerance could also result from opioid-induced hyperalgesia.[15] The development of tolerance and hyperalgesia during acute treatment is rare, but can occur, especially when opioid infusions are used (e.g., remifentanil during surgery, or opioid infusions on an intensive care unit [ICU]).[29] More importantly, many patients now enter hospital or present for surgery who are already opioid

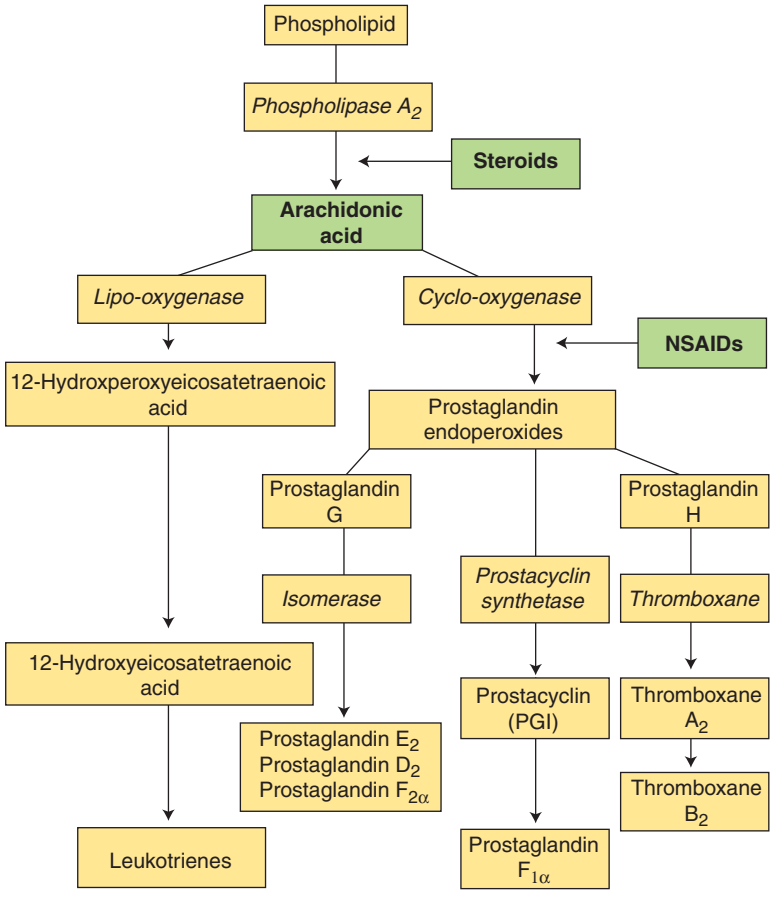

FIGURE 74–2. A schematic showing the metabolism of phospholipid and arachidonic acid. Nonsteroidal antiinflammatory drugs (NSAIDs) inhibit cyclooxygenase and thereby suppress the synthesis of prostaglandin E, prostacyclin, and thromboxane, and alter the balance between these eicosanoids and the leukotrienes. tolerant as a result of chronic opioid use or abuse. The management of these patients is further described under Special Populations below. *Dependence,* also known as *physical dependence,* arises after chronic opioid use, and is thought to reside in the norepinephrine pathways of the locus ceruleus, and results in a typical withdrawal syndrome when an opioid-dependent patient is deprived of opioid. The typical opioid withdrawal syndrome comprises central neurologic arousal and sleeplessness, irritability, psychomotor agitation, diarrhea, rhinorrhea, and piloerection. In the management of acute pain, withdrawal may occur if habitual doses are not maintained during acute pain treatment. Patients who use opioids illicitly are not typically honest about their usage, so physicians must be watchful for the signs of withdrawal if there is any suspicion of illicit usage. Treatment consists of reestablishing previous opioid levels, before a gradual taper. Clonidine can be a useful adjunct, and effectively treats many of the manifestations of opioid withdrawal. *Addiction,* a behavioral syndrome with a neurobiologic basis, virtually never arises out of hospital treatment of pain with opioids—patients who are worried about the addiction risk can be assured of this.[30] However, addicted patients present for surgery and with acute trauma-related pain, and require skillful pain management. The management of these patients is further described under Special Populations below.

Nonsteroidal Antiinflammatory Drugs and Acetaminophen

The NSAIDs are a group of drugs that inhibit cyclooxygenase (COX), an enzyme in the arachidonic acid pathway, thereby inhibiting prostaglandin and thromboxane production (Fig. 74–2). Table 74–4 summarizes prostaglandin and thromboxane actions. Inhibition of prostaglandin and thromboxane accounts for the analgesic and antiinflammatory effects of NSAIDs, as well as for their adverse effects. Acetaminophen is not strictly an antiinflammatory drug, but is included here because it shares many of the properties of the NSAIDs. In contrast to the true NSAIDs, which are polarized and therefore do not readily cross the blood–brain barrier, acetaminophen is nonacidic and crosses the blood–brain barrier. Its action resides mainly in the central nervous system where prostaglandin inhibition produces analgesia and antipyresis. Its peripheral and antiinflammatory effects are weak. Table 74–5 list commonly used NSAIDs and their doses.

The NSAIDs and acetaminophen are commonly used over-the-counter analgesics, and have a long history of use for mild to moderate surgical pain, especially during home treatment. They are also used with opioids in oral combination formulations. The advent of ketorolac, the first injectable NSAID with Federal Drug Administration

TABLE 74–5.

Standard Doses of Commonly Used Oral NSAIDs

Generic Name	Trade Name	Adult Oral Dosage
Acetaminophen	Tylenol	650–975 mg q4–6h
Acetylsalicylic acid	Aspirin	650–975 mg q4–6h
Celecoxib	Celebrex	100–200 mg BID
Diclofenac sodium	Voltaren	25–75 mg q8–12h
Diflunisal	Dolobid	250–500 mg q8–12h
Etodolac	Lodine	200–400 mg q6–8h
Fenoprofen calcium	Nalfon	200 mg q4–6h
Flurbiprofen	Ansaid	100 mg q8–12h
Ibuprofen	Motrin	400–800 mg q6–8h
Indomethacin	Indocin	25–50 mg q8–12h
Ketoprofen	Orudis	25–75 mg q6–8h
Ketorolac	Toradol	10–50 mg q6–8h
Meclofenamate sodium	Meclomen	50 mg q4–6h
Meloxicam	Mobic	7.5–15 mg qd
Naproxen	Naprosyn	250–500 mg q8–12h
Naproxen sodium	Anaprox	250–550 mg q6–8h
Phenylbutazone	Butazolidin	100 mg q6–8h
Piroxicam	Feldene	10–20 mg qd
Sulindac	Clinoril	150–200 mg q12h
Tolmetin	Tolectin	200–600 mg q8h

(FDA) approval for use in surgical patients, triggered a surge in interest in the use of NSAIDs as sole analgesics and as adjuncts for the treatment of moderate to severe acute and surgical pain. Ketorolac is a potent NSAID, unfortunately with a side-effect profile that reflects its potency, which can be used as a sole analgesic, even for severe pain. The NSAIDs and acetaminophen have emerged as useful adjuncts in multimodal analgesic regimes, and have a possible role as preemptive analgesics.[9]

A new subclass of NSAIDs has recently been released for clinical use—the selective COX-2 inhibitors. COX-2 is an inducible isoenzyme, and a source of prostaglandins during inflammatory processes. COX-1, in contrast, is a constitutive isoenzyme, and has protective effects on the stomach where it mediates the production of cytoprotective prostaglandins (Fig. 74–3).[32] The selective COX-2 inhibitors were developed in the hope of being able to reduce NSAID side effects, particularly the damaging gastrointestinal (GI) effects. Early clinical trials, and clinical experience confirmed the analgesic efficacy and favorable side-effect profile of these drugs with regard to their effect on the gastric mucosa and their platelet effects, although some of the early trial results have now been brought into question. The great hope for these drugs was that they would replace standard NSAIDs and reduce complications, particularly NSAID-induced GI bleeding which is thought to account for up to 100,000 hospitalizations and 20,000 deaths per year in the United States. However, these hopes have been crushed by the steady emergence of evidence that deleterious cardiovascular and thrombotic effects preclude the use of these drugs in many patients.[34,35] In fact, most are now withdrawn, and the only selective COX-2 inhibitor on the market in the United States at the time of writing is celecoxib (Celebrex).

Adverse Effects and Limitations on Perioperative Use Table 74–6 lists the adverse effects of NSAIDs in surgical patients. Contraindications arise out of these adverse effects, and these are listed in Table 74–7. Acetaminophen is relatively safe, and not associated with the adverse effects listed for standard NSAIDs. The COX-2 inhibitors are less likely to cause bleeding (platelet effects), particularly GI bleeding (unprotected GI mucosa), but carry the same risk as standard NSAIDs of the other listed adverse effects, and additional cardiovascular and thrombotic risks. Consequently, these drugs have similar contraindications to the standard NSAIDs.

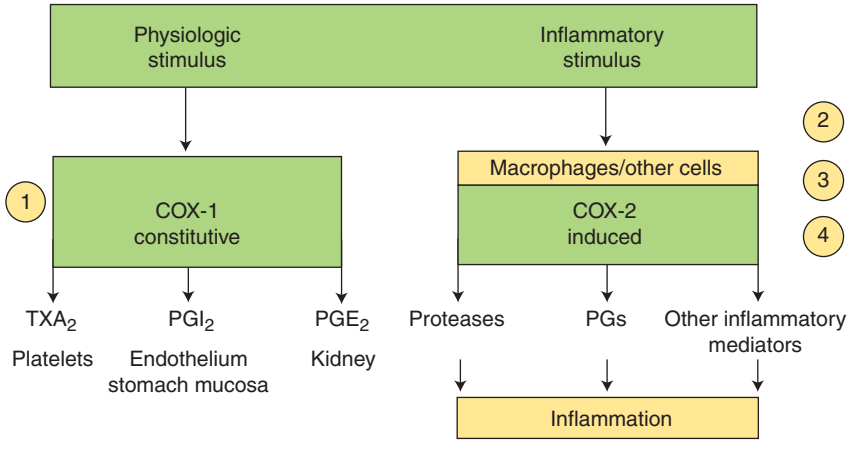

FIGURE 74–3. Relationships between the pathways leading to the generation of eicosanoids by COX-1 and COX-2. Under physiologic conditions, activation of COX-1, for instance in platelets, endothelium, stomach mucosa, or kidney, results in the release of thromboxane A_2 (TXA_2), prostacyclin (PGI_2), or prostaglandin E_2 (PGE_2). The release of these eicosanoids is selectively inhibited by drugs such as aspirin (**1**). Inflammatory stimuli release cytokines, such as interleukin-1, that induce the synthesis of COX-2 in cells such as macrophages, resulting in the release of prostaglandins (PGs). The release of PGs together with proteases and other inflammatory mediators (such as reactive oxygen radicals) results in inflammation. The COX-2 pathway can be interrupted at several levels by antagonists or antibodies to cytokines and mitogens (**2**), inhibitors of the induction of COX-2 (e.g., glucocorticoids) (**3**), or selective inhibitors of COX-2 (**4**). (Reprinted from Van Der Ouderaa FJ, Buytenhek M, Nugteren DH. Purification and characterization of prostaglandin endoperoxide synthetase from sheep vesicular glands. Biochim Biophys Acta 1977;487:315–331, with permission from Elsevier.)

TABLE 74–6.

Adverse Effects of NSAIDs in Surgical Patients

- Gastrointestinal hemorrhage (occasionally catastrophic)
- Renal dysfunction or failure
- Decreased hemostasis and hematoma formation
- Asthma in susceptible individuals (due to blockade of the cyclooxygenase pathway, leading to exaggerated effects of the metabolites of the lipooxygenase pathway [i.e., leukotrienes])
- Anaphylaxis (risk of immune-related anaphylactoid reactions is small, although some individuals suffer anaphylaxis-like symptoms that are unrelated to an immune process)
- Decreased healing of gastrointestinal anastomoses (proposed)
- Delayed fracture healing (not established in humans, but demonstrated in animals)

Reproduced with permission from Ballantyne JC and Barna SB.[31]

TABLE 74–7.

Contraindications to NSAIDs Use

- History of peptic ulcer disease or intolerance to NSAIDs
- Bleeding, bleeding diatheses, or anticoagulant therapy
- Renal failure, renal dysfunction or risk factors for renal dysfunction (i.e., hypovolemia, sodium depletion, congestive heart failure, hepatic cirrhosis, concurrent use of nephrotoxic drugs including aminoglycosides)
- Old age, particularly in the presence of any of the above[a]
- Prophylactic use in major surgery (i.e., preoperative or Intraoperative use, particularly if there is a potential for bleeding)

[a]The elderly (>60 years of age) appear to be especially vulnerable to the effects of prostaglandin inhibition by NSAIDs.
Reproduced with permission from Ballantyne JC and Barna SC.[31]

Patients should be advised to stop taking NSAIDs before surgery, chiefly because of their platelet effects, and their propensity to increase surgical bleeding. Aspirin, whose platelet effects are not reversible, should be stopped for up to 10 days before elective surgery. Other NSAIDs have rapidly reversible platelet effects, and 24 hours cessation is probably sufficient, although 2–3 days cessation is usual. Acetaminophen and COX-2 inhibitors can be continued because they do not have platelet effects.

A factor that makes perioperative NSAID use relatively safe is the fact that they are used for a short period while most adverse effects are associated with prolonged use. This is true of platelet, GI, and renal effects. Thus even in patients chronically treated with NSAIDs who have stopped the treatment to minimize surgical bleeding, short-term perioperative use may be appropriate. This brings into question the issue of timing of NSAID administration, which is linked to the drugs' liabilities. There are theoretical advantages to giving NSAIDs early in the surgical course, even preoperatively. These include the drugs' pharmacokinetics—for example, the peak effect of ketorolac may occur as late as 4 hours after administration—and the consideration that the drugs may have preemptive effects.[9] However, for major surgery, where there is a likelihood that there will be bleeding and/or hypotension with deleterious effects on clotting and renal function, it is probably better to wait until the extent of any derangement is clear. Surgical considerations are also important when deciding whether to use an NSAID. These include possible postoperative bleeding, especially into closed cavities such as the knee joint, as well as retardation of bone remodeling, a consideration after bone fusion, especially of the spine.

Use of NSAIDs and Acetaminophen for Postoperative and Acute Pain For mild postoperative or acute pain, NSAIDs or acetaminophen can be used as sole analgesics. In addition, even though they are considered weak analgesics, they have an important role as adjuncts and in multimodal analgesic regimes. Their mechanism of action—prostaglandin inhibition—means that they are synergistic with many other analgesic interventions, particularly with opioid analgesia. Multiple studies and meta-analyses confirm an average 30–50% opioid-sparing effect of NSAIDs.[36–42] Whether this reduction in opioid dose with NSAIDs translates with into improved recovery and morbidity is less clear. The most recent meta-analysis of 22 RCTs by Marret et al. affirms a 30% reduction in nausea and a 29% reduction in sedation, but effects on urinary retention and respiratory complications were inconclusive. Overall, studies assessing the effects on adjunctive NSAID use on recovery have had mixed results.[36,37,43–45] The availability of the injectable NSAID ketorolac has extended perioperative use to the many patients who cannot tolerate oral medications after surgery. Initially, the side effects of this drug seemed unacceptable, but this was an effect of an initial recommendation to use a 60-mg first dose with 30-mg repeat doses. Now that the recommended dose has been halved (30-mg first dose, 15-mg repeat doses) and a 5-day limit has been placed on ketorolac use, the early problems of catastrophic bleeding (GI, surgical, and joint) seem to be resolved. Injectable acetaminophen is available and widely used perioperatively in Europe, but is not available in the United States.

Novel Adjuncts

Although the NSAIDs are the most widely used and useful systemic analgesic adjuncts in postoperative pain regimes, there has recently been interest in testing other possible adjuncts.

NMDA receptor antagonists are known to reduce central sensitization, hyperalgesia, and opioid tolerance.[11,15] This makes them theoretically an attractive option for treating acute pain: By reducing central sensitization they might reduce postoperative pain and possibly reduce the likelihood of developing chronic pain; they could also reduce opioid requirements and opioid tolerance. Ketamine is the most widely tested of currently available NMDA receptor antagonists (ketamine, dextromethorphan, and amantadine), but usage has been limited by this drug's side effects (psychomimetic effects, including nightmares and hallucinations). These side effects can be reduced by concomitant use of benzodiazepines and by dose restriction; efforts to study the possible usefulness of ketamine as an adjunct analgesic for postoperative pain have centered on dose-finding and regime modeling. A recent detailed study suggests that although ketamine has demonstrable

antihyperanalgesic effects (as shown by skin measurements around the surgical incision), this may not translate into a useful opioid-sparing effect.[18,46] A 2005 systematic review by Elia and Tramer incorporating 53 trials (2839 patients) found a small difference (< 1 cm on a 0–10-cm visual analog scale) in postoperative pain level, a significant difference in opioid use during the first 24 hours after surgery, and no difference in opioid side effects.[47] The highest risk of hallucinations occurred in awake or sedated patients receiving ketamine without a benzodiazepine. Given the mixed results of published trials (other studies), and the small (clinically insignificant) difference in pain plus a lack of difference in opioid side effects (lack of important opioid sparing) in a large systematic review, the role of ketamine and other NMDA receptor antagonists in postoperative pain regimes remains uncertain.

Neuropathic pain medications (anticonvulsants and antidepressants), as their name suggests, have their chief pain indication for the treatment of chronic neuropathic pain. "Neuropathic pain" is caused by a primary lesion or dysfunction in the nervous system. Because neuropathic pain medications act by modifying hyperactivity in the nervous system, and because acute injury does result in neural changes both peripherally and centrally, it seems logical that neuropathic pain medications might also help acute, even nociceptive, pain. This premise has been tested in multiple studies using gabapentin, currently the most widely used neuropathic pain medication, favored because of its excellent safety record.[48] Published RCTs consistently show reduced opioid consumption after a typical dose of 1200 mg given as a single dose before surgery, but there is no reduction in opioid side effects. Side effects (dizziness and sedation being the most common gabapentin side effects) did not appear to interfere with treatment efficacy in these trials. Without a demonstrable reduction in opioid side effects, the value of this treatment must remain questionable. However, this is an interesting area worthy of further study, especially as newer neuropathic pain medications become available.

Patient Controlled Analgesia

Simple though it seems, PCA technology represents a huge advance in acute pain management. Computer-controlled pumps allow patients to control their own injections, and to do this safely. Additionally, microchips have made controllable pumps easily portable. PCA satisfies the needs of patients to receive pain medication easily and quickly, when needed. Nursing time spent obtaining, checking, documenting, drawing up, giving, and monitoring frequent doses is eliminated. The hospital's need to comply with JCAHO's pain mandate is greatly aided. Most moderate to severe postoperative pain in hospitalized patients can be managed satisfactorily using routine intravenous opioid PCA for 24–48 hours after surgery, with or without adjuncts. A proviso is that pain in the immediate postoperative period is controlled by nurse bolus injections until it is under adequate control; patient-triggered boluses using standard settings may be inadequate for treating immediate postoperative pain, and early failed analgesia can prove difficult to overcome. Ideally, patients should be educated in the use of PCA before surgery.

The Inherent Safety of PCA

Because of the ease with which each PCA bolus dose can be given, PCA dosing regimes were devised using small frequent doses. For example, a standard regime for morphine is 1 mg every 6 minutes. A maximum hourly limit can be used, as can a background infusion if desired (the latter is particularly useful at night so that the patient can sleep). Part of the logic was to avoid the large swings between high peaks and low troughs associated with less frequent and larger doses (Fig. 74–4), but another was to improve safety. Small patient-controlled doses are inherently safe because a single dose is too small to produce overt sedation or respiratory depression, and an obtunded patient will stop pushing the button so that there will be no further dosing beyond this early warning stage. The inherent safety of PCA also means that there is less need for monitoring, and no need to use the intramuscular route (with its slower absorption) for the sake of safety. Naturally, no method of delivery of opioids is completely safe, so a degree of vigilance is always required. The inherent safety of PCA is lost if persons other than the patient are permitted to push the button.

Benefits of PCA

Since PCA became popular in the 1980s, many studies have been conducted to assess whether the use of PCA results in better analgesia, lower opioid requirements, fewer side effects, better surgical outcome, or superior patient satisfaction. Two meta-analyses of PCA versus "conventional analgesia" (intermittent large-dose opioid injection) have been published, the first in 1993[50] and the second in 2001.[51] The second analysis added 17

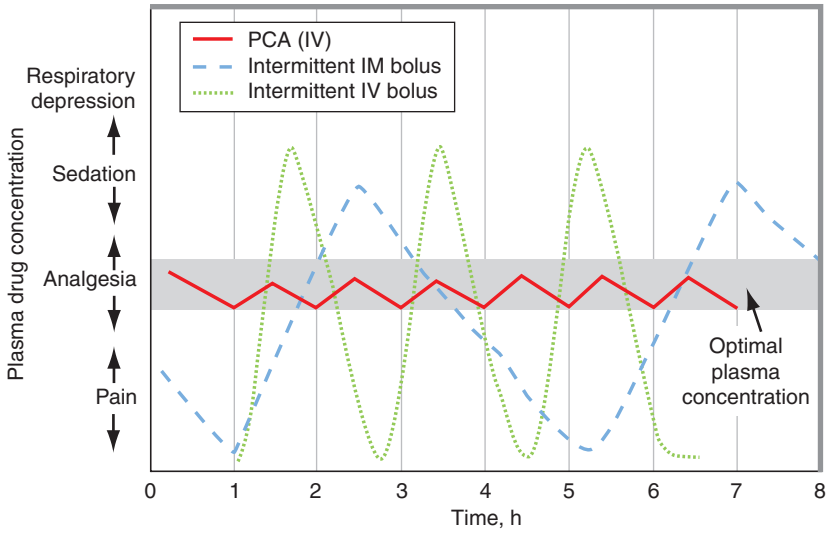

FIGURE 74–4. Serum drug levels from frequent small dosing using PCA compared with large, intramuscular or intravenous dosing given every 2–4 hours. Ideally, serum drugs levels are kept within the "analgesic" range, avoiding the high peaks associated with oversedation and respiratory depression and the low troughs associated with inadequate analgesia. Frequent small dosing would not be practicable without PCA. (Reprinted from Ballantyne JC. Systemic opioids and patient controlled analgesia. In: Neal JM, Rathmell JP, eds. Complications in Regional Anesthesia and Pain Management. Philadelphia: Elsevier, 2006:1667–175. Copyright 2006, with permission from Elsevier.)

new trials to the first, but its results were essentially similar to those of the first. There was slightly better analgesia associated with PCA use (difference of 5.6 on a 0–100 scale, $p = 0.006$, debatably not a clinically important difference), and a large difference in patient satisfaction favoring PCA (42% improvement, $p = 0.02$). There was no difference in opioid usage, side effects, or surgical outcome. Thus, the overriding benefit of PCA seems to be that patients like it. It has, in fact, become a standard of care in a majority of U.S. hospitals.

Cost of PCA The issue of cost of PCA is frequently analyzed and debated.[52–54] It has proven difficult to come up with a global assessment of PCA costs and the cost savings associated with reduced nursing involvement, improved safety, and other factors. This is because all related costs, including the initial outlay or rental of the PCA systems and their hardware, and including nursing costs, vary from location to location. Overall, it seems that the literal costs to a hospital are slightly higher for PCA versus "conventional analgesia," but imponderables such as increased safety and greater patient satisfaction, are hard to translate into cost benefits.

Patient-Controlled Epidural Analgesia PCA technology can also be used for epidural analgesia. As with intravenous PCA, the main advantage is that patients like the sense of control offered by the patient triggered pump.

Novel PCA Technologies New methods of providing PCA that use iontophoretic transdermal and intranasal delivery systems are now in development.[55,56] The most advanced of these is the fentanyl patient-controlled transdermal system, which is a noninvasive, needle-free, credit card size, self-contained drug-delivery system. A small imperceptible electric current drives ionized drug across the normally impenetrable stratum corneum—the outer layer of skin. The adhesive system can be placed on any patch of hairless skin, and for convenience, the upper arm is usually chosen. The system is preprogrammed to deliver 40 μg fentanyl per dose and can deliver up to 6 doses per hour for 24 hours, or 80 doses, whichever comes first. Each dose is triggered by the patient pushing a button on the system twice (twice so it is not triggered accidentally). Cost is likely to play a large part in whether this type of system is adopted for hospital versus home use, or acute versus cancer/chronic pain.

Epidural Analgesia

The provision of epidural analgesia is probably the single most important contribution that anesthesiologists currently make to postoperative pain management for individual patients. There are two reasons for this: (a) after major surgical procedures, particularly abdominal and thoracic, epidural analgesia has proven analgesic superiority,[57] an effective opioid-sparing effect, and probably a beneficial effect on surgical outcome,[17,58,59] and (b) the ease with which the alternative (systemic opioid) can be provided using PCA has diminished the role of anesthesiologists in the provision of standard treatment. A perplexing thought, however, is how much we truly understand the risk versus benefit of epidural analgesia, especially in an era of potent thrombosis prophylaxis, and some further risk of epidural hematomas. How do we weigh rare but catastrophic outcomes against common benefits of debatable value? This is one of the most important issues we face as we continue the use of epidural analgesia.

Indications A review of indications for intraoperative epidural use is outside the remit of this chapter, but there are also independent indications for postoperative epidural analgesia, including patients having thoracic or abdominal surgery, patients having lower-limb surgery in whom early mobilization is important, patients having lower-body vascular procedures in whom a sympathetic block is desirable, and patients with compromised cardiac or pulmonary function.

Contraindications Epidural placement is always contraindicated in patients who refuse this option. It is also contraindicated in patients with coagulopathy, concurrent or planned treatment with low-molecular-weight heparin or with potent antiplatelet agents that will not allow adherence to American Society of Regional Anesthesia and Pain Medicine (ASRA) guidelines,[67] and in patients with bacteremia or local infection at the insertion site. The presence of spine pathology is a relative contraindication: the placement may be technically challenging and the treatment may fail if distorted anatomy prevents good distribution of the epidural medications. Neurologic disease is considered a relative contraindication by some because if there is a change in neurologic status—which is not uncommon after the stress of surgery—diagnosis of the deterioration can be confused in the presence of an epidural.

Drug Choices and Drug Effects Drugs injected or infused into the epidural space will diffuse and spread according to their pharmacokinetics profile. The epidural space is complex because it contains arteries, veins, and lymphatics that are capable of absorbing drugs into the systemic circulation, nerve roots upon which drugs can act directly, and fat in which drugs can form a reservoir (Fig. 74–5). The intrathecal space is a close neighbor of the epidural space, and diffusion into this space brings the epidural drugs access to more nerve roots, to the spinal cord, and if spread is extensive enough, into the ventricular system of the brain (Fig. 74–6). When planning epidural

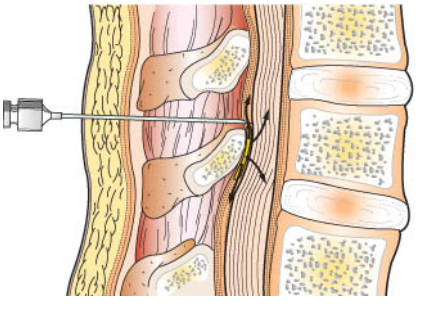

FIGURE 74–5. The epidural space. The space is always approached via the elastic and resistant ligamentum flavum. The space itself contains fat, veins, arteries, lymphatics, and nerve roots. Drugs injected or infused into the space will diffuse into all the tissues and structures within the epidural space, as well as to neighboring structures. Thus, local anesthetics will have a direct effect on nerve roots within the space, as well as diffusing through the dura and arachnoid membranes to cerebrospinal fluid and intrathecal nerve roots. Opioids have little activity in the epidural space itself, but will diffuse into the systemic circulation (the more lipophilic the opioid, the more the systemic uptake), and across to the opioid receptors in the substantia gelatinosa of the dorsal horn.

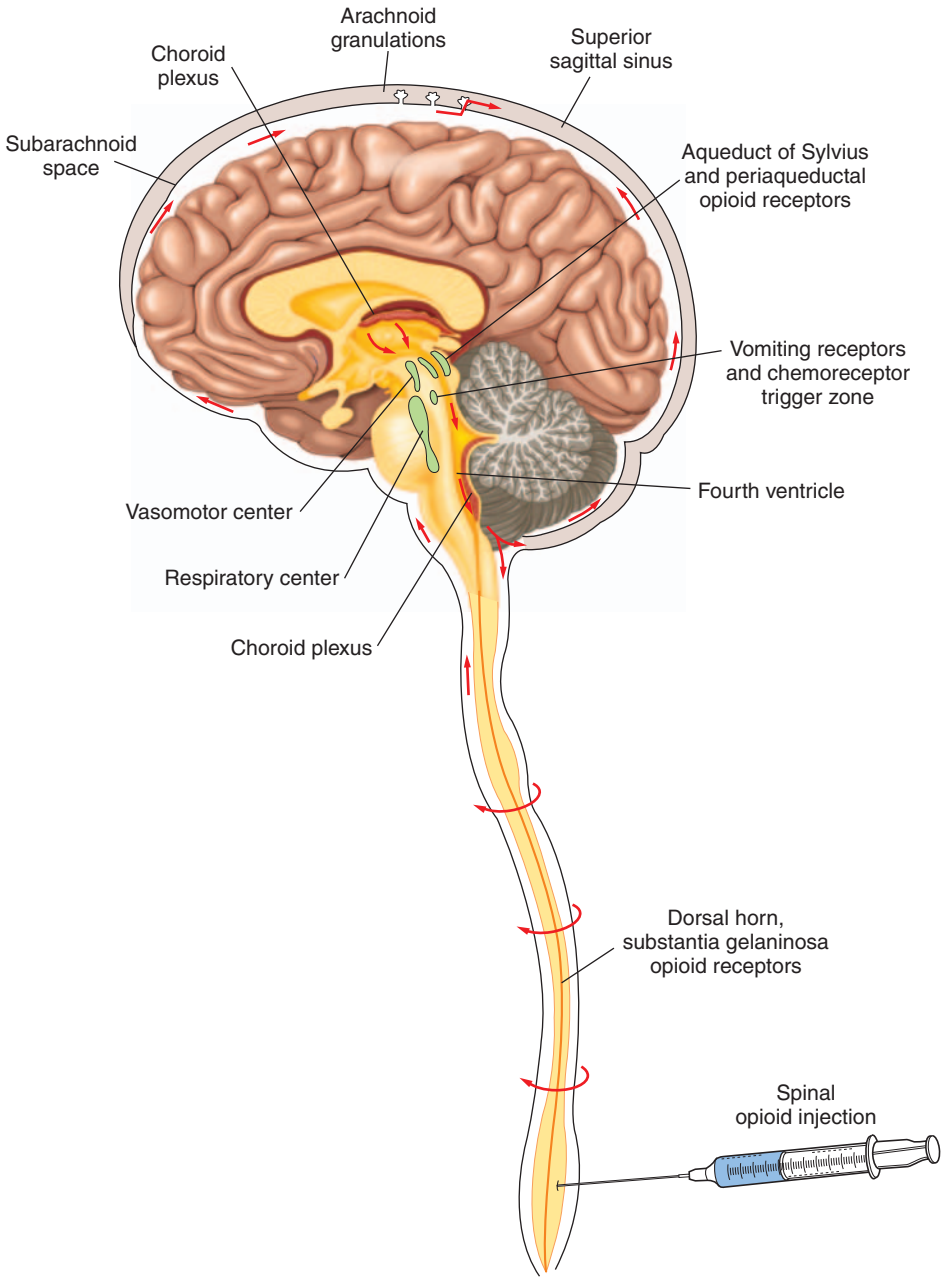

FIGURE 74–6. Cerebrospinal fluid flow. Drugs injected into the epidural space or intrathecal space will tend to accumulate in cerebrospinal fluid (CSF) at the level of injection. The accumulation of hydrophilic drugs such as morphine tends to be greater than that of more lipophilic drugs such as fentanyl. Slowly diffusing drugs such as morphine is subject to bulk flow of CSF, and tend to move cephalically toward the ventricular system in the brain. Bulk CSF flow varies markedly from patient to patient. If drug does reach the ventricular system, notably the fourth ventricle, it is likely to cause respiratory depression, and possibly nausea, as the respiratory center and chemoreceptor trigger zone are at the base of the fourth ventricle. Slowly diffusing drugs are likely to provide a good spread of analgesia, as drug spreads widely to the opioid receptors concentrated in the substantia gelatinosa of the dorsal horn.

infusion regimes, one has to consider not only local effects, but also distant effects, as related to the individual drug's epidural pharmacokinetics.

Local anesthetics act directly on nerve axons to block sodium channels and thus block saltatory conduction. They can block nerves in the epidural space itself, or more widely once they cross into the intrathecal space. Because of the arrangement of nerve fibers within the nerve roots, with small fibers lying outside larger fibers, small fibers are the first to be blocked and the most sensitive to local anesthetics. This characteristic of the spinal nerve roots means that differential blockade can be achieved using low dose local anesthetics to block only small fibers (C-fibers—sympathetic, pain, and temperature fibers), and high-dose local anesthetics to achieve total sensory blockade, often accompanied by motor blockade (Aα and β fibers). To achieve analgesia without sensory decrement, low-dose local anesthetic (e.g., 0.1% bupivacaine) is chosen for postoperative use. Epidurals with low-dose local anesthetic infusion are sometimes termed "walking epidurals"—a useful term because it emphasizes that patients can and should be walking around to hasten recovery and minimize complications.

Opioids have a completely different target—the opioid receptors in the dor-

sal horn of the spinal cord. Epidural opioid analgesia is also more likely to be complicated by systemic effects as, in contrast to the local anesthetics, which also undergo a degree of systemic absorption, there are clinically relevant systemic effects, especially when highly lipophilic opioids such as fentanyl are used. The degree to which opioids are absorbed systemically versus into cerebrospinal fluid (CSF) versus onto spinal cord receptors depends almost entirely on their lipophilicity (Table 74–3). As Table 74–3 shows, morphine is several-fold less lipophilic than all the other commonly used opioids. Because of this, it tends to be less-readily absorbed into the systemic circulation, providing a better selective spinal effect, and also tends to spread more within the intrathecal space as it will favor staying in the watery medium of the CSF. This has advantages—more widespread spinal analgesia—and disadvantages—a higher risk that the drug will reach the ventricular system and cause respiratory depression (Fig. 74–6). In contrast, more lipophilic opioids, such as fentanyl, tend to have much greater systemic absorption (less selective spinal analgesia) and absorption onto spinal cord receptors tends to be localized, with poor spread. There is a great deal of experience using morphine and other opioids safely and effectively, and individual institutions must design suitable regimes on the basis of the published experience and their ability to adequately evaluate and monitor patients receiving epidural analgesia.

The addition of *clonidine* to the local anesthetic and opioid significantly improves the quality and duration of neuraxial analgesia.[61] The effect is mediated by descending modulatory pathways to the spinal dorsal horn. Despite the low doses used for neuraxial administration, systemic side effects (hypotension, bradycardia and sedation) can occur. Dose finding studies are still underway, and the therapeutic window for useful analgesia without side effects seems to be narrow. A reasonable regime uses a 1–2 μg/kg bolus followed by 0.4 μg/kg/h.

Management Principles The management of epidural catheters should always be under the direct supervision of anesthesiologists. Patients should be evaluated daily to ensure that catheters and medications are working effectively, and that possible complications are recognized, and recognized early. Pain reports should be satisfactory, and side effects, such as pruritus, sedation, and changes in sensation or motor function, should be carefully evaluated. Medication charts should be checked, especially for unintentional anticoagulant administration. Catheters and their insertion sites should be inspected for migration, integrity of the dressing, and for inflammation or back tenderness. Anesthesia personnel should make changes to the analgesic regime and administer specific medication as necessary. At the end of treatment, the anesthesia team should be responsible for removing the catheter and ensuring that it is removed intact. Nurses should be properly educated before they care for patients with epidural catheters. Important teaching points include typical medication doses and concentrations, anticoagulation issues, assessment parameters, the normal appearance of the catheter and catheter site, operation of the infusion pumps, common medication side effects that can be treated by them, and side effects requiring a call to the physician in charge.

If an epidural does not appear to be functioning well, it is first necessary to test whether the catheter is well positioned. The ideal way to do this is to attempt to produce a discernible level using a bolus dose of local anesthetic. However, the dose of local anesthetic needed to produce a sensory level may also induce hypotension, which would not be desirable in an unmonitored situation such as a regular floor, particularly if there are no means readily available to treat the hypotension. A surprisingly helpful test is to inject 5–7 mL of the analgesic infusion (low-dose local anesthetic), in which case no special monitoring is needed because the low-dose anesthetic is unlikely to produce extreme hypotension. If the catheter is well positioned, analgesia should be noticeably improved by the injection.

Once good catheter function is established, several approaches to improve analgesia can be taken. Bolus injections can be continued until good analgesia is achieved. The infusion rate can be titrated upwards, as tolerated. Systemic analgesic can be added to the regime. NSAIDs are useful adjuncts to epidural analgesia, especially when the epidural level does not cover the entire area of surgical pain, for example when the incision is high, or when pain is referred outside the epidural area as occurs when chest tubes irritate the diaphragm and produce shoulder pain via the phrenic nerve. Systemic opioids (including PCA) can also be added, in which case it is preferable to remove the opioid from the epidural infusate, if used.

Managing Side Effects Hypotension, mild sensory and/or motor changes and urinary retention are the most common side effects of epidural local anesthetic, whereas pruritus, sedation, dizziness, and urinary retention are the most common side effects of epidural opioids. Most side effects are alleviated by either lowering the infusion rate, or changing the drug or dose. Hypotension can become a considerable nuisance during epidural analgesia, even though the sympathectomy from low-dose local anesthetics is theoretically minimal. Some patients are particularly sensitive to the local anesthetic, and manifest hypotension that does not respond to the primary measure of fluid replacement. For these patients, the local anesthetic can be removed from the epidural mix, or the epidural treatment may have to be abandoned altogether. Pruritus is a common side effect and usually responds well to antihistamine treatment. The mixed agonist–antagonist nalbuphine (Nubain) (5–10 mg IV, given every 4–6 hours) also works well, as does low-dose naloxone infusion. Contrary to popular belief, nausea rarely occurs because opioid doses are low. Gut mobility is in fact improved by epidural therapy, because of opioid sparing and the favorable effects of neuraxial local anesthetic on bowel motility. Urinary retention is common, and it is common practice to keep a urinary catheter in place until epidural therapy is discontinued.

Unilateral lower-extremity numbness with occasional weakness or motor block occurs fairly frequently. It is often a result of the epidural catheter tip migrating along a nerve root so that the local anesthetic is concentrated in one area. Pulling the catheter back, or lowering the infusion rate, often rectifies the problem. However, one should always remain vigilant and continue to watch for more serious complications.

Complications The most common complications are failed block/analge-

sia, and postdural puncture headache (PDPH). Both are considered benign, although they may be devastating to patients who have committed to an epidural in order to optimize their surgical recovery. The exact incidence of these common complications is difficult to establish as reports vary, and the occurrences likely vary according to reporting and practice habits. Recent reports suggest that failed analgesia occurs in as many as 15% of cases.[62–64] PDPH may occur in up to 86% of patients after accidental dural puncture (rate 0.16–1.3%).[65] The incidence of other self-limiting neurologic complications such as radicular pain and peripheral nerve lesions is difficult to determine, because these occurrences are rarely reported.

PDPH is thought to result from a small CSF leak secondary to unintentional dural puncture. Typically, there is a delay in onset of the headache of up to 24 hours, so that the complication tends to manifest on the first postoperative day. Because PDPH tends to worsen on sitting up, and particularly on walking, it may not present itself until the patient gets out of bed for the first time after surgery. Other characteristics of the headache are that it tends to occur at the back of the head (occiput) and neck, and produces a tight, pulling and throbbing sensation. Conservative management consists of bedrest (up to bathroom only), plenty of fluids (IV or oral) and headache medication (NSAIDs, acetaminophen, Fioricet, caffeine, and theophylline all work well). If there is no resolution, or if conservative measures are contraindicated, a blood patch is recommended. This consists of an epidural injection of up to 20 mL of the patient's own blood (drawn under aseptic conditions). The exact mechanism by which an epidural blood patch works is uncertain, but is probably either a pressure effect, or a laying down of clot or fibrosis onto the puncture site.

Epidural hematoma with consequent paraplegia is extremely rare, but is a catastrophic complication of epidural therapy. Permanent paraplegia can occur even when a hematoma is diagnosed and treated in a timely manner—although early intervention usually reverses the neurologic injury. Persistent lower-extremity neurologic changes or cauda equina syndrome (loss of bowel and bladder control) should always be taken seriously, especially if there is accompanying back pain and tenderness, which are cardinal signs of epidural hematoma and abscess in nonanalgesia patients, thus symptoms and signs cannot be counted on in patients receiving epidural analgesia, although neurologic consultation can be obtained, but early imaging, preferably with MRI (second choice, CT), should always be instituted. The presence of a space-occupying intracanal spinal lesion should always herald immediate transfer to the operating room for surgical decompression.

The incidence of epidural hematoma after neuraxial injection, catheter placement, or catheter removal is estimated to be 1 in 190,000 cases, with many of the reported cases associated with anticoagulant use.[66–68] A rash of reports of epidural hematoma occurring after neuraxial interventions in patients receiving low-molecular-weight heparin (LMWH) alerted physicians to the dangers of epidural injections and catheters in patients receiving highly effective thrombosis prophylaxis. More problems followed when chronic treatment with potent and long-acting antiplatelet agents such as clopidogrel became more widespread.[67] In view of the rapidity with which new agents are being introduced, and the time lag before the extent of a problem can be assessed, we are left with a great deal of uncertainty about how to best mix anticoagulant prophylaxis and epidural analgesia. Table 74–8 summarizes guidelines for managing epidurals in patients receiving anticoagulants. These recommendations are based on the consensus guidelines published by ASRA. The guidelines are updated periodically and published on ASRA's website. Epidural bleeding is known to occur secondary to single shot neuraxial techniques as well as neuraxial catheter insertion and removal, so recommendations are needed for the start and end of neuraxial therapy, as well as for starting anticoagulant therapy after neuraxial instrumentation or catheter removal.

Epidural abscess occurs less often than epidural hematoma, but can be equally catastrophic, and may cause permanent and serious neurologic injury, even death.[45] Fever is a likely accompaniment to epidural abscess, otherwise it presents much as epidural hematoma. In fact, it may not be clear whether a neuraxial mass is blood or pus until it is exposed during surgery. The mortality of spinal abscess can be as high as 18%.[70] The incidence of epidural abscess secondary to neuraxial blockade is estimated at 1 in 250,000 cases in healthy patients, but 1 in 2000 cases in diabetic or immunocompromised patients.[43,71] Other serious complications such as anterior spinal artery syndrome, transverse myelitis and meningitis have been reported, but are extremely rare.

Epidurals and Surgical Outcomes In terms of truly understanding the benefit versus the risk of epidural analgesia in any individual patient, it is important to understand whether or not the benefit extends beyond that of the simple provision of excellent analgesia. Is mortality improved? Is recovery hastened? Are high-risk patients such as those with serious cardiac disease less susceptible to cardiac morbidity? Do the bowels recover function quicker? Do epidurals reduce thromboembolism? Is postoperative pulmonary function improved? These are all questions that have been asked in countless trials often with conflicting results.[58,59] Perhaps the clearest result is that epidural analgesia (particularly that from thoracic epidurals) does improve bowel mobility and reduce the period of ileus, with consequent earlier hospital discharge.[72] There is also considerable support for improved pulmonary function.[73–77] But support for a beneficial effect on other outcomes, particularly catastrophic outcomes, is less clear. Large multicenter studies published relatively recently found no advantage to epidural analgesia in terms of mortality or major morbidity.[75,77] Yet earlier trials and meta-analyses had suggested significant improvements in mortality and serious morbidity.[73,74,76,78,79] Has some of the earlier advantage of neuraxial anesthesia and analgesia dissipated because they no longer provide the benefit of reduced thromboembolism in this era of improved thromboprophylaxis? And could general improvements in perioperative care such as better preoperative optimization, shorter-acting anesthetic drugs, improved standards of vigilance and monitoring, and accelerated recovery programs, have diminished the role of neuraxial anesthesia and analgesia?[59]

TABLE 74–8.

Guidelines for Epidural Placement and Removal during Anticoagulant Therapy

Drug	Monitoring	Time after Last Dose before Placing or Removing Catheter	Time after Placing or Removing Catheter before Restarting Medication
Warfarin	INR (<1.5)	Check INR if treatment >24 hours	Same day
NSAID, ASA	No significant risk		
Thrombolytics	None	10 days	10 days
SC heparin	No significant risk		
IV heparin	PTT	2–4 hours	1 hour
LMWH	Anti-Xa (however, not predictive of risk of bleeding)	12 hours	2 hours
Low dose			
Dalteparin (Fragmin) (<5000 U qd)			
Enoxaparin (Lovenox) (<60 mg qd)			
High dose			
BID dosing			
Ticlopidine (Ticlid)	None	14 days	24 hours
Clopidogrel (Plavix)	None	7 days[a]	24 hours
Abciximab (Reopro)	None	48 hours	12 hours
Tirofiban (Aggrastat)	None	8 hours	4 hours
Eptifibatide (Integrilin)	None	8 hours	4 hours

ASA, acetylsalicylic acid; INR, international normalized ratio; LMWH, low-molecular-weight heparin; NSAID, nonsteroid antiinflammatory drug; PTT, partial thromboplastin time; SC, subcutaneous.
NOTE: Regional anesthesia is contraindicated in patients receiving fondaparinux (Arixtra).
[a]After a single dose, catheter can be removed within 24–48 hours. If this window is missed, it is necessary to wait 7 days before catheter removal.
Reproduced with permission from Ballantyne JC and Ryder E.[69]

Epidural or No? Despite all the blows against epidurals—incompatibility with modern thromboprophylaxis and dwindling returns in terms of improvements in mortality and major morbidity—they remain a beneficial and helpful intervention for selected patients undergoing invasive surgical procedures. For patients who accept the risks because of a promise of good postoperative pain relief, that promise is usually fulfilled. Patients with serious respiratory disease, and those undergoing extensive lung resection, benefit from opioid sparing and the favorable effects of epidural analgesia on pulmonary mechanics. Recovery can be hastened after bowel surgery because of favorable effects on bowel mobility. And patients with cardiac ischemia or failure can benefit from the moderate reductions in afterload and the negative inotropy and chronotropy of a well-managed thoracic epidural.

Nerve Blocks

The primary indication for nerve blocks is for the provision of surgical anesthesia. But there are secondary benefits in terms of pain relief in the postoperative period, and in some cases analgesic effects can be prolonged using perineural catheters. As nerve blocks wear off, there remains some degree of analgesia (probably from residual small fiber blockade), and surprisingly, these effects appear prolonged beyond the known half-life of the local anesthetic, especially in the case of distal peripheral blocks such as hand and ankle blocks. Certain nerves are accessible enough to be injected intermittently should the need arise: femoral nerve blocks provide good but incomplete analgesia after knee surgery, and intercostal nerve blocks can be useful after thoracic surgery or chest trauma, when epidural analgesia is contraindicated. The analgesia from single-shot neuraxial blocks can be prolonged by injecting an opioid at the time of placing the block. Injection or infiltration of local anesthetic into the wound by the surgeon can provide helpful analgesia during the early postoperative phase. The two techniques that are particularly useful for postoperative pain control are prolongation of neural blockade using catheters and neuraxial opioid injections.

Prolongation of Neural Blockade Using Catheters

Continuous analgesic/anesthetic infusions can be administered at various sites, offer an alternative to neuraxial techniques, and are particularly useful when active mobilization is needed. Infusion near the brachial plexus is useful after shoulder or hand surgery, and infusion near the femoral nerve is useful after knee surgery. Patients are most often hospitalized, at least while the treatment is stabilized, and bupivacaine 0.1% at 10–20 mL/h is used initially. If that is ineffective, a higher concentration (0.25%) can be used, and/or a bolus injection of 20 mL of 0.25–0.375% bupivacaine can be tried. Bolus injection is useful prior to physical therapy. Patients may also use supplemental analgesics. Increasingly patients are allowed home with a plexus catheter, either with a home pump, or reserving the catheter for injection prior to physical therapy sessions.

Infusion into joints may be useful after joint surgery, and infusion into

wounds may also be useful. Pumps for use at home have been developed (e.g., the Pain Buster Pain Management System) for infusing into joints and wounds. Local anesthetics and opioids have been used. Patients seem enthusiastic about these pumps, but they are still considered investigational because they have not been shown to improve pain or reduce systemic analgesic used in trials to date.

Neuraxial Opioid Injections

Neuraxial morphine does not increase risk of analgesia provided dosing is reasonable and patients are appropriately monitored. A single shot of morphine into the epidural space (1–4 mg) or intrathecal space (0.1–0.4 mg) can provide prolonged analgesia (up to 24 hours), but carries a risk of delayed respiratory depression. Morphine is poorly lipophilic, tends to stay in CSF once there, and is subject to CSF bulk flow with passage to higher centers including the respiratory center (Fig. 74–6). At the same time, the fact that morphine tends to remain in CSF is the reason that it produces excellent selective spinal analgesia (i.e., good spread to spinal cord receptors). Single-shot neuraxial morphine is an excellent means of providing analgesia when there is no epidural catheter. Patients should be monitored in the same way as those receiving epidural opioid infusions. PCA can be used to provide supplementary analgesia if necessary, but for safety, only demand doses should be used, and continuous background infusions should be avoided.

Nondrug Approaches

Transcutaneous Electrical Nerve Stimulation

The transcutaneous electrical nerve stimulation (TENS) device consists of a series of electrodes that are placed on the site of the pain (either side of the surgical incision in the case of postoperative pain) through which a low-voltage electrical stimulus is passed. Stimulation analgesia has been used since the 1950s when Melzack and Wall proposed that stimulation of large sensory fibers (Aβ fibers) could somehow shut down transmission through the smaller pain fibers (C fibers). TENS is the original, simplest, and most widely used stimulation technique and is applicable to surgical pain. TENS does not stand up against drug therapies as a sole treatment for anything other than mild postoperative pain, but it may be useful for reducing analgesic requirements and possibly for improving pulmonary function in selected patients. Randomized controlled trials have confirmed its efficacy in postoperative pain compared with controls (no TENS), but it appears to be no better than sham TENS (electrodes with no current). Sham TENS is better than no TENS, suggesting there is a strong placebo effect.[80,81] TENS can be useful in patients who do not tolerate or choose to avoid medications and invasive interventions.

Behavioral Therapy

The goal of behavioral therapy is to provide patients with a sense of control over their pain. All patients benefit from being well-prepared psychologically for the experience of surgery and postoperative pain.[4] Simple relaxation strategies and imagery can be helpful for patients who find such interventions appealing. Other strategies, such as brief jaw relaxation, music-assisted relaxation, and recall of peaceful images, can reduce anxiety and analgesic requirements; they take only a few minutes to teach, although they may require continual practice and reinforcement. Patients who wish to learn simple relaxation exercises can be given a brochure describing the exercises. Therapeutic touch is another popular method and is particularly helpful when postoperative pain is refractory to other modalities. Elaborate behavioral therapy techniques (i.e. biofeedback or counseling), have limited place in the treatment of acute postoperative pain.

SPECIAL POPULATIONS

Neonates, Infants, and Children

Throughout childhood, the management of pain presents special challenges. Very young children—neonates and infants—tolerate opioids poorly because they are prone to apnea, and their handling of this and other groups of drugs is altered by several factors, including slow conjugation by the liver. It is no longer acceptable to avoid giving opioids to neonates on the basis that they don't feel pain, as there is now a great deal of evidence that they do feel pain just as do adults, and that untreated pain can produce an imprint that may have long-term psychological, and even physical, consequences.[82–85] Older children can also be scarred by traumatic and painful experiences, and it is sometimes difficult for adult caregivers to understand childhood and adolescent psychology and to communicate effectively so as to optimize pain management. Pain assessment is challenging, particularly in preverbal children (see Pain Assessment above). Good pediatric pain management requires a great deal of time and patience, and is therefore labor intensive; unlike adults, children, especially young children, cannot simply be left with a PCA pump. Unfortunately, the resources for providing excellent and safe pain care for children, which often must be done at the bedside, may be lacking other than in specialty hospitals and centers of excellence.

Planning for the Postoperative Experience

Anesthesiologists play a key role in preparing children and their parents for the postoperative period and the pain the children are likely to experience. First, they can explain what is going to happen and how pain will be managed and assessed. They can explain treatment options and help parents (and older children) select the right approach. Often an intervention such as an epidural, a single-shot caudal, or a nerve block is helpful, and these options can be discussed. For children who are old enough for PCA (generally 6 years and older), this should certainly be discussed, and the children should understand how to use the pump. Parents should understand that the inherent safety of PCA will be bypassed if they press the button themselves, and that it is better if they do not intervene other than to encourage the children to take doses. If the child has had past surgery, it is helpful to know what pain treatments worked well.

Treatment Choices

Essentially the treatment options available to adults are available to children. However, there are differences in the way neonates and infants metabolize drugs, particularly opioids, and these must be understood. In general, smaller, more frequent dosing is needed in the very young, but there is no substitute for referring to pediatric dosing guidelines. As in adults, opioids are the mainstay for treating severe pain, but

given the safety issues, especially in young children, it is always preferable to reduce opioid requirements whenever possible by using adjunctive treatments such as NSAIDs and acetaminophen which are generally well tolerated. Epidurals, caudals, and other nerve blocks, even single-injection techniques can be helpful and are usually successful because patient anatomy is straightforward. However, catheters can be difficult to maintain, especially if they are small-diameter catheters (when they have a tendency to block) and especially if the insertion site is within the diaper area (when the skin can become macerated and the catheter tends to migrate). Opioids can be given as a low-dose infusion in neonates and infants, which obviates the need for intermittent injections and is generally safe and effective, provided breakthrough pain is controlled by bedside bolus injections and the temptation to try and overcome uncontrolled pain by repeatedly increasing an infusion rate is resisted.

Safety

Maintaining safety while providing good pain relief is an especial challenge in children, chiefly because of their sensitivity to opioids. Young children require extra vigilance, and great care with dosing. Dosing is calculated on a per-kilogram basis, and because children's weights and sizes vary considerably, always warrants careful calculation. Frequent checking of vital signs is mandatory in neonates and infants receiving opioids, and the use of respiratory rate and oxygen saturation monitors may improve safety and is a standard of care for this population in many institutions.

The Elderly and Infirm

Just as children present a special challenge, so do the elderly and infirm. Again, this is a group of patients that is particularly sensitive to opioids: they are prone not only to opioids' respiratory depressant effects, but also to their central dysphoric and euphoric effects. Opioid-induced confusion is common in this age group. The elderly are liable to become confused with other psychotropic drugs such as benzodiazepines, and are sensitive to NSAID side effects, particularly GI bleeding and renal dysfunction. They can also develop a confusional state simply because they are moved from familiar surroundings. These factors combined make good pain control hard to achieve. Pain control may become a low priority because it is hard to assess pain in confused patients, and drugs are blamed for the confusional state and therefore withdrawn.

The elderly tend to appear stoical and it is not clear whether they have a different threshold for pain, whether past experience has altered their attitude toward pain, or whether they truly do not feel pain to the same extent as younger adults. It is probably best to treat pain according to the patients' demands, and not to project pain on them because of a preconceived notion that their pain must be worse than they say it is. PCA is not a suitable technique for confused patients, and may not work well even in nonconfused elderly patients because they tend to undermedicate. A simple approach, such as nurse-determined intermittent low-dose opioid with acetaminophen as an adjunct, is often the best approach. Epidurals and nerve blocks are useful for reducing reliance on poorly tolerated systemic medications.

Opioid-Tolerant Patients

Pain specialists and acute pain services are increasingly preoccupied treating patients who are opioid tolerant and who get into difficulty when an episode of acute pain, notably because of surgery or trauma, proves refractory to standard treatments.[86] Nonspecialists are often uncomfortable prescribing the high doses of opioid that may be needed to overcome acute pain in opioid-tolerant patients. There are several reasons that the numbers of patients presenting with opioid tolerance is increasing, some related to societal factors, others to changes in medical practice. (a) All efforts to control drug and heroin abuse by means of regulation have failed, and illicit drug trading, distribution, and use steadily increase as high illicit drug prices and profits are maintained. (b) Prescription drug abuse increased exponentially during the 5 years before 2001,[42] largely because opioid use for chronic pain was liberalized during the late 1900s, resulting in a greater availability of prescription opioids in homes, pharmacies, and on the streets. Addicts choose prescription drugs over illicit drugs because of their greater reliability and safety. (c) In the 1980s and 1990s, pain advocates, carrying the success of their much needed lobbying for the use of opioids for acute and cancer pain, extended the principle to the treatment of chronic noncancer pain. Consequently, today there are many more patients with chronic pain conditions who are treated with opioids than there were just 20 years ago. (d) Cancer is now a curable disease for many patients, and others experience long remissions. They often need treatment for pain associated with their primary disease, or with its treatments, and may need this treatment for years. Because of a tradition of opioid use for cancer pain, opioids are being used for long-term treatment of cancer-related pain.

Managing pain in opioid-treated patients, whether they are substance abusers or chronic pain patients, can be extremely challenging. There are issues related to opioid tolerance and pain refractoriness, and a withdrawal syndrome could further complicate the clinical picture. In addition, there may be difficult behavioral issues in both groups of patients, so that the dedication and professionalism, particularly of the nursing staff, can be severely tested. The possibility that drugs are being diverted complicates matters even further. Prejudices set in about the veracity of pain complaints, there is a breakdown in trust, and the simplicity of treating pain according to the patient's report is lost.

Substance Abusers

Substance abusers are notorious deceivers, but they recognize that they put themselves at risk if they deny use, and are usually honest about whether or not they are currently using drugs, including opioids. They are less honest about past use, and unreliable in terms of reporting doses. The treating physician must be cognizant that opioid requirements for pain are unknown and can only be learned by titration; that a withdrawal syndrome may arise if doses are underestimated; and that manifestations of other abused drugs (e.g., cocaine, amphetamines, alcohol) or withdrawal from these, may also require treatment. Treatment for withdrawal syndromes is generally supportive, but in the surgical setting, opioid withdrawal should be treated with opioid. An α_2-agonist such as clonidine may help reduce norepinephrine effects.

The period of hospitalization for surgery or trauma is not the time for

tackling an entrenched addiction problem. Nevertheless, if the patient agrees (and they often do not), the involvement of a psychiatrist or addictionologist during the hospitalization can be helpful. The surgical and pain teams should focus on optimizing pain management, and direct the patient to the appropriate resource after discharge, assuming the patient wants treatment. An opioid-abusing patient may have an inadequate response to the opioids given for pain, and it is helpful to make maximum use of alternatives such as epidurals, nerve blocks, and NSAIDs. At the same time, opioids should not be withheld, particularly if there has been recent usage. Patients in methadone programs should continue their normal dose of methadone, and this should be supplemented with whatever is needed to treat pain. Buprenorphine (Subutex) and buprenorphine with naloxone (Suboxone) are increasingly used for office-based treatment of addiction (detoxification and opioid maintenance).[87,88] Although oral naloxone is quickly degraded and does not present a problem, buprenorphine, which is a partial opioid agonist with high receptor affinity and slow dissociation, can interfere significantly with the treatment of acute pain. Supplemental buprenorphine may be adequate for treating mild acute pain, but severe pain is likely to require standard opioids at high dose. PCA is a useful modality for acute pain treatment in substance abusers because of the sense of control it offers, and its ability to reduce demands on the nursing staff.

Some past abusers (not on methadone or buprenorphine) present real and justified concerns about the risk of relapse if they use opioids for the treatment of surgical pain. The risk of relapse is higher the longer the period of abuse, and diminished the longer the patient has not been using. Relapse is unlikely as long as opioid use for surgical pain is confined to the period of severe pain, and not continued beyond this. A good way to contain this is to use opioids in hospital but not after discharge. It will also satisfy the patients and their pain needs to maximize the use of alternative analgesics and interventions.

Chronic Opioid-Treated Pain

Opioid-tolerant chronic and cancer pain patients are among the most difficult patients to treat for pain after surgery, particularly if they are being treated with high doses of opioids. Despite there now being convincing evidence that the analgesic efficacy of high-dose opioid therapy may diminish over time, and has unacceptable side effects such as gonadal suppression, there are still patients admitted to hospital on doses exceeding the common upper limit of 180 mg morphine or morphine equivalent per day.[15] The addition of chronic intrathecal opioid treatment may further complicate and compromise the treatment of acute pain.

Principles of treatment are similar to those for substance abusers. The normal regime should be continued if possible, and if not, should be converted to an intravenous regime. Nonopioid treatments should be used to as great an extent as possible, to minimize reliance on opioids. Neuraxial interventions should be avoided in patients with implanted stimulators or pumps, unless the position of the implanted system is clear, because the needle can cut or damage electrodes, leads, or catheters. PCA is again a useful mode of delivery for opioids because a background infusion can be used to whatever level is needed, and the ability to get extra bolus doses reassures the patients. High dose boluses are likely to be needed.

The period of hospitalization is not a good time to change the chronic pain regime, and most efforts should focus on treating the acute pain. However, if the surgical or pain team is having difficulty managing a patient, it may be very helpful to talk to the patient's pain physician, or whoever normally manages the patient's pain. Sometimes issues are revealed that are relevant to the management of pain in hospital, but not necessarily clear from the patient or the patient's chart. It is also helpful to have a plan for treating pain after discharge, which could involve the patient's normal physician, or could involve rehabilitation or a pain program.

Behavioral problems can arise in opioid-treated chronic pain patients, although these will be different from those in substance abusers. Chronic pain patients tend to have difficulty coping, and when they are faced with uncontrolled and excruciating pain, which they have not necessarily predicted, they can be angry, mistrustful, demanding, or uncooperative. They may display typical opioid seeking behaviors (frequent demands for pain medication, refusal of all but opioid treatments, accusations against the medical staff for undertreating pain), and these behaviors appear much like addictive behaviors. Yet it will be difficult to determine whether the behaviors have arisen because of undertreated pain (pseudoaddiction) or because there is, in fact, an underlying addiction problem.

Pain Management in the Intensive Care Unit

There are several challenges associated with managing postoperative pain in patients requiring ICU care. In many cases, these patients are unable to communicate, because of severe illness, extensive surgical trauma or because they are ventilated and sedated. Continuous infusion is the most frequently chosen means of delivery for opioids, but prolonged use of opioid infusions may lead to rapid development of tolerance or opioid-induced hyperalgesia, making pain control and weaning from opioids difficult.[14] An obvious manifestation of opioid-induced hyperalgesia is the ICU patient who is treated with high-dose opioid infusion, who cannot tolerate touch, or even the bedsheets. Patients with compromised renal function may accumulate opioid metabolites, notably the active metabolite morphine-6-glucuronide and the toxic metabolite normeperidine: Meperidine is not a good choice for prolonged infusions; if morphine is used, the possible accumulation of active metabolites must be considered in the weaning protocol. Epidural analgesia is an extremely useful option that is opioid sparing and can help during weaning from ventilation.[76,89–91] However, epidurals are often contraindicated in ICU patients because of a need to treat with anticoagulant therapy. Use of activated protein C, our current best agent for severe sepsis, also precludes the use of epidurals.

It is important to treat pain in ICU patients so as to reduce the anxiety associated with pain and inability to communicate pain. When it is impossible to assess pain, as in heavily sedated or unconscious patients, it is reasonable to assess analgesic requirements on the basis of the amount of surgical or other trauma the patient has undergone. Ventilated patients can be treat-

ed with higher-than-normal doses of opioids (if desired) because there is no risk of respiratory depression. However, it is important to remember that prolonged infusions may lose their efficacy if tolerance or hyperalgesia develop, and all opioid-sparing strategies are helpful. Methadone may also be useful for prolonged ICU stays as there is less development of tolerance. It has been found beneficial to use the α_2-agonist dexmedetomidine for ICU sedation, not only because of its hypnotic effects, but also because of its analgesic synergy with opioids (opioid sparing), and possibly a contribution to minimizing opioid withdrawal at the time of weaning.[92,93] Alert or unventilated ICU patients can be treated as normal patients, with the proviso that ill patients may handle drugs inefficiently.

CONCLUSION

Advances in surgery, anesthesia, drugs, and technology have combined to markedly reduce the trauma and morbidity of surgery. Part of this success can be attributed to improvements in pain management, both during and after surgery. In the 1980s, several changes revolutionized postoperative pain management. Portable PCA pumps became available, and gradually PCA was adopted widely. Experimentation with neuraxial opioids began after endogenous opioids and opioid receptors were identified in the 1970s. It was soon recognized that neuraxially administered opioids provide excellent targeted analgesia at low doses without the need for larger systemic doses and associated side effects, or the sensory and motor blockade from the high-dose local anesthetics previously needed for adequate epidural pain relief when local anesthetics were used alone. "Walking epidurals" began to be widely used for postoperative pain control. Several professional and political bodies, recognizing that good pain control was an important component of perioperative care, developed guidelines in order to propagate good evidence-based practice (Agency for Health Care Policy and Research). Insurers, spearheaded by Medicare, also recognized the importance of good pain control and began to reimburse pain management services, allowing for the development of acute pain services. Later, pain advocates succeeded in enlisting JCAHO in the war on pain and their 2001 mandate requires that all accredited hospitals have a systematic means of recognizing and assessing pain, and treating it appropriately. Postsurgical pain may not be fully conquered, and there is certainly room for more research and further improvement. But tremendous progress has been made since the not-so-distant days when uncontrolled pain meant that patients routinely remained motionless in bed for days after surgery, prone to complications of immobility such as thromboembolism, atelectasis. and protein wasting.

PART 6

THE CRITICALLY ILL PATIENT

CHAPTER 75

The Pathophysiology of Critical Illness

Luca M. Bigatello, MD,
Judith Hellman, MD,
David Liu, MD, PhD, and
Warren M. Zapol, MD

The term *critical illness* defines a variety of clinical situations that are cared for primarily in intensive care units (ICUs), and have in common varying degrees of dysfunction of single or multiple organs and systems, and a guarded immediate prognosis. Because the term *critical illness* refers to the predicted outcome rather than a discrete entity, the pathophysiology and clinical manifestations are very inclusive. Anesthesiologists care for critically ill patients in the operating room, in the ICU, and during procedures in areas outside of the operating room, such as radiographic and endoscopic suites. Thus it is crucial that anesthesiologists have an in-depth understanding of the pathophysiologic processes encountered in critical illness in order to contribute effectively to the perioperative management of critically ill patients.

This chapter focuses on a number of basic elements of critical illness, including inciting factors, pathophysiology leading to dysfunction of organs and systems, the role of the immune system in critical illness, and current and potential future therapies for different aspects and stages of critical illness. We analyze the progression of critical illness examining common types of primary injuries, the body's response to them, and the progression of the response either toward healing and recovery or to deterioration and death. Epidemiologic and therapeutic considerations are also reviewed. The chapter begins with a case report of a patient at different stages of critical illness that is referred to in subsequent sections of the chapter.

CASE REPORT

A 77-year-old woman with a history of severe chronic obstructive pulmonary disease and hypertension was admitted to the surgical ICU from a general ward with acute respiratory distress. She had been recovering uneventfully from a Whipple procedure until that morning, when she experienced nausea and general malaise, then vomited a large amount of dark material, and immediately complained of shortness of breath.

Upon arrival at the surgical ICU, she was in obvious respiratory distress, with a marginal (87–89%) arterial oxygen saturation as measured by pulse oximetry (SpO_2) on a non-rebreathing oxygen mask. Following a rapid sequence endotracheal intubation, a large amount of dark green material was suctioned from her airways; the material was similar in appearance to that suctioned from her stomach. A bronchoscopy revealed diffuse staining of the tracheobronchial mucosa with biliary material, down to the lobar bronchi bilaterally. Over the next 4–6 hours, the patient's condition deteriorated. She developed respiratory failure requiring high levels of ventilatory support, and hemodynamic instability that was treated with high-dose intravenous (IV) infusions of vasopressors in order to maintain an adequate systemic arterial blood pressure. A pulmonary artery catheter revealed moderate to severe pulmonary artery hypertension and a low cardiac output, primarily a result of right ventricular dysfunction, which was confirmed by transthoracic echocardiography. She was treated with broad-spectrum antibiotics, recombinant human activated protein C, and inhaled nitric oxide (NO), and was ventilated using a "lung protective" strategy of low tidal volumes. Over the next few days, she remained extremely unstable from the cardiovascular and pulmonary standpoints: she had three episodes of pulseless electrical activity requiring cardiopulmonary resuscitation, and she became hypoxemic with minimal stimulation, which greatly impeded nursing care. By the tenth day her cardiovascular and respiratory function began to stabilize, and a computed tomogram of her chest was taken (Fig. 75–1). Subsequently, hemodynamic and ventilatory support was tapered, and she was transitioned to assisted ventilation; vasopressors were discontinued, and she started to interact with ICU personnel. On ICU day 13, she had a bedside percutaneous tracheostomy. On ICU day 15 her bronchial secretions became purulent, she developed a fever and leukocytosis, and required an increase in ventilatory support. She was diagnosed with ventilator-associated pneumonia from *Pseudomonas aeruginosa* based on bacteriologic, radiographic, and clinical criteria. She was again treated with antibiotics and continued ventilatory support, and she gradually improved and was discharged from the surgical ICU on day 24. She was transferred to a semi-intensive respiratory unit to complete weaning from mechanical ventilation.

Thirty-eight days after ICU admission, and 45 days after her surgery,

KEY POINTS

1. Acute injuries of various etiologies—trauma, infection, shock, etc.—cause immediate local and systemic physiologic responses involving all major organ systems.
2. The timing and intensity of the physiologic response to injury is affected by host factors as well as the virulence of the injury. Often, an initial activation of the inflammatory–immune system is followed by late immunosuppression.
3. Nosocomial infections are a major cause of death of critically ill patients and can be significantly decreased by adopting best practices of antibiotic use and infection control.
4. The vascular endothelium is a major organ system in the initial response to injury, activating vasomotor, inflammatory, and procoagulant phenomena.
5. Our increased understanding of the molecular biology of the immune response to injury will lead to new and effective therapies that may include effective oxygen or nitrogen free-radical scavenging, mitochondrial protection, blocking apoptosis, and enhancing immunity.

FIGURE 75–1. Computed tomography of the chest at the level of the upper thorax shows diffuse bilateral ground-glass parenchymal opacities consistent with acute lung injury/acute respiratory distress syndrome.

she was transferred to a rehabilitation facility. Although she was weaned off mechanical ventilation, she was extremely debilitated: she could not stand for more than a few minutes or walk more than a few steps, and was unable to feed herself. In addition, she continued to require narcotic-based analgesics and antipsychotic medications to allow some sleep at night and diminish her recurring episodes of hyperactive delirium.

PATHWAYS OF INJURY: THE STRESSES LEADING TO CRITICAL ILLNESS

A variety of acute injuries can result in critical illness and a need for ICU care. In the following material, we classify these "stresses" as related to a few main categories: surgery and trauma, metabolic disorders, and infection. In many patients, as in the case described above, multiple stresses (e.g., surgery, inflammation, and infection) coexist.

Direct Tissue Injury During Surgery and Trauma

Direct tissue injury during surgery and trauma can produce major perturbations of the body's homeostasis, including hemodynamic instability, respiratory abnormalities, and marked fluid shifts. Pain, immobility, and prolonged bedrest can contribute to perioperative morbidity. Only a few decades ago, these phenomena constituted a formidable challenge for surgeons and anesthesiologists, and made many surgical procedures complex and dangerous for the patient. Today, the physiologic changes associated with "routine" surgery can be flawlessly managed by the proper administration of perioperative anesthesia care. However, certain situations still carry a significant risk of perioperative complications, including complex elective procedures (e.g., pneumonectomy, thoracoabdominal aneurysm repair), major trauma, emergency surgery, and procedures performed in patients with significant comorbidity. These patients constitute the majority of the population admitted to a surgical ICU.

Trauma is the primary cause of death in individuals below 40 years of age in the United States.[1] In underdeveloped countries, trauma victims may have limited or no access to intensive care, which could save thousands of lives every year. Traumatic injuries are classified as penetrating and blunt injuries (see Chap. 70 and 78). *Penetrating injuries* (stab and gunshot wounds) require immediate control of hemorrhage, drainage of blood or air under pressure, and rapid transfer to a trauma center. Immediate appropriate care increases survival and can reduce the need for intensive care.[2,3] *Blunt trauma* (e.g., motor vehicle accidents, falls) can produce a combination of injuries that may require immediate treatment, such as a ruptured spleen or an open bone fracture, and others that are best treated conservatively. A "damage control" approach minimizes the time of surgical intervention and emphasizes perioperative surgical ICU care, including volume resuscitation, temperature control, hemodynamic monitoring, nutrition, and protocols for the prevention of nosocomial infectious complications. This approach often requires the participation of an anesthesia team during repeated trips to the operating room. The injuries associated with major surgery and trauma derive from three main mechanisms: hemorrhage, tissue injury, and hypoperfusion.

Hemorrhage causes an immediate physiologic response to preserve circulating blood volume and oxygen delivery to vital organs. In healthy individuals, symptoms of shock develop when acute blood loss exceeds 20% of the blood volume (approximately 1 L of blood in a 70-kg adult). Immediate resuscitation is necessary to prevent cardiovascular collapse and death. Even at the low hemoglobin (Hgb) levels often following this degree of bleeding, what limits the tolerability of hemorrhage is the reduced blood volume and cardiac output, and not the decreased oxygen-carrying capacity of the blood. For example, a 30–40% blood loss would eventually reduce the plasma Hgb concentration to a level that still produces ample delivery of oxygen to the tissues. With an adequate cardiac output and arterial oxygen tension (Pao_2), a Hgb concentration as low as 5 g/dL still provides ample oxygen delivery to tissues supplied by normal vessels (Table 75–1).

Implementing early and effective therapies has critical importance in determining the subsequent clinical course. Despite a long-standing belief that aggressive volume resuscitation should be included in the initial care of the bleeding patient, this approach is now being challenged for several reasons. First, the infusion of large volumes of crystalloids can cause a dilutional coagulopathy, characterized by thrombocytopenia and decreased concentrations of circulating clotting factors.[4] Counteracting these defects by infusing platelets and fresh-frozen plasma, in conjunction with massive crystalloid resuscitation,[5] may foster intravascular volume overload and edema in vital organs. Second, there is evidence that massive volume resuscitation for penetrating trauma of the torso may exacerbate bleeding from the site of injury and actually increase mortality.[2] Third, transfusion of blood products may suppress native immunity and increase the risk of infection, cause acute lung injury/acute respira-

TABLE 75–1.

Values of Oxygen Delivery ($\dot{D}O_2$) at Different Levels of Anemia

	Hgb (g/dL)	CO (L/min)	$\dot{D}O_2$ (mL/min)
Normal	14	5	900
Anemia	9	6	700
Severe anemia	5	7	450

$\dot{D}O_2$ = arterial O2 content (CaO2) × cardiac output (CO)
CaO_2 = Hg × 1.34 × oxygen saturation (SpO_2) + PaO_2 × 0.003.
Normal CaO_2 = 14 g/dL × 1.34 × 0.98 + negligible dissolved O_2 = 19 mL O_2 per dL of blood; × CO of 5 L/min, $\dot{D}O_2$ = 900 mL/min.
With severe anemia: Hgb 5 g/dL, normal SpO_2, and increased CO, e.g., 7 L/min, $\dot{D}O_2$ is ≥350 mL/min, still above the resting average oxygen demand of tissues $\dot{V}O_2 \approx 250$ mL/min). We assumed a moderate increase of CO for each level of anemia.

tory distress syndrome (ALI/ARDS), and death.[6–8]

Tissue injury produces local and systemic perturbations that are minimized during elective surgery by using proper anesthetic and surgical techniques, but can produce major damage in the random, unprotected situation of a traumatic injury. Then tissue damage, loss of perfusion, and cell necrosis will result in the immediate release of tissue factors into the bloodstream, which trigger a systemic inflammatory response characterized by the synthesis and release of cytokines. Tumor necrosis factor (TNF)-α and interleukin (IL)-6 are among the earliest cytokines to appear in the systemic circulation immediately after tissue trauma, and amplify the complex inflammatory response that is an integral part of critical illness.[9] Tissue trauma of different types can produce both direct and systemic effects leading to critical illness. One well-documented example occurs in injuries to the lung. In our case report, the initial cause of the patient's complex critical illness was a chemical injury to the alveolar epithelium caused by the aspiration of gastric contents. A similar evolution to critical illness can occur with other lung injuries, such as a lung contusion from blunt chest trauma or pneumonia. Despite the variety of inciting factors, the lung responds to acute injury in a stereotypical fashion, leading to the pathologic picture of "diffuse alveolar damange"[10] and the clinical picture of ALI/ARDS, which is a syndrome combining local and systemic inflammation.[11] Although not as well studied, a similar sequence of events appears to follow major acute injury to the kidneys[12] and the gut.[13,14]

Hypoperfusion and *ischemia* may result from direct tissue trauma, impaired regional blood flow, or a generalized decrease of blood flow—a "low-flow state." A severe reduction of oxygen supplied to the tissues is marked by the local production of lactate from anaerobic glycolysis, and may cause or exacerbate metabolic acidosis. However, even when profound ischemia occurs, tissue viability can often be reestablished. The effects of restoration of blood flow after ischemic injury has been best characterized in the heart, where reversal of arterial occlusion is common with advanced techniques of coronary revascularization.[15] Myocardial *stunning* describes the acute ischemic dysfunction caused by acute cessation of regional coronary circulation, and can be fully reversed by rapid restoration of blood flow.[16] Myocardial *hibernation*, a chronic state of dysfunction caused by insufficient coronary perfusion, can also, but less predictably, be improved with coronary revascularization procedures.[17] However, global hypoperfusion is often irreversible: In the "postresuscitation syndrome" that occurs following prolonged cardiopulmonary resuscitation, stunning of the cardiac muscle (*stony heart*)[15] is largely responsible for the high fatality rate observed early after cardiopulmonary resuscitation, and is characterized by severely depressed contractility and malignant arrhythmias.

Although restoration of tissue blood supply may prevent cell death and reestablish function, acute reperfusion of ischemic tissues can cause significant cellular injury, known as *ischemia–reperfusion injury*. In the absence of adequate oxygen supply, mitochondrial production of adenosine triphosphate (ATP) decreases, causing an increase in adenosine monophosphate (AMP) and its byproduct hypoxanthine, and the conversion of the enzyme xanthine dehydrogenase to xanthine oxidase. Upon reperfusion with oxygen-rich blood, hypoxanthine is oxidized by xanthine oxidase at a high rate, producing large quantities of cytotoxic oxygen free radicals, including molecular oxygen, superoxide, and hydrogen peroxide ions.[18] Ischemia–reperfusion injury has been described in patients with the crush syndrome,[19] organ transplantation,[20] reestablishment of blood flow to limbs or splanchnic organs,[21] and during experimental alterations of ventilation and perfusion of the lung.[22,23]

Metabolic Failure

Metabolic failure is a less common reason for admission to a surgical ICU. The most representative metabolic derangements include the consequences of severe malnutrition, such as extreme weight loss, kwashiorkor, and avitaminosis. These diseases, although prevalent throughout the world, are rarely seen in industrialized societies.

A different metabolic derangement, morbid obesity, has become more prevalent in the United States and other industrialized countries.[24] Morbid obesity (defined as weight 30% in excess of ideal body weight, or a body mass index >40 [body mass index = weight in kg ÷ height in m^2]) increases the risk of complications related to surgery and anesthesia. Morbidly obese patients are increasingly admitted to the ICU because of complications following bariatric surgery or unrelated events, such as trauma. Prevalent comorbidities of obesity include hypertension, diabetes, obstructive sleep apnea, chronic lung disease, and heart failure, which increase their postoperative risk for cardiovascular and respiratory complications. In addition, morbid obesity often presents logistical problems, such as the need for a special bed, a limited ability to perform important diagnostic tests such as MRI and CT scans, difficulty of vascular access and monitoring,[25,26] and complex issues of proper drug dosing.[27]

Common metabolic derangements requiring ICU care include those related to chronic diseases such as diabetes mellitus, diabetic ketoacidosis and hyperosmolar nonketotic coma. See Chaps. 12 and 16 for management

recommendations for diabetes mellitus and its complications.

Infection

Infection contributes importantly to both the onset and the progression of critical illness. In a survey of 198 European ICUs, 25% of the admissions were because of sepsis, and 37% of ICU patients experienced sepsis and septic shock at some time during their stay.[28] Infection is the leading cause of death in ICU patients. It is estimated that approximately 750,000 people develop sepsis annually in the United States, and 30–40% of these patients will die.[29] The presence of a proven infection in patients who remain in the ICU for more than 48 hours increases their mortality rate from 22% to 35%.[30] The terms *sepsis, severe sepsis, septic shock*, and *refractory septic shock* describe the spectrum of severity of sepsis. Multiorgan dysfunction syndrome (MODS) is a severe complication of sepsis and other inflammation-driven critical illnesses. MODS is associated with a high mortality. These terms were reviewed in a recent consensus conference of the Society of Critical Care Medicine and the American College of Chest Physicians[31] and are thoroughly discussed in Chap. 76. In many cases, it is difficult to define the ultimate cause of the ICU patient's death, which is seldom hypoxemia, uncorrectable hypotension, or a sudden fatal arrhythmia, because respiratory function can usually be supported with a mechanical ventilator or an artificial lung, and renal function can be replaced by hemofiltration and hemodialysis. The majority of patients who die from or with a severe infection in the ICU,[32,33] die after care is withdrawn by mutual agreement of their physicians and families, based on futility as a consequence of persistent MODS.

Table 75–2 lists common infections that require ICU admission. Other infections are also important because of their enormous impact on public health, current (tuberculosis, malaria, and AIDS) or potential (severe acute respiratory syndrome [SARS], avian influenza), and are summarized in Table 75–3. See Chap. 17 for a systematic description of the clinical features and treatment of these conditions.

Hospital-acquired, or *nosocomial* infections, are prevalent in the ICU, and contribute to the demise of a large number of critically ill patients. In our case report, the development of a *Pseudomonas aeruginosa* pneumonia halted the course of recovery from ARDS, and most likely prolonged the patient's ICU stay and increased her time of ventilator-dependence. Fortunately, she recovered from her ventilator-associated pneumonia, despite an inherent mortality rate of 20–50%.[34] Nosocomial infections are often caused by multiresistant bacteria that are transmitted to patients by healthcare providers and result from widespread use of antimicrobial agents.[35,36] Indwelling devices such as central venous catheters, endotracheal tubes, and urinary catheters contribute to the development of infections. These factors can be minimized by the implementation of standard but hard-to-enforce clinical practices, such as frequent hand decontamination, use of gloves and gowns when examining patients, proper care of indwelling devices, and appropriate use of antibiotics.[37]

Many nosocomial infections are preventable iatrogenic injuries. Following the publication by the Institute of Medicine of the landmark report *To Err is Human—Building a Safer Health System*,[38] healthcare organizations have focused on maximizing the safety and efficacy of ICU care. As a result, an increasing amount of research is being published on improving ICU patient safety; in addition, there is increasing compliance with safety guidelines. Over the next few years, the tangible effects of safer ICU practices, including decreased iatrogenic infections, will be recorded.[39]

TABLE 75–2.

Community-Acquired Infections That May Require ICU Admission

Community-Acquired Infection	Common Etiologic Agent
Pneumonia	*Streptococcus pneumoniae, Haemophilus influenzae, Staphylococcus aureus, Moraxella catarrhalis.* Atypical pathogens: *Mycoplasma pneumoniae, Legionella pneumophila*
Peritonitis from perforation, necrosis, or suppurative infection	Gut flora: Gram-positive cocci predominate proximally (*Streptococcus* spp., *Enterococcus* spp., anaerobes); gram-negative rods (*Escherichia coli*, *Enterobacter* spp.), anaerobes (*Bacteroides* spp.) in small and large bowel
Acute cholecystitis, cholangitis	Enteric flora: *Klebsiella* spp., *Enterobacter* spp., *E. coli*, *Enterococcus* spp., *Bacteroides* spp., *Clostridium* spp.
Clostridium difficile colitis	*C. difficile*: anaerobic bacillus producing exotoxins
Necrotizing soft-tissue infections	*Streptococcus* spp., *Clostridium* spp., or polymicrobial flora
Urinary tract infections	Enteric gram-negative rods: *E. coli*, *Klebsiella* spp., *Proteus* spp.
Infective endocarditis	*Streptococcus viridans*, *Enterococcus* spp., *Staphylococcus aureus*
Meningitis	*Streptococcus pneumoniae, Haemophilus influenzae, Neisseria meningitidis*
Viral infections	Cytomegalovirus, herpes simplex virus-1 and -2, hepatitis A, B, and C
Infections in the immunocompromised host	Bacteria (including mycobacteria), fungi (*Candida* spp., *Aspergillus* spp., *Torulopsis glabrata*), viruses (Cytomegalovirus, herpes simplex virus, Epstein-Barr virus), and parasites.

SHOCK—THE ULTIMATE STRESS

The term *shock* describes the pathophysiologic manifestations of a catastrophic event that causes a profound, protracted reduction of perfusion to vital organs. Originally used to describe refractory hypotension, a more modern definition of shock indicates a state of tissue hypoperfusion caused by low blood flow, toxic agents, or both, where the circulation fails to meet the metabolic requirements of the cell. Initially, neurohumoral com-

TABLE 75–3.

Infections That Constitute a Public Health Threat

Disease	Spread	Current Status	Treatment
TB (bacterial)	Person to person droplets	14,000 cases in the U.S. in 2003; enormous public health problem in Africa, Asia; on the rise in Europe; association with HIV	Antibaterial combinations are effective, but induced resistance develops
Malaria (parasite)	Anopheles (mosquito) bites	Widespread to warm and humid areas; sub-Saharan Africa has highest prevalence	Prevention and treatment with oral chloroquine and IV quinine; resistance is a problem
AIDS (virus)	Blood and body fluids, sexual	Relatively contained in U.S.; enormous public health problem in Africa, Asia, South America	Antiretroviral therapy slows progression, but is not universally available
SARS (virus)	Person to person droplets	Worldwide outbreak in 2003; little in U.S., now quiescent	Supportive
Avian flu	Birds to humans; sporadically person to person	Isolated cases; small outbreaks in Asia and Eastern Europe	Supportive

SARS, severe acute respiratory syndrome; TB, tuberculosis.
Data from http://www.cdc.gov/nchstp/tb/faqs/qa_introduction.htm#Introl; http://www.cdc.gove/ncidod/sars/factsheet.htm; http://www.cdc.gov/malaria/faq.htm; http://www.cdc.gov/hiv/topics/surveillance/index.htm; http://www.cdc.gov/flu/avian/outbreaks/current.htm. Last accessed October, 2006.

pensatory mechanisms maintain perfusion to vital organs. However, if appropriate supportive treatment is not promptly instituted, these compensatory mechanisms are overwhelmed, and progressive tissue ischemia leads to organ failure. Clinically, signs and symptoms of end-organ hypoperfusion include mental status changes, loss of skin turgor, cool extremities, oliguria, acidemia, a high serum lactate concentration, and a reduced mixed or central venous oxygen saturation.

Shock is classified on the basis of its cause and characteristic hemodynamic pattern. *Hypovolemic shock* is caused by an acute volume loss of ≥20–25% of the circulating blood volume, from events such as hemorrhage, heat stroke, and sequestration of fluid within the body following bowel obstruction. Hemodynamically, there is a decrease in arterial blood pressure, central vascular pressures, and cardiac output. *Cardiogenic shock* is caused by primary heart failure. The most common cause of cardiogenic shock is myocardial infarction and its acute complications. Cardiogenic shock is characterized by systemic hypotension and a low cardiac output in the face of an adequate or increased blood volume, as indicated by increased central venous and pulmonary artery wedge pressures, or equivalent indices of volemia. *Distributive shock* is characterized by generalized vasodilatation, venous pooling, and redistribution of systemic blood flow, and is characteristically associated with a high cardiac output. It may be caused by the body's response to circulating live bacteria and their byproducts during septic shock, by inflammatory mediators in the absence of infection, by endogenous circulating vasoactive compounds during anaphylactic shock, or by a loss of vascular tone as a result of neurogenic shock or bilateral adrenal hemorrhage. *Obstructive shock* is associated with a mechanical impediment to venous return and/or arterial outflow of the heart, and may occur because of a tension pneumothorax, pericardial tamponade, abdominal compartment syndrome, and, occasionally, as a consequence of iatrogenic positive pressure ventilation and auto-positive end-expiratory pressure. Obstructive shock is characterized by a low systemic blood pressure, low cardiac output and increased central vascular pressures.

Traumatic shock is a useful teaching model of shock, because it may present with coexistent and diverse physiologic features, including hypovolemia, hypoxemia, myocardial dysfunction, vasodilatation, and neurologic failure, and, after blood volume resuscitation, a hyperdynamic pattern.[3] It has been demonstrated on the battlefield that immediate control of hemorrhage, pain relief, avoidance of profound hypothermia, and rapid transport to an appropriate treatment facility can prevent the development of shock, and reduce mortality (see also Chap. 78). Similarly, in the hospital environment, appropriate fluid resuscitation and airway management, timely administration of antibiotics, damage-control surgery, and admission to the ICU may prevent the onset of shock and increase survival rates.

QUANTIFYING SEVERITY OF ILLNESS AND RELATIONSHIP TO OUTCOME

Although ICUs grew in number and complexity in the 1970s, there were scant data to support the effectiveness of ICU care. The necessity that ICU outcomes be quantified was multifold, including optimizing resource use, quality analysis, and the need to explain to critically ill patients, their families, and their treating clinicians what to realistically expect from intensive care. Obtaining meaningful outcome data examining complex medical practices is intrinsically difficult, because of the variability of the underlying severity of illness, which changes over time whereas treatment varies between different units. For example, a review from 1973 showed that the

death rates in several surgical ICUs in North America varied from 2% to 44%;[40] although the quality of care may have been responsible for some of the observed difference in mortality rates, it was impossible to determine this with certainty from the available data.

The development of the Acute Physiology and Chronic Health Evaluation (APACHE) scoring system by Knaus et al. began in 1978 with a grant from the U.S. Health Care Financing Administration. The goal was to develop better methodology for measuring severity of illness among ICU patients. The result was the development of a comprehensive and prognostic scoring system that estimates the pretreatment risk of death of acutely ill hospitalized patients based on the patient's major disease process, their physiologic reserve, and the contribution from the acute severity of disease as determined by derangements of important physiologic parameters.[41]

After the initial validation of this instrument, the original APACHE, which was based on 33 potential physiologic measurements to define the degree of physiologic derangement, was streamlined to the current 12 physiologic variables. With further changes in weighting for age, definitions for chronic health status, and whether or not the admission to the ICU was after elective surgery, the resultant system was the APACHE II prognostic scoring system. Over the ensuing two decades, a number of other systems have been developed and validated to aid in predicting survival, allocating resources, and verifying the quality of our practice.[42–44] Each of these instruments has its advantages and flaws. Nevertheless, it is clear that the capability to categorize patients early in their course based on the severity of their illness, even if imperfect, has enhanced the quality of clinical research trials of critically ill patients, and more importantly, has chronicled the extremely poor prognosis of patients with very high scores.

HOST RESPONSES DURING CRITICAL ILLNESS

The body responds to an acute injury—such as the aspiration of gastric contents into the lungs as in our case report, or a bacterial infection, or a surgical wound—in a reproducible way. The initial local inflammatory response aims to control the immediate effects of the injury, and generates signals from various cells at the site of injury that activate a systemic response. Hence, an injury of sufficient severity triggers a combined response from nerve endings and endothelial and immune cells, which rapidly extends to the entire organism. When these homeostatic responses are coupled with our correct interventions, they enable us to maintain or restore the function of vital organs, expedite repair, and lead to healing and rehabilitation. When the injury hampers the host's regulatory processes, or when our intervention is inadequate or delayed, the attempt to preserve the body's integrity is overwhelmed by the injury and organ dysfunction, and death ensues.

Timing

The complexity of the body's response to injury over time constitutes a major challenge to our ability to develop effective treatments that will inhibit the progression of traumatic, inflammatory, and infectious injuries to MODS and death. The classical view of an initial "ebb" (hypodynamic) and a subsequent "flow" (hyperdynamic) phase of the cardiovascular and metabolic responses to injury[45] now appears simplistic. It seems likely that the timing and intensity of this complex response varies widely among patients, and is influenced by the magnitude of the injury, the patient's physiologic status, and our therapies. Figure 75–2 illustrates three hypothetical time sequences of the evolution of critical illness, showing different patterns of activation and suppression of the immune system following an infectious injury. Although studied thoroughly in the case of sepsis, this sequence of events is likely to be applicable to other noxious events, such as after major surgery, trauma, and shock.[9,46,47]

Physical examination following a serious injury may reveal changes of skin color and turgor, body temperature, arterial blood pressure, breathing pattern, and mental function. Other easily measured parameters, including urine output, base deficit, and serum lactate level, may also be abnormal. These findings likely reflect the complex underlying homeostatic re-

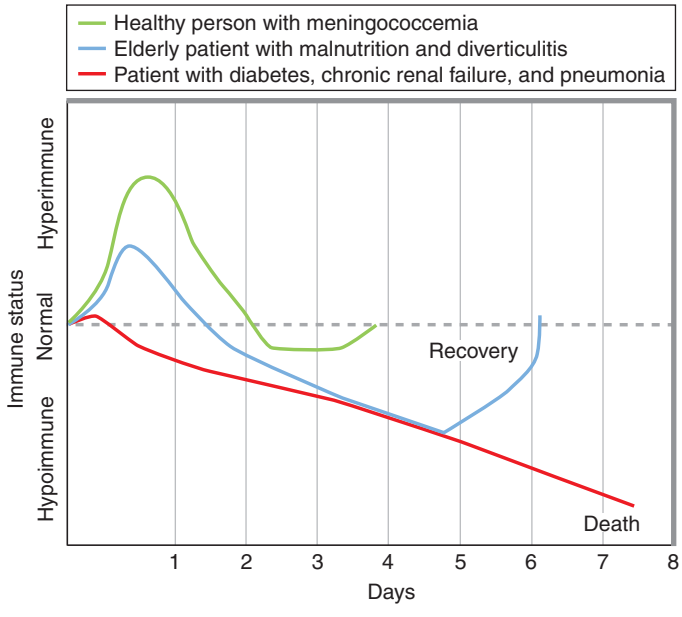

FIGURE 75–2. The immune–inflammatory response to injury: hypothetical time course of three representative patients. The healthy individual with a severe infection (e.g., meningococcemia, *top line*) shows a robust inflammatory response; if this patient survives the initial phase, there will be only a short hypoimmune period, and the patient will progress along the path of recovery. For an elderly, malnourished patient with a moderate infection (e.g., acute diverticulitis, *middle line*), the initial inflammatory response is limited and, if the infection is not promptly eradicated, a prolonged hypoimmune state ensues, and death can occur from further infectious complications. For a patient with significant comorbidity (e.g., diabetes, obesity, chronic obstructive pulmonary disease, and a pneumonia, *bottom line*) the initial inflammatory response may be completely blunted, and the clinical course is dominated by a hypoimmune state, where the risk of death from persistent or new infection is high. (Hotchkiss RS, Karl IE. The pathophysiology and treatment of sepsis. N Engl J Med 2003;348:138–150. Copyright 2003, Massachusetts Medical Society. All rights reserved.)

sponses that are initiated by injury. Although we separately describe the characteristic responses of various organ systems, in the body these systems are highly interconnected and have certain similar characteristic responses, such as upregulation of inflammatory mediators. Dysfunction of one system will often impair the functions of other organs; a classic example is the development of functional renal failure because of decompensated hepatic failure (hepatorenal syndrome) as can arise in a cirrhotic patient with intraabdominal infection.

The Immune–Inflammatory Response

The immune–inflammatory response plays a central role in the evolution of critical illness. The *innate* immune system is the first line of defense, but both innate and *adaptive* immune responses are activated by injury and infection.

Immediately following acute tissue injury, a variety of inflammatory mediators are released by activated leukocytes—in particular, monocytes and macrophages—as well as endothelial cells and fibroblasts. These mediators include cytokines, arachidonic acid metabolites, complement fractions, various acute phase proteins, and oxygen and nitrogen free radicals.[48] Cytokines are polypeptide messengers of this huge cascade of reactions that have been extensively studied, and have been identified as critical mediators of physiologic and laboratory manifestations of inflammation, including fever, leukocytosis, hypotension and tachycardia, changes in mental status, and catabolism. Unlike hormones, which are produced by specialized endocrine tissues, cytokines are not stored, and their acute increase following tissue injury reflects upregulated gene transcription, translation, and synthesis by activated immune and/or endothelial cells. A characteristic of this type of response is that it tends to modulate itself by upregulating the expression of both pro- and antiinflammatory cytokines and acute-phase reactants. There continues to be considerable debate over the ultimate role of an overzealous inflammatory response in the pathogenesis of critical illness. Over the past three decades there has been a prevailing view that the pathogenesis of traumatic and infectious injury is based on an excessive and uncontrolled response to the initial insult ("cytokine storm") that turns a beneficial defense system into the actual offender, and, ultimately, causes critical illness. This appealing view, brought forward by Lewis Thomas in the 1970s[49] and further championed by the late Roger Bone in the 1990s,[50] lead to the development and testing of many therapies that targeted or modulated inflammatory mediators, including high-dose corticosteroids, ibuprofen, antibodies against bacterial endotoxin (lipopolysaccharide [LPS]), TNF-α, and IL-1 receptor antagonists.[51–53] However, human trials with these agents were largely unsuccessful. Given the complexity of the inflammatory response, it is not surprising that an agent that inhibits the activity of a single mediator may not provide sufficient benefit. More recently, some degree of success has been achieved by supplementing individual substances or pathways that seem deficient during certain phases of critical illness, and treating these "relative insufficiencies" with natural or synthetic equivalents of the undersupplied substance. Examples of such strategies are described in the following sections.

The Central Nervous System

The central nervous system (CNS) response to major injury and stress involves activation of the autonomic system, as well as interactions with the endocrine and the immune systems. The classical neurohumoral response to acute injury includes early activation of the autonomic sympathetic system resulting in tachycardia, increased myocardial contractility, tachypnea, splanchnic and cutaneous vasoconstriction, and increased availability of metabolic substrates. This "fight-or-flight" response is closely linked to activation of the hormonal pathways of the adrenal medulla, the pituitary–adrenal axis, antidiuretic hormone (ADH), and angiotensin–aldosterone (see The Hormonal Response below); all these physiologic pathways, in various ways, tend to preserve perfusion to vital organs.[54]

The brain also interacts with the immune system, and recent experimental observations have identified a vagal-mediated neural pathway that participates in the regulation of inflammation. Figure 75–3 shows a schematic of this "cholinergic antiinflammatory pathway."[55] Inflammatory stimuli (including LPS, TNF-α and IL-1) activate visceral vagal afferents that reach multiple vagal nuclei in the medulla and hypothalamus. This neural input elicits an immediate antiinflammatory response mediated by the same autonomic, parasympathetic system. Experimental activation of the cholinergic–antiinflammatory pathway inhibits function and reduces the expression of TNF during endotoxemia through the binding of nicotinic receptors on macrophages.[56] Knowledge of this cholinergic–antiinflammatory pathway has possible therapeutic implications: experimental activation of vagal output by electrical, as well as pharmacologic, vagal stimulation has inhibited macrophage activation and cytokine release.[55]

The Hormonal Response

The hormonal response to acute injury tends to increase vascular pressures, preserve circulating blood volume, and provide substrates for tissue metabolism and regeneration. These hormonal pathways include the synthesis and release of adrenal corticosteroids and catecholamines, ADH and aldosterone–angiotensin, prolactin, growth hormone, and other antiinsulin hormones. The role of these hormones in the acute response is complex, and significant understanding of their role has been gained over the past several decades.[57] Recent evidence reveals that some of these pathways may be key determinants of survival for critically ill patients, and suggests they may be successfully modulated pharmacologically.[58]

The output of the *pituitary–adrenal axis* increases several-fold as a normal response to acute illness.[59] Any malfunction of this axis, whether at the level of the precursors, the end-product (cortisol) or the cellular receptors, leads to an ineffective response and may be associated with a reduced chance of survival.[60] The term *relative adrenal insufficiency* refers to a state wherein the pituitary–adrenal axis fails to mount a sufficient response in the presence of an acute and severe stress, despite functioning adequately in health.[61] A recent randomized controlled trial demonstrated that treatment with physiologic doses of a combination of gluco- and mineralocorticoids improved survival in patients with septic shock and a

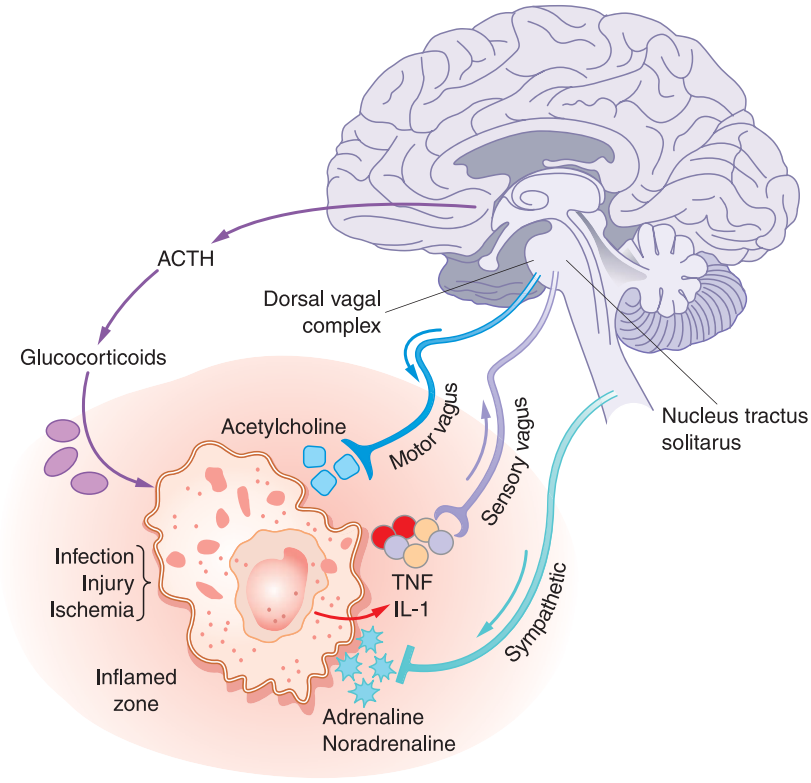

FIGURE 75–3. The cholinergic–antiinflammatory pathway. Inflammatory products produced at the site of injury activate neural signals that are relayed to the nucleus of the *tractus solitarius*. From there, efferent vagal activity (the cholinergic–antiinflammatory pathway) inhibits cytokines expression. In addition, vagal afferents can also be relayed to the hypothalamus and stimulate adrenocorticotropic hormone (ACTH) release. (Tracey K. The inflammatory reflex. Nature 2002;420:853–859. Reprinted by permission from Macmillian Publishers Ltd.)

depressed adrenal response.[62] However, debate remains over the proper patients to select for steroid treatment.[63]

Similarly, ADH is insufficiently synthesized in a significant fraction of critically ill patients.[64] The administration of a low dose of vasopressin, a synthetic analogue of ADH, appears to improve general systemic hemodynamics, reduce the need for infusing other vasopressor medications such as norepinephrine, and possibly increase gastric and renal perfusion in septic shock.[65,66]

Recent evidence suggests that tight control of plasma glucose levels in critically ill patients, by infusing *insulin,* improves survival in critically ill surgical patients.[67] Insulin incretion is deficient in the early phases of critical illness because of an increased synthesis of hormones such as catecholamines, glucocorticoids, glucagon, and growth hormone. This surge of antiinsulin hormones increases the availability of glucose to tissues during a time of forced starvation; however, the resulting high blood glucose levels may be associated with an increased susceptibility to infections, immunosuppression, and neurologic damage.[68,69] In a seminal clinical trial in cardiac surgery ICU patients in Belgium, Vandenberghe et al. demonstrated that by maintaining the blood sugar level between 80 and 120 mg/dL via a continuous insulin infusion, they significantly decreased the incidence of bacteremia, critical illness polyneuropathy, and mortality.[67] This study and its more recent companion in medical ICU patients[70] have encountered criticism, but it has affected the way we treat hyperglycemia in the ICU. Time and additional studies should lead to more uniform practices over the next few years.

The Hemodynamic Response

The hemodynamic response to injury has been extensively investigated by monitoring central vascular pressures, cardiac output, and indices of oxygen delivery and consumption.[71] Systemic vasoconstriction commonly predominates in the immediate period following an acute injury, most likely as a response to intravascular hypovolemia from hemorrhage or sequestration of body fluids outside the vascular compartment. After normovolemia is restored, a hyperdynamic pattern of high cardiac output and normal-to-low blood pressure ensues. The extent of this hyperdynamic response varies with the type and magnitude of the injury. It is important to note that hyperdynamic states occur in other conditions, such as hyperthyroidism, liver cirrhosis, and with large arteriovenous fistulae, even if acute injury and/or inflammation are not present.

This hyperdynamic response may be part of a systemic inflammatory response syndrome (SIRS) that is associated with acute injury of various etiologies, and is caused by the release of cytokines and other inflammatory mediators such as prostaglandins, bradykinins, and complement fractions.[31] The cardinal manifestations of SIRS include hyper- or hypothermia, tachycardia, leukocytosis or leukopenia, and hyperventilation. In addition, a number of other signs and symptoms, such as hypotension, platelet and coagulation abnormalities, and changes in mental status, are characteristic of SIRS, although each taken individually lacks specificity both as a diagnostic sign and as an end point for defining therapy.

Systemic Vasodilatation, Inflammation, and Coagulation: The Endothelium

A number of substances are believed responsible for the decrease in systemic vascular tone that is part of the hyperdynamic response. The vascular endothelium plays an important role in the inflammatory and procoagulant state that can result from an acute traumatic or infectious injury (see The Immune–Inflammatory Response above).[72,73] The endothelium contributes to the maintenance of homeostasis in a number of ways, including the prevention of coagulation, the regulation of vascular tone and permeability, and the orchestration of the migration of leukocytes into the tissues by the expression of adhesion molecules. Figure 75–4 is a schematic of the interaction between inflammatory stimuli, the endothelium, and leukocytes.

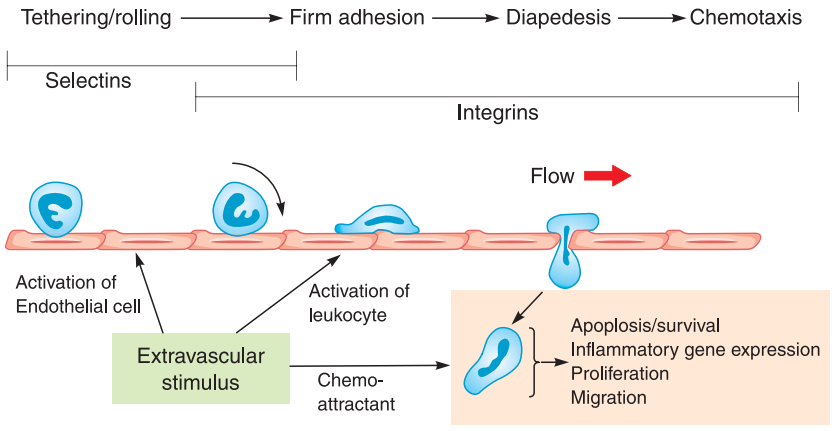

FIGURE 75–4. Schematic of leukocyte adhesion to the activated endothelium during inflammation. Leukocytes are initially tethered, and roll along the endothelium predominantly via interactions with selectins. Once on the endothelium, leukocytes' integrin receptors are activated and bind to ligands on the extracellular matrix, favoring migration of leukocytes between endothelial cells. Signaling from integrin receptors also modulates leukocytes survival or apoptosis and gene expression and proliferation. (Reproduced with permission from Harlan and Winn.[141])

Immediately following injury there is upregulation of adhesion molecule expression on endothelial cells and leukocytes leading to increased endothelial cell–leukocyte interactions and eventual migration of leucocytes across the vessel wall into the adjacent tissues (Fig. 75–4).[74,75] Direct injuries and inflammatory mediators cause the endothelium to lose its anticoagulant properties; there is concomitant imbalance between thrombin and plasmin, and increased platelet stickiness, ultimately resulting in clot formation on the endothelial surface. Widespread activation of the coagulation system in response to stress may lead to disseminated intravascular coagulation (DIC), intravascular formation of fibrin, decreased fibrinolytic activity, and widespread thrombosis.[76] Although the full syndrome of diffuse vascular thrombosis is rare, DIC often presents a considerable clinical challenge because of the concomitant presence of a consumptive coagulopathy and thrombosis. The coagulation system has been targeted therapeutically in patients with sepsis and septic shock. Antithrombin III and *protein C* are both anticoagulants that are maintained in an active state by endothelial activity, and are decreased in conditions of stress such as SIRS and sepsis. Although a clinical trial of the therapeutic administration of antithrombin III was unsuccessful,[77] the infusion of recombinant human activated protein C (drotrecogin-α) significantly increased the survival rate of critically ill patients with severe sepsis and septic shock by 6%.[78]

The endothelium produces multiple mediators that have diverse functions. Some mediators have multiple effects, such as protein C, vasodilator mediators like the gas NO and prostacyclin (both also inhibit platelet aggregation), and the vasoconstrictor endothelins, all have potent vasoactive and immunologic properties. NO is produced constitutively in endothelial cells by the isozyme nitric oxide synthase (NOS-3, endothelial nitric oxide synthase [eNOS]). Following stimulation of various kinds, there is upregulation of an inducible form of NOS (NOS-2, iNOS), which results in greatly increased production of NO, and contributes to the profound vasodilatation that occurs with severe systemic inflammatory processes.[79] Activation of endothelial cells also results in the production of mediators with opposing effects, such as the endothelins, which can cause vasoconstriction while NO causes vasodilatation.[80] When the induction of iNOS is overwhelming, such as in septic shock, the massive vasodilatation of the extreme hyperdynamic syndrome results in profound hypotension that may compromise vital tissue perfusion and lead to MODS and death (see Chap. 76). Nitric oxide-induced vasodilatation has been reversed by the administration of nonspecific NOS-inhibitors such as methylene blue,[81] L-nitroarginine methyl ester (L-NAME)[82] and *N*-methyl-L-arginine hydrochloride.[83] However, this clinical strategy has been unsuccessful, possibly as a result of the importance of the constitutive isoenzymes of NO that were also inhibited by these nonselective compounds.

The Metabolic Response

The metabolic response to traumatic injury is characterized by hypercatabolism and increased urinary nitrogen excretion. Once initial hemodynamic resuscitation and stabilization are achieved, substrates are used to enhance tissue repair and preserve vital organ function. Tissues that do not have a high resting energy requirement, such as fat and skeletal muscle, release nutrients from storage (glucose and fatty acids), or proceed to break down their structural proteins to provide fuel for visceral organs. High levels (3- to 4-fold increase) of circulating catecholamines coexist with this metabolic response. Epinephrine, in particular, promotes glycogenolysis in muscle and liver, lipolysis and ketogenesis in adipose tissue, and hepatic gluconeogenesis.[84,85] These processes provide energy for the high metabolic requirements during the phases of recovery and repair. In addition, epinephrine induces insulin resistance in skeletal muscle, which contributes to the development of hyperglycemia. Like many homeostatic responses, this high catecholaminergic state has dual and opposing effects; although catecholamines promote healing and repair, high catecholamine levels may cause excessive catabolism, hyperglycemia, muscle wasting, and reduced host defenses. One clinical study that was carried out in children with acute burn injuries has shown the benefits of blocking the catecholaminergic response to acute burn injury. Because children with burns have a particularly high metabolic demand,[86] it remains uncertain whether or not this benefit can be extrapolated to critically ill adults without burns.

THE CELLULAR RESPONSE TO INJURY

At the tissue level, the ability to live or die can be simply reduced to the ability of the body to supply adequate amounts of oxygen and nutrients (e.g., glucose) for cellular respiration and to remove metabolic by-products (CO_2 and toxins). These two seemingly sim-

ple end points are reached through enormously complex phenomena. This section reviews several aspects of this process that are relevant to acute injury, whether traumatic, inflammatory, or infectious.

The Cellular Response to Traumatic Injury

The extent of the damage caused by a traumatic injury (e.g., amount of energy received on impact, size of the wound) often determines the immediate outcome of a patient. An uncontrollable hemorrhage will result in early death, with the possible salvage strategy being very simple—a tourniquet and immediate transport, not ICU care. A complex but not immediately lethal injury will then evolve over time, and the outcome will depend on the adequacy of the endogenous response to injury and the ability to support it successfully.

The body's immediate response to traumatic injury requires the generation of signals that communicate the presence of a threat to the rest of the body. These danger signals, which may include necrotic tissue byproducts and local changes in pH and temperature, activate endothelial cells, monocytes, and macrophages to produce and release inflammatory mediators. Production and release of cytokines commences within a few minutes of injury, and facilitates a systemic response that has protean clinical manifestations. Early measurements of plasma cytokine levels in trauma and surgical patients indicate that the degree of increase in IL-6, one of the earliest responders, correlates with the degree of injury.[9,87] In addition to the immediate synthesis and release of cytokines, soluble receptors and antagonist mediators are released following trauma, further modulating the effects of the cytokines, and initiating a competitive antiinflammatory, immunosuppressive response.[88,89] This balance between the activation and suppression of inflammation continues throughout the course of critical illness, and likely affects the ultimate evolution toward recovery or death.[90] Better understanding of the determinants of this balance between the pro- and antiinflammatory responses could guide the generation of effective therapeutic strategies. A state of immunosuppression or anergy is well described after severe trauma and surgery and may increase susceptibility to nosocomial infections, a common determinant of further morbidity and a longer ICU stay.[91]

Infection

Like traumatic injury, wherein the extent of damage determines the bodily response, a sufficient inoculum of pathogenic microorganisms triggers the host's systemic inflammatory response, manifesting in its most severe form as septic shock. The host response to infection is initiated by interactions between structural components of the invading organism (pathogen-associated molecular patterns [PAMPs]) and the immune cells of the host. All classes of microbes, including gram-positive and gram-negative bacteria, fungi, viruses, and parasites, have PAMPs, although their exact PAMPs vary. For instance, gram-negative bacteria have endotoxin (LPS) in the outer membrane of their cell walls. LPS is a potent bacterial toxin that is thought to play an important role in gram-negative sepsis. Gram-positive bacteria do not have LPS, but they have other PAMPs that have inflammatory effects, such as peptidoglycan and lipoteichoic acid. Other PAMPs include nucleic acids from bacteria and viruses, and zymosan from yeast.

LPS is the best-characterized and most extensively studied microbial PAMP. LPS is a complex glycolipid in the outer membrane of the gram-negative bacterial cell wall. Injection of LPS into animals and human volunteers elicits inflammation and other responses that are similar to those that occur in septic patients. Because of the high toxicity of LPS, it has been targeted for many novel therapies over the last few decades. LPS is composed of a lipophilic domain (lipid A) and a polysaccharide tail that varies considerably between different bacteria. Because lipid A is conserved among different bacteria, therapeutic strategies have targeted the lipid A portion of LPS for antibody development.[92] However, despite promising results in animal and early clinical trials, phase 3 clinical trials failed to establish significant improvement in patients given antilipid A antibodies. Although LPS is a highly potent toxin, the fact that LPS is not present in a large number of microorganisms that cause sepsis clearly indicates that other microbial components contribute to the pathogenesis of sepsis.

A variety of host mediators, including soluble mediators in the blood, cell surface receptors, and intracellular signaling pathways, are involved in PAMP-induced activation of inflammation. For instance, both LPS-binding protein and the monocyte surface antigen CD14[93] bind LPS, and are involved in initiating inflammatory responses to LPS. CD14 is vital for LPS-induced activation of immune cells, and has both membrane-bound, and soluble forms. Soluble CD14 is required for LPS-induced activation of CD14-negative cells.[94] CD14 also seems to play a role in cell signaling by gram-positive bacterial PAMPs, such as peptidoglycan.[95]

Over the last decade, a great deal has been discovered about the mechanisms of inflammation induced by microorganisms. Despite considerable structural heterogeneity, inflammatory responses to different microbial components are mediated through common receptors and intracellular pathways. Toll-like receptors (TLRs) recognize various classes of PAMPs and are critical proximal mediators of inflammation during infection. TLRs are evolutionarily conserved innate immune receptors that are present in both insects and mammals. They are pattern recognition receptors (PRRs) that sense common motifs in components of microorganisms (PAMPs). Toll receptors were initially discovered in *Drosophila melanogaster* in 1985, and were found to be important embryologically in dorsoventral polarity.[96,97] Subsequently, the *Drosophila* toll receptor was shown to be required for fly immunity to *Aspergillus*.[98] Mammalian TLRs were discovered in 1998. TLR4 was identified as the LPS receptor, based on studies using strains of mice that were known to be hyporesponsive to the effects of LPS, but were highly susceptible to infection.[99] The same year, human TLRs 1–5 were cloned, and were postulated to be involved in immunity based on sequence homology with the *Drosophila* toll receptor.[100] Since that time multiple mammalian TLRs have been identified, each recognizing a different PAMP. For example, TLR2 mediates effects of microbial lipoproteins, peptidoglycan, lipoteichoic acid, and zymosan, a component of yeast; TLR3 responds to double-stranded RNA;

TLR4 mediates the effects of LPS; TLR5 responds to flagellin; TLRs 7 and 8 sense single-stranded RNA; and TLR 9 recognizes unmethylated DNA.

Extensive knowledge of TLR structure and signaling pathways has rapidly been gained since their discovery (Fig. 75–5). TLRs are transmembrane proteins with two primary domains. The extracellular amino-terminal contains leucine-rich repeats and is involved in the recognition of PAMPs. The intracellular carboxy-terminal toll-IL-1 receptor (TIR) domain is required for intracellular signaling. Most TLRs signal exclusively through the adapter molecule MyD88, which ultimately leads to nuclear transcription factor-κB (NF-κB) translocation to the nucleus, which induces transcription of inflammatory genes, ultimately leading to the production of cytokines and other mediators of inflammation. TLR3 signals through a different adapter molecule than MyD88, and ultimately leads to nuclear translocation of interferon regulatory factor 3 (IRF3) and upregulation of β-interferon genes. TLR4, the LPS receptor, signals through both pathways. It is believed that through the coordinated sensing of different TLRs, the host is able to discriminate between different types of infections and to mount an appropriate inflammatory response to the particular pathogen.

Because most PAMPs signal through NF-κB, blocking NF-κB seems a potential strategy for antisepsis therapies. Although in animal models of pure endotoxemia the inhibition of NF-κB has been shown to improve survival and limit organ damage,[101–103] there has not been a clear-cut benefit of NF-κB inhibition demonstrated in models of live bacterial sepsis such as infectious peritonitis from cecal ligation and puncture.[104] Likely, NF-κB has tissue- and time-specific functions, and global inhibition is too nonselective a strategy that may interfere with the native beneficial effects of this mediator.

As with all biologic systems, intercellular signaling in early inflammation and infection has an intrinsic redundancy. In addition to the TLRs, other innate immune receptors and signaling pathways also seem to be important in the recognition of and response to infection, including NOD receptors, scavenger receptors, mannose binding lectins, and dectin. Please refer to recent reviews for a more inclusive discussion.[105–108]

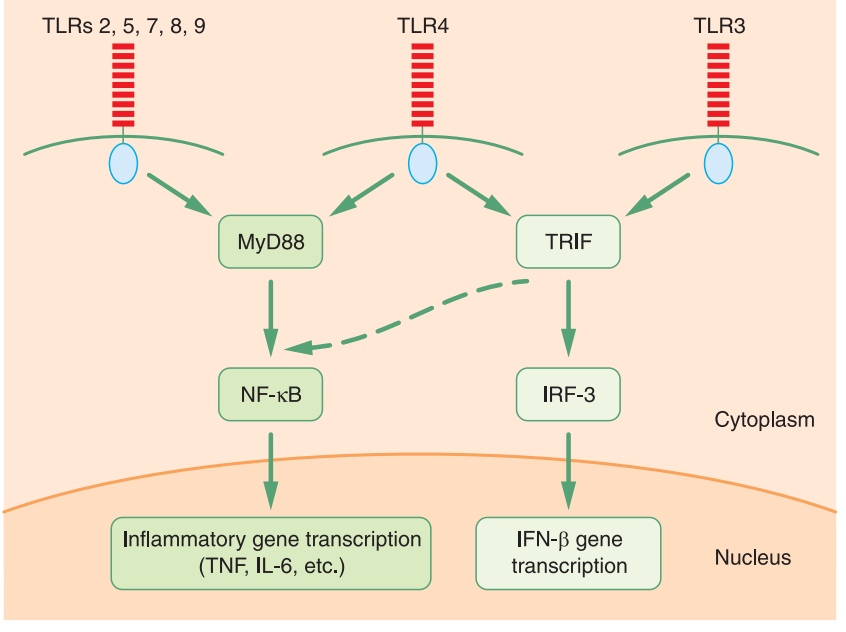

FIGURE 75–5. Overview of the toll-like receptors (TLRs) and schematic of TLR signaling pathways. TLRs sense components of microorganisms and are centrally involved in innate immune responses during infection. Activation through TLRs results in production of early inflammatory mediators such as the cytokines tumor necrosis factor (TNF) and interleukin (IL)-6, and in some cases production of interferon-β. Different TLRs sense different microbial structures, and there are distinct but interconnected intracellular signaling pathways that are activated by TLRs.

Immunomodulation: From Inflammatory Response to Immunosuppression

Within the first 30–90 minutes after exposure to LPS, mononuclear cells release proinflammatory cytokines such as TNF-α, IL-6 and IL-1β.[48] This activates inflammatory cascades that stimulate further production and release of cytokines, chemokines (chemoattractant cytokines), lipid mediators, and free radicals, which are involved in leukocyte migration and adhesion, and in tissue injury.[74,75] A similar inflammatory response can be triggered by all of the stressors or insults described in earlier sections of this chapter. The failure of early therapies aimed at blocking isolated aspects of the inflammatory response, such as infusing high-dose corticosteroids, TNF antagonists, IL-1 receptor antagonists, and non–isozyme-specific inhibitors of NO synthesis, has led investigators to search for a deeper understanding of this extraordinarily complex and redundant system.

There is mounting evidence to support the concept of immunomodulation, that is, an equilibrium between activation and suppression of the immune system, during critical illness. It is postulated that a state of immunoparalysis occurs, whereby the host has inadequate immune responses to microorganisms, plays an important role in subsequent morbidity and mortality following injury or infection. Antiinflammatory mediators and altered cellular responses are believed to predispose patients to the development of nosocomial infections and subsequent MODS.[109,110] At various times after the initial proinflammatory state of traumatic and infectious injury, counterregulatory cytokines, soluble decoy receptors for cytokines, and antagonists of proinflammatory cytokines are secreted. Immunosuppression is believed to occur when this response supersedes its function of restoring immunologic balance. This is exemplified by studies that indicate that blood from septic patients has reduced LPS-induced cytokine production, unlike blood from control patients.[111] Anergy, or the inability of T cells to proliferate and secrete lymphokines upon stimulation, is often observed in severe trauma and septic patients.[112–114] In trauma, a decrease in the number of T cells probably results from interactions between T cells and immunosup-

pressive mediators such as IL-10.[115,116] Regulator T cells (T-reg), which are important elements of the normal immunologic equilibrium, may play a role in the immunosuppression resulting from burn injury.[115,117]

In acute infection, adaptive immunity may be impaired because of apoptosis of T lymphocytes[118] rather than cell necrosis. The term *necrosis* refers to *accidental* cell death, whereas the term *apoptosis* refers to *programmed* cell death. In contrast to necrosis (an *accidental* cell death), which generally has a stimulating effect on the innate immune system, apoptosis (a *programmed* cell death) can induce secretion of antiinflammatory cytokines leading to immunosuppression and anergy. It has been shown that the B lymphocytes, CD4 T lymphocytes, and dendritic cells undergo apoptosis, but that CD8 T lymphocytes or natural killer (NK) cells do not undergo apoptosis.[118] After the initial decrease in the number of CD4 T-cells, the subset of these cells that recovers are selectively T-reg and not T-helper (Th) cells.[119] T-reg cells (see above) have multiple negative regulatory effects on immune function, and can contribute to immunosuppression.[115] The importance of immune cell apoptosis in sepsis has also been demonstrated in animal models. Strains of mice that produce the antiapoptotic protein Bcl-2 are protected from death after intraabdominal sepsis induced by cecal ligation and puncture.[120]

With late immunosuppression as the predominating state after the initial injury, critically ill patients become a target for nosocomial infections, which can lead to vital organ failure and death.

Metabolic Disturbances and Cytopathic Hypoxia

Critically ill patients may develop metabolic disturbances that lead to the inability to generate sufficient energy to maintain body homeostasis. ATP is the primary fuel source for cellular respiration. The mitochondria are the principle sites of aerobic ATP production. Here, the end-product pyruvate, a product of glucose metabolism, is used in the citric acid cycle to generate the reducing agents reduced form of nicotinamide adenine dinucleotide (NADH) or the reduced form of flavin adenine dinucleotide ($FADH_2$) and provide the flow of electrons necessary to synthesize ATP by oxidative phosphorylation. Ultimately, 36 or 38 moles of ATP are generated from the oxidation of 1 mole of glucose. Conversely, anaerobic glycolysis occurs in the cytoplasm, and generates only 2 moles of ATP per mole of glucose, with the production of lactate or ethanol as end-products. During critical illness, the failure to generate adequate amounts of ATP can lead to cellular and organ dysfunction.

Several studies describe a decrease in ATP production in septic patients,[121–123] and lower ATP levels in the tissues of critically ill septic patients who died, when compared to tissues of those who survived.[124] One reason for the failure to generate ATP during critical illness is inadequate delivery of oxygen to vital tissues, secondary to impaired oxygenation and perfusion. During SIRS and septic shock, multiple factors may decrease tissue perfusion, including inadequate cardiocirculatory performance, hypoxemia from acute lung injury, mediator- or vasopressor-induced vasoconstriction, and/or coagulation derangements causing microvascular obstruction.

Cytopathic Hypoxia

Cytopathic hypoxia is also postulated to contribute to the failure to generate adequate ATP, because of the inability of the cells to use available oxygen.[125] Experimental and clinical studies show that tissue oxygen tension during sepsis is often higher than in nonseptic states.[126–128] Mitochondrial dysfunction is hypothesized to underlie the apparent disconnection between the cellular oxygen tension, which is usually adequate, and the low ATP levels. Mitochondrial dysfunction is reported in cells exposed to macrophages, inflammatory cytokines, LPS, and infection.[129–131] Multiple factors may contribute to mitochondrial dysfunction in acute injury, including the production of NO and reactive oxygen species. Low doses of LPS can increase iNOS messenger RNA activity in the intestinal tissues of experimental animals,[130] and physiologic concentrations of NO can reversibly inhibit the activity of cytochrome oxidase by competition with oxygen.[132,133] In addition, NO can damage mitochondria by generating peroxynitrite when reacting with the molecular oxygen of the superoxide radical anion. Peroxynitrite is a potent oxidizing and nitrating agent, which can inhibit multiple mitochondrial functions.[134] Mitochondria normally produce a low basal level of superoxide anion, which can increase during inflammation.[135] The presence of peroxynitrite is associated with mitochondrial inhibition, DNA breakage, and activation of poly(ADP-ribose)polymerase (PARP), an enzyme responsible for repair of single-strand DNA breaks.[136] PARP activation can lead to energetic failure by causing a decrease in the oxidized form of nicotinamide adenine dinucleotide (NAD^+) and NADH, an important electron donor in mitochondrial oxidative phosphorylation (see above).[137]

ORGAN FAILURE, SURVIVAL, AND DEATH

At present there is limited understanding of the nature and degree of organ dysfunction during critical illness. An autopsy study of patients who died from sepsis showed discordance between the clinical manifestations and histologic findings in various organs.[120] In the heart, there was no histologic evidence of injury to myocytes despite the reduced contractility that is often observed clinically; in the kidneys there was only focal injury with preservation of normal glomerular and tubular architecture despite the acute impairment in indices of renal function. Furthermore, it is a common observation that most patients who survive septic shock recover baseline function of their heart, lungs, and kidneys, suggesting that reversible factors, rather than cell death, are responsible for organ dysfunction.[138] Similarly, death from sepsis is also poorly understood. As discussed at the beginning of this chapter, death of critically ill patients occurs most often by voluntary withdrawal of care rather than being caused by refractory shock, extreme hypoxia, or a malignant arrhythmia.

The mechanisms of the organ failure of critical illness are described in detail in Chap. 76. Here we provide a schema of pathophysiologic events occurring in the progression of critical illness. At successive steps, different therapeutic approaches may be useful for influencing the progression of illness toward survival and away from death (Fig. 75–6).

Initially, the inciting "stress" should be countered with resuscitation as per

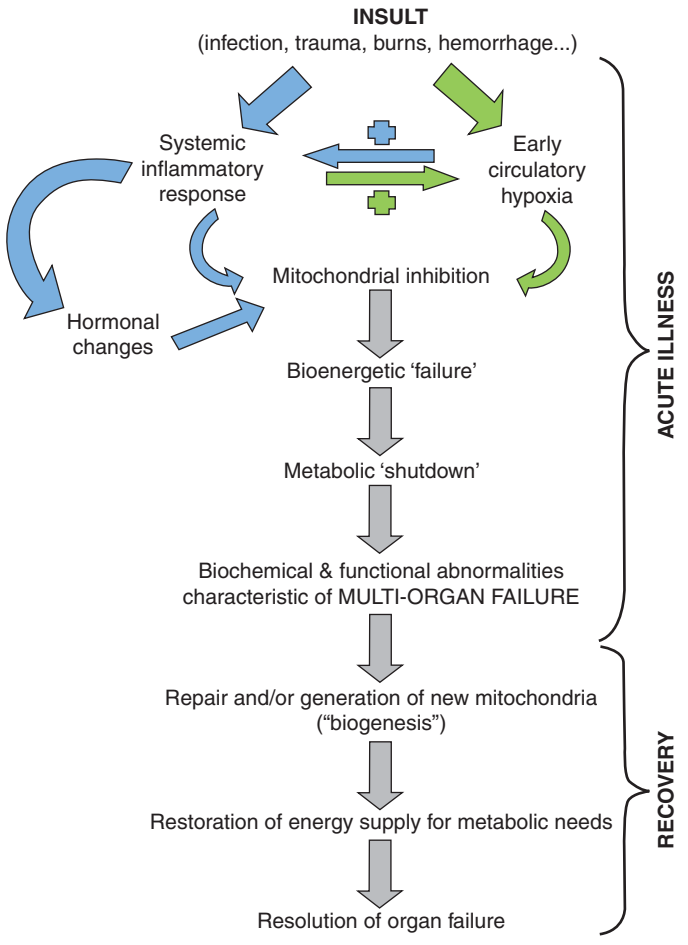

FIGURE 75–6. A proposed paradigm of the evolution of critical illness (see text).

early goal-directed therapy,[139] ensuring that no tissue hypoxia occurs. However, even this principle is not universal, as exemplified by the successful use of limited fluid resuscitation in selected trauma patients.[2] In our case report, the presence of pulmonary hypertension and right ventricular insufficiency further complicated the management of resuscitation per goal-directed therapy, prompting the use of invasive monitoring with a pulmonary artery catheter, which may not be indicated routinely in the management of ALI/ARDS.[140]

Subsequently, therapies supporting the natural response to acute stress, such as the infusion of activated protein C as was done in our case report, may improve survival of the most critically ill patients. In the future, therapies targeting mitochondrial protection, such as the administration of PARP inhibitors, superoxide and peroxynitrite scavengers, or selective NOS-2 inhibitors, can attenuate the cytopathic effects of oxygen and nitrogen free radicals, and decrease mitochondrial dysfunction. Immunosuppression, a persistent catabolic state, and poor nutritional status can both decrease host defenses and cause increased susceptibility to infectious complications. Inappropriate use of antibiotics and lack of adequate attention to basic procedures to prevent transmission of antibiotic-resistant bacteria may further increase the chances of nosocomial infections at this stage. In our case report, a *Pseudomonas* pneumonia hindered the progression of our patient's course toward recovery, although ultimately our patient survived. Future therapies may target various aspects of immunosuppression, including apoptotic mechanisms (e.g., by manipulation of Bcl-2), and may provide an appropriate balance of nutrients that can stimulate immune function. In addition, stimuli to increase mitochondrial energy generation can potentially play a role, so that cellular energy production regains baseline levels.

As the basic mechanisms of critical illness are further defined through basic and clinical research, it is likely that the therapeutic algorithms for treating critical illness will evolve, from a gross physiologic approach supporting respiration and circulation to a more targeted mechanistic approach.

CONCLUSION

Acute injuries of various etiologies, such as the aspiration of gastric contents into the lungs, cause immediate local and systemic physiologic responses that are mediated by well-characterized inflammatory and humoral phenomena. Despite the complexity of these phenomena, our understanding of the evolution of critical illness has greatly increased in recent years, as investigators have started to elucidate the cellular and molecular mechanisms of the host's response to injury. The interaction between the initial "stress" (usually trauma, surgery, or infection) and the response of the host determines the evolution of a critical illness towards either healing and recovery or complications and death. Although a robust inflammatory response is necessary to fend off the most severe injuries, a subsequent decrease in its intensity, and the onset of a hypoimmune state favor the onset of late infections that may lead to dysfunction of organs and death.

The outcome of large ICU patient populations can be predicted using validated systems that score the severity of illness, but these systems are not accurate on a patient-by-patient basis. Hence, critically ill patients often undergo complex therapies and invasive interventions until they, their families, and their doctors believe that it is no longer worthwhile to pursue recovery versus allowing a comfortable death. The effectiveness of our therapies depends on a number of factors, including our ability to intervene properly and at the optimal time. Recent therapeutic interventions have improved the probability of survival of many critically ill patients. As knowledge of the basic mechanisms that underlie critical illness evolves, additional effective therapeutic strategies should emerge that will improve the care and outcome of critically ill patients.

CHAPTER 76

Evaluation of the Patient with Multiple Organ Dysfunction Syndrome

Jean Kwo, MD, and
Judith Hellman, MD

Progress in medical therapies, in particular life support therapies, has led to the recognition of pathophysiologic states that are unique to critically ill patients, and an increasing number of critically ill patients can now undergo surgical procedures. Diverse disease states can cause progressive dysfunction and ultimately complete failure of various organs and systems (Table 76–1). This condition is commonly referred to as the multiple organ dysfunction syndrome (MODS). High-grade organ failure that necessitates life-sustaining therapies, continuous venovenous hemofiltration (CVVH) or hemodialysis (HD) for renal failure, vasopressors and/or inotropes for circulatory failure, and maximal ventilatory support for respiratory failure, is often referred to as multiorgan system failure. It is generally recognized that the development of MODS is often lethal and portends a poor outcome, particularly if the underlying process that triggers the syndrome cannot be identified or treated. In fact, MODS has become the leading cause of death for intensive care unit patients.[1,2]

The first part of this chapter reviews basic aspects of MODS, including its epidemiology, pathophysiology, etiologies, manifestations, management, and the types of surgical and nonsurgical procedures that are commonly performed in patients with MODS. Subsequent sections address the evaluation, preoperative preparation, and optimization of patients with MODS for surgery.

MULTIORGAN DYSFUNCTION SYNDROME

The development of organ dysfunction as a separate disease process, both temporally and physically, from the initial injury was first appreciated during World War II. Wounded soldiers were rapidly and aggressively resuscitated with blood products to normal blood pressure levels, and they were more promptly evacuated and treated at medical facilities than in previous wars. Although initial survival was improved, some proportion of soldiers that survived the initial trauma subsequently died of renal failure.[3,4] This led to changes in fluid resuscitation practices in subsequent wars, including the rapid infusion of crystalloids and more aggressive resuscitation. During the Vietnam War, many soldiers who survived their initial trauma developed "shock lung" (acute respiratory failure). At the same time, acute lung injury (ALI) and acute respiratory distress syndrome (ARDS) were increasingly being described in civilian ICUs.[5] During the 1970s advances in the care of various organs, systems, and injuries resulted in improved initial survival from many injuries. However, some patients that survived the initial resuscitation subsequently developed sequential progressive dysfunction and failure of various organs and systems.[6,7]

Over the last several decades various terms have been used to describe the spectrum of dysfunction causing the failure of different organs and systems (reviewed in ref. 8), including "multiple organ failure,"[9] "multiple-organ-failure-syndrome,"[1] "multiple system organ failure,"[10] "progressive or sequential organ failure,"[6] or "MODS."[8,11] The term *MODS* is now most widely used because it encompasses the entire spectrum from mild organ dysfunction to complete organ failure.

In addition, various scoring systems have been devised to assess critically ill patients and to predict outcome.[4,12–16] Although the definitions have varied slightly over time as our understanding of the syndrome has evolved, the basic syndrome described by all these terms reflects the same pathophysiologic processes. In this chapter the term *MODS* is used as an inclusive definition for all the studies and papers that have used all of these terms over the past several decades.

Definitions

ACCP/SCCM Consensus Conference

In 1992, a series of recommendations for the definitions of sepsis, systemic inflammatory responses, and organ dysfunction were published based on a consensus conference of the American College of Chest Physicians (ACCP) and Society of Critical Care Medicine (SCCM).[8] The goal of the consensus conference was to gain uniformity in definitions and criteria used by clinicians and researchers to describe these processes and to enter patients into research studies. The acronyms SIRS (the systemic inflammatory response syndrome) and MODS were coined at the consensus conference, and continue to be widely used in the

KEY POINTS

1. Multiple organ dysfunction syndrome (MODS) is common in critically ill patients and is associated with a high mortality rate.
2. There are many underlying etiologies of MODS. In the overall ICU population, sepsis is the most common cause of MODS.
3. MODS is characterized by dysfunction of 2 or more organs or systems. The respiratory system is most frequently involved.
4. The pathophysiology of MODS is still not well understood. Systemic inflammation and microvascular abnormalities are involved in the development of MODS.
5. Therapies for MODS should target the underlying cause and attempt to support the physiologic and metabolic derangements that are caused by dysfunction of the various organs and systems.
6. Patients with MODS often require surgery and other invasive procedures to correct the underlying causes and to manage complications of MODS.
7. Whenever possible, optimize MODS patients preoperatively.
8. Methods of optimization are dictated by the specific organs that are affected and the pattern and severity of consequent physiologic and metabolic derangements.

Systemic Inflammatory Response Syndrome (SIRS) Criteria

Diagnosis of SIRS requires at lest 2 of these criteria

1. Tachycardia—heart rate >90 beats/min
2. Leucocytosis (white blood cell count >12,000), leucopenia (white blood cell count <4000), or high band count (>10%)
3. Fever (temperature >100.4°F [38°C]) or hypothermia (temperature <96.8°F [36°C])
4. Tachypnea (respiratory rate >20 breaths/min), low $PaCO_2$ (<32 mmHg), or mechanically ventilated

Data from Bone RC, Balk RA, Cerra FB, et al.[8] and Levy MM, Fink MP, Marshall JC, et al.[11]

care of critically ill patients and in the design of clinical studies and trials.

SIRS The term *SIRS* describes a complex inflammatory process that is driven by many differing disease states. Underlying etiologies of SIRS include, but are not limited to, infection, trauma, burns, aspiration, pancreatitis, vascular compromise with resultant ischemia and/or necrosis, malignancy, and multiple blood transfusions. Table 76–2 lists the criteria for SIRS. SIRS is frequently complicated by the development of organ system dysfunction.

Sepsis Sepsis was defined as the systemic inflammatory response to infection. Sepsis was further stratified based on its severity, with severe sepsis and septic shock representing the spectrum of progressively worsening status.

MODS The term *MODS* was coined to describe a pattern of progressive dysfunction of organs that is related pathogenically regardless of the inciting process and that requires intervention to maintain homeostasis.

Etiologies

There are two broad categories of MODS.[17] Primary MODS results from direct injury to organs, such as might occur following major direct trauma; primary MODS occurs early after the injury. Secondary MODS results from the systemic host response to an injury as opposed to direct injury to the organ, and occurs later than primary MODS. For the remainder of the chapter, the term *MODS* is used to describe secondary MODS, which is a far more frequent occurrence than primary MODS in the ICU.

MODS is believed to be mediated by a systemic inflammatory process that may be initiated by one or more of a multitude of injuries (Table 76–1). Common etiologies include infection, trauma, aspiration, pancreatitis, transfusion of multiple units of blood, ischemia–necrosis, and burns.[18] MODS occurs in both surgical and nonsurgical patients. In patients with MODS who are not receiving surgery, the most frequent ICU admission diagnoses are cardiac arrest, sepsis, pneumonia, congestive heart failure, upper gastrointestinal (GI) bleeding, and nonoperative head trauma.[19] Postoperative MODS occurs most frequently following surgery for head trauma, elective abdominal aneurysm repairs, aortic dissection or rupture, GI perforation, GI inflammatory diseases, and GI malignancy. Other risk factors for the development of MODS include preexisting organ dysfunction, delayed or inadequate resuscitation, an ongoing infection or focus of inflammation, major hematoma, age ≥65 years, surgical complications, seriously deranged physiologic parameters on admission to the ICU, and chronic health problems (e.g., cancer or alcoholism).[12,13,18–21]

Sepsis is a pathophysiologic response to overwhelming infection and has a wide spectrum of presentations (Table 76–3). Sepsis is the most common cause of MODS. In septic shock,

TABLE 76–3.

Spectrum of Sepsis[a]

Systemic inflammatory response syndrome (SIRS)	2 or more of the following:	• Body temperature >101.3°F (38.5°C) or <95°F (35.0°C) • Heart rate >90 beats/min • Respiratory rate >20 breaths/min or $PaCO_2$ <32 mmHg or need for mechanical ventilation • White blood cell count >12,000/mm^3 or <4000mm^3
Sepsis	SIRS and:	• Documented source of infection
Severe sepsis	Sepsis and at least one sign of organ hypoperfusion or organ dysfunction:	• Areas of mottled skin • Capillary refill ≥3 sec • Urine output <0.5 mL/kg/h or renal replacement therapy • Lactate >2 mmol/L • Abrupt change in mental status • Platelet count <100,000/mL or disseminated intravascular coagulation (DIC) • Acute lung injury (ALI) or acute respiratory distress syndrome (ARDS) • Cardiac dysfunction
Septic shock	Severe sepsis and either:	• Mean arterial pressure <60 mmHg after adequate fluid resuscitation • Need for vasopressor to maintain mean arterial pressure >60 mmHg

Levy MM, Fink MP, et al. 2001 SCCM/ESICM/ACCP/ATS/SIS International Sepsis Definitions Conference. Crit Care Med 2003;31:1250.

systemic inflammation triggers pathophysiologic processes that cause vasodilatation, relative or absolute hypovolemia, myocardial dysfunction, and an altered systemic blood flow distribution.[22] Despite the restoration of intravascular volume, microcirculatory abnormalities in important organs may persist, leading to a maldistribution of cardiac output and a failure to maintain adequate cellular perfusion. About half of the patients who succumb to septic shock die of multiple organ failure.

Epidemiology

MODS occurs in approximately 15% of ICU admissions[23] and is associated with to up to 80% of ICU deaths.[2,19,24] MODS appears to occur more frequently and have a higher mortality in patients who are admitted to the ICU for medical problems as opposed to patients who are admitted to the ICU for surgical problems or following trauma.[2,25] A large multicenter study of the risks and outcomes of MODS found that approximately 75% of patients with MODS had nonoperative underlying diagnoses.[19] In addition, Acute Physiology and Chronic Health Evaluation (APACHE) III scores were found to be significantly higher on the first day for patients with multiple organ system failure than for patients without MODS.[19]

Studies suggest that there are differences in the patterns of organ dysfunction based on the reason for the admission to the ICU. For the general ICU population, the risk of MODS is related to age >65 years, severity of coexisting diseases, and a nonoperative ICU admission diagnosis.[2,19] However, trauma patients who develop MODS do not seem to fit this profile. A prospective study of multiple organ failure (MOF) following major trauma showed that age, a large red blood cell transfusion requirement, a high Injury Severity Score, a large base deficit, and elevated lactate levels all are risk factors for the subsequent development of MOF.[26]

MODS Scoring Systems

Over the last several decades, many scoring systems have been devised to assist with the diagnosis and quantification of severity of MODS. Two such scoring systems, the sepsis-related or sequential organ failure assessment (SOFA) score[14] and the MODS score[15] are currently widely used systems that take into account not only the number of dysfunctional organs or systems, but also the degree of dysfunction of each organ. Both MODS and SOFA scores are generated using the same basic systems.

SOFA Score

The SOFA score was created to describe organ dysfunction in individual patients and groups of patients over time.[14] The SOFA score is calculated based on the degree of dysfunction of 6 organ systems (respiratory, hepatic, cardiovascular, coagulation, renal, and CNS) and is commonly used to follow the progression of organ dysfunction rather than to predict outcome.

MODS Score

The MODS score was developed to provide a "reliable and meaningful index of the severity" of MODS in individual ICU patients and to attempt to quantify the association between the degree of dysfunction and the risk of mortality.[15] The MODS score also incorporates 6 organ systems (respiratory, renal, cardiovascular, hematologic, CNS, and hepatic), each of which is assigned a number from 0 to 4 based on the severity of dysfunction. A unique feature of the MODS score is the use of the pressure-adjusted heart rate to represent the cardiovascular (CV) system. The pressure-adjusted heart rate is calculated by multiplying the heart rate times the ratio of central venous to mean arterial pressure. Data is collected repeatedly during the ICU stay. The highest possible score is 24, which indicates the most severe MODS.

Denver Multiple Organ Failure Score

The Denver MOF score was devised to provide an end point for clinical studies of trauma and is widely used in outcome studies of trauma patients.[4] The revised Denver MOF score takes into account 4 organ systems: pulmonary, cardiac, renal, and hepatic. Each organ system is assigned a grade based on the degree of dysfunction (0 = none, 3 = severe).

Prognosis of MODS

The overall mortality of MODS is in excess of 50%.[16,26,27] Studies consistently show that across all ICU populations, mortality in MODS is proportional to the number of failing organs. Whereas single-organ failure is associated with a low mortality, the mortality in patients with 3 failing organs is 80–90% in most studies, and approaches 100% with 4 failing organs.[2,17,19,23] In the study described above that developed and validated the MODS scoring system, mortality was correlated in a graded fashion to the MODS score.[15] Patients with MODS scores of 9–12, 13–16, 17–20, and >20, had ICU mortality rates of 25%, 50%, 75%, and 100%, respectively.

Neurologic failure is associated with the highest mortality.[23] In the general ICU population, a very high mortality rate has been shown when there is concomitant renal failure and either cardiovascular or respiratory failure.[2,28] In addition, mortality is higher in MODS patients that are ≥65 years old.

Other factors also influence mortality, especially the inciting diagnosis. For example, in the prospective study of MOF following major trauma described earlier, the mortality was lower for MODS associated with trauma (45%) than for MODS associated with sepsis or cardiac arrest (75–80%).[19] In addition, the degree of physiologic derangement on the first day of failure of the organ is an important determinant of mortality.[19]

Pathogenesis

The precise mechanisms underlying MODS are still not fully understood. It is believed that some combination of uncontrolled generalized inflammation (SIRS), microcirculatory abnormalities, and impaired oxygen delivery and/or use play important roles in the initiation and perpetuation of MODS (reviewed in refs. 18, 29, and 30). SIRS is believed to be initiated the by release of locally produced inflammatory mediators into the circulation. The localized inflammatory responses are triggered by infection, trauma, or other process, and are in place to protect the host against toxins and infection or to initiate normal healing processes. Once inflammatory mediators circulate, they can gain access to organs that are remote from the inciting site.

White blood cells, platelets, and endothelial cells are also involved in the generalized inflammation of SIRS. These cells secrete or express on their surface a variety of inflammatory mediators including, but not limited to, cytokines, reactive oxygen species, nitric oxide, adhesion molecules, and factors that are involved in coagulation and anticoagulation. The endothelium is believed to play a critical role

in systemic inflammation and organ dysfunction in several ways.[31] Endothelial cells are involved in maintaining a balance between coagulation and anticoagulation.[31–34] An imbalance in coagulation and anticoagulation can result in disseminated intravascular coagulation (DIC) and is believed to be important in the development of microvascular thrombosis leading to abnormal microcirculation and impaired oxygen delivery to organs.[35,36] The endothelium also plays an active role in recruiting inflammatory cells to sites of infection and inflammation through the secretion of chemokines and the expression of adhesion molecules.

The GI tract has been postulated to contribute to MODS through both failure of GI mucosal integrity with translocation of bacteria and their products out of the lumen, and/or through increased production of inflammatory mediators by the gut.[29,37] It has long been believed that various stresses, such as trauma, hemorrhage, burns, and septic shock impair gut perfusion and cause failure of GI barrier function. The hypothesis that bacteria or bacterial products translocate from the GI lumen into the bloodstream under clinical circumstances was originally suggested by Fine.[38] Although there is some suggestive data that bacterial translocation may occur in some situations, clinical studies have not thus far proven this phenomenon of bacterial or endotoxin translocation into the blood.[29,39,40]

It is also believed that there are destructive interactions between different organs, such that dysfunction of one organ will amplify or contribute to dysfunction of other organs. Preexisting organ dysfunction, such as chronic obstructive pulmonary disease or end-stage liver disease, also negatively impacts on the development and outcome of MODS. Similarly, many of the supportive therapies used in MODS can contribute to organ dysfunction. For example, mechanical ventilation can cause or contribute to direct lung damage and can reduce cardiac output by impairing venous return.

MODS: MANIFESTATIONS, COMPLICATIONS, PREVENTION, AND THERAPIES

Manifestations

MODS can affect any organ or system (Table 76–4). The pattern, degree, and progression of organ dysfunction are variable. Dysfunction can range from mild, requiring minimal intervention, to complete failure requiring aggressive support. The lungs and circulatory system are most commonly involved, and one or both of these systems are involved in the majority of cases.[2] Trauma patients often follow a different course than medical and nontraumatic surgical patients. In trauma patients, a biphasic pattern of organ failure occurs.[26,41] Early organ failure (within 3 days of trauma) results from the initial shock, resuscitation, and tissue injury, whereas later organ failure (more than 3 days after trauma) frequently results from infection.[41]

Acute Respiratory Failure

ALI and ARDS form a continuum and can comprise a lethal syndrome of hypoxemia and diffuse progressive pulmonary edema.[42] Overall respiratory failure occurs in approximately 70% of patients with MODS. Risk factors for the development of ARDS include pneumonia, aspiration, trauma, sepsis, and pancreatitis. Patients with respiratory failure in the context of MODS have a very high mortality rate.[2] The degree of respiratory impairment varies in severity, from mild pulmonary dysfunction to full blown ARDS. ALI and ARDS occur most frequently in patients with sepsis as the underlying diagnosis, particularly when the source of the sepsis is pulmonary.[43–45] In addition, mortality is highest when ARDS is caused by sepsis.[46] A recent large study reported a 99% incidence of respiratory failure in trauma patients with multiple organ failure.[47] They also found that the severity of respiratory failure correlated with the degree of other organ impairment, but that the presence of respiratory failure did not correlate with mortality.

Cardiovascular

Cardiovascular dysfunction occurs in approximately 87% of MODS cases, and the in-hospital mortality rate of MODS patients with CV dysfunction is approximately 58%.[2] A variety of cardiovascular abnormalities may be present in patients with MODS, including hemodynamic instability and dysrhythmias.

Hemodynamic Patients may manifest hemodynamic instability secondary to hypovolemia, vasodilatation, and/or myocardial dysfunction. Hypovolemia can result from blood or fluid losses, inadequate fluid intake or replacement, or capillary leakage with extravasation of fluid out of the intravascular space, and inadequate replacement of fluids. Septic patients who have been volume resuscitated often manifest a "high output" state and are described as being "hyperdynamic," that is, they have an elevated cardiac output and stroke volume associated with a decreased systemic vascular resistance. These classic

TABLE 76–4.

Organs and Systems Affected by Multiorgan Dysfunction Syndrome

Organ or System	Manifestations
Lung	Acute lung injury, acute respiratory distress syndrome, ventilator dependence
Cardiovascular	Arterial hypotension, hyperdynamic physiology, vasodilatation, myocardial dysfunction, pulmonary hypertension, shunting
Kidneys	Oliguria, anuria, renal failure, acute tubular necrosis, renal tubular acidoses, acid–base abnormalities, electrolyte abnormalities
Neurologic	Confusion, lethargy, agitation, coma
Liver	Elevated liver enzymes, hyperbilirubinemia, coagulopathy, hepatic encephalopathy
Hematologic	Anemia, thrombocytopenia, coagulation abnormalities, disseminated intravascular coagulation
Endocrine	Hyperglycemia, inappropriate adrenal response to stress ("relative adrenal insufficiency")
Metabolic	Electrolyte and glucose abnormalities, hyper- and hypokalemia, hyper- and hyponatremia, hypomagnesemia, hyper- and hypophosphatemia, hypocalcemia
GI Tract	Hypomotility, inability to tolerate enteral nutrition, GI hemorrhage, stress ulcers

CV manifestations of sepsis may also be present in patients with MODS caused by other systemic inflammatory processes. Nitric oxide (NO) is believed to be a key mediator of the systemic vasodilatation and hypotension in patients with systemic inflammatory processes such as sepsis.

Although cardiac output is usually maintained or elevated in volume-resuscitated patients with sepsis or other systemic inflammatory processes, patients often develop myocardial dysfunction. This myocardial dysfunction is characterized by a decreased left ventricular ejection fraction, ventricular dilation, and an impaired contractile response to volume loading. The mechanisms of cardiac dysfunction are complex and not well understood. Myocardial edema, alterations of sarcolemmal or intracellular calcium homeostasis, and uncoupling or disruption of adrenergic signal transduction may all be involved. Systemic inflammatory mediators such as cytokines, nitric oxide, prostanoids, and platelet-activating factor are postulated to be involved in the pathogenesis of myocardial dysfunction in SIRS. Although myocardial dysfunction is not uncommon, death from myocardial failure is rare.

Dysrhythmias Patients with MODS may develop dysrhythmias on the basis of metabolic abnormalities, intravascular volume disturbances, hypoxemia, and myocardial ischemia in patients with coronary artery disease. Atrial dysrhythmias are common. Although immediate interventions, such as cardioversion, may be required for hemodynamically unstable dysrhythmias, correction of the underlying stimulus is usually required to prevent further occurrences.

Renal

Renal disturbances are common in MODS patients and range from mild renal dysfunction leading to an elevated blood urea nitrogen (BUN) and creatinine, to frank anuric renal failure with uremia, severe electrolyte disturbances, metabolic acidosis, and hypervolemia.[48] In a large, multicenter ICU study, acute renal failure occurred in approximately 25% of patients who remained in the ICU for more than 48 hours, and approximately 65% of patients with acute renal failure had MODS.[28] Preoperative renal dysfunction is the single most important predictor of renal failure postoperatively. The nature of the surgical procedure also significantly affects the incidence of postoperative acute renal failure with the highest incidence in patients who have undergone cardiopulmonary bypass or surgery on the aorta and other major vessels.

Renal dysfunction commonly results from acute tubular necrosis (ATN) and/or decreased perfusion caused by hypovolemia or shock. The urine sediment can be helpful in diagnosing ATN, which causes granular or "muddy" casts in the urine. Urine electrolytes can be useful for diagnosing a low flow state or prerenal azotemia which, provided that the patient is not receiving a diuretic and does not have intrinsic renal disease, will show a low fractional excretion of sodium. Other causes of acute renal dysfunction in MODS patients include circulatory endogenous toxins such as myoglobin in patients with rhabdomyolysis, nephrotoxic drugs such as aminoglycosides or amphotericin B, IV contrast agents for imaging procedures, and cholesterol emboli caused by manipulation of the diseased aorta. The mortality in MODS patients with renal failure is high, particularly in the context of either cardiovascular or respiratory failure.[2,28]

Hepatic

A variety of hepatic disturbances may occur in noncirrhotic patients with MODS. These include elevation of liver enzymes, hyperbilirubinemia, hypoglycemia, and impaired synthesis of proteins, including clotting factors. Hepatic dysfunction may complicate MODS in several ways. First, patients with cirrhosis fare poorly when they develop MODS and have a particularly high mortality. Mortality rates in excess of 80% have been reported in cirrhotic patients with either coma, renal failure, CV instability, or acute respiratory failure.[49] Second, liver failure often worsens in critically ill cirrhotic patients. Third, a coagulopathy and a propensity for bleeding may result from decreased synthesis of clotting factors by the liver, in addition to DIC (described in the following section on Hematologic Disseminated Intravascular Coagulation). Fourth, acute liver failure can also cause MODS. MODS resulting from acute liver failure has a very poor prognosis.[50]

Hematologic

Multiple hematologic abnormalities occur in MODS patients, including platelet and coagulation derangements, anemia, and white blood cell abnormalities. Patients commonly exhibit either leucocytosis or leucopenia. Coagulation problems in patients with MODS may arise from impaired hepatic synthesis and/or from increased consumption of coagulation factors, as occurs in DIC. Thrombocytopenia often occurs in DIC, but may also result from decreased production or increased destruction from other causes.

Anemia Anemia may result from acute blood loss after trauma, GI hemorrhage, or surgery. Critically ill patients are often exposed to frequent phlebotomy. Furthermore, inflammatory cytokines may contribute to anemia by limiting the endogenous production of erythropoietin, by directly hindering the production of red blood cells in the bone marrow, and by altering iron metabolism. These observations have led to the development of the term *anemia of critical illness*.

Coagulation Disturbances Coagulopathies are commonly evaluated by measuring the prothrombin time (PT), activated partial thromboplastin time (aPTT), and fibrinogen levels. The PT assesses the function of the extrinsic coagulation pathway and the final common pathway, which requires adequate levels of tissue thromboplastin (tissue factor), factors V, VII, and X, and prothrombin and fibrinogen. The aPTT is used to evaluate intrinsic coagulation and the degree of anticoagulation by heparin, lepirudin, and argatroban. The aPTT is sensitive to deficiencies of factors VIII, IX, XI, and XII.

A prolonged PT or aPTT can be caused by either an absence of coagulation factors or the presence of factor inhibitors. Transfusion with normal plasma should correct a factor deficiency. Factor inhibitors should be suspected when the prolonged PT or aPTT does not correct, or only partially corrects, when measured using a 1:1 mix of the patient's and normal plasma. Antiphospholipid antibodies (e.g., lupus anticoagulant) can also produce a prolonged aPTT that is not corrected by normal plasma infusions. Paradoxically, lupus anticoagulants and the antiphospholipid antibody syndrome carry an increased risk of thrombosis and not bleeding.

Platelet Abnormalities Platelets play a vital role in hemostasis by form-

ing a mechanical plug at the site of vascular injury. Three basic mechanisms are responsible for thrombocytopenia in critically ill patients: decreased platelet production, increased platelet destruction or sequestration, or dilution. Decreased platelet production may be caused by underproduction of thrombopoietin caused by liver disease, suppression or damage of the bone marrow by viral infection, drugs, or toxins (e.g., alcohol, chemotherapy, radiation therapy), nutritional deficiencies (folate, cobalamin), and congenital or acquired disorders of hematopoiesis. Increased platelet destruction can cause thrombocytopenia in patients with the systemic inflammatory response syndrome (Table 76–2 lists the SIRS criteria) resulting from infectious and noninfectious processes. Possible mechanisms include a shortened life span because of immune-mediated platelet destruction and DIC. Transfusion with banked blood for massive blood loss can cause dilutional thrombocytopenia. Thrombocytopenia may also be a result of sequestration of platelets in the liver, spleen, and in patients with acute respiratory failure, lungs.[51]

Drug-induced thrombocytopenias may be hard to diagnose because many drugs can impair platelet production rates, and critically ill patients often receive multiple medications. Heparin-induced thrombocytopenia (HIT) is common in critically ill patients. There are two types of HIT. Type I HIT occurs in 10–20% of patients who receive unfractionated heparin. Nonimmune mechanisms cause a decrease in platelet counts from 1–4 days after initiating heparin therapy. The platelet nadir in type I HIT is >100,000/μL, and platelet counts generally normalize promptly after discontinuation of heparin. Type I HIT is not associated with hemorrhagic or thrombotic sequelae.

Type II HIT occurs in 1–3% of patients who receive unfractionated heparin and is associated with more catastrophic sequelae. Type II HIT generally occurs 5–10 days after initiation of heparin therapy, and is mediated by antibodies. Type II HIT is diagnosed by testing for heparin-platelet–associated antibodies. In type II HIT, 30–80% of patients experience thrombotic sequelae, including venous and arterial thromboses. Life-threatening pulmonary embolism occurs in 25% of patients who exhibit thrombosis.[52] Treatment of HIT involves discontinuation of all heparin administration, including both unfractionated heparin and low-molecular-weight heparins, to avoid thrombotic sequelae, and the use of alternative anticoagulants. Anticoagulant alternatives for patients with HIT include lepirudin, argatroban, and fondaparinux. Lepirudin and argatroban are direct thrombin inhibitors.[53] Lepirudin is cleared by the kidneys, whereas argatroban is cleared by the liver. Thus the choice of one agent over another depends on the patient's renal and hepatic function. Both agents have short plasma half-lives (80 minutes for lepirudin and 40 minutes for argatroban) allowing for rapid reversal of anticoagulation after administration is stopped. Platelets should never be given to patients with type II HIT because of an increased risk of thrombosis after platelet transfusions.

Disseminated Intravascular Coagulation The coagulation–fibrinolytic systems are active in SIRS. DIC is common in sepsis, occurring in up to 70% of patients with septic shock.[54] In DIC, there is simultaneous activation of both the coagulation and fibrinolytic systems. Activation of the fibrinolytic portion of the clotting system can lead to hemorrhage including widespread oozing of blood, and excessive bleeding from surgical wounds and sites of other invasive procedures. The activation of coagulation can result in thrombosis, particularly of the microvasculature. One dramatic manifestation of thrombosis is digital necrosis, which can be severe enough to require amputation. It is believed that microvascular thrombosis causes impaired oxygen delivery to tissues and resultant ischemia, which is postulated to contribute to the development of organ dysfunction.

The diagnosis of DIC is suggested by prolongation of the PT and/or the partial thromboplastin time (PTT) and a reduction in the platelet count. Elevated D-dimer and reduced plasma fibrinogen levels provide useful supplemental diagnostic tests, but they may not be diagnostic of DIC. For instance, D-dimers are elevated in patients with DIC, but are also increased in postoperative patients and in patients with deep venous thrombosis (DVT) or pulmonary emboli. Fibrinogen levels are often decreased in patients with DIC, but may be increased by inflammatory processes leading to normal or even elevated fibrinogen levels in some patients with DIC.

Neurologic

Alterations of consciousness frequently occur in patients with MODS. Central nervous system manifestations range in severity from mild confusion and lethargy or agitation to frank coma. It is estimated that CNS disturbances occur in approximately 70% of patients with sepsis.[55] The presence of severe neurologic impairment, as manifested by a Glasgow Coma Scale score <6, in the context of MODS has been shown to be associated with a high mortality rate (≥70%).[2]

Patients with MODS may also develop neuromuscular disorders including profound weakness. Complications of these neuromuscular disorders include difficulty weaning from mechanical ventilation and a prolonged rehabilitation period.[56]

Critically ill patients frequently require sedative–hypnotic agents and analgesics to treat anxiety, delirium, and pain. Adequate treatment of pain and anxiety is associated with an improved quality of life in ARDS survivors.[57] Patients may receive either intermittent bolus sedation or continuous infusion sedation. Typical sedative medications include narcotics, benzodiazepines, barbiturates, and hypnotic agents such as propofol and ketamine.[58] Delirium is frequently treated with haloperidol. However, atypical antipsychotic agents such as olanzapine, risperidone, and quetiapine are being prescribed with increasing frequency because of their low incidence of side effects in the elderly population.

Metabolic/Endocrine

Patients with MODS may have a variety of plasma electrolyte abnormalities, including hyperkalemia, hypokalemia, hypernatremia, hyponatremia, hypocalcemia, hypomagnesemia, hyperphosphatemia, and/or hypophosphatemia. These abnormalities can result from organ dysfunction, nutritional issues, intravenous fluid composition, and hormonal abnormalities. Renal dysfunction causes a variety of electrolyte abnormalities. Electrolyte abnormalities should be monitored and treated.

Glucose disturbances, including both hyper- and hypoglycemia, are common in critically ill patients. Glucose abnormalities may result from endogenous issues, such as hypoglycemia with liver failure, or from exogenous issues, such treatment with steroids. There is evidence that insulin therapy to achieve tight glycemic control improves outcome in septic patients,[59] and many ICU physicians employ insulin infusion protocols to treat their patients.

Adrenal dysfunction is believed to complicate the course of many critically ill patients, particularly patients with septic shock. Although frank adrenal insufficiency is uncommon, there is evidence that critically ill patients experience a state of "relative adrenal insufficiency," which is characterized by an insufficient adrenal response for the augmented level of stress.[60,61] Many critical care units now use protocols for assessing and treating patients with septic shock for adrenal dysfunction based on studies that suggest an improved outcome with steroid replacement. The evaluation, role, and optimal management of adrenal dysfunction in critically ill patients is an area of intensive current investigation.

Gastrointestinal

Common gastrointestinal disturbances in MODS patients include GI hypomotility and GI bleeding. GI dysmotility may lead to gastric distension, which places these patients at risk of aspiration of regurgitated stomach contents, particularly during intubation. Critically ill patients frequently require nasogastric decompression. In addition, GI dysmotility may lead to an inability to tolerate enteral nutrition and a poor nutritional status.

GI hemorrhage may result from stress ulceration, and critically ill patients that are at risk of stress ulceration should be treated with prophylactic agents (H_2 blockers, proton pump inhibitors, or sucralfate) to reduce their propensity to develop stress ulcerations. Patients may also develop low-grade GI bleeding from mucosal breakdown related to indwelling nasogastric tubes.

MODS and Predisposition to Infections

In addition to MODS frequently being caused by infection, patients with organ dysfunction are at high risk of developing infectious complications.[4] The propensity for patients with MODS to develop infections is postulated to be related to a state of immunosuppression, sometimes called the *compensatory antiinflammatory response*, that occurs in patients with systemic inflammation.

Preventive Strategies

Prevention of MODS is a major goal in managing critically ill patients. Preventive strategies include prompt therapy targeting the underlying source of inflammation, optimizing oxygen delivery to balance the increased demands that accompany SIRS, maintaining adequate tissue perfusion, and providing physiologic support to maintain homeostasis when required. The failure of GI tract barrier function is believed to be involved in the development of sepsis, and studies suggest that early enteral nutrition and special supplements, such as glutamine, may reduce infectious complications in ICU patients.[62–64] The role of selective gut decontamination with antibiotics to prevent bacterial translocation, a process that some believe plays a role in the development of MODS, remains controversial.[65–67]

Managing Patients with Established MODS

Supportive Therapies

Once MODS is established, therapy is primarily supportive and targets specific organs and systems. Consequently, respiratory failure is managed with mechanical ventilation, and the cardiovascular system is supported with transfusion of fluids, vasopressors, and inotropic agents, whereas renal failure is managed with renal replacement therapies. Management of specific organs and systems is discussed later in Preoperative Preparation of Patients with MODS.

Adjunctive Therapies

Numerous studies have tested the effects of agents that interfere with inflammatory responses. Most of these studies focused on SIRS caused by sepsis.

Antimediator therapies Experimental therapies that have targeted specific inflammatory mediators including cytokines such as tumor necrosis factor- or interleukin-1, have not improved patient outcomes in large clinical trials (reviewed in ref. 68).

Adrenal Replacement Therapy Although still somewhat controversial, recent studies suggest that physiologic steroid supplementation improves the outcome in patients with vasopressor-dependent septic shock.[61]

Activated Protein C Activated protein C (APC) infusion is reported to reduce the absolute mortality from 30.8% to 24.7% in patients with severe sepsis,[36] and is approved by the FDA for the treatment of patients with severe sepsis. The results of the APC trial[36] are provocative, particularly given the postulated effects of APC in preventing microvascular thrombosis and subsequent impaired-organ microcirculation. The results of these trials underscore the potential importance of coagulation and the microcirculation in SIRS, and the need to increase the depth of our understanding of the roles of the microcirculation, the endothelium, and the coagulation and inflammatory cascades in MODS. It is not yet clear whether steroids or APC will be useful in the management of MODS as a result of noninfectious causes.

Insulin Therapy Recent studies suggest that surgical ICU patients may benefit from tight glycemic control.[59] Although target plasma glucose values may vary, many ICU physicians use protocols to regulate insulin infusions for glycemic control. A prospective, randomized ICU trial associated the maintenance of plasma glucose concentration between 80 and 100 mg/dL with improved outcome, including lower mortality, fewer infections, decreased transfusion requirements and a shorter duration of mechanical ventilation.[59] More recent data suggest that less stringent glycemic control with target blood glucose levels of less than 140 mg/dL may provide a similar survival advantage to the "tighter" control described in the earlier study.[69]

Nutritional Support Patients with MODS are often profoundly malnourished and require nutritional support. The GI tract is the preferred route of nutrition, in part because it is believed that enteral feeding may have a protective effect by maintaining GI mucosal integrity. MODS patients often do not tolerate enteral feedings well, and

require total parenteral nutrition. Many practitioners advocate continuing tube feeds at a low rate for patients who do not tolerate high-rate feeding to facilitate mucosal integrity.

Hemofiltration for Toxin Removal Recently there has been interest in using continuous venovenous hemofiltration as a means of clearing toxins and inflammatory mediators in sepsis.[70,71]

SURGICAL AND NONSURGICAL PROCEDURES IN PATIENTS WITH MODS

Patients with MODS may require a variety of procedures during their ICU stay. Some procedures may be required to correct the underlying cause of the MODS, such as pancreatic debridement for necrotizing pancreatitis or exploratory laparotomy for bowel necrosis or perforation. Other procedures may be necessary to deal with complications of MODS, for instance a tracheostomy for respiratory failure, a gastrostomy or jejunostomy feeding tube placement for enteral nutrition and medication administration. The timing of procedures should be based on the urgency of the intervention balanced against the precariousness of the physiologic status of the patient. It may be appropriate for nonemergent procedures to be delayed to stabilize patients and to optimize the function of various systems and organs. However, if it is anticipated that a patient will continue to deteriorate, or will fail to improve without a prompt intervention, for instance as with necrotizing fasciitis, immediate surgery may be required, even in the unstable patient.

Common Surgical Procedures in Patients with MODS Based on Etiology

Infection

Infection is the most common cause of MODS. Although some infections, such as urinary tract infections or pneumonia may be treated with antibiotics alone, many infections require either surgical debridement, or surgical or percutaneous catheter drainage. Immediate debridement for necrotizing fasciitis and infectious myonecrosis is of paramount importance, even in unstable patients. Similarly, exploratory laparotomies are performed immediately on patients with sepsis as a result of perforation of the intestines. Other infections that may require surgery include toxic megacolon caused by *Clostridium difficile* colitis, empyema that has failed thoracostomy drainage as a result of a pleural peel or adhesions, and mediastinitis. Abscesses located in the thorax, abdomen, and pelvis may be treated with drainage, either with surgery or using catheters placed under CT or ultrasonogram guidance.

Pancreatitis

Patients with pancreatitis may require surgery for a variety of reasons, including pancreatic necrosis, drainage of pancreatic abscesses or infected pseudocysts, and pancreatic hemorrhage.[72]

Trauma

There are a multitude of processes requiring surgery in trauma patients. Often surgery is performed early in the trauma patient's course, prior to the development of MODS. However, in some situations, surgery may be delayed while the patient is stabilized after the acute injury. Some of these patients will develop MODS prior to definitive procedures for their traumatic injuries, for instance, before pinning of hip fractures or prior to definitive procedures for spine stabilization.

Limb Ischemia–Necrosis

Patients with limb ischemia–necrosis may require fasciotomies, vessel exploration with revascularization (embolectomy or bypass procedures), or amputation.

Burns

Patients require excision and grafting, and other treatments.

Surgical Procedures Stemming from MODS

Patients with MODS often require procedures to deal with their complications or long-term care needs. Common procedures include tracheostomy tube placement for ventilator dependence as a consequence of persistent acute respiratory failure, or issues with profuse secretions, or muscular weakness, and placement of gastric or jejunal feeding tubes for nutritional support and drug administration. Other surgical procedures that are sometimes required include amputations to remove gangrenous digits or distal limbs as a consequence of severe DIC and debridement of secondarily infected wounds.

Nonsurgical Procedures in Patients with MODS

Patients with MODS can require a variety of procedures during their ICU stay. Some procedures are required to treat the underlying etiology of MODS, such as catheter drainage of infected fluid collections in the abdomen, pelvis, or chest. Other nonsurgical procedures may be required to facilitate basic care and to optimize physiologic parameters and implement supportive therapies for failing organs. For instance, central venous, pulmonary arterial, and peripheral arterial catheters may be placed for hemodynamic monitoring and drug administration, and central venous lines for renal replacement therapy. Bronchoscopy may be performed to assist with secretion clearance, and chest tubes may be placed for management of pneumothorax or drainage of pleural fluid collections.

PREOPERATIVE ASSESSMENT AND CONSENT

A thorough preoperative evaluation with prioritization of the importance of the various physiologic derangements is essential in anticipating the needs for every phase of the perioperative period (Table 76–5). Based on a comprehensive preoperative evaluation, the anesthesiologist should (a) determine whether or not additional therapies should be initiated to optimize the patients condition prior to going to the operating room, (b) anticipate and arrange for appropriate transportation of the patient to the operating room, (c) prepare an anesthetic plan for the patient, (d) prepare the operating room in advance for the arrival of the patient, and (e) set up tentative plans for postoperative care. Several of these issues are discussed in more detail in Chaps. 79, 80, and 81.

The preoperative assessment should include a review of past and present medical problems, a targeted physical examination, a complete review of the medications and available laboratory and radiographic data, assessment of the ventilator settings, determining which tubes and lines are present, and, in some cases, clarifying issues

TABLE 76–5.

Preoperative Assessment and Optimization

Organ System	Questions to Answer
Cardiovascular	• Is the patient adequately volume resuscitated? • Does the patient require pressors or inotropic agents to maintain an adequate blood pressure and cardiac output? • Is there any clinical evidence of hypoperfusion
Respiratory	• What are the ventilator settings? • Does the patient need a critical care ventilator intraoperatively?
Neurologic	• What is the patient's baseline neurologic status? • What sedative medication is the patient receiving and will they be continued intraoperatively?
Renal	• Does the patient exhibit renal dysfunction? • If the patient is on renal replacement therapy, what is the volume status, electrolyte balance, and acid–base status?
Endocrine	• Is there any evidence of adrenal insufficiency? • How is the patient's glycemic control?
Hematologic	• What is the patient's hemoglobin/hemacrit? • What is the patient's coagulation status? • Is the patient receiving anticoagulants? Type?

regarding the plan for resuscitation in the operating room.

Review of Past Medical History

The basic aspects of the past medical history that are important in planning any anesthetic should be reviewed, with careful attention to processes that may complicate the management of the current problems. Preexisting vascular disease, cardiac dysfunction, dysrhythmias, the presence of pacemakers or an implantable cardioverter-defibrillator, preexisting respiratory disease, and cirrhosis may all profoundly impair the response of MODS patients to anesthesia and surgery.

Review of Recent History

Clearly identifying the underlying diagnosis and a thorough knowledge of the inciting event(s) and all of the organs and systems that are involved is a crucial part of the preoperative assessment.

Respiratory

The respiratory system is frequently involved in MODS. Information about the degree and nature of respiratory dysfunction and past responses to different ventilation strategies should be actively sought out. In addition, the chart should be reviewed for information on the airway, including anatomical issues with intubation, difficulties with the endotracheal tube or cuff, quantity and frequency of suctioning of respiratory secretions, and any need for cervical spine immobilization.

Circulation

Critically ill patients have myriad cardiovascular problems, including hypotension, hypertension, dysrhythmias, and myocardial ischemia/infarction. The preoperative assessment should seek knowledge about the patient's current hemodynamic status, including intravascular volume status, myocardial function, and peripheral vascular tone. Bedside clinical assessment can provide useful information about global perfusion. Indications of decreased perfusion include oliguria, clouded sensorium, delayed capillary refill, and cool skin. However, organ dysfunction and regional hypoperfusion can occur in the absence of overt signs of global hypoperfusion.[73] Elevated blood lactate concentrations may reflect anaerobic metabolism caused by hypoperfusion and an increasing trend of lactate concentrations may be an excellent indicator of septic shock. The central venous pressure may adequately reflect intravascular volume status in some patients, but may not correlate well with intravascular volume status in the context of cardiac dysfunction, pulmonary hypertension, or elevated intraabdominal or intrathoracic pressures. Patients with these problems may require a pulmonary artery catheter or echocardiography to help estimate their volume status, ventricular filling, myocardial function, and vasomotor tone.

The preoperative assessment should gain information about hemodynamic lability and dysrhythmias, and responses to vasopressors, inotropes, and fluids. The electrocardiogram (ECG) should be examined for evidence of myocardial ischemia or infarction, conduction delays or blocks, and dysrhythmias.

Renal

Renal dysfunction or failure should be noted and consequent metabolic and intravascular volume disturbances should be identified. Volume status, electrolyte balance, and acid–base status should be assessed. The heart should be auscultated for the presence of a pericardial friction rub, which is evidence of significant uremia, and lungs should be examined for evidence of pulmonary edema resulting from volume overload or increased vascular permeability. Patients with renal failure may be hypervolemic, hypovolemic, or euvolemic, and they may have a narrow margin for error in fluid management. Although physical examination may be used to help determine the fluid status in the stable patient, in critically ill patients, continuous invasive hemodynamic monitoring is often required. Although these patients are often total-body-volume overloaded, they may also be intravascularly depleted. The degree of renal failure, including the BUN and creatinine, plasma potassium, arterial blood pH, and urine output rate, should be assessed.

In patients receiving renal replacement therapy, the type of therapy—CVVH, CVVHD, or intermittent HD—should be noted. If the patient is on HD, the frequency and timing of the last dialysis should be noted. The ability of the patient to tolerate being without continuous forms of renal replacement therapies should be assessed to guide decisions regarding continuation of CVVH or CVVHD in the operating room. Because hemofiltration removes virtually all the ions from the plasma, including calcium, magnesium, and bicarbonate, their levels should be measured often and replaced when appropriate. Phosphate elimination is dependent on renal excretion. Phosphate binders and dietary restriction are often used to control the phosphate levels of patients with chronic renal failure. Because phosphate is also cleared by CVVH, pro-

found hypophosphatemia may occur leading to muscle weakness, increased susceptibility to muscle relaxants, and respiratory muscular insufficiency. Potassium elimination is also dependent on renal excretion. Hyperkalemia can lead to life-threatening arrhythmias. Aggressive preoperative dialysis can cause hypokalemia, producing increased myocardial excitability, a reduced arrhythmia threshold, and the precipitation of supraventricular or ventricular arrhythmias.

A chronic metabolic acidosis can occur in patients with chronic renal failure. While the acidosis is usually mild and well-compensated, profound acidemia can occur in patients with shock because of a diminished buffering capacity. During hemofiltration, bicarbonate is lost to the ultrafiltrate and is usually replaced in the form of lactate which is metabolized to bicarbonate. In patients with severe lactic acidosis, lactate will increase the plasma lactate concentration and decrease arterial pH. In these patients, bicarbonate ions should be provided directly and lactate should not be given.

Uremia is associated with platelet dysfunction due to impaired release of a macromolecular complex of von Willebrand factor and factor VIII from the capillary endothelium, which is necessary for normal platelet aggregation and clot formation. This form of platelet dysfunction is improved by dialysis, or the infusion of cryoprecipitate, 1-deamino-8-D-arginine-vasopressin (DDAVP), or estrogen conjugates.

Hepatic

The presence of hepatic dysfunction can have important effects on a patient's response to stress and surgery. Hepatic failure can cause diverse problems, including hypoglycemia, coagulation disturbances, and impair processing of drugs and toxins. A variety of blood studies should be performed preoperatively, including: plasma coagulation studies (PT/PTT), blood glucose, bilirubin, and transaminase levels to assess the degree of liver injury and failure.

Hematologic

Anemia, thrombocytopenia, and coagulation dysfunction are common problems in the ICU that should be identified, and in some cases corrected, preoperatively. It may be necessary to assess the hemoglobin, platelet count, and coagulation studies immediately prior to surgery. The patient's medication record should be reviewed for anticoagulants such as heparin (high- or low-molecular-weight), Coumadin (warfarin), thrombolytic agents, and antiplatelet drugs.

Metabolic/Endocrine

Major metabolic and endocrine disturbances and recent use of steroids should be identified preoperatively. The acid–base status should be analyzed. Appropriate preoperative chemical studies in MODS patients should include plasma potassium, sodium, chloride, bicarbonate, calcium, magnesium, phosphate, glucose, and arterial blood gases (pH, $Paco_2$, Pao_2).

Insulin infusions are often used in critically ill patients to achieve glucose control. The insulin infusion rate should be noted as well as how frequently the rate needs to be adjusted.

Neurologic

The preoperative evaluation should include an assessment of baseline neurologic function and the frequency and dose of sedative–hypnotic and analgesic agents. Dosages and rates of infusions should be noted, and decisions should be made whether or not these agents should be continued intraoperatively. Narcotic, benzodiazepine, and hypnotic infusions used in the ICU may be titrated intraoperatively as part of the anesthetic, or alternative agents can be used.

Infection

The presence of infection, including the site and severity should be noted. Patients who are actively infected often have more pronounced hemodynamic depression with anesthetic administration. In addition, if the purpose of the surgery is source control, manipulation of the infected site may precipitate instability, including hypotension, metabolic acidosis, DIC, and/or worsening respiratory dysfunction. This is postulated to result from the release of bacteria and/or bacterial toxins into the circulation. Patients with baseline hemodynamic instability may become profoundly unstable during or after manipulation of the infected site.

Physical Examination

The respiratory system evaluation should include visual assessment of the airway and the respiratory pattern and auscultation of breath sounds. Visual inspection should be performed to assess for respiratory distress, as evidenced by tachypnea, labored breathing with use of accessory respiratory muscles, and the inability to clear respiratory secretions. The airway should be examined with attention to positioning and fixation of the endotracheal tube, ability to open the mouth, degree of oropharyngeal edema, deviation of the trachea, and the dental situation. The chest should be auscultated, and abnormalities such as wheezing caused by bronchospasm, rales caused by pulmonary edema, and rhonchi caused by secretions, should be noted.

The positions of drainage tubes and catheters (e.g., chest tubes, percutaneous catheters) and the locations of arterial, peripheral venous, central venous, and pulmonary arterial catheters should be noted. Pressure sores and areas of skin breakdown should be identified in order to plan for appropriate padding to provide protection in the operating room.

Review of Monitors

A review of the monitors and lines already present, including locations, trends of important hemodynamic parameters (e.g., blood pressure, heart rate, central venous pressure, peak airway pressure, pulmonary capillary wedge pressure, cardiac output, stroke volume), and any issues with the monitors is necessary to plan for the perioperative period. In addition to standard ICU monitors, including a pulse oximeter, ECG, and noninvasive blood pressure, monitors that are commonly used in patients with MODS include intraarterial catheters, central venous and/or pulmonary artery catheters, and intracranial pressure monitors.

Review of Scheduled Medications and Infusions

All medications should be reviewed. There should be close attention to continuous drug infusions, including rates of infusions, the lines being used for infusions, and their compatibility with drugs that will be infused in the operating room. Because abrupt cessation of total parenteral nutrition (TPN) can cause hypoglycemia, plans should be made to either continue the TPN infusion in the operating room, or to

provide another continuous source of sugar, such as an infusion of a 10% aqueous dextrose solution ($D_{10}W$).

Laboratory and Radiographic Data

As MODS can involve many different organs, the basic laboratory data to review should include recent values of electrolytes (Na^+, K^+, Cl^-, HCO_3^-, ionized Ca^{2+}, Mg^{2+}), BUN and creatinine, hemoglobin or hematocrit, coagulation studies, and an electrocardiogram. Liver-function studies, including transaminases and bilirubin levels also may be useful. All pertinent radiographic data should be reviewed, and the chest radiograph should be visualized to assess appropriate endotracheal tube positioning and seek evidence of infiltrates, pulmonary edema, pneumothorax, and pleural fluid.

Ventilator Settings

Most patients with established MODS have respiratory dysfunction or failure requiring mechanical ventilation. Ventilator settings should be noted in detail, including the mode of ventilation (controlled vs. spontaneous ventilation, pressure vs. volume ventilation), the ventilator rate, the FiO_2, the level of positive end-expiratory pressure (PEEP), tidal volume and airway pressures, and inspiratory-to-expiratory (I:E) ratios or inspiratory time.

Patients who are intubated for airway protection, to facilitate secretion clearance, or for profound weakness may be on minimal ventilatory support and should not have major issues related to ventilation. In contrast, patients with moderate to severe respiratory failure (ALI or ARDS) may be receiving high levels of ventilatory support, and may not tolerate changes of ventilation strategies or even abbreviated periods without ventilation. For patients with major ventilatory requirements, it may be necessary to continue the same mode of ventilation in the operating room as was used in the ICU. Often the standard operating room ventilators are inadequate for patients with severe respiratory failure. Thus arrangements should be made to transport the ICU ventilator to the operating room, or the operating room should be equipped with a ventilator that can produce identical ventilatory conditions.

Generally, patients receiving ventilation with high levels of PEEP should travel with a PEEP valve in place. In patients with severe respiratory failure, it may be necessary to perform a trial of manual ventilation in the ICU prior to transporting to the operating room, and in some situations it may be appropriate to perform the surgical procedure in the ICU. For instance, in many centers, percutaneous tracheostomies are now performed at the bedside in the ICU.

Consent for Anesthesia

Unless the surgery is emergent, informed consent must be obtained from either the patient or from a designated surrogate if the patient is unable to give consent.

Resuscitation Status

Occasionally, critically ill patients who have a do not resuscitate (DNR) order require surgical procedures. In some cases, based on the wishes of the patient or their surrogate decision maker, the DNR status is suspended for the intraoperative and immediate postoperative period. This is based on the notion that acute, but reversible intra- and postoperative events, as opposed to the underlying process, may precipitate a cardiac arrest during and immediately after surgery. It is important to clarify whether or not the ICU DNR status will remain in effect or will be suspended in the operating room.

PREOPERATIVE PREPARATION OF PATIENTS WITH MODS

Whenever possible, efforts should be made to correct reversible physiologic derangements and optimize the patient's condition prior to surgery (see Table 76–5). Some examples of situations that may require preoperative optimization include cardiovascular instability, respiratory failure, bronchospasm, renal failure, coagulopathy, severe thrombocytopenia, significant electrolyte imbalances, and hyperglycemia or hypoglycemia.

Immediate versus Delayed Surgery

Depending on the degree of physiologic/metabolic derangements resulting from organ dysfunction and the urgency of a surgical procedure, it may be appropriate to delay surgery to provide time for optimization. The risk-to-benefit ratio of doing immediate surgery, versus delaying surgery for optimization must be carefully assessed. The extremes are usually fairly obvious: Totally elective surgery should not be performed until the patient's physiologic/metabolic situation has been fully optimized, whereas emergency surgery, such as for a ruptured aortic aneurysm or necrotizing fasciitis, needs to be performed before or during optimization. For urgent surgery, there may be a few hours available to improve preoperative physiologic/metabolic parameters. The amount of time available for optimization depends on the surgical procedure and the patient's status, among other variables (e.g., operating room availability). Decisions regarding the timing of urgent surgery should be made with close communication between the anesthesiologist, the surgeon, and the intensivist.

Respiratory

A variety of respiratory issues may complicate transport, intraoperative management, and postoperative care of patients with MODS. Bronchospasm should be treated aggressively with bronchodilators. For intractable bronchospasm, a short course of steroids should be considered. Copious secretions should be treated with suctioning, and possibly bronchoscopy, and the secretions should be cultured. Antibiotics may be appropriate if cultures of purulent secretions are positive and the clinical scenario is consistent with pneumonia or tracheobronchitis. Consideration should be given to intubating patients that have a tenuous respiratory status prior to transport to the operating room. A chest tube should be placed if a pneumothorax is present and the patient is to be given positive pressure ventilation.

Because mechanical ventilation with positive pressure is not a normal physiologic process, it can reduce cardiac output or lead to ventilator-associated lung injury[74] and may play a role in causing or worsening MODS.[75] The precise manner in which patients with ARDS are mechanically ventilated can significantly affect their outcome. A large, multicenter, prospective trial demonstrated that in patients with ALI, mechanical ventilation with low tidal volumes (6 mL/kg ideal body weight) was associated with decreased mortality, improved respiratory function, and decreased MODS.[76] The

ARDS Network strategy of limiting tidal volumes and airway pressures is employed by most ICU physicians. The current standard for mechanical ventilation (Table 76–6) for patients with ARDS includes setting the tidal volume to ≤6 mL/kg predicted body weight, the plateau pressure to ≤30 cm H_2O, and adjusting the respiratory rate to achieve an arterial pH ≥7.30 when possible.[77] These volume and pressure goals may need to be modified based on the patient's thoracoabdominal compliance, which can markedly affect chest wall compliance. PEEP should be titrated to maintain the FiO_2 below 60% to reduce the toxic effects of oxygen exposure on the lung. Recommended oxygenation goals are to achieve an arterial partial pressure of oxygen (Pao_2) from 55–80 mm Hg or an oxyhemoglobin saturation (SpO_2) by pulse oximetry from 88–95%. A minimum amount of positive end-expiratory pressure (PEEP) of 5–10 cm H_2O should be applied to prevent lung collapse at end-expiration.

Hypercapnia may be required in patients with ALI/ARDS to minimize plateau pressures and tidal volumes. No upper limit for the arterial partial pressure of CO_2 ($Paco_2$) has been established. Although some authorities recommend maintaining an arterial pH of 7.20–7.25, this has not been prospectively established. The use of hypercapnia should be limited in patients with preexisting metabolic acidosis and is contraindicated in patients with an increased intracranial pressure.

Several other therapies have been investigated in patients with severe ARDS. Inhaled NO selectively vasodilates areas of the pulmonary vasculature that are in contact with ventilated alveoli and thus decreases ventilation–perfusion mismatch and improves oxygenation. Because studies have not shown a reduction in mortality rate with NO treatment, and because the effect of inhaled NO on oxygenation may be limited to the first 24–48 hours of therapy, the use of NO is usually limited to rescue therapy in patients with life-threatening hypoxemia or pulmonary hypertension who are not responding to traditional therapy.[78] Similarly, prone positioning in respiratory failure is considered to be a rescue option for patients who are particularly difficult to oxygenate.[79] High-frequency oscillation ventilation has theoretical advantages of providing low tidal volumes, thus mitigating the adverse effects of conventional ventilation, such as overdistension and the repetitive opening and closing of collapsed lung units. Although high frequency oscillation used as salvage therapy may improve oxygenation, especially in patients with large bronchopleural fistulas, it has not been shown to improve mortality rates in ARDS.[15] Whether these adjunctive therapies are continued in the operating room requires a risk-to-benefit assessment. For example, gradual weaning from inhaled NO may be required to avert adverse rebound effects such as acute oxyhemoglobin desaturation, increased pulmonary artery pressures, and systemic hypotension.[16]

Patients with an abdominal compartment syndrome may develop severe respiratory dysfunction as a result of high intraabdominal pressures. These patients often benefit from a strategy of controlled ventilation with moderate PEEP, and may require neuromuscular blocking agents. In addition, distension of the abdominal contents into the thorax may alter airway anatomy with a resultant mainstem intubation. This possibility should be considered if there is a sudden increase in airway pressures or reduction in tidal volume when these patients are receiving volume-controlled and pressure-controlled modes of ventilation, respectively.

Ventilators on conventional anesthesia machines may be unsuitable for use in the critically ill patient with respiratory failure. For example, some ventilators do not have an integrated method of applying varying quantities of PEEP. Other ventilators may predispose the patient to barotrauma because while they may have a high-pressure alarm, they do not have a pressure-limiter in the breathing circuit. The set tidal volume may not be the delivered volume be-

TABLE 76–6.

Optimal Ventilator Setting for Patients with Acute Lung Injury or Acute Respiratory Distress Syndrome

Ventilator Mode	Volume Assist Control
Tidal volume	6 mL/kg of predicted body weight
Plateau pressure	≥30 cm H_2O
Ventilator rate	6–35 breaths/min to achieve pH goal of 7.3–7.45
I:E ration	1:1–1:3
Oxygenation	PaO_2 55–80 mmHg
	SpO_2 88–95%
FiO_2/PEEP combinations	0.3 and 5
	0.4 and 5

cause of gas compression losses in the breathing circuit due to its compliance. Furthermore, at high gas flow rates, the contribution of fresh gas during the inspiratory phase may significantly increase tidal volumes and airway pressures. In addition, advanced modes of ventilation such as pressure control ventilation may not be available. Thus, one must preoperatively assess whether the patient can be adequately ventilated using the ventilator present on the anesthesia machine or whether a critical care ventilator should be supplied in the operating room. The main disadvantage of employing a critical care ventilator is that inhaled anesthesia agents cannot be easily given.

Cardiovascular

Patients with MODS may have hemodynamic instability as a result of impaired myocardial function, decreased systemic vascular tone, hypovolemia, and/or restrictive and obstructive processes that impair ventricular filling. Anesthesia and surgery may further exacerbate the hemodynamic issues, or may introduce new hemodynamic problems. For instance, many anesthetics can impair myocardial contractility and reduce vascular tone. Also, patients may become more hemodynamically unstable during and after the manipulation of infected sites. The hemodynamic effects of blood loss and third-space fluid losses may be more pronounced, particularly in patients with underlying myocardial dysfunction, a low peripheral vascular tone, or pulmonary hypertension.

Preoperative optimization should focus on correcting intravascular hypovolemia. Prior to volume repletion, patients with septic shock may have a combination of low peripheral vascular tone, low cardiac filling pressures, and decreased stroke volume. A hyperdynamic picture only emerges after volume resuscitation. Often patients with MODS have significant ongoing volume requirements because of bleeding or extravasation of intravascular fluid into the extravascular space resulting from capillary leakage following systemic inflammation. Such patients may require up to 10 L of crystalloid or other solutions for initial resuscitation. Hypovolemia should be corrected with balanced electrolyte solutions and/or blood products, depending on the etiology and associated issues (such as a coagulopathy).

Fluid infusion alone will reverse the hypotension and restore hemodynamic stability in roughly half of the septic patients who present with hypotension.[73] However, infusion of pressors and/or inotropic agents may be required in patients with myocardial dysfunction and/or low peripheral vascular tone to optimize cardiac performance and tissue perfusion. If appropriate amounts of fluid resuscitation fail to promptly restore adequate systemic blood pressure and organ perfusion, therapy with vasopressor agents should be immediately commenced.[73] Inotropic agents such as dobutamine can be added to augment cardiac output, particularly in patients with a low cardiac output.

Patients with MODS will often have peripheral arterial and central venous catheters inserted in the ICU. In some cases thermodilution pulmonary artery catheters (PACs) may be indicated for preoperative optimization, and/or for intraoperative and postoperative care. For example, a PAC may be extremely helpful in patients with significant myocardial dysfunction, pulmonary hypertension, constrictive or restrictive cardiac processes, or renal failure who are undergoing major surgery. In addition, patients with underlying cardiac disease or pulmonary hypertension undergoing vascular procedures that will involve cross-clamping of the aorta may benefit from a PAC to optimize management of the extreme hemodynamic perturbations that occur with clamping and unclamping the proximal aorta.

It is often appropriate to place the PAC in the patient in the ICU prior to surgery. The data from the PAC will provide information about the patient's current hemodynamic state and physiologic reserves, as well as responses to therapy. In addition, the hemodynamic data measured with the PAC may be used to optimize the patient's volume status, myocardial function, and level of systemic vasomotor tone. A full description of indications for PAC placement is found in Chap. 79.

Renal

Patients with renal failure may have a variety of metabolic and physiologic problems. Goals for renal optimization prior to surgery include correction of metabolic and physiologic derangements related to renal failure, and protecting the kidneys from further damage.

Whenever possible, acid–base and electrolyte disturbances, including hyperkalemia and hypernatremia, should be corrected prior to surgery. Some patients with renal failure may require preoperative renal replacement therapy to treat metabolic acidosis, electrolyte imbalances, uremic pericarditis, or volume overload. Hyperkalemia should be corrected, either with binding agents such as sodium polystyrene sulfonate, or with renal replacement therapy. Consideration should be given to infusing DDAVP to correct uremic platelet dysfunction.

Both CVVH and intermittent hemodialysis are employed in critically ill patients who require renal replacement therapy. However, in the unstable patient, CVVH is preferred because it is better tolerated hemodynamically and allows continuous control of fluid balance and toxin removal. In hemofiltration, blood under pressure passes along one side of a highly permeable membrane that allows transfer of both water and substances below a molecular weight of approximately 20,000 daltons.[80] Urea, creatinine, and phosphate are cleared from the blood at similar rates. Larger molecules, such as heparin, insulin, and vancomycin, are also cleared. The filtrate is discarded and the patient receives a replacement fluid comprised of physiologic levels of the major crystalloid components of plasma. Total-body-fluid balance is regulated by varying the amount of replacement fluid the patient is given.

A variety of factors may negatively impact on kidney function, particularly the already failing kidney. The intravascular volume status, ongoing systemic inflammation, infusions of nephrotoxins such as intravenous contrast agents for vascular procedures and aminoglycosides for infections, and manipulation of the aorta which can lead to cholesterol emboli to the kidneys all can contribute to worsening renal dysfunction in the perioperative period. Preventive measures include preoperative optimization of intravascular volume and when possible, avoidance of nephrotoxins. In patients with acute renal failure who are to receive an IV contrast agent, preemptive strategies, including volume loading, alkalinization

using IV $NaHCO_3$, and/or administration of *N*-acetylcysteine should be undertaken.[81]

Hepatic

Patients with hepatic dysfunction have a variety of issues that should be dealt with prior to surgery if possible. Hypoglycemia should be identified and plasma glucose levels should be maintained in a normal range using a dextrose infusion. Severe coagulopathy should be corrected prior to major surgery. Hepatic encephalopathy should be treated with lactulose.

Hematologic

Critically ill patients often have hematologic disturbances, including anemia, coagulopathy, and thrombocytopenia. The preoperative management of anemia, coagulation disturbances, and thrombocytopenia will depend on the cause and severity of the disturbance, and the nature of the surgery. The anesthetic plan should take into account the anticipated blood loss for the procedure, the risks and benefits of stopping anticoagulant therapy preoperatively, and the need for transfusing red cells or other blood products both preoperatively and intraoperatively. If transfusion of blood or blood products is anticipated, an adequate recipient sample should be available in the blood bank for typing and crossmatching and the availability of sufficient supplies of blood products should be confirmed preoperatively. Patients who have had multiple transfusions may have developed circulating antibodies to non-ABO antigens. A consultation with a blood bank physician may be needed to select appropriate blood components for transfusion.

Anemia

Red blood cell transfusions are given to augment the delivery of oxygen to the tissues and avoid the deleterious effects of oxygen debt. However, critically ill patients are at increased risk for complications of transfusion therapy, including the immunosuppressive effects that may predispose to infections, and microcirculatory complications. Current recommendations are that in the absence of active coronary artery disease red blood cell transfusion should only be given when the hemoglobin level decreases to 7.0 g/dL and should target a circulating hemoglobin level of 7.0–9.0 g/dL.[82,83]

Coagulopathy

A coagulopathy may result from consumptive processes, such as DIC, or from decreased factor production, as occurs in hepatic failure. Plasma product infusions are indicated to correct hemostasis when bleeding arises from malfunction, consumption, or underproduction of plasma coagulation proteins.[82,84] Prophylactic administration of plasma products may be indicated to correct a coagulopathy before invasive procedures or surgery. If there is active bleeding that is associated with a coagulopathy, plasma products should be administered until bleeding stops or the coagulopathy is reversed. Vitamin K administration is indicated if vitamin K deficiency is present in order to raise the levels of vitamin K-dependent clotting factors (II, VII, IX, and X).

The choice of the plasma product for transfusion depends on the clinical circumstances. In the absence of coagulation inhibitors (including heparin) and in the presence of adequate fibrinogen levels (>100 mg/dL), hemostasis can usually be achieved when the activity of coagulation factors is at least 25–30% of normal. Fresh-frozen plasma (FFP) contains all the plasma clotting factors and is used to correct coagulopathies that result from a factor deficiency, such as occur in liver disease, DIC, or anticoagulation with warfarin. Cryoprecipitate is rich in von Willebrand factor (vWF), factor VIII, factor XIII, and fibrinogen, and is administered to treat congenital and acquired deficiencies of fibrinogen and factor XIII. Cryoprecipitate is a preferred source of vWF and required to manage von Willebrand disease.

Some patients may be receiving anticoagulation therapy (e.g., unfractionated or low-molecular-weight heparin, argatroban, lepirudin) because of DVT, atrial fibrillation/flutter, presence of prosthetic valves, or HIT. If possible, time should be allowed for Coumadin (warfarin) anticoagulation to reverse prior to surgery, which may require several days. For emergent or urgent procedures, the PT can be rapidly corrected with infusions of FFP. If vitamin K is used to reverse the effects of Coumadin (warfarin), very low doses should be administered (~1 mg), as larger doses may make it difficult to re-anticoagulate after the procedure. Patients with severe vascular disease or with coronary artery stents may be receiving antiplatelet agents such as Plavix (clopidogrel) and aspirin. When possible, surgery should be delayed in patients who are on these agents until 7 days after the last dose.

Thrombocytopenia

Platelet transfusions are used to manage patients who are bleeding or who are at risk of bleeding as a consequence of thrombocytopenia or impaired platelet function. Surgical bleeding solely caused by thrombocytopenia usually occurs when platelet counts are below 50,000/μL, and spontaneous bleeding occurs when platelet counts drop below 10,000/μL. However, additional factors, such as a concomitant coagulopathy, fever, renal failure, or treatment with nonsteroidal antiinflammatory drugs, may increase the bleeding risk from severe thrombocytopenia. Consequently, the threshold platelet count for triggering a prophylactic platelet transfusion should take into account these clinical considerations.[82,84]

Metabolic/Endocrine

Acid–Base Status

A variety of acid–base disturbances may be present in patients with MODS, and may complicate intraoperative management and/or be exacerbated by major surgery. For instance, metabolic acidosis may occur during and after surgery that involves significant volume or blood losses during periods of hypovolemia and decreased organ perfusion. Metabolic acidosis may also result from ischemia–reperfusion events, such as relief of vascular occlusion, opening an aortic cross clamp, or releasing a tourniquet on a limb at the conclusion of a peripheral orthopedic procedure.

In the preoperative period, acid–base disturbances should be identified, classified, and if severe should be corrected. Common causes of metabolic acidosis in MODS patients include impaired tissue perfusion due either to hypovolemia and/or hypotension, limb or GI vascular occlusion (e.g., ischemic bowel), renal failure, and administration of large volumes of normal saline. The preoperative management will depend on the degree of acidemia and the underlying etiology. GI or limb ischemia may require surgical intervention. Metabolic acidosis as a result of renal failure may be treated with hemodialysis (or CVVH) and/or bicarbonate, often given as a continu-

ous infusion. Metabolic acidosis caused by hypoperfusion may be treated medically by increasing intravascular volume and/or correcting myocardial or vascular tone problems with inotropic agents or vasopressors, depending on the underlying physiology. Hypovolemia can also cause metabolic alkalosis caused by decreased renal perfusion, and resultant increased secretion of aldosterone, and should be corrected by volume administration.

Depending on the mode of ventilation, respiratory acidosis caused by respiratory failure is often dealt with by increasing the ventilator rate, or by increasing the tidal volume or level of pressure control. However, some patients with severe hypercapnic respiratory failure do not have improved CO_2 exchange with increased rates (high V_{DS}/V_T [dead space gas volume-to-tidal gas volume ratio]). Moreover, currently used ventilation strategies often require patients to have a high $Paco_2$, in an effort to protect the lungs from ventilator-induced lung injury. Although permissive hypercapnia may decrease ventilator-induced lung injury, in the perioperative period, baseline respiratory acidosis may be more problematic because of the propensity to develop a superimposed metabolic acidosis.

Electrolytes

If time permits, electrolyte abnormalities should be corrected prior to surgery. The method of correction is dictated by the nature and source of the abnormality. For instance, CVVH or hemodialysis may be required to correct hyperkalemia. Hypokalemia and hypomagnesemia can generally be corrected using IV supplementation. If surgery is emergent, intravenously treatment with insulin and glucose, and rectal or oral administration of sodium polystyrene sulfonate may be required to treat hyperkalemia.

Glucose

Hyperglycemia and hypoglycemia should be corrected with insulin and glucose infusions respectively. As mentioned earlier in Insulin Therapy, strict glycemic control is practiced in many ICUs, and patients will frequently be receiving insulin infusions to maintain normoglycemia. All patients who are receiving an insulin infusion should also receive an infusion of glucose to prevent hypoglycemia. Consideration should be given to continuing insulin infusions and obtaining frequent blood sugar levels both intra- and postoperatively.

Adrenal Dysfunction

Adrenal insufficiency should be considered in patients that have persistent vasopressor requirements despite adequate intravascular volume repletion and other appropriate therapies. A cosyntropin stimulation test may help to identify patients with inappropriate adrenal responses. Baseline low cortisol levels or a failure to respond appropriately to cosyntropin should prompt consideration of treating patients with persistent vasopressor dependence with low-dose steroids. Patients that have been receiving steroids for sustained periods of time may have suppressed adrenal function, and should receive perioperative "stress-dose" steroids, depending on the nature of their surgery.

PLANNING THE ANESTHETIC AND PREPARING THE OPERATING ROOM FOR PATIENTS WITH MODS

Planning the Anesthetic

As is the case for all procedures, the anesthetic should be carefully planned and should be tailored to the individual patient's constellation of problems/issues. Specific issues regarding developing the anesthesia plan in critically ill patients, and pharmacologic issues in patients with MODS is reviewed in Chaps. 79. Decisions regarding the goals for fluid management can be difficult in patients with MODS. In particular, fluid management of patients with concomitant respiratory failure, worsening renal function, and/or cardiac dysfunction must take into account the often conflicting goals of these systems, and a thermodilution PAC may be useful in achieving an appropriate balance.

Decisions Regarding Continuation of ICU Therapies in the Operating Room

During the preoperative visit, the anesthesiologist should decide whether or not to continue various therapies that are ongoing in the ICU. Some therapies, although required for longer-term management, may not be required for intraoperative management, and may be quite cumbersome to transport. For instance, because CVVH requires equipment and fairly extensive education in its use, it may be appropriate to discontinue CVVH prior to surgery, and to make plans to resume CVVH immediately after the operation. If CVVH is to be continued in the operating room, arrangements will need to be made to have someone with CVVH expertise (usually not the anesthesiologist) to manage CVVH in the operating room. Decisions should be made regarding continuation of TPN, and infusions of drugs such as sedatives, narcotics, vasoactive agents, inotropic agents, and insulin in the operating room. As mentioned in Table 76–5 and in Transporting Patients with MODS to the Operating Room, if the patient requires high levels of ventilatory support or a complicated mode of ventilation, arrangements should be made to have the ICU ventilator accompany the patient to the operating room, and to have someone who is skilled in its use immediately available to assist with ventilatory changes in the operating room.

Preparing the Operating Room

The operating room should be completely ready to receive the patient prior to leaving the ICU. With some patients, arrangements should be made to equip the operating room with the patient's ventilator, or with another ventilator that can achieve identical ventilatory conditions. The operating room should be stocked with the same vasopressors and inotropic agents that the patient is receiving in the ICU.

TRANSPORTING PATIENTS WITH MODS TO THE OPERATING ROOM

Transportation to the operating room can be risky for patients with MODS. This topic is reviewed in detail in Chap. 80. The anesthetist should plan to accompany the patient from the ICU to the operating room, and should carefully plan the trip. Arrangements should be made to continue monitoring appropriate parameters, such as systemic arterial, pulmonary artery, and intracranial pressures. It may be necessary to transport the patient with severe respiratory failure who is receiving high levels of ventilatory support with a ventilator. Transport with a PEEP valve may be appropriate in patients who are PEEP-dependent and who can tolerate

short periods of manual ventilation. If there is uncertainty as to whether or not a patient can tolerate transportation from a respiratory standpoint, a trial of manual ventilation in the ICU prior to transport can be helpful.

SUMMARY

As technology and therapies for basic diseases and acute processes such as shock and respiratory failure advance, a more modern syndrome has evolved. Multiorgan dysfunction syndrome is an enigmatic process that seems to be caused by generalized inflammation and microvascular circulatory abnormalities. The similarity in MODS resulting from either infectious or noninfectious diseases suggests that common pathways are involved. Defining these pathways will likely yield new targets for treatment in critically ill patients.

Anesthesiologists are frequently involved in the care of patients with MODS, either in the ICU or in the operating room. MODS patients often require surgery, either for the primary process or to deal with complications. The anesthesiologist will be involved in the decisions regarding the timing of surgery, and in optimizing the patient for surgery. Communication between the anesthesiologist, the ICU team, and the surgeon is crucial as part of the preoperative preparation.

Prior to transport to the operating room a comprehensive plan that is tailored to the patient's individual constellation of abnormalities should be in place. Preoperative planning should include decisions regarding continuation of therapies such as CVVH, TPN, insulin; arrangements for the patient's ventilator to accompany the patient to the operating room if appropriate; sedation and analgesia; availability of appropriate fluids, blood products and monitoring equipment; and a clear understanding of the plan regarding perioperative resuscitation for cardiac arrest or catastrophic events. Preoperative and intraoperative interventions will be dictated by the pattern and intensity of organ failure.
