All three of the ^{133}Xe-based techniques have been combined with the measurement of arterial and venous blood samples to permit calculation of CMR, with calculations identical to those described above. However, there is one caveat. If CBF and the venous samples represent the same tissue compartment, there are no problems. If not, beware. Blood from the jugular bulb is representative of blood draining the whole brain (with some hemispheric predominance, particularly in the presence of severe unilateral injury).[709] However, none of the ^{133}Xe washout methods, strictly speaking, measure whole-brain or hemispheric CBF; typically they yield a CBF value that is dominated by the cortical mantle. Hence the calculation of CMR involves multiplying a whole-brain arteriovenous difference value by an rCBF value. As long as regional and global CBF change in parallel (e.g., during anesthetic administration), calculations of CMR should be reasonable (although the absolute values may differ from those based on Kety-Schmidt flows). If the intervention or disease process being studied results in major flow redistribution or regional heterogeneity, calculated CMR may be misleading.

Transcranial Doppler Sonography

Doppler-based methods for assessing blood flow in many vessels have been used for decades. These typically involved the use of "continuous wave" Doppler methods, with the probe being placed very close to the vessel of interest. However, in the early 1980s, "pulsed-wave" methods were developed. With this method, packets (brief bursts) of sound are emitted, with an interim period of silence during which the reflected signal is awaited. The time needed for the "round trip" can be used to measure the distance from the probe to the target—and by adjusting the time interval during which the instrument will accept a returning signal ("range gating"), the Doppler signal can effectively be focused on a target a given distance away. This is the basis for transcranial Doppler (TCD) sonography.[52,531] In practice, a hand-held Doppler probe is placed over a thin area of the skull (a "window"). By adjusting the insonation angle and depth it is possible to identify flow signals from multiple cerebral vessels. For example, from the temporal window, it is relatively easy to record signals from the internal carotid, middle cerebral, and anterior cerebral arteries. Other vessels can be found via other windows (e.g., transorbital, occipital). This method has been used extensively to aid in the diagnosis of cerebral occlusive disease.

Physiologic and pharmacologically induced changes in CBF have been assessed by following the changes in TCD signal from a single vessel during some intervention. This is typically done using the middle cerebral artery (MCA). The probe is placed over the temporal window, and the MCA is identified as it moves toward the probe (which means a high-intensity signal can be recorded as the focal depth is adjusted over a range sometimes as great as 10 mm (e.g., from 45 to 55 mm from the skin). Since red blood cells (RBCs) are moving almost directly toward the probe, the insonation angle is essentially zero, and flow velocity is proportional to absolute flow (although absolute flow can't be known without knowing vessel diameter). If probe position is fixed, changes in flow velocity (denoted as V_{mca}) can be measured during various interventions (e.g., drug administration, CO_2 changes). As long as the depth and insonation angle remains constant—and as long as the number of interventions is kept to a minimum—multiple studies have shown that changes in V_{mca} parallel changes in absolute CBF as measured with more traditional methods.

It can be argued that TCD has now become the preferred method for examining the acute impact of anesthetic agents and adjuncts on CBF.[202,390,450,756] It is also being increasingly used as a monitor during carotid surgery,[435] to aid in the diagnosis of vasospasm in patients with subarachnoid hemorrhage (where a decrease in vessel diameter results in an increase in flow velocity),[491] and to measure flow and detect emboli during cardiac surgery.[114,588,766] We comment more on TCD measurements in our discussion of physiology and anesthetic effects below. However, it is important to understand that this method does not yield absolute flow values—only flow velocities. Its primary advantages are its noninvasiveness, nonradioactive nature, and its ability to monitor at least an index of CBF continuously, something that cannot be done with any other widely used method.

Although it is possible to multiply a V_{mca} value by an arteriovenous content difference, the resultant number cannot be called "CMR." V_{mca} is a velocity measurement (in cm/sec), not absolute flow (in mL/100g/min). In addition, we have little or no information on the tissue compartment being perfused by the insonated vessel. Beware of manuscripts that include such

calculations and attempt to draw conclusions about changes in CMR.

Jugular Venous Oximetry It is often impractical to quantify CBF (or CMR) in clinical practice. In an effort to obtain such information, many centers have begun monitoring cerebral venous oxygenation, particularly in the ICU. This is done either via intermittent sampling of jugular venous blood, or by continuously using an "oximetric" catheter. When combined with a measure of arterial saturation, this technique provides a measure of cerebral arteriovenous oxygen content difference ($AVDO_2$); if arterial oxygen saturation (SaO_2) remains near ≈100%, one need not calculate $AVDO_2$, but simply follow the jugular venous oxygen saturation ($SjvO_2$). This value is a measure of "the balance" between cerebral blood flow and $CMRO_2$, even though neither value can be directly calculated from the data. If $SjvO_2$ decreases, then one can conclude that CBF must be decreasing relative to demand (or, alternatively, $CMRO_2$ must be increasing disproportionately). This method has been advocated as an adjunct to ICP monitoring; an increase in ICP associated with a rise in $SjvO_2$ is probably caused by an increase in CBF and CBV, whereas an identical ICP change associated with a fall in $SjvO_2$ represents a different physiology (e.g., more edema). If venous lactates are also monitored, it may be possible to determine when a CBF reduction is "critical."[224,613,678]

Significance of CBF and CMR: Control of Intracranial Pressure

Studies of regional CBF and CMR have provided invaluable information concerning the roles played by different anatomic structures in normal and pathologic brain function. Studies with anesthetics have provided some insights into the anatomic substrate of drug action, and other observations have improved our understanding of changes occurring during cerebral ischemia or after trauma. However, such studies have not yet made much of an impact on clinical neuroanesthetic practice. Why should we be so interested in these variables? This is a difficult question to answer satisfactorily. In simple terms, there seem to be two reasons: (a) CBF bears an important relationship to ICP, and (b) CBF and CMR are clearly important in the etiology of cerebral ischemia. Because this chapter does not deal directly with ischemia, we direct our attention to the issue of ICP.

Physiology of Intracranial Pressure

The bulk of investigative efforts in neuroanesthesia have dealt with ICP. Why such intense interest? First, pressure within the intracranial space is defined by unique conditions. The brain is enclosed in a rigid container. Because neither water nor solids are compressible, any increase in *total* intracranial volume will result in a rapid increase in pressure. Second, large increases in ICP may have profound effects on the well-being of the brain. Intracranial hypertension can reduce global cerebral perfusion pressure (CPP = mean arterial pressure ICP) or lead to physical shifts in the intracranial contents, with resultant *focal* compression of tissue against the falx, the tentorium, or the foramen magnum (Fig. 50–3); patients dying from intracranial mass lesions or trauma often have very high ICPs, and autopsy studies show clear evidence of compression-related ischemia.[335] If the skull is open, compression problems do not occur as readily, but the brain can swell out of the craniotomy site and impede the surgeon's ability to carry out the required procedures (or make it impossible to close the wound). It may also be necessary to use excessive retraction pressure to obtain the necessary exposure, which can itself lead to tissue injury.[18] In extreme cases, the surgeon may be forced to amputate portions of brain to achieve access (e.g., to an aneurysm) or to allow the dura/skull to be closed.

Any increase in total intracranial volume will increase ICP (or brain bulk). Figure 50–4 shows this phenomenon as the "real" compliance curve, which is what would be expected if we rapidly injected a noncompressible liquid into a rigid container. This real compliance curve differs from the "typical" compliance curve presented in many reviews. The confusion arises because the x-axis on the "typical curve" is often mislabeled as representing "intracranial volume." In fact, it does not represent total intracranial volume but rather "the volume of the growing mass." The initial portion of this typical curve is flattened because total volume does not change much during the early period of tumor growth (or, e.g., hematoma expansion). This occurs because of "spatial compensation," a phenomenon shown schematically in Fig. 50–5.

This diagram, the physiology of ICP, and its control are easier to understand if we conceptually divide the

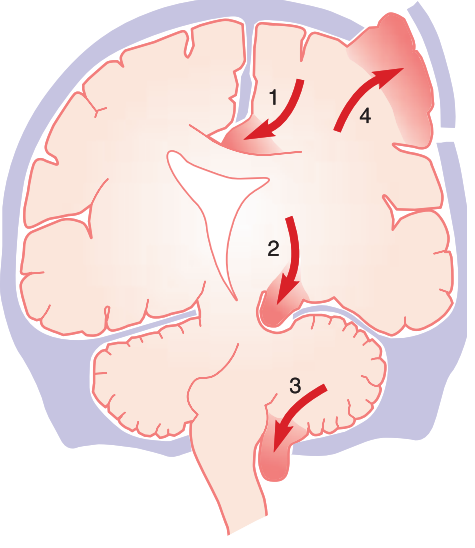

FIGURE 50–3. Brain herniation patterns: (**1**) herniation of the cingulate gyrus under the falx; (**2**) transtentorial herniation of the temporal lobe; (**3**) herniation of the cerebellar tonsils through the foramen magnum; and (**4**) transcalvarial herniation (via a fracture site of craniectomy). In each case, an increase in brain volume combined with physical shift of the intracranial contents results in intense compression of brain against some rigid structure. (Fishman RA. Brain edema. N Engl J Med 1975;293:706. Copyright 1975, Massachusetts Medical Society. All rights reserved.)

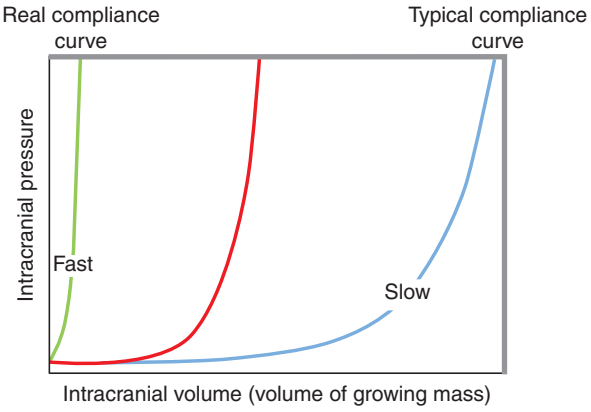

FIGURE 50–4. Intracranial pressure "compliance curves." If intracranial contents are noncompressible and the skull were truly rigid, then the injection of any "extra" volume into the system would produce a very rapid increase in pressure (left curve, labeled *real*). However, this is not the pattern typically seen with a slowly growing mass lesion, which is shown on the right curve (labeled *typical*). Note however, that the x axis is often mislabeled. This should not read "intracranial volume" but rather "volume of growing mass." As a mass grows, total volume remains almost constant because of compensatory mechanisms (see Fig. 50–5). Only when these are exhausted does pressure rise precipitously. Note also that the faster volume is added, the more quickly are compensatory mechanisms exhausted.

intracranial contents (weights/volumes given are relative to a "normal" brain) into four compartments:

Tissue water (≈78% or 1092 g)

Cerebrospinal fluid (75 mL)

Blood (50 mL)

An increase in the mass of solid material occurs only during the growth of new cellular material (a tumor). By contrast, edema (an increase in either intracellular or extracellular water) can occur without any alteration in tissue solids. Cerebrospinal fluid (CSF) volume increases when (a) its reabsorption is inhibited (e.g., hydrocephalus) or (b) the mass of solid material/tissue decreases (e.g., cerebral atrophy). Increases in CSF production are rare. In many pathologic states, changes occur in all compartments: a growing tumor may increase interstitial fluid volume (edema) and either increase or decrease CBV. If the tumor obstructs CSF pathways, hydrocephalus can also occur.

The compartment that plays the greatest role in spatial compensation is CSF. (There is no room to discuss CSF physiology and pharmacology in detail in this chapter, as our emphasis is on blood flow and volume. However, there are two excellent and comprehensive reviews of this subject in the anesthesia literature by Artru.[36,37]) As a mass lesion expands, the size of the CSF space will decrease by an approximately equal volume. This is seen on a CT/MRI scan as a progressive reduction in the size of the cerebral ventricles and/or of the basal cisterns, etc. ICP will increase rapidly only when the CSF space can no longer be "squeezed" (Fig. 50–6) or when intracranial compartmentalization results in some obstruction to CSF flow/absorption. Spatial compensation takes time, and rapidly increasing masses (e.g., hematomas) "exhaust" compensatory mechanisms quickly and can lead to severe increase in ICP much sooner than slowly growing lesions.

The control of intracranial hypertension can also be discussed in terms of these tissue compartments. ICP will increase when the volume of one or more of the compartments increases enough to exhaust compensatory mechanisms. To *decrease* ICP, we need only to decrease the volume of one compartment. We can drain CSF via a ventriculostomy, alter its production rate with acetazolamide or furosemide, decrease peritumoral edema using steroids, or decrease interstitial (or even cell) volume using mannitol or furosemide. Finally, the surgeon can remove the tumor mass. However, except for CSF drainage, most of these interventions are relatively slow, requiring hours or days of effort.

Blood is the smallest of the four compartments. However, its importance to neuroanesthesia is related not to its size but to the fact that CBV can change very rapidly; for example, witness the rapid increase in ICP seen with jugular compression in Fig. 50–6. Other than CSF drainage, the volume of no other compartment can be so rapidly altered by physiologic or phar-

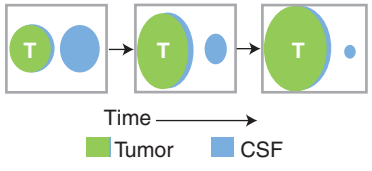

FIGURE 50–5. Schematic of spatial compensation. As a mass slowly increases in size (*solid ellipse, T*), the volume of some other compartment should get smaller. In most cases, this is cerebrospinal fluid (CSF) volume (*dotted ellipse*). Compensation can be said to be exhausted when this second compartment can no longer decrease in size, and hence total intracranial volume begins to rise.

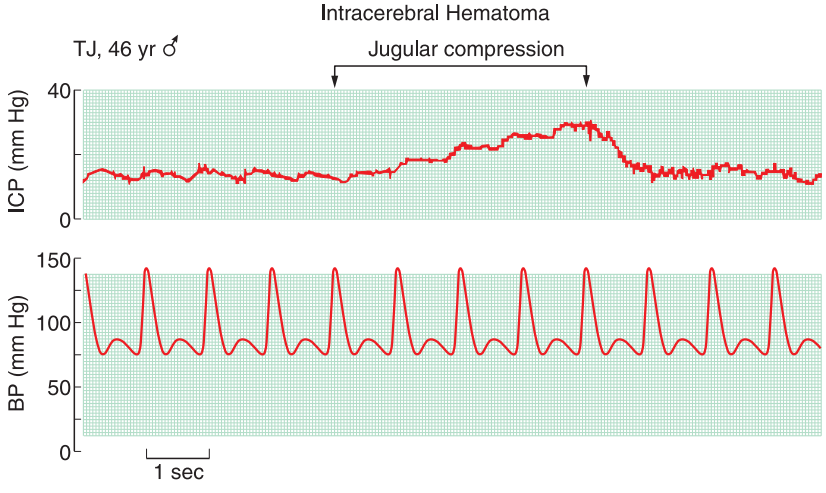

FIGURE 50–6. Simultaneous intracranial pressure (ICP) and arterial pressure tracing before and during bilateral jugular vein compression. Note the "arterial" pulsation of both traces, and the "stairstep" rise in ICP when venous outflow is prevented. Each "step" represents the injection of a small increment of blood into the intracranial space.

macologic methods. It can be argued that the neuroanesthesiologist is, in fact, an expert in the controlled manipulation of cerebral blood volume. As a result, in the following discussion of ICP, we focus almost exclusively on the manipulation of CBV. We defer comments concerning tissue water content to a later section, Hyperosmolar Agents in Neuroanesthesia, dealing with the clinical management of the swollen brain.

Measurement of CBV

To determine the *volume* of blood in the intravascular space at any point in time (CBV), one must examine the brain concentration of a tracer that remains within the vasculature (which is not true of most flow tracers). CBV is calculated as the brain concentration of intravascular tracer divided by the arterial concentration. The most common method is to inject radioiodinated serum albumin (RISA) or ^{99m}Tc-labeled RBCs, measure the concentration in arterial blood, and determine the radioactivity in brain using an external counter.[257] This is complicated by the fact that counts seen by an external detector are emitted from both brain and scalp, and the resultant values are contaminated by extracranial blood (although this can be eliminated by single-photon emission computed tomography [SPECT]). This does not invalidate the technique but does make it more suitable for examining *changes* in CBV rather than absolute volume. This problem can be resolved by using positron emission tomography (PET) or other tomographic techniques to determine only the intracranial (and regional) concentration of an appropriate isotope.[57,582] A simpler semiquantitative approach is to use the subject's own RBCs as a volume tracer, with transcranial near-infrared absorption spectroscopy (NIRAS) used to examine the changing concentrations of hemoglobin. To date, this method has proven useful only in infants in which transcranial illumination is feasible[107]; all developmental efforts are being made to extend it to adults. (NIRAS technology may someday also be useful for the measurement of hemoglobin oxygenation in the brain,[387] and to monitor changes in CBF.[200])

CBV Control

To increase CBV you have to put blood into the head faster than it leaves, at least until a new steady state is reached. This can be done in two ways: impede the egress of blood, or increase the rate at which it enters.

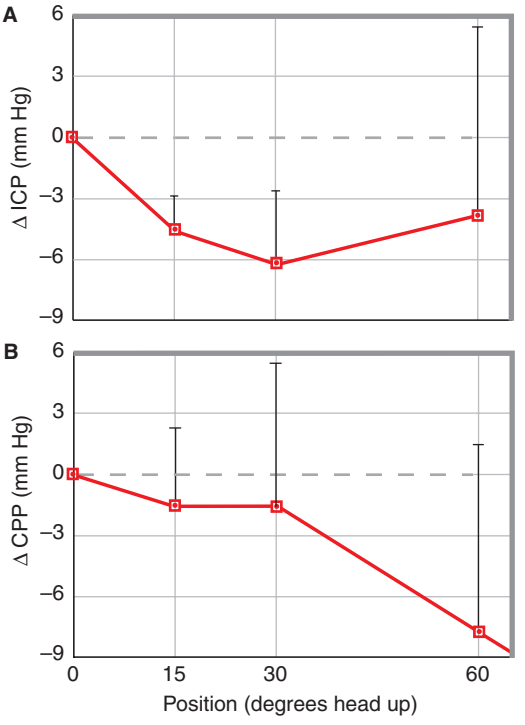

FIGURE 50–7. Although a head-up posture can reduce intracranial pressure (ICP), it can also reduce perfusion pressure at the head. Changes in both ICP (**A**) and in calculated cerebral perfusion pressure (CPP) (**B**) at the head are shown (values are mean ± standard deviation [SD]). Note that at 30° head up, ICP has been reduced to the lowest possible level without compromising CPP. (Data from Durward QJ, Amadner AL, Del Maestro RF, et al. Cerebral and vascular responses to changes in head elevation in patients with intracranial hypertension. J Neurosurg 1983;59:938.)

Impede the Egress of Blood There are many ways to slow the exit of cerebral venous blood. The most important are occlusion of the jugular veins or an increase in venous pressure. The ways to occlude the jugular veins are legion. The easiest is to rotate the head to one side, or to fully extend the neck (e.g., during a tracheostomy). Direct pressure can be applied with circumferential neck ties (e.g., to secure an endotracheal tube) or a tight cervical collar. It may be possible to obstruct venous drainage by the placement of large catheters into the internal jugular vein (IJV), and some clinicians avoid using the IJV in neurosurgical patients. However, the IJV is very large, and catheters occupy only a small portion of the lumen. At least one study has measured the diameter of the IJV by echo before and after IJV cannulation and showed no changes.[545] The real problems are the positions often used during cannulation (head down/rotated). As a result, many experienced neuroanesthesiologists will first attempt to obtain central access via antecubital or subclavian routes, but are still willing to use the IJV as an alternative.

Venous distension can also occur by elevating right heart pressures (major volume overload, right-heart failure), increasing intrathoracic pressure (e.g., positive end-expiratory pressure [PEEP], short expiratory phase, endotracheal tube obstruction), or placing the patient in a head-down posture. Positioning is a crucial factor in the control of CBV, and several studies demonstrate the advantages of a modest head-up posture in minimizing ICP.[193,616,618] However, an angle greater than 30° above horizontal tends to reduce arterial pressure at the head more than it alters ICP and can reduce CPP (Fig. 50–7).[618] We also believe that the problems of PEEP are overrated, and that the use of small amounts of PEEP to improve oxygenation intraoperatively is generally benign.[318] If a patient has lung disease serious enough to warrant high levels of PEEP, only a small fraction of the

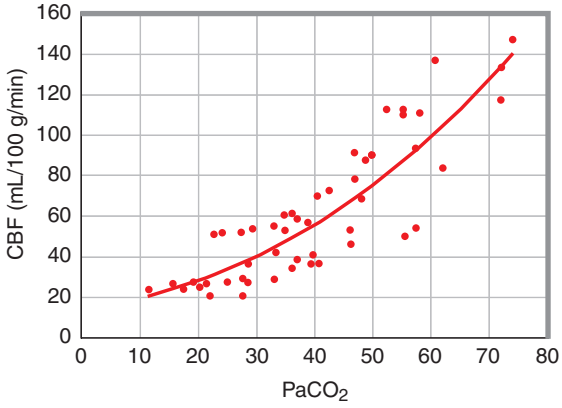

FIGURE 50–8. The "bottom half" of a normal cerebral blood flow (CBF)–$Paco_2$ response curve. Each point represents one measurement. (Data from Grubb RL Jr, Raichle ME, Eichling JO, et al. The effect of changes in $Paco_2$ on cerebral blood volume, blood flow and vascular mean transit time. Stroke 1974;5:630, and Wollman H, Smith TC, Stephen GW, et al. Effects of extremes of respiratory and metabolic alkalosis on cerebral blood flow in man. J Appl Physiol 1968;24:60.)

intrapulmonary pressure is transmitted to the intrathoracic space[408] and the ICP changes produced by PEEP are often minimal or can be offset by a head-up posture.[144,404] The more common problem is the unintentional or unwarranted application of PEEP in patients with normal lungs. PEEP can also increase respiratory dead-space volume and increase $Paco_2$.

A third (theoretical) way of increasing CBV is to pharmacologically increase intracranial venous capacitance. Because perhaps 90% of the blood in the brain is postcapillary, this could be important.[649] Venodilation is clearly produced by both volatile anesthetics and by drugs like sodium nitroprusside,[375] but the relevance of this to the ICP effects of these agents remains unknown.

Increase Inflow "Increase inflow" is just another way to saying "increase CBF," which is the focus of the next section of this chapter. However, it is strictly incorrect to say that an increase in CBF will produce an increase in ICP. ICP changes in response to changes in *volume* not flow. When someone says that hypercapnia increases ICP because it increases CBF, what is really meant is that hypercapnia increases CBF, which is, in turn, accompanied by an increase in CBV.

Normal Control of CBF and CBV

Before we can discuss the influence of drugs on CBF, CBV, and ICP, it is necessary to understand the "normal" factors that control them: $Paco_2$, Pao_2, arterial O_2 content, hydrostatic pressure (autoregulation), metabolism (flow-metabolism coupling), and the autonomic nervous system.

$Paco_2$ CBF varies with $Paco_2$ (Fig. 50–8).[416] This response is typically shown as a sigmoid curve, with lower and upper plateaus. The upper portion of the curve is of little interest in anesthesia, as it does not occur until $Paco_2$ is ≈80–100 mm Hg. In normal primates and humans, the lowest CBF that can be achieved by hyperventilation is ≈18–20 mL/100 g/min at 10 mm Hg.[259,813] In the midportion of the curve, CBF changes by 1.5–2.0 mL/100 g/min for each mm Hg change in $Paco_2$. The slope of the CBF–$Paco_2$ response curve depends on the baseline normocapnic flow values; as regional CBF increases, the slope of the response curve for that region also increases. As a result, CO_2 responsiveness in gray matter is greater than in white matter.

CO_2 responsiveness is driven by changing *extravascular/interstitial* H^+ concentration. As pH around the extraluminal surface of the vessel decreases, the vessel dilates. By contrast, the intravascular administration of a "fixed" acid or base has little effect. Because CO_2 readily diffuses across the blood–brain barrier into the interstitial space where it is converted to H^+ and HCO_3, an increase in intravascular CO_2 is accompanied by extravascular acidosis and hence vasodilatation. The CBF response to changing $Paco_2$ is very fast. Severinghaus et al. demonstrated that CBF reached a new steady state within less than 1 minute after a step change in $Paco_2$.[678] TCD studies suggest that response may be even faster. This indirectly indicates that the site of action must be very close to the vessels themselves (as CO_2 can diffuse only a short distance in the time noted).

How does a change in pH change vascular diameter? Several mediators have been studied. Blockade of cyclooxygenase activity (with indomethacin) can blunt CO_2 response, suggesting some role for prostaglandins.[210] CO_2 responsiveness can be transiently abolished (for 12–24 hours) by events such as spreading depression that release of glutamate into tissue.[396] Given the well-known link between glutamate, the *N*-methyl-D-aspartate (NMDA) receptor and nitric oxide (NO) release, this suggested that NO may play some role in CO_2 responsiveness. There is now substantial support for this. Treatment of rats with nitric oxide synthase inhibitors, e.g., L-nitroarginine methyl ester (L-NAME) attenuates response the response to hypercapnia.[214,328] Similar chemicals block the response to extravascular H^+. However, this hypothesis is incomplete, and nitrous oxide synthase (NOS) inhibition in primates does not dramatically alter hypercapnic CO_2 response.[459]

CBV and Intracranial Pressure CBV also changes with CO_2, but the CBF and CBV response curves are not parallel. Grubb et al. demonstrated a CBF–$Paco_2$ response curve in primates with a midrange slope of approximately 1.8 mL/100 g/mm Hg change in $Paco_2$ (Fig. 50–8).[259] However, a simultaneously determined CBV–$Paco_2$ curve was much flatter (0.041 mL/100 g/mm Hg) (Fig. 50–9). Hence decreasing $Paco_2$ from 40 to 20 mm Hg will decrease CBF by 36 mL/100 g/min (a 65% decrease), while CBV will decrease to 2.8 mL/100g (a 28% change). This translates into a 10–14 mL fall in whole-brain volume. This seems to be small, but a brief lesson in intracranial compliance demonstrates the contrary. Shapiro et al. showed that the amount of fluid that must be rapidly injected into or withdrawn from the intracranial space to change ICP tenfold (e.g., from 10 to 100 mm Hg) is normally ≈26 mL.[677] This is called the *pressure-volume index* (PVI). However, PVI values in patients with mass lesions or closed head injuries may be as low as 5 mL.[379] In such situations, a change in CBV of 10–15 mL would be enormous, and it is not surprising that hyperventilation has come to occupy

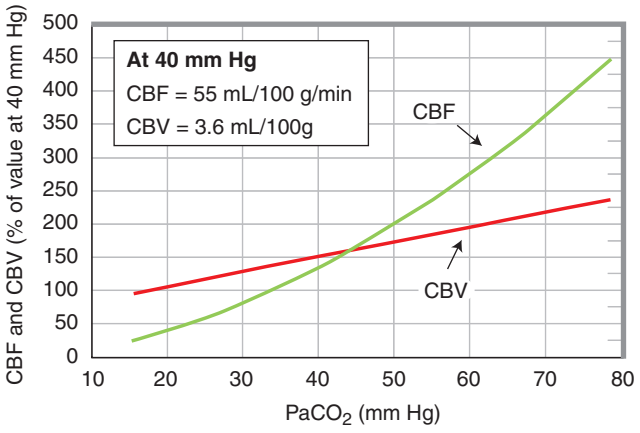

FIGURE 50–9. Cerebral blood flow (CBF) and cerebral blood volume (CBV) responses to $Paco_2$, with each value expressed as a percentage of that observed at a $Paco_2$ of 40 mm Hg. Note that the slope of the CBV–$Paco_2$ response curve is much flatter than that for CBF. (Data from Grubb RL Jr, Raichle ME, Eichling JO, et al. The effect of changes in $Paco_2$ on cerebral blood volume, blood flow, and vascular mean transit time. Stroke 1974;5:630.)

such an important position in acute ICP/brain-volume control.

The Clinical Utility of Hypocapnia The ability of rapid reductions in $Paco_2$ to acutely reduce ICP is indisputable. Whereas cardiac arrest, stroke, subarachnoid hemorrhage, head trauma, and brain tumors can decrease the slope of the CBF–$Paco_2$ curve, CO_2 responsiveness is almost never completely lost in a viable patient. Consequently, it is unnecessary to worry whether responsiveness is present or absent in a given individual. If there is no CO_2 response, the patient will probably die, or survive in only a severely debilitated state.

The more important questions are (a) is profound hypocapnia detrimental, and (b) is there any benefit to prolonged hypocapnia. In anesthetized animals, hypercapnia has little influence on $CMRO_2$ except at values greater than 200 mm Hg.[83] Moderate hyperventilation also does not alter $CMRO_2$. However, during profound alkalosis ($Paco_2$ ≈10 mm Hg) glucose consumption (CMRGlu) increases, as does lactate production. This has been interpreted as indicating excessive cerebral vasoconstriction and tissue ischemia. This may not be true, because alkalosis alone will stimulate glycolysis. Nevertheless, other studies indicate that excess lactate production and some depletion of high-energy phosphates may occur at $Paco_2$ values of 10–15 mm Hg.[717] The EEG slowing seen with extreme hypocapnia can also be reversed by increasing Pao_2, suggesting ischemia. This probably *does not* have any relevance in elective surgery. In a study of the most extreme conditions likely to be encountered clinically, Artru examined cerebral metabolism and tissue high-energy phosphate concentrations during induced hypotension (mean arterial pressure = 40 mm Hg) in dogs with a $Paco_2$ of 20 mm Hg.[35] Although hypotensive/hypocapnic conditions resulted in an increase in tissue lactate, $CMRO_2$ and high-energy phosphate values were unchanged compared with normocapnic hypotension. What about hypocapnia in the presence of disease? People have long argued that hypocapnia might constrict normal vessels, and redistribute blood into ischemic areas ("inverse steal"). Unfortunately, although theoretically attractive, such an event does not appear to occur; hypocapnia seems to increase the total amount of tissue "at risk" during focal ischemia, and primate outcome studies show no benefit.[473,622] Hypocapnia is commonly used to control ICP in head trauma. Again, however, available data do not provide much support for anything other than transient value. Robertson et al. used CBF, arteriovenous O_2, and lactate measurements (via jugular venous catheters) to define different subgroups of head-injured patients. They showed that a modest *increase* in $Paco_2$ (from previously severe hypocapnia) in *some* patients with very low CBF values can reduce lactate production.[613] Others have shown that reductions in $Paco_2$, although reducing CBF and ICP, may result in evidence of tissue ischemia.[678] A small but important clinical trial compared chronic hypocapnia ($Paco_2$ ≈25 mm Hg) with "normocapnia" ($Paco_2$ ≈35 mm Hg) and with hypocapnia combined with infusions of *Tris*(hydroxymethyl)-aminomethane (THAM, an alkalinizing agent that crosses the blood–brain barrier, and hence maintains CSF alkalosis).[515] ICP management was not improved in the hypocapnic patients, and there was a small suggestion of a worsened outcome.

In summary, although reducing $Paco_2$ is of value in the acute control of ICP or brain bulk in an operating room setting (and does not seem to be accompanied by any adverse consequences), essentially no data exist to demonstrate the value of prolonged hypocapnia. Furthermore, in patients with both stroke and head trauma, there is some reason to believe that it may be detrimental.

Pao_2, Arterial O_2 Content, and Hemodilution Cerebral blood flow does not change much until Pao_2 is less than 50 mm Hg; it then increases progressively. Under normoxic condition, tissue PO_2 is ≈25 mm Hg (or lower). Shinozuka et al. showed that regional pH begins to fall (and CBF to rise) when tissue PO_2 values fall below this level.[681] This does not imply, however, that H^+ is the direct mediator; it is far more likely that multiple "sensors" are involved, including the endothelium, vascular smooth muscle, and neurons. Vasodilatation may be the direct result of O_2-sensitive ion channels in smooth muscle, or be produced by vasoactive substances released from multiple sites. Recent work suggests that adenosine, NO, prostacyclin (and other cyclooxygenase products), and angiotensin are involved, with vasopressin and opioids (met-enkephalin and leu-enkephalin) playing a role in the fetus and newborn.[215,328,562,574,581,769,781] This multiplicity of involved pathways strongly suggests that there is no single chemical or receptor responsible, but instead indicates the likelihood of substantial redundancy.

Although the cerebral vasculature can directly "sense" changes in Pao_2, evidence also suggests that arterial O_2 *content* is an important determinant.

Autoregulation: CBF and CBV Autoregulation refers to the maintenance of a constant CBF in the face of changes in *perfusion pressure.*[560] This must not be confused with the other factors that control flow. Most texts describe

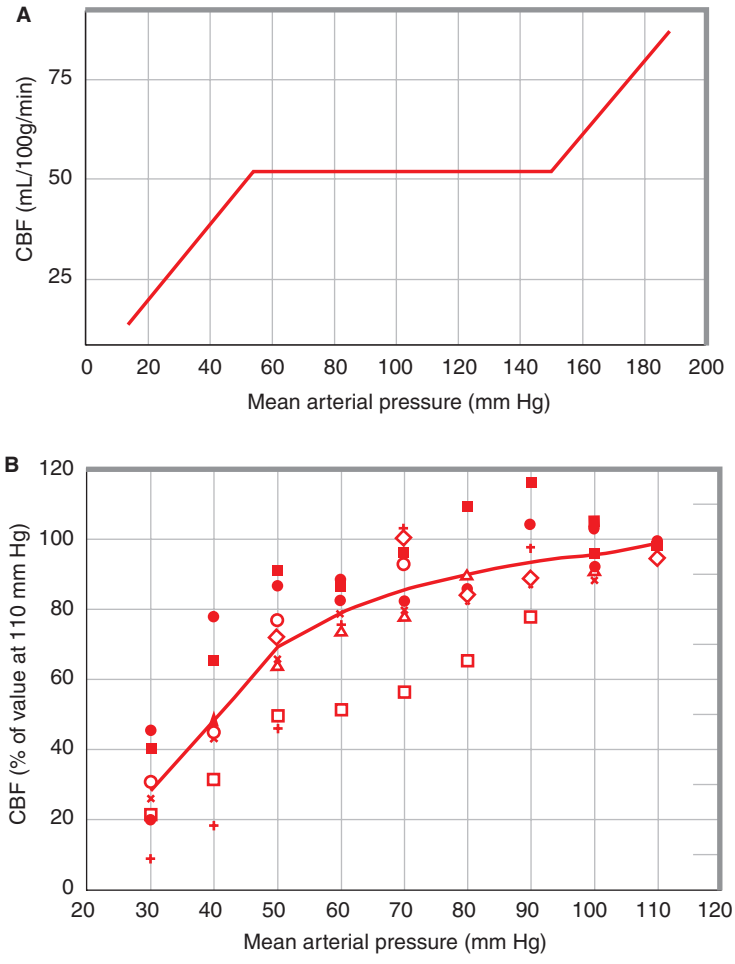

FIGURE 50–10. A. Typical autoregulatory curve. Flow is generally shown as being stable between mean arterial pressures (or more strictly, perfusion pressure) of 50 and 150 mm Hg. However, although this expresses the concept of autoregulation well, it does not depict reality. **B.** Data collected from 8 rats during progressive hemorrhagic hypotension, with a fitted average line. Flow was measured continuously with a laser Doppler but summarized in 10 mm Hg steps. Because the laser Doppler does not yield flow in typical units, CBF is expressed as percentage of flow at 110 mm Hg. Note the lack of a sharp "knee" and the wide scatter around the line.

autoregulation with a curve similar to that in Fig. 50–10A; in reality it is much less "distinct" (Fig. 50–10B). Nevertheless, we typically say that CBF is "constant" as long as perfusion pressure is within the range of 50–150 mm Hg. The shape of the curve is similar whether perfusion pressure is altered by changing arterial pressure or changing ICP.[462] Artru et al. also showed that the lower knee of the autoregulatory curve occurs at the same arterial pressure in normocapnic and hypocapnic dogs, even though lower flows are present during normotension in the hypocapnic animals.[40] These studies suggest that *transmural* vessel tension is the controlling factor rather than flow or intraluminal pressure per se (but see McPherson et al.[462]). This is supported by work in isolated vessels, where several workers have shown that increasing transmural pressures result in depolarization of vascular smooth muscle with subsequent constriction.[371,532]

The sympathetic nervous system can modulate autoregulation. Both α-blockade and cervical sympathectomy can change the lower limit of the autoregulatory curve (shifting it to the left), even though they do not change baseline flow.[196,276,362,624] Conversely, intense sympathetic stimulation and chronic hypertension can shift the curve to the right. Angiotensin also plays a possibly important role.[561,782]

There are a number of misconceptions regarding autoregulation. First, autoregulation is readily abolished. Changes in the shape of curve, shifts in the knees, or complete loss of autoregulation (i.e., parallel changes in CBF as blood pressure changes) are commonly present in patients with, for example, tumors, arteriovenous malformations (AVMs), ruptured aneurysms, and strokes. In fact, dysautoregulation is described in neurologically normal individuals and it is thus not clear that alterations in the curve have any serious clinical implications. This, along with the typical scatter seen in Fig. 50–10B, indicates that we cannot rely on the published "normal" limits for autoregulation, at least not in an individual patient. Arguments supporting the safety of some hemodynamic intervention based on the idea, for example, that "the normal lower limit of autoregulation is not exceeded" must always be suspect. This is particularly true if we don't really know what tissue perfusion pressure is, that is, when there is some proximal carotid stenosis. Second, autoregulation is not instantaneous. Early studies suggested that the autoregulatory responses required 20–60 seconds. Recent studies using TCD indicate that the response is faster at least in normal subjects (i.e., 1–10 seconds).[1] Nevertheless, very abrupt blood pressure changes will lead to transient changes in CBF even when autoregulation is normal. In a patient with disrupted autoregulation, similar changes can lead to large and sustained alterations in CBF and presumably CBV and ICP. This is perhaps most relevant during the abrupt changes in blood pressure produced by, for example, laryngoscopy and tracheal intubation, pin insertion, skin incision, and tracheal suctioning. Because volatile anesthetics appear to slow (and in high enough doses abolish) autoregulation, CBF responses to such stimuli may be exaggerated.[711,738]

The lower end of the curve is of greatest concern during hypotension. CBF is adequately maintained down to perfusion pressures of 30–40 mm Hg during hypotension produced with nitroprusside, halothane, or isoflurane, but signs of cellular dysfunction (e.g. EEG, evoked response changes, acidosis, K^+ escape) appear at notably higher pressures with hemorrhage and with ganglionic blockers, indicating that direct vasodilators shift the knee to the right.[484,508] However, it is not clear that there are any important differences between hypotensive agents at *clinically employed blood pressures*

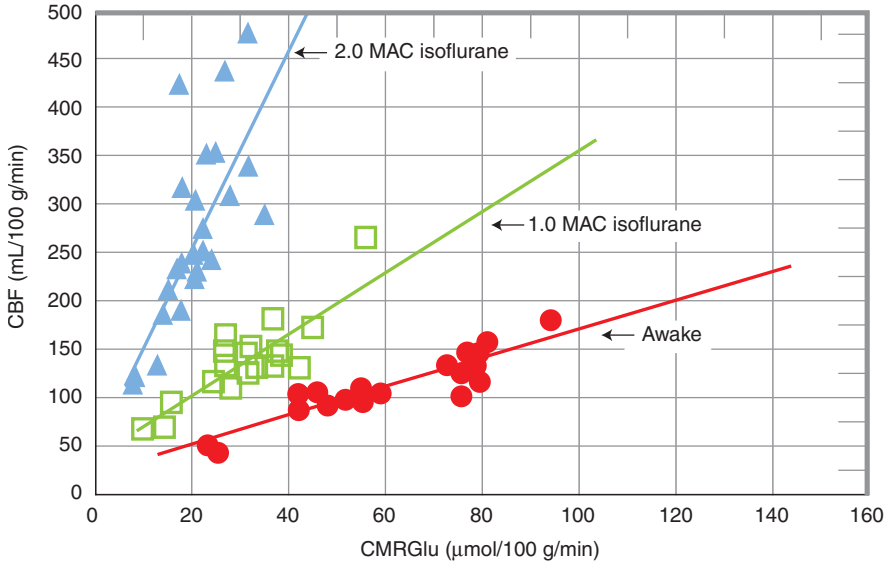

FIGURE 50–11. Regression plots of regional cerebral metabolic rate for glucose (CMRGlu) versus regional cerebral blood flow (rCBF) in the rat. Each point on the curve represents the average CBF and CMRGlu value for one anatomic region (e.g., auditory cortex, caudate), determined by ^{14}C-iodoantipyrine and ^{14}C-deoxyglucose autoradiography, respectively. Animals were studied awake and at stable isoflurane doses of 1 and 2 MAC (minimum alveolar concentration). For each situation, a significant straight-line relationship between CMRGlu and CBF is seen, indicating the persistence of a coupled relationship between these variables. As the concentration of isoflurane is increased, however, the slope of the regression line increases (i.e., higher CBF for a given CMRGlu value). This indicates that isoflurane is a cerebrovasodilator in the rat brain but it does not uncouple flow and metabolism, even at 2 MAC. (Data from Maekawa T, Tommasino C, Shapiro HM, et al. Local cerebral blood flow and glucose utilization during isoflurane anaesthesia in the rat. Anesthesiology 1986;65:144.)

(e.g., mean arterial pressure [MAP] = 50–60 mm Hg), and no pharmacologic hypotensive technique has been shown to be preferable to any other. Furthermore, when autoregulation is clearly altered (e.g., in a patient with vasospasm), hypotension induced with even "good" drugs can exacerbate tissue injury.

Flow-Metabolism Coupling Obviously there must be a method for matching O_2/glucose delivery to metabolic demand. This is commonly referred to as "flow-metabolism coupling" and is reflected by parallel changes in CBF as CMR changes; tissue regions with high metabolic rates (e.g., gray matter) will have higher flows than regions with low CMR (Fig. 50–11).[388,406] This is reflected by a constant ratio between CBF and CMR (and by the straight line in Fig. 50–12). Under dynamic conditions, any change in CMR is rapidly matched by an appropriate change in CBF. A relationship between *functional* cerebral activity, CMR, and CBF is clearly present in humans.[397] For example, a light flashed into one visual field results in increases in both CBF and CMRGlu in the contralateral occipital visual cortex, and repeated clenching of one hand is accompanied by changes in the contralateral sensorimotor cortex. In fact, multiple studies indicate that coupling is probably the major mechanism by which the delivery of O_2 and nutrients is regionally modulated.

Many situations encountered in anesthesia and neurosurgery change CMR and have the potential to change CBF, CBV, and ICP. The most dramatic example is a seizure (which increases CBF, CBV, and ICP-8),[192] but examples also include fever, shivering, and pain. However, the most common cause of changing CMR is the anesthetic itself. This is discussed in greater detail in the following section. These CMR changes play a major role in defining the CBF changes produced by many anesthetics.

Finally, one other misconception needs to be corrected. Drugs that increase CBF without increasing CMR (or that decrease CMR) are often said to "uncouple" flow and metabolism. This divergence of CBF and CMR is seen with volatile anesthetics. However, these drugs do not *uncouple* CBF and CMR because the previously mentioned linear relationships (Fig. 50–11) persist during anesthesia with these drugs, except at very high concentrations.[281,421] True uncoupling can be demonstrated only by showing that an increase in either neuronal activity or CMR occurs without any accompanying increase in CBF.

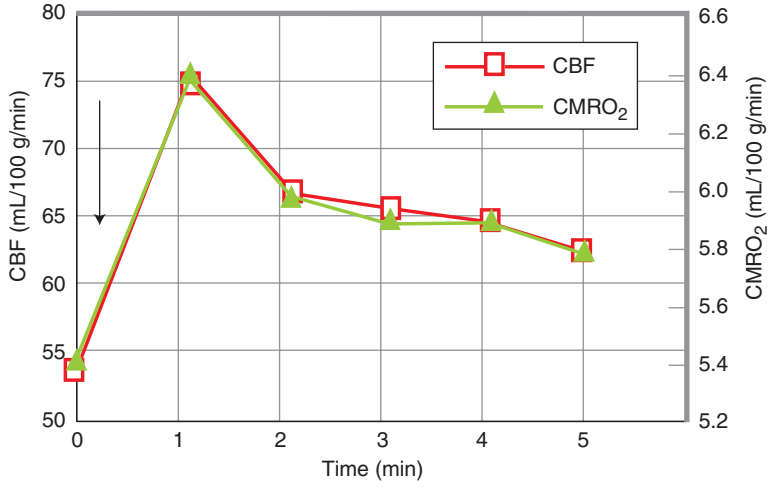

FIGURE 50–12. Flow-metabolism coupling as a dynamic event. Dogs were prepared for the near-continuous measurement of both cerebral blood flow (CBF) and cerebral metabolic rate for oxygen ($CMRO_2$) using a venous outflow method. At the arrow, the femoral nerve was electrically stimulated. This is immediately followed by a matched increase in both $CMRO_2$ and CBF, demonstrating the presence of coupling. (Data from Kuramoto T, Oshita S, Takeshita H, et al. Modification of the relationship between cerebral metabolism, blood flow, and the EEG by stimulation during anesthesia in the dog. Anesthesiology 1979;51:211.)

Autonomic Control Many early reviews of anesthesia and cerebrovascular physiology ignored the effect of the autonomic nervous system. This stemmed largely from the observation that clinically relevant doses of most adrenergic and cholinergic agents have

little effect on resting CBF. However, brain vessels are well innervated by postganglionic sympathetic nerves that originate from the superior cervical sympathetic ganglia, and by fibers that appear to modulate parasympathetic activity.[84,524,718,781] Under physiologic conditions (normotension, normoxia, and normocapnia), sympathetic nerves exert very little effect on cerebral blood flow. In contrast, high levels of sympathetic activity (such as encountered during hemorrhagic shock) shift the autoregulatory curve to right, and blunt both hypoxic and hypercapnic vasodilatation.[115,162,563] Conversely, adrenergic antagonists (e.g. phentolamine) or sympathetic ganglionectomy shift the curve to the left.[276,362,624] During acute hypertension, sympathetic nerves are activated and vasoconstrict cerebral vessels thus providing some protection against cerebral hyperemia and disruption of the blood–brain barrier. This phenomenon appears to be more effective in the brain stem then in the supratentorial part of the brain. Stimulation of parasympathetic pathways may play some role in cerebral vasodilatation—particularly during anesthesia.[712] Atropine has relatively little influence of CBF except in huge doses.

α_1-Receptor agonists such as phenylephrine and norepinephrine exert little effect on cerebral vessels except in very high doses, and then often only by shifting autoregulatory limits. This may be altered somewhat depending on the preexisting state of the cerebral vasculature (e.g., in the presence of vasodilators),[559] but we believe that there is little reason for the oft-expressed concern that the clinical use of these drugs will somehow result in cerebral ischemia. In contrast α_2-agonists such as clonidine and dexmedetomidine produce peripheral vasodilatation and cerebral vasoconstriction.

β-Agonists (isoproterenol) exert important influences on CBF only if the blood–brain barrier is disrupted. β-Receptors are present on neurons. When the barrier is open—or in very high doses—β-agonists may increase CMR with a resultant coupled increase in CBF. Whether this is of clinical relevance remains unclear.

MICRODIALYSIS

The technique of cerebral microdialysis allows the clinician to estimate the regional chemical composition of the brain's interstitial tissue fluid[513] and indirectly obtain an assessment of changes in brain-tissue chemistry.[263] Although this technique has been used extensively in animal models of brain injury, the first microdialysis studies in human were not published until the early 1990s.[301,466] Microdialysis requires inserting a fine catheter (diameter 0.62 mm) into the brain tissue, in a fashion similar to brain-tissue oxygen monitoring (Fig 50–13).[513] The catheter, with its polyamide dialysis membrane lining, is perfused with a physiologic solution (e.g., lactated Ringer solution) at ultralow flow rates (0.1–2.0 μL/min) using a precision pump.[263] The probe is perfused continuously so that low-molecular-weight constituents of the extracellular space can diffuse across the membrane and into the perfusion medium of the probe.

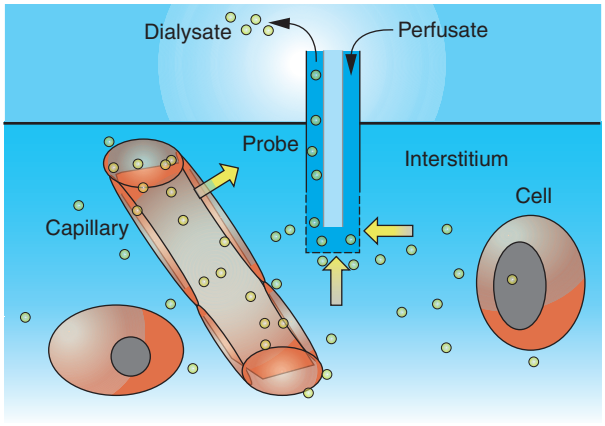

FIGURE 50–13. Diagram of a microdialysis probe. The semipermeable membrane at the probe tip allows exchange of soluble molecules between the probe and the surrounding tissue. When the probe is implanted into tissue interstitium, molecules continuously diffuse out of the interstitial space fluid into the perfusion medium. Samples are continuously collected and analyzed by standard chemical analytical techniques. (Reproduced with permission from Muller M.[517])

In theory, any soluble molecules that are in the interstitium and that are small enough to diffuse through the dialysis membrane can be detected in the perfusate.[341] The perfusate exiting the dialysis catheter is collected in aliquots for subsequent analysis, allowing for temporal resolution of changes in the composition of the interstitium. The concentration of any molecule in the perfusate will be dependent on the diffusing capacity (area) of membrane (length and diameter of diffusion membrane), molecular weight of the molecule, pore size of the membrane, rate of perfusion, diffusion gradient, temperature, pH, shape and charge of the molecules influencing the diffusion coefficient, and the binding of the proteins to the membrane and the tubing, and possible degradation of the proteins.[198,364,365] Conventional microdialysis uses CMA70 catheters with 20-kDa molecular weight cut-off membranes enabling the measurement of small molecules such as glucose, lactate, pyruvate, and glutamate. The CMA71 100-kDa molecular weight cut-off microdialysis catheter was introduced to allow detection of larger molecules such as cytokines.[327] Microdialysis is just a sampling tool and needs to be linked to an analytical device. In 1995, CMA Microdialysis (Stockholm, Sweden) introduced microdialysis instruments for clinical use (including catheters for peripheral and brain tissue, a microdialysis pump, and a bedside chemical analyzer). Good correlation has been shown between the CMA analyzer and the gold standard of high-performance liquid chromatography (HPLC).[326]

The key substances measured by microdialysis can be divided into four groups: energy metabolites (e.g., glucose, lactate, pyruvate, adenosine, xanthine); neurotransmitters (e.g., glutamate, aspartate, γ-aminobutyric acid [GABA]); markers of tissue damage and inflammation (e.g., glycerol, potassium, cytokines); and exogenous substances (e.g., drugs).[263] Microdialysis has also been used to estimate the brain concentration of drugs that have been administered either systemically or centrally.[516] Microdialysis can also be used to directly administer drugs into targeted brain areas while simultaneously measuring their effects on brain concentrations of other compounds (e.g., neurotransmitters) of interest.[517]

In vivo cerebral microdialysis is a powerful research technique for purposes of analyzing neurochemical dynamics of brain injury.[89] Over the last few years, extension of laboratory-based studies have been reported,[80,81,652] in patients with large hemispheric infarctions, traumatic brain injury,[820] global cerebral ischemia,[525] and subarachnoid hemorrhage.[534,706] Neuroprotective strategies,[377] including hypothermia,[322,403,507] and their effects on neurotransmitter release have been well-described using this technique.[89]

However, this technique has significant limitations in the clinical setting.[89] Because microdialysis only allows for a very small sampling volume of brain tissue (at best, a radial distance of a few millimeters around the probe), it may not represent pathology that exist at distant brain locations. [105] Although some sense of time of change may be gained from analyzing dialysate samples collected over individual epochs,[377] time resolution is poor because of the slow perfusion rates required to accumulate enough solute to measure.[105,534,706] In addition, there is evidence that chronic indwelling probes may cause the development of reactive gliosis around the probe.[89] The reactive gliosis influences the recovery of substances through the microdialysis membrane, but this gliosis plays a minor role in the first hours after implantation.[76,77,105,685,804]

Use of microdialysis is associated with wide intersubject variability in basal neurochemical values and following tissue perturbations[89] and the lack of reference values taken, for example, from the contralateral hemisphere as described by other authors is a fundamental problem of microdialysis studies in humans. But ethical aspects make investigations of basal or reference values delicate or impossible.[105]

CEREBROVASCULAR PHARMACOLOGY OF ANESTHETICS AND ADJUVANTS

As stated earlier, neuroanesthesia is the practice of applied cerebrovascular physiology and pharmacology, particularly the manipulation of CBV. Anesthetics affect all of the parameters discussed in the previous sections, as does natural sleep.[229,367] The oft-noted attempt in the experimental laboratory to design a combination of anesthetic agents that have no such effects can only be viewed with humorous disdain. However, differing drug-induced changes do have some bearing on clinical practice, and it is important to understand them.

Intravenous Anesthetics

Barbiturates

Barbiturates were the first anesthetics whose cerebrovascular effects were examined. Thiopental is the prototype, and all other clinically used barbiturates are similar (although their pharmacokinetics differ). Increasing doses of thiopental progressively decrease CMR and CBF (assuming that $Paco_2$ does not change).[375,468] The changes in CBF appear to occur as the result of metabolic suppression and a coupled decrease in flow. If coupling is disrupted, if CMR is already maximally depressed *vasodilatation* in response to barbiturates can be demonstrated.[465] This can also be seen in isolated vessels.[289,402,431,543] The relationship between dose and CBF/CMR is not linear, with large decreases seen with small doses, and progressively less effect as blood concentrations increase further. The maximal decrease in both CBF and $CMRO_2$ occurs coincident with the appearance of isoelectricity on the EEG, and is equal to ≈50% of awake normal (although the metabolic/CBF difference between burst suppression and isoelectricity is small).[353,468] Thiopental even in very high doses, does not appear to abolish autoregulation, CO_2 response, or flow-metabolism coupling. Barbiturates have also been shown to result in lower CBV values than volatile agents.[746]

Propofol

Like thiopental, propofol produces dose-related EEG suppression (including isoelectricity) and progressive reductions in both CBF and CMR, with minimum CMR values of 40–60% of control values.[43,576,593,770] The relationship between these CBF changes and reductions in ICP was initially clouded by the decreases in blood pressure sometimes seen with the recommended induction doses, but subsequent data indicate that propofol does reduce CBF independent of any systemic hemodynamic changes.[593] The only available CBV data again suggests similarities with the barbiturates.[746] The drug has been used successfully in many neurosurgical procedures and in neurosurgical intensive care units in both Europe and the United States.[109,295,694]

In recent years, a number of case reports have appeared suggesting that propofol can induce seizures. However, this event is uncommon and the drug has been given uneventfully to epileptic patients.[195,698]

Etomidate

Etomidate is remarkably barbiturate-like, producing similar CBF and CMR changes. In dogs, etomidate reduces CBF more rapidly than $CMRO_2$, suggesting that it may have some direct cerebral vasoconstricting properties.[489,608] No CBV data are available, but the drug does reduce ICP.[161,171,489] It is possible to produce an isoelectric EEG, but this may be preceded by intermittent spiking, which may be associated with myoclonus.[603] True seizure activity (as distinguished from myoclonus) is not typically seen in normal patients. However, in patients with convulsive disorders, small doses (8–12 mg) of etomidate can elicit seizures, and the drug can be used to unmask seizure foci during operative EEG mapping.[194,603]

Recently, toxicity related to the propylene glycol solvent has been reported in patients given etomidate infusions for long periods of time.[398]

Ketamine

Ketamine is capable of producing increases in CBF,[320,724] and in ICP, particularly in spontaneously breathing patients.[153,675] It has also been reported to increase ICP when used for anesthetic induction.[74] Thus, for many years, ketamine was one of the few agents whose use was deemed absolutely contraindicated in neuroanesthesia. The subsequent literature on this drug is extremely contradictory. In 1982, Schwedler et al. reported no important CBF changes in chronically instrumented goats (as long as ventilation was supported),[667] although others have reported significant increases in both rabbits and dogs.[40,604] In 1990, Werner et al., using TCD to assess CBF, demonstrated a clear dose-related CBF increase, whereas Mayberg et al. saw no changes in either V_{mca} or ICP when the drug was given to anesthetized and ventilated individuals.[452,803] Friesen et al. found that ketamine could block the ICP response to intubation and infants, and had no direct ICP effects when ventilation was supported.[229,230] It is difficult to draw firm conclusions from such data, other than to concur with suggestions that ketamine is probably

inappropriate as a sole agent for neurodiagnostic procedures.

Eltanolone

Eltanolone is a new steroid hypnotic with a rapid onset of action and short duration of action.[120] Only one study of its cerebrovascular effects has appeared, and this demonstrates an action very similar to other intravenous agents.[811]

Opioids

It was once believed that narcotics had no effect on CMR or CBF because even 1–3 mg/kg doses of morphine have little effect on CBF and CMR in ventilated patients who were also receiving N_2O.[340] However, drugs like fentanyl have changed this picture. Low doses of fentanyl (e.g., 5–15 μg/kg) probably have little effect, but much larger doses of fentanyl (e.g., ≈50–100 μg/kg), sufentanil, alfentanil, and remifentanil progressively decrease CMR and CBF in many species, including humans.[121,312,367,502,518,829] The maximum reduction is ≈40–50%, with $CMRO_2$ values of ≈2 mL/100 g/min and CBF values of 20–25 mL/100 g/min being observed in patients given "cardiac" doses of fentanyl (typically combined with small doses of diazepam).[518,519] The CMR/CBF changes occur in parallel with progressive EEG slowing[668,797] although isoelectricity is not achievable. High doses of most opioids can produce rare seizures in humans[595,625] and seizure-associated histopathologic injury in some animals;[378] however, efforts to consistently demonstrate seizures in normal humans have been generally unsuccessful.[520] Low-voltage spikes similar to discharges seen during sleep have been reported in cardiac surgical patients[363] and seizures have been reported following high-dose fentanyl in patients with complex partial epilepsy.[728] Finally, meperidine is a well-known convulsant as a consequence of the activity of its metabolite, normeperidine.

Although opioids produce dose-related reductions in CBF and CMR, they have never found a major role in the control of ICP. One reason may relate to a unique property of these drugs. In 1990, Milde et al. reported that bolus administration of 2–200 μg/kg doses of sufentanil produced transient but often pronounced increases in ICP in lightly anesthetized dogs.[487] This report was the subject of great debate, but several subsequent human studies have shown that the synthetic opioids can increase ICP under some (poorly defined) conditions.[9,442,700] Fentanyl and sufentanil can also increase CBF (as measured by TCD) in normocarbic human volunteers.[756] The mechanism for such changes remains unclear—perhaps activation of mu (μ) receptors on cerebral vessels plays some role. However, the only available clinical trials suggest that opioid–N_2O anesthesia is acceptable for elective neurosurgery,[745] and show no clear advantages of any particular opioid.[233] This latter conclusion may change as experience is gained with the ultrashort-acting opioid remifentanil.[248,312]

The CNS effects of naloxone also have been the subject of numerous studies. Naloxone alone probably has no important CBF/ICP effects.[44] When carefully titrated, it normalizes CBF and $CMRO_2$ in narcotized subjects.[446] However, abrupt reversal with excessive doses of naloxone has resulted in hypertension, pulmonary edema, dysrhythmias, and intracranial hemorrhage.[212,585]

Sedative Agents

Benzodiazepines and Antagonists

Diazepam, midazolam, and lorazepam typically produce small falls in CBF or $CMRO_2$, in both sedative and anesthetic doses.[221,223,372,612,771] A distinct ceiling effect is present, and an isoelectric EEG is never produced.[221] No data on CBV are available. The ICP effects of these drugs are strikingly small.[244,726]

Flumazenil was introduced as a receptor-specific benzodiazepine antagonist. Like naloxone, it has little or no CNS effect when given alone.[222] It also appears to have no unique properties when used to reverse a benzodiazepine.[372,611] However, Fleischer et al. noted a dramatic rebound increase in canine CBF (and ICP) to values higher than baseline when a high-dose midazolam anesthetic is reversed by the bolus administration of a large dose of flumazenil.[221] Similar changes have been recorded by Chiolero et al. in humans.[127] This phenomenon is akin to the withdrawal phenomena seen when naloxone is given in large doses after narcotic anesthesia. Flumazenil is also known to precipitate seizures.

Butyrophenones (Droperidol)

Most data on droperidol were been obtained when it was used in combination with opioids. Large doses (0.35 mg/kg) in dogs can reduce CBF by 40% but not change $CMRO_2$.[480] This change occurred very gradually, and the pattern of decreasing CBF without changing $CMRO_2$ or blood pressure is unique among anesthetics. In humans, the combination of droperidol (5 mg) and fentanyl (100 μg) uniformly reduced CBF and ICP, but droperidol alone (in relatively large doses) seems to produce a small increase.[137,492,497] In view of these data, it is unlikely that small antiemetic (0.0625–1.25 mg) or sedative (2.5–5 mg) doses of droperidol have any important CBF/ICP effects.

Dexmedetomidine

Since the early 1990s, there has been intense interest in the sedative/anesthetic properties of drugs that act as agonists at central α_2-adrenegeric receptors.[99,453,454] The best characterized (and most potent) of these agents is dexmedetomidine.[182] Although there is little clinical experience with this drug in neurosurgery, experimental studies clearly demonstrate its ability to markedly reduce CBF in both animals and humans,[350,843] and to reduce ICP in animals.[846] What remains uncertain is whether this vasoconstriction (which is at least partially independent of changes in CMR) is beneficial or not. The drug also may reduce seizures thresholds (and hence may be a "proconvulsant").[496]

Volatile Agents

When halothane was introduced in the 1950s, it was hailed as the neuroanesthetic of choice. It was nonflammable, induction and emergence were rapid and smooth (compared with ether), anesthetic depth and arterial pressure could be easily and quickly controlled, >95% O_2 could be given, and ventilation was usually adequate to prevent severe brain swelling. If not, ventilation was easily controlled. However, in the late 1960s it was discovered that halothane could increase ICP. Despite its decade-long record of success, the use of halothane in neurosurgery declined. This was accelerated by the enthusiasm for barbiturates that appeared in the early 1970s and by the development of short-acting opioids. A resurgence in the use of volatile anesthetics for neurosurgery was prompted by the introduction of insoluble ethers, first enflurane and then isoflu-

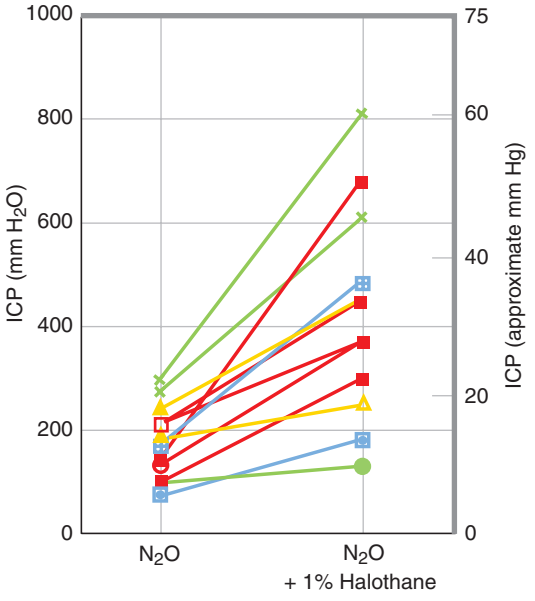

FIGURE 50–14. Intracranial pressure (ICP) responses to the addition of 1% halothane in a series of patients with space-occupying intracranial lesions. ICP was measured with a ventriculostomy. (Modified and reprinted from Jennett WB, Barker J, Fitch W, et al. Effects of anesthesia on intracranial pressure in patients with space-occupying lesions. Lancet 1969;I:61, with permission from Elsevier.)

rane. Both of these drugs were initially reported to have advantages over halothane in terms of CNS effects. Unfortunately, despite widespread beliefs, these "advantages" remain generally unproved.

Halothane, Enflurane, and Isoflurane

The effects of halothane on CBF were first examined in humans in 1964.[812] During normocapnic administration of ≈1.2% halothane (inspired), global CBF was 51 mL/100 g/min, as compared with awake normal values of 44 mL/100 g/min in the same group of subjects. The authors concluded that "halothane in the concentration studied was "…a mild cerebral vasodilator." (*Note:* Compare the magnitude of these CBF changes with that produced by a 5 mm Hg change in $Paco_2$; see Fig. 50–9.) The first "clinical" correlate was reported by Jennett et al. in 1969, who demonstrated ICP increases in neurosurgical patients (Fig. 50–14).[336] This was confirmed by Adams et al. in 1972.[4] Neither group found any evidence of clinical deterioration in the patients given halothane, although Adams et al. demonstrated that ICP changes were not seen in the presence of hypocapnia.

In 1974, enflurane was introduced into clinical practice, followed in 1981 by isoflurane. Numerous human and animal studies have compared the CBF/CMR effects of these agents with those of halothane.[101,197,280,417–419,476,644,741,829] Since some of the earlier studies (particularly that of Eintrei et al.[197]) showed that halothane (at least in doses >1 MAC [minimum alveolar concentration]) resulted in the largest CBF changes, many clinicians concluded that isoflurane and enflurane were "better" than halothane. Because the capacity of enflurane to induce electroencephalographic seizures, particularly during hypocapnia, is viewed as "bad," the result was growth in the popularity of isoflurane as a neurosurgical anesthetic.

Unfortunately, this scenario may be wrong. The reported CBF differences among these drugs may be an "artifact" of the specific measurement methods used. Recent work disputes the idea that volatile agents "uncouple" flow and metabolism and also supports the idea that changing CMR plays a major role in defining the CBF changes produced by the drugs. Finally, data exist concerning the relationships between the CBF, CBV, and ICP effects of these drugs, and lastly it may be incorrect to conclude that differences in CBF can be translated into differences in clinical usefulness and safety.

CBF: Flow Distribution and Method-Related "Artifacts" In an earlier section, Significance of CBF and CMP, we cautioned against interpreting CBF measurements without understanding the limitations inherent in the specific measurement method used. This caveat applies to volatile anesthetics. In 1988, Hansen et al. demonstrated that 1 MAC halothane and isoflurane produced identical hemispheric CBF values in rats.[280] However, ^{14}C-iodoantipyrine autoradiography revealed that the two drugs produced remarkably different flow *patterns.* Subsequent SPECT studies by Reinstrup et al. confirmed different flow distribution pictures.[606] Halothane selectively increased flow to the cortex while reducing subcortical flow. By contrast, isoflurane resulted in more uniform flow patterns. This implied that if one were to compare the CBF effects of these volatile agents using a technique that selectively looked at the cortical mantle (e.g., most ^{133}Xe washout methods), halothane would appear to have the greater effect. By contrast, if whole-brain flow were examined (e.g., using a Kety-Schmidt technique), flows would be very similar.

There is animal and human evidence to support this hypothesis (Table 50–3). At least 13 studies compare halothane and isoflurane in some manner. These were all carried out at roughly 1 MAC doses but with variable background anesthetics (e.g., N_2O, morphine, subarachnoid tetracaine). However, *within* each study the CBF effects of the volatile agents were determined under similar conditions, and hence the differing background conditions do not confuse the comparison. When the method used to measure CBF provides cortically weighted data, flow values average 1.6 times greater with halothane than with isoflurane. However, when *global* measurements are compared, there are no differences between these agents.

We recognize that this is circumstantial evidence but believe that it is compelling. All volatile agents are mild cerebral vasodilators. However, there appear to be no major differences in their effects on global CBF. If the CBF–CBV relationships are similar for these different drugs, we would predict that isoflurane and halothane would have similar CBV effects. Taking the argument one step further, we would also predict that these agents should have identical effects on ICP. This is explored in the following sections.

It is tempting to dismiss the regional differences in the CBF effects of these drugs as an academic curiosity. However, such observations have impor-

TABLE 50–3.

The Relative Cerebral Blood Flow Effects of Volatile Agents and the Influence of Measurement Method

Authors	Reference	Year	Species	Method	Cortical/ Global	Halothane	Isoflurane	Halothane/ Isoflurane Ratio
Todd et al.	416	1984	Cat	IC ^{133}Xe	Cortical	61 ± 15	48 ± 24	1.3
Eintrei et al.	111	1985	Human	Topical ^{133}Xe	Cortical	177 ± 39	67 ± 27	1.8
Scheller et al.	372	1986	Rabbit	H_2 clearance	Cortical	138 ± 94	62 ± 27	2.2

Hansen et al.	158	1988	Rat	Autoradiography	Cortical	185 ± 18	154 ± 19	1.2
Young et al.	458	1989	Human	IH/IV ^{133}Xe	Cortical	34	24	1.4
Madsen et al.	226–228	1986–87	Human	Kety-Schmidt	Global	36 ± 8	33 ± 11	1.1
Hansen et al.	158	1988	Rat	Autoradiography	Global	150 ± 16	147 ± 19	1.0

Where available, all values are presented as mean ± standard deviation (SD) (with SD calculated when standard error of mean [SEM] is reported in the original article). The designation of cortical vs. global refers to the primary area studied using the cerebral blood flow (CBF) method listed in the fourth column. For example, cortical measurements obtained with microspheres indicates that cortical tissue was specifically separated from underlying regions, whereas cortical measurements using H_2 clearance indicates electrode placement in the cortex. "Global" indicates that flow values reflect both cortical and deep structures combined (e.g., H_2 electrode placed in the confluence of venous sinuses). In all cases, CBF values within a row are reported either in the same manuscript, or represent work from the same laboratory using the same methodology. Background anesthetics do differ from study to study, but are consistent within a row, except for the values listed in parenthesis. All measurements were made at approximately 1 minimum alveolar concentration (MAC) of volatile agent, except for Boarini et al. (1.3 MAC). The data from Michenfelder et al. represents values obtained prior to carotid cross-clamping in grade 1 patients undergoing carotid endarterectomies.

tant implications relative to the *mechanism* by which volatile agents influence CBF. If these drugs acted by directly relaxing vascular smooth muscle, we would expect to see either more uniform flow distribution patterns or at least *similar* distribution patterns with different agents. How does one explain markedly different regional effects? We believe that some factor must be acting as an intermediary. Additional support for this hypothesis comes from experiments in our laboratory, in which a focal cryogenic injury dramatically attenuated the CBF increase seen with isoflurane.[592] Most important, this altered flow response was seen in brain regions far removed from the site of injury, regions in which the response to CO_2 was unaltered. The nature of this hypothetical mediator is unknown at present but could be biochemical, metabolic, or neurogenic. There are now a growing body of data suggesting that either NO, a prostaglandin, or acetylcholine may play some intermediary role in the effects of volatile agents, although the data are still incomplete.[375,376,460,503,712,749]

CBV and ICP Based on the apparent similarity of the CBF effects of halothane and isoflurane, we predicted that the two drugs should produce similar changes in CBV and ICP. In 1982, Artru[32,33] measured the acute changes in CBV produced by 1 MAC concentrations of halothane, enflurane, and isoflurane in dogs ventilated with 70% N_2O. All three drugs produced 8–11% increases in volume, with no statistical differences. Subsequently, Weeks et al. quantified cerebral plasma volume in rats anesthetized with 1 MAC halothane and isoflurane. There were no differences between these agents during normocapnia.[800]

There is less information available regarding ICP. All three volatile agents are capable of increasing ICP.[3,4,258,336,510] However, the only human comparative data came from the two studies by Adams et al. with halothane and isoflurane.[3,4] The two agents were not studied concurrently nor in equipotent doses, but both studies indicated that (a) the two drugs could increase ICP when given during normocapnia, (b) neither drug had any ICP effect when given to hypocapnic patients, and (c) none of the ICP increases seen with either agent were associated with any adverse clinical outcome. Finally, animal work by Scheller et al. showed that in rabbits with severe brain injuries and preexisting intracranial hypertension, the ICP effects of the drugs were essentially identical (Fig. 50–15).[645]

There are two possible exceptions to this "halothane = enflurane = isoflurane" hypothesis. Artru showed that volatile agents have quite different effects on CSF production and reabsorption.[31,33,42] Enflurane produces an increase in CSF production, and prolonged exposure can lead to slightly higher ICPs. By contrast, halothane decreases CSF production, a change that Maktabi et al. suggest is mediated by vasopressin.[425] Drummond et al. and Scheller et al. have provided evidence that there may be some unique interaction between CO_2 and isoflurane. Drummond et al. showed that the slope of the CBF–$Paco_2$ response curve between 20 and 40 mm Hg was steeper for isoflurane than halothane,[189] whereas Scheller et al. noted that when isoflurane was given to hypocapnic rabbits, CBF actually decreased (but rose with halothane).[644] Weeks et al. found that although CBV was identical during normocapnic anesthesia with halothane and isoflurane, CBV fell more readily during hypocapnic isoflurane anesthesia than with halothane.[800] Thus it is possible that there may be agent-specific ICP differences during hypocapnia although this was not observed by Scheller et al. in injured animals.[645]

CMR Volatile agents increase CBF at the same time CMR is decreasing. This was interpreted by many as indicating that these drugs "uncoupled" flow and metabolism. We now know that this is not true. As noted, Kuramoto et al. showed parallel increases in CBF and CMR during stimulation of the femoral nerve in dogs anesthetized with halothane.[385] Furthermore, Maekawa et

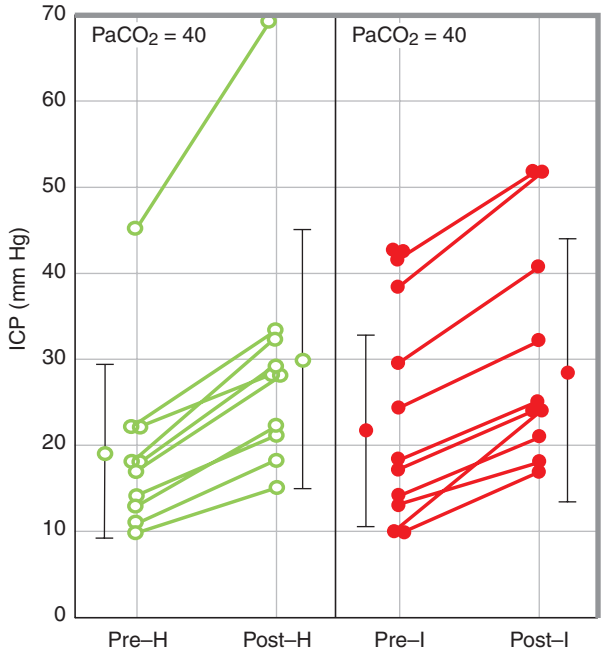

FIGURE 50–15. Maximum intracranial pressure (ICP) responses to the addition of 1 MAC (minimum alveolar concentration) halothane (on the *left*) or isoflurane (on the *right*) to normocarbic rabbits after a focal cortical brain injury. The background anesthetic was morphine-N_2O. Baseline ICP in both groups was elevated by the injury (to 18–20 mm Hg), but the increases produced by the volatile agents were statistically identical. (Scheller MS, Todd MM, Drummond JC, et al. The intracranial pressure effects of isoflurane and halothane administered following cryogenic brain injury in rabbits. Anesthesiology 1987;67:507–512.)

al. and Hansen et al. both showed that linear relationships between CBF and CMRGlu are maintained during halothane and isoflurane anesthesia, at least with concentrations of ≈1 MAC (and possibly higher) (see Fig. 50–11).[281,421] These experiments demonstrate that coupling is present during these relatively modest doses of volatile agent, although Kuramoto et al. did provide some evidence for true uncoupling at higher concentrations of halothane (>2 MAC).

The persistence of coupling has two implications. First, because the different volatile agents have different effects on CMR, observed variations in cortical flow may be the result of differing effects on metabolism, rather than different direct effects on the cerebral vasculature. With intact coupling, the direct vasodilating effects of a drug may be offset by the indirect, metabolically linked vasoconstriction. Two agents with identical direct vasodilating properties, but with differing metabolic effects, may have very different effects on CBF. Second, they suggest that the CBF effects of a volatile agent may depend on the metabolic condition of the brain at the time of agent administration. This latter possibility is best demonstrated by Drummond et al., who exposed rabbits to equi-MAC concentrations of halothane and isoflurane and noted that halothane appeared to produce a greater increase in cortical CBF (as expected).[190] However, when baseline $CMRO_2$ was reduced by the administration of barbiturates, the flow effects of the two drugs were identical. An essentially identical experiment was carried out in humans by Matta et al. using TCD—with essentially identical results.[450] Such experiments suggest that the influence of a volatile agent may depend highly on the other drugs that have been given to the patient during that anesthetic.

Precautions The previous comments indicate that the simple concepts concerning the different effects of volatile agents on the brain are not correct. Although it would be incorrect to state that there are no differences between volatile agents, these three agents are certainly more similar than heretofore believed. All three can increase CBF, CBV, and ICP. Nevertheless, these drug-induced ICP increases have never been demonstrated to be detrimental and are easily counteracted by other ICP control measures, such as hyperventilation. To conclude that such agents are contraindicated in all but a tiny fraction of neurosurgical patients is a serious misinterpretation of the available data. More importantly, to conclude that "halothane is bad but isoflurane is good (or better)" is simply wrong, at least with respect to cerebrovascular physiology.

Desflurane and Sevoflurane

These newer agents may have some advantages over the current drugs because of their low blood-gas solubility characteristics (0.6 for sevoflurane; 0.4 for desflurane), which should allow more rapid titration of anesthetic depth and faster emergence. Several studies of the cerebrovascular effects of sevoflurane have appeared.[141,370,429,642,643] Of interest is that essentially all of these showed a modest decrease in flow, even under conditions where isoflurane resulted in small increases. Although it is tempting to conclude that this suggests some "advantage" to sevoflurane, it is also important to realize that the reported differences were small. One potential problem with sevoflurane is that it is metabolized actively, releasing inorganic fluoride.[682] Prolonged use can lead to elevated fluoride concentrations,[373] and this process can be accelerated in animals given enzyme-inducing drugs, such as phenobarbital and phenytoin.[307] Because many neurosurgical patients are taking such drugs, the potential for renal toxicity, particularly with long operations, needs to be addressed in future research studies.

In the early 1990s, the group at the Mayo Clinic reported dose-related increases in CBF with desflurane (as long as MAP was supported), and reductions in $CMRO_2$.[410] When blood pressure fell, CBF declined.[486] The most direct comparison of desflurane with isoflurane was performed in humans by Ornstein et al.[554] These measurements were performed in hypocapnic patients undergoing craniotomy, and showed essentially identical reductions in CBF with both drugs after induction, with no subsequent increases as dose was raised. The one unique finding with desflurane is that it appears to produce a small but steady increase in ICP.[523] Artru has demonstrated a decrease in intracranial compliance with desflurane, which may be the result of altered CSF dynamics.[38]

None of these physiology studies have addressed the crucial issue of the clinical acceptability/advantages of these agents. However, given the relatively minor differences seen between the cerebrovascular behavior of these drugs and isoflurane, it is unlikely that their use poses any significant problems—although it is equally uncertain that they offer any practical advantages.

Nitrous Oxide

For some inexplicable reason, most clinicians think of N_2O as having few cerebrovascular effects. This is not true. N_2O can increase CBF in animals and humans by more than 60–100%,[66,173,566] and can produce large ICP increases in patients with mass lesions.[293,511] Similar increases in CBF and ICP can be seen when N_2O is added to a volatile agent or opioid background,[11,188,281,346,390,629] and Archer et al. showed that N_2O can increase CBV.[24] The CBF changes are not altered by hypocapnia[740] although the ICP response can be blunted if compliance is improved. A similar alteration of the ICP response to N_2O can be achieved by the administration of any agent that will decrease CBV (e.g., thiopental).[575]

Several investigators have attempted to compare the CBF effects of N_2O with those produced by volatile agents. Their results suggest that N_2O may be a *more potent* vasodilator than either halothane or isoflurane. For example, Hansen et al. compared the CBF effects of a 1 MAC anesthetic provided either with a volatile agent alone, or by a combination of 0.5 MAC volatile agent and 0.5 MAC N_2O.[281] In all cases, CBF was higher in the presence of N_2O. Similar results have now been obtained in two human studies.[11,390] Adding N_2O to a volatile agent background did not have any CMR effects, suggesting that one reason for the dramatic CBF effects of N_2O is that vasodilatation is unopposed by indirect, CMR-mediated vasoconstriction.[600]

One unique property of N_2O is its low solubility in air, and its propensity to diffuse rapidly into closed, air-filled spaces, such as a pneumocephalus.[627] Because pneumocephalus is an almost uniform consequence of intracranial surgery[556,602] some have argued against the use of the drug. However, as long as N_2O is used throughout the procedure and can equilibrate with any air bubble before the dura is closed, its use poses no problems, and discontinuation can actually reduce ICP at the end of surgery.[178,691]

Adjuvant Drugs

Nondepolarizing Muscle Relaxants

Intracranial Pressure Effects Although many studies have been done, one is struck by the extraordinarily benign nature of these agents in terms of CBF and ICP. The only suggestion of a detrimental effect follows the bolus administration of large doses of *d*-tubocurarine, where histamine release can increase both CBV and ICP.[725]

Interactions with Phenytoin and Other Anticonvulsants There is one practical concern regarding nondepolarizing relaxants and neurosurgery. Case reports and clinical studies have demonstrated that treatment of patients with phenytoin (and possibly carbamazepine) increases the dose requirements for all nondepolarizers except perhaps atracurium, and markedly reduces the duration of action.[552,553] The mechanism involves changes in both protein binding and in the number of acetylcholine receptors.[368,441]

One other factor occasionally complicates the use of nondepolarizing relaxants in neurosurgery. This is the presence of local neurologic deficits, particularly hemiplegia. It has long been known that paretic/plegic extremities are relatively resistant to the action of nondepolarizing relaxants.[504] Titration of relaxants in response to twitch monitoring of this extremity can lead to relative overdosage and difficulties with reversal. This can pose certain unique problems during intracranial surgery because in many institutions, the operating table is positioned such that the paretic extremity is the most readily available (i.e., contralateral to the surgical hemisphere).

Succinylcholine

There is little question that succinylcholine can increase ICP in humans.[437,494,512] In early work, these ICP changes could not be separated from those caused by laryngoscopy or changes in ventilation, but more recent studies indicate the drug has ICP effects that are clearly independent of other events.[494,708] Animal studies indicate that these changes are associated with increased CBF and may be related to increases in muscle spindle afferent activity.[391,392] These ICP effects can be completely blocked by prior paralysis or "precurarization" with pancuronium or metocurine,[284,391,494] indicating that the peripheral neuromuscular junctions play some role.

Does this mean that succinylcholine is contraindicated in neurosurgery? Probably not. The changes in ICP are modest and transient. There seems little reason to avoid the drug in situations where very rapid paralysis is needed. This does not apply to most elective situations, but under emergency conditions, the consequences of an unsecured airway and hypoxia/hypercapnia are far worse than any changes that might occur with succinylcholine. Furthermore, when succinylcholine is given to severely head-injured patients in ICU situations (or to animals with intracranial hypertension), it appears to have no such detrimental effects.[213,272,380]

Antihypertensives

Smooth Muscle Relaxants: Nitroprusside, Nitroglycerin, and Hydralazine All antihypertensive drugs with direct smooth muscle relaxant properties are capable of increasing ICP in humans, and this is clearly true for these particular agents.[148,149,242,438,760] However, the idea that these drugs (at least nitroprusside and nitroglycerin) increase CBF as well has little consistent support.[474] Essentially all studies (human and animal) have reported either no change or a fall in CBF.[45,139,294,395,577] These indicate that these drugs are capable of increasing CBV independently of their effects on flow. This possibility has been directly investigated in two studies. Michenfelder and Milde gave dogs nitroprusside under conditions where blood pressure was maintained constant and observed an increase in ICP without a rise in CBF.[474] Dahl et al. measured flow velocity in the basilar cerebral vessels using transcranial Doppler methods and also measured CBF using SPECT during nitroglycerin infusion.[163] They found that MCA flow velocity decreased while CBF was unchanged. These changes can be explained only by an increase in the diameter of the MCA, which did not translate into a flow change. In both cases, the results are compatible with drug effects on CBV independent of CBF. This may be a manifestation of completely normal physiology. If autoregulation is intact, a reduction in arterial pressure must be accompanied by cerebral vasodilatation, which acts to maintain CBF constant.

This vasodilatation is manifested by an increase in CBV. In other words, some of the ICP increases seen with antihypertensives (or hypotensive agents) may be a reflection of a normal process rather than a pathologic one.

One can argue that an increase in ICP combined with a fall in CBF may be detrimental, and these changes have lead some to conclude that these drugs are contraindicated in patients with mass lesions. Is this concern reasonable? In this case the answer is both yes and no. Nitroprusside can produce ICP-related neurologic deterioration in animals with mass lesions,[509] and there is one report of a decrease in the level of consciousness in a human given modest doses of the drug.[438] No similar observations have been made with nitroglycerin, but since most work suggests its ICP effects are identical, it is reasonable to accept the possibility. The difficulty with this caveat is that it limits the anesthesiologist to a group of clearly less useful/reliable drugs, e.g., trimethaphan (assuming that similar ICP changes don't occur). Furthermore, nitrates (and hydralazine) have been successfully used for many years in patients with a wide variety of neurologic disorders. Part of this success probably relates to the techniques with which the drugs are used. Marsh et al. documented that the magnitude of the ICP change is related to the speed of onset of drug effect.[436] When the dose of nitroprusside was gradually increased over many minutes, no ICP changes were seen. Presumably this allowed time for spatial compensation. This is also probably the reason that hydralazine, which has a very slow onset, has been used so widely with such safety in neurosurgical practice. In addition, these drugs are most often used in combination with other drugs (e.g., β-blockers, captopril) that act to reduce the total dose of vasodilator given and hence their ICP effects.

Antiadrenergic Agents: α- and β-Blockers and Trimethaphan As stated, nonanesthetic adrenergic agonists and antagonists appear to have little effect on resting CBF. These drugs also have little effect on ICP. Labetalol has been studied extensively in both animals and humans. Orlowski et al. administered labetalol to 15 postoperative neurosurgical patients who previously had required nitroprusside for the control of hypertension.[551] Mean ICP decreased from 11.3 mm Hg with nitroprusside to 8.6 mm Hg after conversion to labetalol. Esmolol has also been used for blood pressure control in neurosurgical patients.[522] Its ICP effects have not been well evaluated but are expected to be minor.

There is relatively little information available concerning the CBF/ICP effects of pure α-blocking drugs (phenoxybenzamine, prazosin) in the context of neurosurgery, and much of this is quite old. Most authors suggest that these agents have little direct CBF/ICP effects, but shift the autoregulatory curve to the left, at least when hypotension is produced by hemorrhage.[276,362] Presumably, this results from blocking the effects of high circulating catecholamine concentrations.

For many years, the ganglionic blocker trimethaphan has been touted as an antihypertensive with little or no cerebral vascular effects. This is probably untrue—or at least the drug is not remarkably "better" than nitroprusside.[474] However, because this agent is now effectively obsolete, we do not discuss it further.

Calcium Channel Antagonists Most work with calcium channel blockers has focused on their potential as cerebral protectants. However, in many hospitals, these drugs are used for the acute control of hypertension. All of the available agents (verapamil, diltiazem, nifedipine, nimodipine, and nicardipine) can increase ICP in both animal models and humans.[63,71,237,238,535] Consequently, they have no apparent cerebrovascular advantages over smooth muscle relaxants, except perhaps in certain patients with ischemic heart disease. They are relatively long acting, and nifedipine can be given sublingually. Nicardipine has now supplanted verapamil and diltiazem as an intravenous antihypertensive.

Adenosine Adenosine is used for the treatment of supraventricular dysrhythmias.[117] It (or its analogue, adenosine triphosphate [ATP]) can be given intravenously, and its effects are rapid in onset and of generally short duration. Unlike nitroprusside, the drug appears to have few toxic side effects, and tachyphylaxis is rare.[697] However, modest degrees of blood pressure reduction have been associated with increases in ICP.[765] It has not been well evaluated as an antihypertensive (as opposed to being used for induced hypotension).

HYPEROSMOLAR AGENTS IN NEUROANESTHESIA

The intraoperative fluid management of neurosurgical patients presents special challenges for anesthesiologists. Osmotic agents are among the most important tools to control ICP, however prospective data to establish clear guidelines for the use of these agents are lacking.[542] When the planned strategy only involves fluid restriction, patients are at risk for systemic hypotension, and a decrease in cerebral perfusion pressure resulting in brain ischemia. During surgery, administration of volatile anesthetics and potent vasodilators may further decrease cardiac filling pressures without actual changes in intravascular volume.[844]

One of the key physical features of any solution is its osmolality (the others are vapor pressure, freezing point and boiling point). Osmolality is a function of the number of particles in solution, commonly expressed as milliosmoles (mOsm) per kilogram of solvent.[842] Table 50–4 lists the osmolarity and oncotic pressure of some commonly used intravenous fluids.[844] Oncotic pressure is the osmotic pressure generated by the solutes larger than some arbitrary limit (usually 30,000 molecular weight).[844] All plasma proteins (e.g., albumin, globulins, fibrinogen) contribute to the oncotic pressure, which represents less than 0.5% of the total osmotic pressure. For most physiologic solutions, the terms "osmolality" and "osmolarity" can be used interchangeably.

Osmolarity is an important determinant of fluid movement between various physiologic compartments, as water from the solution of lower osmolarity, will move across a semipermeable membrane, and into the solution of higher osmolarity until the osmolarities of the two solutions are equal or the hydrostatic pressure is great enough to prevent additional flow of water across the membrane.[844]

In normal brain tissue, the blood–brain barrier limits the diffusion of molecules between the intra- and extravascular spaces. Small pore sizes of the blood–brain barrier prevent the movement of plasma proteins and even of ions (e.g., sodium, chloride, potassium) between the intravascular compartment and the interstitium of the brain.[218] The blood–brain barrier acts very much like a semipermeable membrane and the movement of water across it is deter-

TABLE 50–4.

Osmolarity of Commonly Used Intravenous Fluids

Fluid	Osmolarity (mOsm/L)	Oncotic Pressure (mm Hg)
Lactated Ringer solution	273	0
D5 lactated Ringer solution	525	0
0.9% saline	308	0
D5 0.45% saline	406	0
0.45% saline	154	0
20% mannitol	1098	0
Hetastarch (6%)	310	31
Dextran 40 (10%)	approx. 300	169
Dextran 70 (6%)	approx. 300	19
Albumin (5%)	290	19
Plasma	295	21

mined by the relative differences in the concentrations of impermeable constituents on either side of the membrane.[844] The situation is different in peripheral tissue, where the pore sizes between the capillary endothelial cells can be of much greater magnitude and movement of water is primarily determined by the plasma concentration of large macromolecules; primarily plasma proteins.[496,842] The differences between the mechanism for fluid movement in brain and peripheral tissue explain why administration of the large volumes of isoosmolar crystalloid results in peripheral edema (dilutional reduction in plasma protein concentration) but does not increase brain water content or ICP. Likewise, it follows that fluid restriction typically has no direct effect on brain water content.[844] Only the infusion of hyperosmolar or hypoosmolar solutions cause a net flux of water (by creating an osmotic gradient) across the intact blood–brain barrier.

Administration of large volumes of hypotonic (e.g., hypoosmolar) solutions increases brain water content and edema,[842] which can be deleterious in cases of intracranial hypertension.[88,287,615] Conversely, administration of hypertonic solutions "dehydrates" normal brain tissue and decreases ICP.[844] The acute effect of hyperosmolar solutions on lowering the ICP has been demonstrated.[154,260,261,673,744,845]

If the blood–brain barrier is intact, plasma osmolarity is the key determinant of water movement into brain. Therefore, compromise of blood–brain barrier integrity greatly decreases the effectiveness of any hyperosmolar agent. If the blood–brain barrier is profoundly disrupted, plasma proteins will extravasate into the interstitial space and in addition to being unable to generate an osmolar gradient, it will be impossible to generate even an oncotic gradient. In such situations, changes in plasma oncotic pressure will not have any effect on water movement because no oncotic gradient between the plasma and the brain interstitial space can be produced (i.e., the proteins leak out of the capillaries into the brain tissue).[844] Therefore, the beneficial effects of the hypertonic solutions in cases of the localized brain injury, with disruption of the blood–brain barrier, are most likely derived from the ability of hyperosmolar solutions to cause a fluid flux out of brain tissue where the blood–brain barrier remains intact.[844,845]

Historically, a variety of osmotic agents (urea, mannitol, glycerol, and sorbitol) have been used for the treatment of cerebral edema. The ideal osmotic agent creates a desirable osmotic gradient by remaining largely in the intravascular compartment, is inert, nontoxic, and has minimal systemic side effects.[88,287,555,640,841]

Mannitol

Mannitol, a simple alcohol derivative of the sugar mannose, came into clinical use in the 1960s. In current practice, mannitol is the mainstay of hyperosmolar therapy. Its popularity comes from the stability of solution, lack of toxicity and less vein irritation as compared to urea or hypertonic saline (HS). The effects of a single injection of mannitol on intracranial pressure are rapid, ranging from 30 to 60 minutes and a return to baseline values in 2–10 hours.[646] Mannitol lowers ICP as a result of its osmotic properties and potent diuretic effect, and it decreases brain water content and cerebrospinal fluid volume.[78,179,810] Mannitol is considered to act first rheologically, improving cerebral perfusion by decreasing viscosity[18] and enhancing oxygen delivery, and then osmotically. But the rheologic effect of mannitol is not well documented and still remains debatable. Mannitol is commonly administered as 0.25–1 g/kg doses via a rapid intravenous infusion.[844] Neurotrauma guidelines recommend 20% mannitol (2 mL/kg) infused over 20 minutes for patients with elevated ICP and for patients with clinical signs of herniation and/or progressive neurologic deterioration before placement of an ICP monitor.[87]

The effects of 1 and 2 g/kg doses of mannitol on serum electrolytes and plasma osmolality have been examined.[427] In addition to an increase in plasma osmolality, there was a decrease in bicarbonate concentration. Mannitol doses of 1 g/kg result in an initial mild hyponatremia and hypokalemia from dilutional/osmotic effects. Hypernatremia can occur after diuresis. Neurotrauma guidelines identify 320 mOsm/L as a safe level to avoid nephrotoxicity from mannitol.

Glycerol

Glycerol is naturally present in mammalian tissues. Intravenous glycerol has less hemodynamic impact than mannitol and can produce hemolysis when administered rapidly.[555] Oral glycerol can reduce ICP without significant gastrointestinal side effects. The use of glycerol for control of intracranial hypertension in the United States has become obsolete.

Hypertonic Saline

Since the first description by Weed and McKibben in 1919, the beneficial effects of intravenous HS solutions on brain tissue have attracted interest for clinical use.[799] In the early 1980s, hypertonic solutions were shown to be beneficial in hemorrhagic shock.[381,572,703] Subsequently, the cerebral effects of these solutions were explored in animal models, supporting use in human brain injury. The goal of osmotherapy for cerebral edema is to maintain a euvolemic (or a mildly hypervolemic) but also hyperosmolar state.[88,287] A serum osmolality of 300–320 mOsm/L (corresponding serum

Na^+, 145–155mEq/L) has been recommended for patients with poor intracranial compliance/elastance.[615,716]

Experimentally the symptoms of hypernatremia (Na^+ >145 mEq/L) have been correlated with the speed of increase in serum sodium concentrations and appear at an osmolality >350 mOsm/L.[29,451,773] A sudden increase in natremia of more than 30 mEq/L will likely lead to lesions.[773] Clinical data on the complications of hypertonic states are found mostly in anecdotal reports of hypernatremia linked to dehydration.[29,773]

HS is an effective agent for hyperosmolar therapy that also has hemodynamic, vasoregulatory, and immunomodulatory effects.[20,22,181,283,549] Mechanisms explaining the vasoregulatory properties of HS include plasma volume expansion leading to increased vessel diameter, decreased endothelial cell edema, and decreased vascular resistance secondary to accentuated release of nitric oxide[69,145,762] HS administered in bolus form demonstrates a biphasic response, suggesting first rheologic, then osmotic effect. Although a reduction in cerebral water content has been demonstrated in many animal models of cerebral edema,[53,750,751] the cerebral rheologic effects have only been established in animal models of hemorrhagic shock.[672] Under conditions of disrupted blood–brain barrier, the benefit of HS is tempered by extravasation of osmotically active substances into injured tissue (reverse osmotic gradient).[555,640,841]

Traumatic Brain Injury

Osmotic agents reduce traumatic brain injury (TBI)-induced intracranial hypertension.[241,319,589,713] Shackford et al. demonstrated that treatment with either HS or hypertonic lactated Ringer solution ameliorated elevated ICP in TBI patients.[671] Vialet et al. described more effective treatment with isovolemic bolus (2 mL/kg) of 7.5% HS solution than with 20% mannitol in patients with refractory elevated ICP after severe TBI.[773] However, no difference in clinical outcome was demonstrated between the two groups.

Ischemic Stroke

Ischemic stroke results in biphasic cerebral edema. Early anoxic injury results in cell death and intracellular swelling or cytoxic edema. Blood–brain barrier disruption after hypoxia–ischemia involves a cascade of events in which cytokines, vascular endothelial growth factor (VEGF), and nitric oxide are important mediators.[55] Disruption of blood–brain barrier and consequent vasogenic edema are known to intensify 3–72 hours after cellular injury.[314,583,648,784] Randomized clinical trials have not shown the routine use of mannitol in cases of ischemic stroke to be beneficial.[78,79] Mannitol boluses effectively reduce ICP but have no effect on clinical outcome.[2] Current guidelines recommend the use of mannitol in patients with large ischemic strokes only to control episodes of intracranial hypertension.

The efficacy of HS solutions in ischemic stroke is still not well defined. In patients experiencing intracranial hypertension resulting from large hemispheric stroke, HS seems to exert an effective transient improvement that is at least as reliable as, and may be greater than, mannitol.[666]

Subarachnoid Hemorrhage

HS boluses have been reported to be effective in patients with subarachnoid hemorrhage (SAH) and elevated ICP refractory to mannitol.[319] Suarez et al. demonstrated that HS solutions could be used in patients with vasospasm and mild hyponatremia after aneurysmal SAH.[714] HS solution increases central venous pressure (CVP) and CPP; both are desirable effects of hypervolemic therapy for cerebral vasospasm. Likewise, intravenous infusion of HS enhanced CBF in patents with high-grade SAH.[759] However, the increase in global perfusion observed after HS appears to only be of transient duration.

Tumor Edema

The space-occupying lesion and peritumor edema both play an important role in ICP elevation. The mechanisms leading to tumor-induced cerebral edema are not well understood but are related to histologic grade, the degree of brain invasion, and, in the case of meningioma, the amount of cortical blood supply.[542] Brain edema secondary to tumor responds well to corticosteroids. Hyperosmolar therapy is used for ICP crises, usually as a step before surgical decompression. There is only one study where investigators have examined the effect of HS on cerebral edema secondary to tumor effects.[753] They found HS to be more effective than either furosemide or mannitol in reducing both ipsilateral and contralateral water content as measured by wet-to-dry-weight ratios.

Caution is required in the clinical use of HS as there are risks associated with the HS therapy. Table 50–5 summarizes the potential complications of using the HS.[89]

Although some suggest that HS solution administration may be particularly efficacious for lowering ICP in patients with head trauma, SAH, and postoperative cerebral edema, there are few, if any, direct comparisons of equiosmolar loads of hypertonic saline versus mannitol. Furthermore, no study of HS has reported a survival benefit of using HS as a treatment or prophylaxis for ICP episodes in intracerebral hemorrhage patients, this may be because of the generally poor prognoses of patients with intracerebral hemorrhage.[89,542]

ANESTHETIC NEUROPROTECTION

The potential neuroprotective effect of anesthetic agents was originally described in the 1960s[252,802] when patients under general anesthesia appeared to demonstrate greater tolerance to ischemia than those who were not anesthetized. It was hypothesized that the mechanism for this increased tolerance was that the anesthetic-induced suppression of electrocortical activity enabled the brain to better tolerate a disruption in metabolic substrate delivery.[483]

The putative neuroprotective effect of anesthetics may be especially important for patients undergoing procedures known to have increased risk for cerebral ischemia (e.g., carotid endarterectomy, cardiopulmonary bypass, cerebral aneurysm clipping). However, until the therapeutic efficacy of individual anesthetics is established in humans, specific clinical recommendations are unwarranted. Although there are many preclinical studies that demonstrate the potential for anesthesia-induced neuroprotection, results of those animal studies have often been conflicting. Human trials are few, underpowered, and rarely assessed long-term efficacy.

The apparently conflicting results of laboratory outcome studies may be at least partially explained by consideration of methodologic details. During

TABLE 50–5.

Potential Complications with HS Therapy

Potential Complication	Comments
Myelinolysis	Occurs commonly with rapid overcorrection of preexisting hyponatremia. Not reported with a change in serum sodium from a normonatremic to hypernatremic state in humans. In naïve, uninjured rats, induced hypernatremia (145–155 mEq/K) with HS solution does not cause myelin injury (Δ 17 mEq/L) and a rapid increase of 35–40 mEq/L is required to induce myelinolysis.
Encephalopathy	Confusion, lethargy, seizures, and occasionally coma.
Subdural hematomas	Shearing of bridging veins owing to hyperosmolar contracture of the brain or effusions away from the dura
Transient hypotension	Occurs with rapid intravenous bolus injections, usually transient.
Pulmonary edema, heart failure, ventilatory failure	Rapid volume expansion is especially important in patients with poor cardiovascular reserve and a history of heart failure, neurogenic cardiac stun or pulmonary edema.
Hypokalemia	Rapid expansion of plasma volume without concomitant potassium replacement could lead to hypokalemia and cardiac arrhythmias.
Hyperchloremic academia	HS solution as a mixture of chloride-to-acetate (50:50) is recommended to avoid metabolic acidemia.
Coagulopathy	Caused by elevations in prolonged activated prothrombin and partial thromboplastin times impaired platelet aggregation.
Intravascular hemolysis	Slow infusion of HS solution is recommended because rapid changes in osmotic gradients in the serum may lead to hemolysis.
Phlebitis	Central route of administration is recommended. May occur if concentrated HS solution (› 2%) is given via the peripheral route.
Rebound cerebral edema	Usually occurs because of rapid withdrawal leading to elevated intracranial pressure or herniation syndromes. Slow withdrawal of therapy with HS solution is recommended.

Reproduced with permission from Bhardwaj A and Ulatowski JA.[89]

the first 30 years of research, there was little or no effort to control brain temperature, plasma glucose, or perfusion pressure in animals exposed to anesthetics for the purpose of studying neuroprotection. All of these factors are now known to be major determinants of ischemic outcome.[788] Also long-term outcome studies have been infrequently conducted. Finally, in the majority of studies, the presumed neuroprotective anesthetic was compared with another anesthetic that was assumed to be inert. Later studies, capitalizing on development of minimally invasive stroke models, have shown that these "control" anesthetics, in fact, may also have neuroprotective effects.

Anesthetics provide protection in animal models of both cerebral ischemic and traumatic insults when used during the insult but anesthetics have failed to provide benefit when administered after the insult.[635,705] This likely eliminates their use for postischemic neuroresuscitation.

Another important limitation of anesthesia-induced neuroprotection is the timing of the outcome assessment in animal models. When the outcome is assessed within a few days (less than 1 week) after an ischemic insult, protection is often robust, but 2 weeks after the ischemic insult, no protection is present. Kawaguchi et al. subjected rats to prolonged focal ischemia while awake or anesthetized with isoflurane. Isoflurane markedly reduced cerebral infarct size when assessed 2 days postischemia.[360] However, when assessed at 14 days, the infarct sizes of the isoflurane group had expanded to a size similar to the awake group. Subsequent work provides evidence that the infarct expansion was attributable to apoptosis, which isoflurane failed to inhibit.[331] These results suggest that isoflurane delays but does not, by itself, prevent cerebral infarction caused by focal ischemia. However, these studies examined durations of vessel occlusion that markedly exceed those typically observed in clinical practice. It remains possible that sustained protection by volatile anesthetics can occur when more clinically relevant durations of ischemia are studied.

There are no data on long-term benefit from barbiturates given either prior to or during ischemia. Nehls et al. showed improved histologic outcome in baboons anesthetized with thiopental relative to those anesthetized with isoflurane following 6 hours of middle cerebral artery occlusion.[527] However, they did not evaluate long-term outcome intervals of weeks to months, now recognized to be essential in defining neuroprotective efficacy.[98,135,331,359,763] No effort has been made in vivo to determine whether barbiturates suppress apoptotic responses to ischemia. Thus, it remains unknown if barbiturate administration provides meaningful long-term neuroprotection following an ischemic event.[98,135,331,359,763] Based on the observation that brain continues to deteriorate for days to weeks after an ischemic insult, the concept of "neuroprotection" has been reconsidered. Classically, neuroprotection has been defined as prevention of cell death by treatment administered prior to the ischemic insult. In contrast, neuroresuscitation has been defined as treatment initiated after the ischemic insult, intended as a rescue for dying cells. Thus, the concept of neuroprotection can be extended to include protection of cells from delayed demise, attributable to apoptosis, inflammation, and oxidative stress that persists long after blood flow has been restored. The mechanisms of anesthetic neuroprotection remain under investigation. Barbiturates decrease $CMRO_2$,[798] inhibit protein kinase C (PKC), decrease production of free fatty acids,[683] scavenge reactive oxygen species,[693] inhibit white blood cell function,[529] and inhibit excitatory neurotransmitter receptors.[727]

Volatile anesthetics share many of these properties. It has been postulated that a principal mechanism of anesthetic protection is potentiation of GABAergic afferentation consistent with an important known mechanism of anesthetic action. This would serve to balance markedly increased excitation occurring during the acute phase of energy failure. Others suggest that volatile anesthetics also serve to regulate intracellular calcium concentrations, which are critical to cell survival.[256]

Halothane,[472,527,628,791,792] isoflurane,[65,66,240,476,488,530,789] and sevoflurane[792] have been extensively studied in animal models of ischemia, most with short-term outcome analysis. In most cases, substantive protection was observed. However, there have been no attempts to define efficacy in human outcome trials. Thus, while volatile anesthetics have both theoretical and experimental bases to expect protection in humans, their efficacy in clinical scenarios remains speculative.

Nitrous oxide has been the subject of numerous studies. It carries the theoretical advantage of inhibiting glutamatergic hyperexcitation during ischemia because it is an *N*-methyl-D-aspartate antagonist. However, nitrous oxide can cause an increase in cerebral metabolic rate, especially if administered alone. Available evidence indicates that nitrous oxide is inert in the context of ischemic brain injury and its use during high risk procedures is better defined on the basis of criteria other than neuroprotection.[786]

Propofol (2,6-diisopropylphenol) attenuates neuronal injury in a number of experimental conditions, but studies in models of cerebral ischemia have yielded conflicting results. Moreover, its neuroprotective mechanism is poorly defined. Propofol reduces postischemic damage in models of transient ischemia[239,374,579,609] but not permanent focal ischemia.[757]

Etomidate showed similar efficacy as thiopental in a model of severe forebrain ischemia[634] but was less effective than thiopental in transient focal ischemia.[184] Etomidate was less effective than desflurane in maintaining tissue PO_2 during cerebral aneurysm surgery in humans.[310] Etomidate may even increase brain injury from focal ischemia in rat in part by a nitric oxide mechanism.[186] For these reasons, etomidate is rarely advocated as an intraoperative neuroprotective agent.

α_2-Adrenergic agonists (e.g., dexmedetomidine) showed neuroprotection in some models of cerebral ischemia[383] but α_2-agonists may also prevent hyperemia and appropriate oxygen supply during hypoxia[461] because of a direct cerebral vasoconstriction.[329]

In addition to the anesthetics listed, many other nonanesthetic drugs are reported to have credible experimental neuroprotective properties. These drugs have been exploited to target specific mechanisms of ischemic injury by serving as reactive oxygen and nitrogen-species scavengers, excitatory amino acid antagonists, caspase inhibitors, inducible and neuronal nitric oxide synthase inhibitors, stimulators of endothelial nitric oxide synthase, protease inhibitors, and antiinflammatory/neutrophil adhesion agents. However, none have yet been found to provide clinically evident benefit and that implicates an exceedingly complex response of brain to ischemia.

Despite the many reports defining the neuroprotective effects of general anesthetics in animal models, there also are reports that under some conditions isoflurane, nitrous oxide, and ketamine have direct toxic effects in the brain, which are manifested by apoptotic neurodegeneration.[337,755] The developing brain (i.e., newborn animals) appears to be particularly sensitive to the toxic effects of these anesthetics. Anesthetic-induced brain injury is at least partially related to an excitatory amino acid toxicity and can be prevented by treatment with GABA agonists.[330,332] The clinical importance of this experimental finding has yet to be determined.

ANESTHETIC PRECONDITIONING

Activation of injury cascades by a sublethal stimulus induces tolerance toward a subsequent lethal insult.[128] Preconditioning in the brain relies on the fact that prior exposure of the brain to minor "insults" will result in increased tolerance to future, more severe events. Acquired tolerance may be transiently and rapidly induced, or delayed and sustained.

Preconditioning can be classified as early or delayed. Early preconditioning produces tolerance within minutes to hours after the inducing stimulus, whereas delayed preconditioning requires hours to days to develop a tolerant state.[102] In the brain, more attention has been paid to delayed preconditioning,[369] although from an anesthesiologist's perspective, acute preconditioning might offer more clinical relevance. Preconditioning can be induced by different stimuli such as mild ischemia, oxidative stress, hyperbaric oxygenation, inflammation, seizures, spreading depression, heat stress, and pharmacologic agents, including anesthetics.[128,177,369]

The underlying mechanism of preconditioning-induced neuroprotection remains controversial, but many studies described increased mitochondrial resistance as a consequence of preconditioning.[26,166,835,837] In clinical medicine, it has been suggested that preconditioning may be achieved with preoperative short-duration anesthetic administration, hyperoxia, electroconvulsive shock, the potassium channel opener diazoxide, and erythromycin.[279] However, none of these strategies has been tested in humans and thus none is (yet) clinically employed.

Hypothermia

The neuroprotective quality of systemic hypothermia in neurosurgery was first reported in 1955.[407] Many laboratory studies have since demonstrated that mild hypothermia (a clinically relevant temperature of approximately 91.4–95°F [33–35°C], which does not require cardiopulmonary bypass) improves outcome from experimental ischemic and traumatic brain injury.[132,176,493] Translation of these observations to humans has been more difficult. A large-scale trial of mild hypothermia applied after traumatic brain injury failed to show benefit in humans.[133] Similarly, a study employing moderate hypothermia in patients undergoing cerebral aneurysm surgery found no benefit in 3-month outcome.[743] Both studies evaluated a large number of patients and were expected to find benefit. It remains plausible that study designs are in part accountable for the absence of benefit. For example, in the trauma study, cooling was not started for many hours after the injury occurred. Plausibly, an earlier onset of induced hypothermia might provide a different result and this is being investigated. Regarding aneurysm surgery, the goal was to achieve hypothermia at the time the aneurysm was clipped, after which rapid rewarm-

ing was begun. Perhaps earlier onset of hypothermia and/or a prolonged interval of postoperative cooling might have provided a different result. However, until such studies are conducted, we are left with no evidence that hypothermia provides benefit to patients with these disorders.

A large number of drugs have been studied in humans and to date none have been proven to be effective neuroprotectants. This raises the question whether it will ever be possible to achieve improved outcome when treatment is begun after the primary injury has occurred. We now know this is possible. Recent studies in patients with out-of-hospital cardiac arrest,[82] and with perinatal birth hypoxic/ischemic encephalopathy,[250,674] have been positive when cooling was begun shortly after the primary insult. In cases of cardiac arrest, the effects observed were sufficient for both the American Heart Association and the International Liaison Committee on Resuscitation[537] to recommend sustained cooling of patients remaining comatose after out-of-hospital ventricular fibrillation-induced cardiac arrest. The pediatric community has been less welcoming to the positive-outcome studies in infants and recommends that induced hypothermia be considered as an evolving therapy.[299]

The case of cardiac arrest may be the most relevant to management of anesthetic complications. The suggestion that patients suffering unanticipated perioperative cardiac arrest sufficient to sustain brain injury should be cooled to improve outcome is not novel.[75] Because of the low incidence of cardiac arrest in the operating room, it is unlikely that we will ever achieve a randomized prospective trial that definitively states whether or not induced hypothermia is efficacious in improving neurologic outcome. Similar issues pertain to cases of drowning which are sporadic. The American Heart Association has recognized the dilemma in defining efficacy in populations other than out-of-hospital cardiac arrest. They have stated that similar therapy may be beneficial for patients with nonventricular fibrillation cardiac arrest.

Thus hypothermia has been proven to offer postischemic efficacy in two discrete human conditions. The question arising from these studies is how widely can this data be extrapolated to circumstances that have not been specifically studied. We know from the traumatic brain injury and intraoperative aneurysm surgery trials that hypothermia, at least as it was employed in those trials, offers no benefit. Thus it cannot be expected to be universally protective. Conversely, both the trauma and aneurysm studies found negligible complications from the use of hypothermia. Consequently, current practice decisions, outside the bounds of out-of-hospital cardiac arrest, rest on the clinician's interpretation of the clinical circumstances resulting in an ischemic or hypoxic insult (e.g., loss of airway, drug-induced respiratory arrest, drowning, accidental asphyxia), and feasibility of rapid induction of moderate hypothermia. When loss of consciousness persists beyond restitution of ventilation and circulation, such patients are typically placed in an intensive care environment and are subjected to mechanical ventilation. Induction of hypothermia and its sustained maintenance for 12–24 hours is readily achieved by surface cooling (or gastric lavage or intravenous infusion with chilled saline). This approach to management should be considered.

PRACTICAL CLINICAL MANAGEMENT

The challenge is now to translate physiology and pharmacology into a rational approach to clinical management. This is not an easy task because few clinical management schemes have been subjected to an objective trial. As a result, most published material, including this chapter, is contaminated by personal opinion and by experiences that may be unique to a particular practice setting. Because there is insufficient space to discuss every possible neurosurgical procedure, we have chosen to concentrate on three major areas: craniotomy for a supratentorial tumor, craniectomy for an infratentorial tumor, and craniotomy for an intracranial vascular lesion. Our discussion concludes with a few brief remarks about the care of patients with cervical spine disease and those undergoing transsphenoidal operations.

Anesthesia for Supratentorial Craniotomy

Preoperative Assessment

Neurosurgical patients require a comprehensive preoperative evaluation as does any other individual scheduled for major surgery. However, other than routine information, three specific questions need to be asked: (a) Where is the mass lesion? (b) Is ICP already elevated? and (c) What is the patient's current neurologic status? The answer to the first question defines the surgical position and hence the placement of monitoring devices. It also tells something about the likely deficits that can arise. If retraction on the lateral sensorimotor cortex is needed to obtain exposure, the patient's contralateral upper extremity may be weak in the early postoperative period. If cranial nerve (CN) III must be manipulated by the surgeon, one pupil may be widely dilated in the postoperative period. With respect to ICP, not all patients with mass lesions have intracranial hypertension (most do not). Conversely, clinically normal patients do not necessarily have normal ICPs. Determining the likelihood of intracranial hypertension requires examination of the patient and a preoperative CT or MRI scan. The clinical diagnosis of intracranial hypertension is obvious in some patients (e.g., diminished level of consciousness, nausea, vomiting, anisocoria, papilledema). However, most patients do not have any of the "classic" signs and symptoms of intracranial hypertension and present to the hospital with headaches, seizures, or a focal neurologic deficit. The changes associated with intracranial hypertension include extensive edema surrounding the tumor and evidence for activation of compensatory mechanisms, including ventricular effacement, shifted midline structures, and compression of the basal cisterns. Alternatively, certain lesions, particularly those in the midline, may obstruct the normal flow of CSF and produce hydrocephalus. Finally, a brief neurologic examination provides the anesthesiologist with some basis for later comparison; the anesthesiologist may be the last person to see the patient before the induction of anesthesia and the first to see the patient awaken. This examination need not be complex. A simple, quick "move your arms, move your legs, open your eyes, where are you, what's your name…" is sufficient.

Premedication and Transportation

After evaluation is complete, it is possible to make an intelligent decision regarding premedication. All sedatives

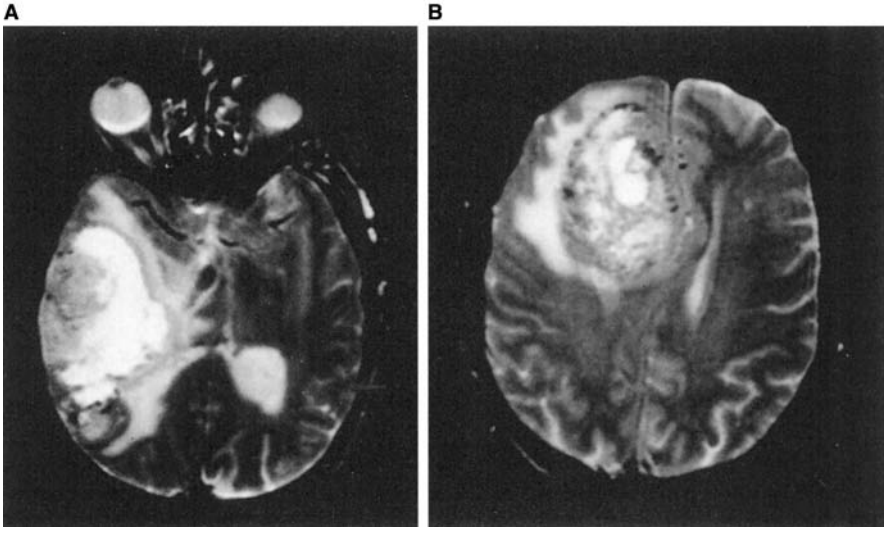

FIGURE 50–16. MRI scans from two patients with very large intracranial lesions. In both cases there was significant edema, ventricular effacement, and some degree of midline shift (most noticeable in **B**). In spite of similar apparent mass effects, however, intraoperative ICP measured under identical anesthetic conditions ($Paco_2$ = 30 mm Hg, isoflurane/N_2O anesthesia. 10° head up, no mannitol until after measurements) was 12 mm Hg in **A**, and 55 mm Hg in **B**. The only difference between patients was that the family of **B** has noted the patient to be a bit more sleepy than usual.

(including benzodiazepines) carry the potential for producing hypercapnia. Fortunately, a few mm Hg increase in $Paco_2$ is probably not important in the great majority of patients, and most experienced neuroanesthesiologists are comfortable with premedicant doses of midazolam. In contrast, opioids are almost universally avoided. A 5-mg dose of midazolam may be appropriate for a neurologically intact patient with a small mass lesion, no midline shift, normal ventricular size, and so forth, but it might be fatally inappropriate in an individual such as the one shown in Fig. 50–16. Most patients are not closely observed after premedicant drugs are given. If they deteriorate, they may do so alone. An alternative is to administer sedatives intravenously when patients arrive in the operating room area where they can be more closely observed.

Given the value of a head-up posture for controlling ICP, we recommend that patients with mass lesions be transported with the head of the bed elevated 15–30°.

Monitoring

Monitoring decisions have become simpler in recent years because of the availability of capnography, pulse oximetry, and automated oscillometric blood pressure cuffs, as well as the routine acceptance of arterial catheters. Arterial catheters serve two roles. First, they assist in the management of arterial blood gases and blood chemistry. Second, they provide a beat-by-beat view of blood pressure, which may be useful in conditions where autoregulation is disturbed. If a patient is cooperative, it is reasonable to place the catheter before the induction of anesthesia, but it is rarely mandatory. It may be entirely acceptable to induce anesthesia guided by expired CO_2, SpO_2 (oxygen saturation as measured using pulse oximetry), and a rapidly cycled automated cuff; the arterial catheter can be placed later. In fact, some cases can be handled without an arterial catheter, particularly in healthy individuals with small and easily accessible tumors.

CVP catheters are used far less commonly. They provide information about intravascular volume when major blood loss is anticipated (e.g., during the resection of a large and highly vascular meningioma or hemangioblastoma). They also can monitor intrathoracic pressure. Finally, they can be invaluable in the fluid management of patients who are at risk for the development of diabetes insipidus, such as those undergoing resections of large suprasellar tumors such as craniopharyngiomas. There are very few "neurosurgical indications" for pulmonary artery catheterization. These include patients with significant cardiac disease or elderly patients for whom massive blood loss or a very long anesthetic is anticipated, or in whom profound induced hypotension is planned. (The use of pulmonary artery catheters as a monitor for venous air embolism is discussed later in Venous Air Embolism.)

A recurrent question concerns the "indications" for the preanesthetic placement of ICP monitors. Fifteen years ago some would have said that any patient with a large mass lesion, particularly with an altered level of consciousness, should have a preoperative ICP monitor placed.[73] This is no longer reasonable. Our current understanding of ICP physiology and the effects of our agents have made it unnecessary to directly measure ICP for purely anesthetic reasons. The intraoperative measurement of ICP before opening the dura (e.g., with an epidural device) may prove useful in determining the need for mannitol, and there is some limited interest in postoperative monitoring, particularly in patients having posterior fossa procedures.[558,617] It is not, however, possible to make any firm recommendations for such use at present.

Anesthetic Induction and Maintenance

There is simply no evidence that any one approach to anesthetizing these patients is better than any other. The fact that one drug increases CBF more than another or has a 10% small effect on ICP is insufficient to conclude that it is a "bad" neuroanesthetic. Agents such as halothane and N_2O have been used successfully in tens of thousands of patients. However, most commonly "accepted" methods have three goals in common: (a) a smooth induction without sudden hypertension or hypotension; (b) the rapid achievement of hypocapnia before the administration of volatile agents and/or N_2O; and (c) that the technique is compatible with a rapid postoperative emergence. There are obviously many ways to accomplish such goals, and the following points represent only the most general guidelines.

Despite many years of effort and many alternative drugs (e.g., methohexital, Althesin, etomidate, diazepam, midazolam, ketamine, alfentanil, propofol, eltanolone), no induction agent is clearly superior to thiopental. Hypotension during induction can usually be avoided by preinduction volume loading (e.g., 10 mL/kg of lactated Ringer

solution) and by adjusting the dose according to patient age and physical status. The patient should be in a modest head-up posture at the time of induction (i.e., 10°). When consciousness is lost, manual hyperventilation is begun with oxygen. When a patent airway is assured (using oral or nasal airways if needed), a paralyzing dose of a nondepolarizing relaxant is given, and administration of the primary agent is started gradually. The most common alternatives involve incremental loading with one of the synthetic opioids (fentanyl, sufentanil, alfentanil—or perhaps remifentanil) combined with N_2O, or the administration of a volatile agent in progressively increasing concentrations (with or without N_2O). A propofol infusion can also be used. However, data now available indicate that none of these approaches offers any major advantages.[745] With respect to the three opioids, fentanyl is equivalent to sufentanil and alfentanil and much cheaper.[232] Remifentanil has been compared with fentanyl, and again, offers no striking advantages other than slightly more rapid emergence (Warner D, Hindman B, and Young W, personal communications). The trachea is intubated when paralysis is complete. The hemodynamic response to intubation can be blunted in many ways. These include additional opioids (e.g., fentanyl to a total loading dose of 10–12 μg/kg), supplementary thiopental, intravenous lidocaine (1–1.5 mg/kg) or short-acting antihypertensives (e.g., labetalol, esmolol). Topical anesthesia of the trachea is also widely used, although this does not alter the response to laryngoscopy per se.[277] Mechanical ventilation is begun, the endotracheal tube is secured, additional monitors are inserted (e.g., esophageal stethoscope, temperature probes), the eyes are securely closed, and surgical positioning is begun. The patient is covered with blankets (or forced air warmer) to maintain body temperature.

Like induction and maintenance, there are a dozen different ways of waking someone up. We believe that blood pressure should be restored to normal before the dura is closed. This is a simple way of verifying the adequacy of hemostasis. Normocapnia should be present before dural closure is complete; if the brain is so badly swollen that the dura cannot be closed, the patient should be taken to the ICU on controlled ventilation. Because uncontrolled hypertension is associated with an increased incidence of postoperative intracranial hemorrhage,[347] aggressive treatment is necessary. As with other aspects of management, the choice of antihypertensive drug is a matter of personal preference (see previous discussion in Antihypertensives). Some added blood pressure control can be obtained by reducing the dose of atropine or glycopyrrolate given at the time neuromuscular blockade is reversed, thereby avoiding any tachycardia. A very brief period of coughing/gagging at the time of extubation is probably acceptable if blood pressure is controlled, although this can be blunted with lidocaine if desired. We also believe that such patients should be transported to the postanesthesia care unit or surgical intensive care unit with at least some form of blood pressure monitoring, particularly if the resection was very bloody.

Management of Severe Intraoperative Brain Swelling The preceding protocols will serve the majority of cases. The most serious deviation from routine involves the management of the severely swollen brain. Because this is so often mismanaged by the inexperienced anesthesiologist, some specific recommendations are appropriate. The course taken is defined by the answers to some simple questions:

- Is this a major ventilatory disaster?
- Is the brain swollen because of a disconnect, severe hypoxia, hypercapnia, etc.?
- Is the chest moving appropriately?
- Does the patient have a reasonable expired CO_2 waveform, and what is the end-tidal carbon dioxide ($ETCO_2$) concentration?
- What is the SpO_2? An arterial blood gas sample should be drawn immediately.
- Is the swelling related to impaired cerebral venous drainage?

As noted earlier, the problems of venous drainage are often overlooked. We believe that the overwhelming majority of swelling problems encountered in the neurosurgical operating room are related to poor venous drainage. The most common are (a) excessive rotation of the neck, (b) inadequate head-up posture, and (c) some form of expiratory obstruction in the patient circuit. There is little reason for employing pharmacologic ICP control methods unless these have been corrected. Simply increasing the degree of head-up tilt is often sufficient.

- Is the swelling hemodynamic?
- Is the patient hypertensive and/or tachycardic?
- Is the anesthesia too light? In some cases, light anesthesia combined with inadequate paralysis can be manifested by chest tightness and increasing intrathoracic pressures, without other movement.

After these three (a), (b), (c) iatrogenic causes have been ruled out, it is best to first assume that the swelling is related to patient disease, not some iatrogenic factor. The next therapeutic step is to reduce $Paco_2$ to between 20 and 25 mm Hg, and verify that Pao_2 is >100 mm Hg. Ideally, this should be achieved without an increase in mean intrathoracic pressure, something accomplished by keeping an inspiratory-to-expiratory (I:E) ratio >1:2. The limitations of greater degrees of hypocapnia have been described in The Clinical Utility of Hypocapnia.

Next, diuretic therapy is begun, typically with osmotic agents. Such compounds (mannitol, urea, sorbitol and hypertonic saline) all act in the same fashion: they produce an osmotic gradient across the intact blood–brain barrier which acts to "draw" water down its concentration gradient from brain to blood.[217] Again mannitol is the best characterized compound and remains the agent of choice when the patient's baseline osmolality is <290 mOsm/kg. A reasonable starting dose is 0.25 g/kg, a value derived from experience with ICP control after head trauma. However, there is a major difference between controlling ICP (where small volume changes can have huge ICP effects when compliance is poor) and controlling brain bulk (where much larger reductions in volume may be needed to facilitate surgical exposure). For this reason, there should be little hesitation to increase the dose to >1 g/kg if swelling does not resolve. The upper dosage limit is defined only by osmolality, which should remain <310–320 mOsm/kg (Fig. 50–17).[604]

Another alternative (or supplementary) choice is furosemide in doses of 0.3 to 1.0 mg/kg.[633,807] It is not as reliable as mannitol, but may be preferable in patients unable to tolerate the transient intravascular volume expansion

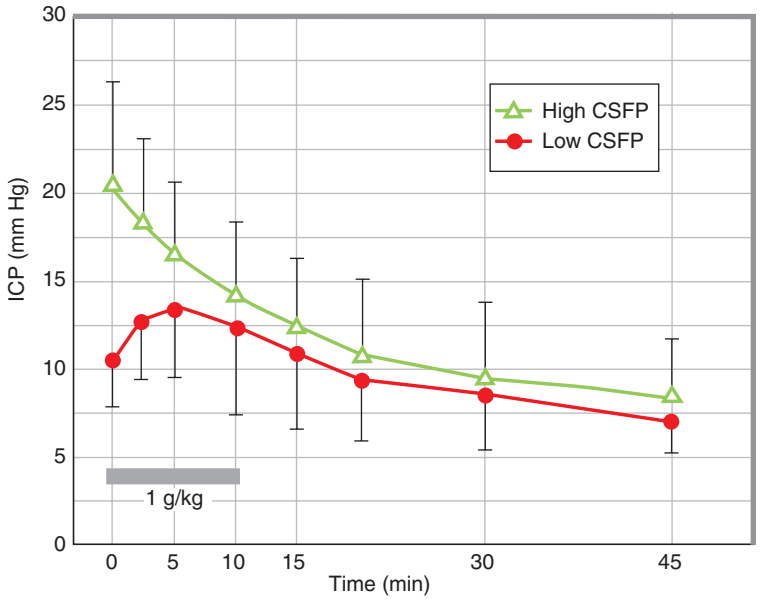

FIGURE 50–17. Changes in ICP (actually lumbar cerebrospinal fluid [CSF] pressure) after the administration of 1 g/kg of mannitol. Patients in the "high CSF pressure" group had a mean premannitol ICP of 20.8 mm Hg, whereas those in the "low CSF pressure" group had a pressure of 10.5 mm Hg. In the low CSF pressure group, mannitol resulted in a significant but transient increase in ICP. Nonetheless, no such transient increase was seen in patients with prior intracranial hypertension. All values are mean ± standard deviation (SD). (Data recalculated from Ravussin P, Abou-Madi M, Archer D, et al. Changes in CSF pressure after mannitol in patients with and without elevated CSF pressure. J Neurosurg 1988;69:869.)

that occurs with mannitol. Its effects are much slower in onset.[807] In situations where brain swelling is severe, a combination of mannitol and furosemide has been used successfully. Under these conditions, the value of furosemide may be related to its unique ability to inhibit the mechanisms that act to maintain normal cell volume in the face of hypertonicity.[458] When normal cells (including neurons and glia) are exposed to a hypertonic environment, they transient shrink, but rapidly regain their normal volume, largely a result of the active importation of chloride. This influx of Cl can be blocked by loop diuretics, with the result being a persistent reduction in cell volume. The major problem with a combination of mannitol and furosemide is the often extraordinary diuresis that ensues—a diuresis that can be difficult to distinguish from severe diabetes insipidus.

If this sequence fails to control swelling, the surgeon should be asked to cannulate one of the ventricles to remove CSF and to decompress any cystic lesions or hematomas. At the same time, anesthetic management should be reevaluated. If fluid removal cannot be accomplished, it may be appropriate to discontinue agents with the potential for increasing CBV. We believe that the first drug to discontinue is N_2O. It can be replaced with a volatile agent, an opioid, or a combination of an opioid and a sedative–hypnotic. If swelling does not resolve, the volatile agent should be discontinued. Only when these interventions fail should high-dose barbiturates be used *as a therapy of last resort.* Before starting, every effort should be made to ensure the patient is normovolemic, using whatever isotonic intravenous fluid is desired. Several groups have shown that barbiturates are both venous and arterial vasodilators, as well as myocardial depressants,[742,754] and Traeger et al. showed that hypotension is most commonly related to inadequate cardiac filling pressures.[754] We begin with incremental doses of 150–250 mg, repeated as often as hemodynamically tolerated. This is continued until swelling is under control or cardiovascular toxicity becomes a problem. In rare situations, inotropic support may be needed.

Anesthesia for Infratentorial Craniectomy: The Sitting Position

Operations in the posterior fossa are unique for several reasons. First, the lesion itself and/or surgical trauma can damage brain areas that control the airway (pharynx, tongue, larynx), respiration, autonomic function, and consciousness. Second, these operations are performed in unusual positions—that is, prone, lateral, or sitting—each of which has particular problems. It is the sitting position that has received the bulk of our attention and that poses the greatest management problems. Consequently, we first discuss the management of the upright craniectomy and then briefly mention the differences introduced by the alternatives.

Problems

In spite of the concerns about venous air embolization, the sitting position is still in widespread use and offers many advantages over alternative positions. These include excellent surgical exposure, particularly of midline structures and those located in or on the high dorsal brainstem or midbrain (e.g., the pineal). There is less pooling of blood and CSF in the surgical field, and blood loss may be less than with nonsitting positions because of the lower venous pressures.[96] It is comfortable for the surgeon. It is often easier to move a large patient into the sitting position. In addition, peak airway pressures may be lower and ventilation–perfusion matching better than those seen in the prone position. The face and airway are accessible, making it easier to monitor facial nerve function. These must be balanced against the disadvantages: (a) venous air embolism, (b) paradoxical air embolism, (c) quadriplegia, (d) hemodynamic deterioration, and (e) pneumocephalus. Other concerns are peripheral nerve injuries and head/neck/tongue edema. In addition, a serious concern in any posterior fossa procedure is the possibility of injury to the lower cranial nerves and respiratory centers.

Venous Air Embolization Venous air embolization (VAE) can occur whenever the pressure within an open blood vessel is subatmospheric. Because normal right atrial pressures range from 2 to 10 mm Hg, this can theoretically occur any time the surgical site is located more than ≈5 cm above the heart. However, experience indicates that clinically significant VAE is rare unless the surgical site is elevated by more than 20–40 cm. (VAE can occur in other surgical settings. However, an enormous number

of patients undergo procedures where the surgical site is higher than the heart, including supratentorial craniotomies, shoulder repairs, hysterectomies, and lumbar laminectomies. VAE has been anecdotally described in all of these, as well as during the injection of air during placement of epidural catheters. However, clinical experience tells us that the incidence of hemodynamically important emboli in such situations is vanishingly low.) In addition, the risk of VAE increases when open veins cannot collapse. This is encountered with injury to, for example, the venous sinuses, cerebellar bridging veins, epidural veins, emissary veins, and marrow spaces in the skull or cervical vertebra. This latter possibility explains occasional embolization of air from pin-fixation sites. Another unusual source of air entry is a *ventriculoatrial* (VA) shunt (*not* a ventriculoperitoneal [VP] shunt). If a bubble enters the ventricles, the shunt acts as a direct route to the heart.

It was once believed that VAE was a rare but fatal complication. When more sophisticated monitors were used, a much higher incidence of generally benign events was seen. Standifer et al. evaluated 322 cases (288 with a Doppler ultrasound) and noted VAE in only 22 patients (7%).[702] However, Matjasko et al. reviewed their experience in 554 seated cases and noted air entry in 41% of patients undergoing suboccipital craniectomies and in 11.4% of those having cervical laminectomies.[445] Young et al. reported a similar incidence (43%) among 146 patients undergoing suboccipital craniectomies, with an overall incidence of 30% (all procedures combined, 255 patients).[827] Black et al. also noted an incidence of 43%.[93] Hence it is reasonable to conclude that among patients undergoing posterior fossa procedures, the incidence of VAE is approximately 40%, compared with 10–15% for cervical spine surgery.

These four studies include ≈1500 reasonably monitored patients, among which VAE was detected in 372. This is probably an underestimate because some earlier patients were not Doppler ultrasound monitored, and there are no data regarding Doppler placement in any study. However, a possible relationship between intraoperative VAE and postoperative morbidity or death could be defined in only 6 cases (≈0.4%). This compares with a "surgical" mortality of ≈2%. Although this, again, may be an underestimate, these data still do not support the idea that the sitting position should be abandoned purely because of the risk of VAE. The obvious caveat is that these results were obtained in centers with a great deal of experience and may not be reproducible in hospitals that do only an occasional sitting procedure.

Paradoxic (Arterial) Air Embolization There is a potential for the passage of air from the right to the left of the heart, with subsequent entry into the coronary or cerebral circulation. This can occur via either the pulmonary vascular bed, or more commonly, a patent foramen ovale (PFO). The incidence of clinically significant paradoxic air embolism (PAE) is unknown. However, a large number of patients are theoretically at risk. Autopsy studies indicate that 25–35% of patients have at least a probe-patent foramen ovale. Given a 40% incidence of VAE, one can calculate that ≈12% of patients are "at risk" for a PAE (30% of 40%). This value is far greater than the number of patients who suffer a deficit/complication of a VAE. Why? First, not everyone with a probe-PFO has a *functional* right-to-left shunt. The number of patients is theoretically reduced even further by the fact that the normal pressure gradient (right atrial pressure less than left atrial pressure) reverses during anesthesia in the sitting position in only approximately 50% of patients. (The importance of this observation has been questioned by Black et al. who demonstrated that changes in the gradient may not be as important as believed, largely because transient reversal of the gradient during a single cardiac cycle occurred commonly in pigs with a surgically created atrial septal defect.[94]) Echocardiographic studies demonstrate that right-to-left shunting of contrast material can be shown in up to 18% of normal volunteers,[412] but was detected in only 6–10% of patients scheduled for surgery.[95] In many cases, shunting was seen only during a Valsalva maneuver that is performed to increase right atrial pressure. Even in anesthetized, sitting patients, echocardiographic studies revealed right-to-left air passage (either during testing or during a clinical VAE) in 3 of 20 patients (15%). The absence of right-to-left shunting, with or without the Valsalva maneuver during the preoperative evaluation, does not preclude the occurrence of paradoxical air embolism intraoperatively.

If 15% of patients suffering a VAE also have PAE, why is the incidence of PAE-related complications so low? The principal reason is that most paradoxical emboli are benign. A review of the anesthetic literature shows a total of 7 patients with echocardiographically documented PAE during sitting surgery.[95,156–158,236] No sequelae were noted in any of these patients. Animal studies in our own laboratory (Dan Reasoner and Brad Hindman, personal communication) suggest that doses of air on the order of 100–150 μL/kg must be directly injected into the internal carotid artery to reliably produce a deficit—which indicates that tiny bubbles are unlikely to detrimental (although continuous streams of bubbles, even small ones, may lead to injury).

These arguments are not intended to suggest that PAE is trivial or that the potential for PAE should be ignored. Quite the contrary—it is a devastating complication. However, every bubble entering the arterial circulation does not mean that a stroke will occur, and *the best prevention of PAE is still the early detection and prevention of VAE*. It has been suggested that all patients considered for a sitting position undergo preoperative echocardiography. Although an attractive idea, it is unlikely to find wide acceptance in an era of cost consciousness, particularly in view of the documented safety of doing the surgery without such studies. A more reasonable approach would be to carry out echocardiographic studies in patients with clinical signs or history suggestive of a PFO, such as unevaluated murmurs now or in the past. This study should be done with contrast medium injected before, during, and immediately after a Valsalva maneuver. If shunting is demonstrated, the procedure should probably be carried out in an alternative position—although surgical considerations must be weighed as well.

Quadriplegia Episodic cases of unexpected quadriplegia/paresis have been reported for many years after cases in the sitting position.[806] Neither the incidence nor the etiology is known with certainty, but two cases were reported among the ≈1500 patients reported in the four studies noted previously. The most likely cause is a combination of cervical cord

compression from extreme neck flexion and a reduced arterial perfusion pressure produced by elevating the neck above the heart. In support of this, McPherson et al. have reported major evoked potential changes with neck flexion/rotation even in a horizontal position.[463] The risk may be greater in persons with cervical cord compression, that is, the same people who undergo cervical procedures in the sitting position.[172] The only suggested preventive measures are the avoidance of extreme flexion and the monitoring of blood pressure at the level of the surgical site, rather than the heart. Somatosensory evoked potential monitoring is a potential but insufficiently evaluated monitor of such conditions.

Hemodynamic Deterioration Moving an anesthetized patient from the supine to the sitting position does result in a number of hemodynamic changes, although few data are available. The most complete study is by Marshall et al., who studied patients receiving one of four anesthetics (enflurane–N_2O, halothane–N_2O, Innovar–N_2O, or morphine–N_2O).[440] In all groups, assumption of the sitting position was accompanied by a decrease in wedge pressure and cardiac output, with an increase in systemic resistance. The smallest changes were observed in patients receiving a combination of morphine–N_2O, but hemodynamic parameters recorded during surgery were remarkably similar with the groups. This study failed to include a "time-control" group of patients receiving the same anesthetic but left in the supine position, and some of the changes may simply be related to the duration of anesthesia, not position. More important, little information is available concerning the hemodynamic consequences of the alternative surgical positions (prone, lateral), but it is noteworthy that Black et al. found essentially identical 20% incidences of hypotension requiring vasopressors in 330 sitting patients and in 229 patients who remained in a horizontal position.[96]

Pneumocephalus Some degree of pneumocephalus occurs in all craniectomies performed in the sitting position;[752] in fact, it is seen in all postoperative craniotomy/craniectomy patients regardless of position.[602] Hence it is not surprising that tension pneumocephalus is a well-described event after such procedures.[702] CSF drains easily in the sitting position, and air will move upward and collect over the cerebral convexity (the "upside-down bottle" effect). If the wound is then closed and the patient returned to the supine position, cerebral venous pressure rises, CBV increases, and the brain reexpands, potentially compressing the gas. This alone may be capable of producing a tension pneumocephalus. Artru has argued that the intraoperative use of N_2O may worsen this situation,[30] although experimental studies disagree[178,691]; the key seems to be whether N_2O administration is delayed until after pathways for air escape have been closed (i.e., whether there is a trapped bubble). Delayed problems can also occur if CSF reaccumulates at a rate faster than the air is absorbed. Tension pneumocephalus may be difficult to diagnose, but should at least be suspected when a patient fails to awaken after an uneventful procedure, deteriorates after awakening, or suffers some unexplained cardiovascular catastrophe. If clinical changes are mild, simple administration of high concentrations of O_2 will speed the resolution of the bubble.[95] If the changes are major, surgical evacuation is indicated.

Other Problems The two final difficulties deserving mention are peripheral nerve injuries[96,456] and severe swelling of the face and tongue.[199,455] Direct pressure injuries can also occur, more commonly in nonsitting positions. Sciatic stretch injuries can also occur if excessive flexion at the hip is allowed. Facial/glossal swelling (sometimes so severe as to preclude extubation) is probably related to excessive neck flexion. Similar swelling can also be seen in the prone position.

Preoperative Evaluation and Premedication

Although intracranial hypertension is a common concern in the patient with a supratentorial tumor, this is less common in those presenting for posterior fossa procedures. The most common cause of elevated ICP in such patients is hydrocephalus, resulting from obstruction of the aqueduct or the fourth ventricle. This is easily recognized on the CT/MRI scan, and in many situations is corrected preoperatively or intraoperatively with a ventricular cannula. Nevertheless, the presence of symptomatic hydrocephalus or elevated pressures in the posterior fossa represent a contraindication to premedication. Asymptomatic persons with small cerebellopontine angle masses or tumors of the cerebellar hemispheres can usually be premedicated without difficulty.

Monitoring and the Physiology of VAE

The principal monitoring challenge of the sitting position is to rapidly detect VAE. Fortunately, extensive clinical and experimental work has removed much of the guesswork from this area.

The slow entrainment of small bubbles is of little significance; either gas dissolves in the blood or the bubbles pass into the pulmonary capillaries and are absorbed. If the embolus is larger and/or enters faster than it can be cleared, one sees progressive occlusion of the pulmonary vascular bed. This results in an increase in pulmonary vascular resistance, a rise in pulmonary artery mean pressure, and an increase in right-heart "afterload" with eventual increase in right atrial pressure. If obstruction is severe, cardiac output will fall, caused by (a) an "air-lock" in the right ventricle (RV), (b) RV failure, or (c) impaired left ventricle (LV) filling caused by displacement of the intraventricular septum by a distended RV. In addition, respiratory abnormalities appear. Vascular obstruction results in an increase in the ventilation/perfusion mismatch ("dead space"; Fig. 50–18). The result is an increased gradient between arterial and $ETCO_2$ concentrations, manifested by a falling $ETCO_2$ and a rising $Paco_2$.[249] These same ventilation–perfusion ($\dot{V}/\dot{Q}$) abnormalities will lead to hypoxemia, partly as a result of mechanical occlusion and partly because of the release of vasoactive compounds from either blood or from the vessel walls. In fact, changes in Pao_2 often precede alterations in positive airway pressure or $ETCO_2$, supporting the idea that vasoactive compounds may be involved. Finally, the bubbles of air entering the capillary bed will result in the appearance of N_2O in expired gas, although this is usually detectable only when a patient is breathing 100% O_2.

In the face of a sudden, massive embolus, these changes occur almost simultaneously. Under such circumstances, "monitoring" is irrelevant. However,

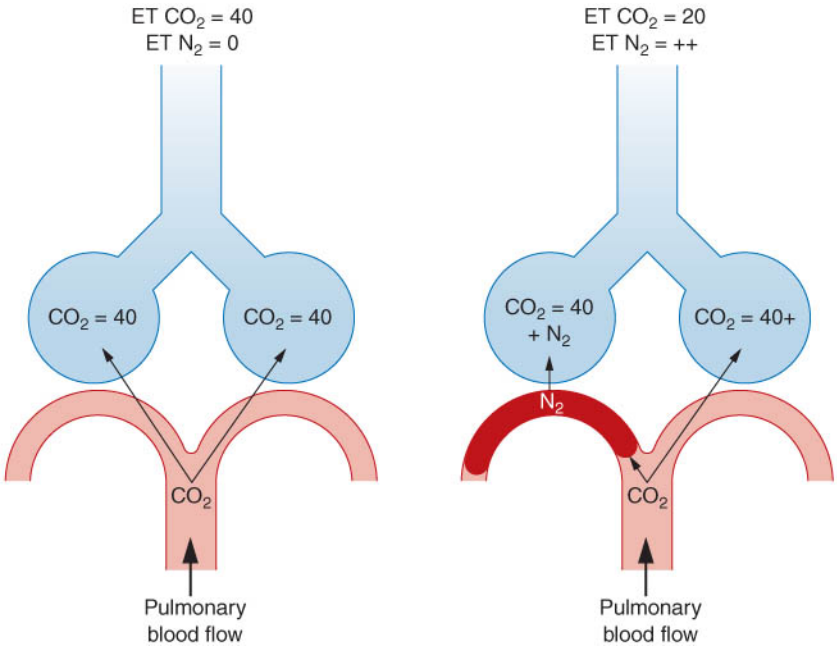

FIGURE 50–18. Changes in expired CO_2 and N_2 in alveoli (***left*** diagram). A VAE does two things (***right*** diagram). First, it occludes a portion of the pulmonary circulation, preventing the delivery of CO_2 to the alveoli. As a result, end-tidal CO_2 (which should represent an alveolar gas sample) will decrease (even though $Paco_2$ may rise). In addition, N_2 present in the gas bubble will diffuse into the alveoli and appear in exhaled gas.

most emboli are not this catastrophic. What typically occurs is a continuous infusion or repeated small boluses of air.

We believe that changes in hemodynamic and respiratory parameters are very insensitive monitors of air entrainment. We believe that the only clinically acceptable "early warning" device is the precordial Doppler ultrasound.[245,475] This device reflects sound waves from moving red blood cells. Bubbles entering the circulation change the reflectance characteristics of the blood and alter the Doppler frequency. Multiple studies and human experience have demonstrated the extraordinary sensitivity of this device. In our operating room, Doppler placement is routinely tested by the injection of 0.25–1.0 mL of air (i.e., 0.004–0.01 mL/kg) or 3–5 mL of agitated saline. Gilgenberg et al. showed that a Doppler can reliably detect air being infused at a rate of 0.021 mL/kg/min in dogs.[245] This is at least 10 times more sensitive than any hemodynamic/respiratory monitor studied under the best of laboratory conditions. It also has the advantage of being audible, allowing the anesthesiologist to attend to other duties. The transesophageal echocardiograph is equally sensitive but requires continuous visual attention (and is far more expensive).[157]

There are admittedly two difficulties with the Doppler: it must be accurately placed and it may be too sensitive. Doppler placement is not a trivial undertaking. It is unacceptable to place the transceiver in the fourth intercostal space to the right of the sternum, hear heart sounds, and proceed (this will identify only 90% of air emboli). One should place the Doppler wherever the right atrium is! Furthermore, this should be done after the patient has been placed in the sitting position and not before, because the heart moves with gravity as the sitting position is assumed. Testing is mandatory and should be repeated at intervals throughout surgery so that all operating room personnel become familiar with the sound of air entrainment and to confirm that the Doppler is still in the right place. The "gold standard" is air or CO_2 injected through a right atrial catheter. If a catheter cannot be placed, air or agitated saline can be injected through a peripheral IV. However, if a convincing change in Doppler sounds is not heard, one cannot depend on the instrument as an early warning device. Under no conditions should a neurosurgical procedure in the sitting position proceed without a properly placed Doppler even in the presence of a capnograph or respiratory gas monitoring.

The question of excessive sensitivity deserves comment. The Doppler commonly presents its audience with a chorus of chirps and blips, none of which appear to be of consequence. Obviously, one cannot disrupt surgery for each. The difficulty lies in deciding which sounds deserve attention. Distinguishing the sounds of air from other sounds is largely a matter of experience, but recognition can be improved by repeated testing of the instrument, by the injection of tiny amounts of air or agitated saline. Determining the amount of air being entrained is a different question, because the Doppler is not quantitative. In some cases, the changed Doppler signal is obvious. In others, one remains uncertain. In the latter, hemodynamic and respiratory monitors become invaluable. In our practice all sitting procedures are monitored with a Doppler, a right atrial catheter, expired CO_2, and expired N_2. If a change in the Doppler signal is noted, attention is shifted to the other monitors. If a change in any of these is noted, the surgeon is notified. A brief Doppler change occurring in isolation rarely brings action. One must be aware of the possibility that the Doppler may miss an embolus. This should not occur with proper positioning, but this may be more easily said than done. Any sudden decrease in $ETCO_2$ or the appearance of expired N_2 should quickly prompt one to aspirate from the right atrial catheter. Any sudden decrease in blood pressure should also be considered as a VAE until proven otherwise.

With these comments, what specific monitors are needed for a posterior fossa craniectomy performed in the sitting position? Almost all patients require arterial catheterization. This is both for blood pressure control and for diagnosis. One needs to remember that blood pressure at the level of the head is lower than that at the heart. For every 30 cm vertical distance between the levels of the heart and that of the brain there are 20 mm Hg difference in mean blood pressure. If the zeroing and calibration of the blood pressure transducer are done at the level of the third or fourth intercoastal space, cerebral perfusion pressure can be estimated by moving the pressure transducer up to the level of the head (the external auditory meatus is a good reference point). Alternatively, one can zero and calibrate the transducer at the level of the

head. Probably the most common and serious complications of such operations involve unintentional injury to cranial nerves or their nuclei, or to other crucial areas on the floor of the fourth ventricle or within the brain stem. Sudden changes in any hemodynamic parameter (blood pressure, heart rate or rhythm) are the most reliable early warning signs of surgical impingement on these crucial structures (although some still believe that respiratory changes in unparalyzed patients are helpful; see the following section, Anesthesia). Beat-to-beat monitoring of arterial pressure provides the necessary early warning. We prefer a right atrial catheter and believe an effort should be made to place one, although failure need not result in cancellation of a case.[469] The greatest value of the right atrial catheter, in our opinion, is to assist in the accurate placement of the Doppler and to help make the diagnosis of VAE when Doppler changes are unclear. A correctly placed Doppler will readily detect a tiny bubble of air injected into the superior vena cava. If it does not, and the catheter location is known to be correct, then the Doppler position needs to be adjusted. Most centers use multiorifice catheters, which allow much more efficient air aspiration.[112,138] The catheter tip should probably be placed just above the right atrium.[112,469] This position can be determined in a number of ways although the most rapid method is still by electrocardiography (ECG). Our practice is to attach the right arm lead of a standard operating room ECG system to the catheter, either via a fluid column (sodium bicarbonate) or via the J-wire used to place the catheter. The catheter is then advanced until a biphasic P wave is seen, then withdrawn 1–3 cm (Fig. 50–19). Some argument exists regarding the site of origin of an ECG signal recorded from a multiorifice catheter.[39] However, because no one has ever shown the clinical need for precise catheter positioning, we think this is generally unimportant. Finally, both expired CO_2 and N_2 are monitored.

Transesophageal echocardiography is a sensitive detector of air and is the only device capable of detecting PAE. However, it requires constant visual attention. It is also not clear whether the use of such a device is cost-effective, given the low incidence of PAE-related neurologic injury. Furthermore, the detection of PAE is quite different from prevention. This is best accomplished by the early detection of VAE, something that the Doppler does exceptionally well. The early detection of large or repeated PAE might be an indication for discontinuation of the sitting position, and the TEE may be useful in those few patients in whom Doppler placement is impossible. On balance, however, we think that it is not justified at present to recommend the routine use of this device, particularly in the absence of any concrete information showing that it can reduce the already low incidence of air-related morbidity. One hopes a more definitive answer to this issue will be available in the future, when current studies with this device are completed.

Anesthesia

As in most neuroanesthetic situations, there are no well-defined indications or contraindications for any particular anesthetic drug combinations. Opioid/N_2O combinations seem to be associated with fewer hemodynamic changes during assumption of the sitting position, although there are few truly important differences between blood pressure in the anesthetized-supine and anesthetized-sitting groups regardless of anesthetic.[440] Some have argued that N_2O should be avoided in all sitting cases because it will diffuse into and expand the size of any entrained bubble. However, it has been shown that the use of 50% nitrous oxide did not increase the risk of venous air embolism in patients operated upon in the sitting position.[405] Alternative anesthetic regimens include volatile agent/O_2, high-dose opioid, or purely intravenous techniques. We believe that nitrous oxide has a major place among the agents used for the anesthetic care sitting position patients. If air embolization takes place, we feel comfortable (as others did in the past) with discontinuing N_2O when air is detected. In this case, the N_2O-free alternative must be determined before the case starts.

Because some degree of neck flexion is required, we routinely place wire-reinforced endotracheal tubes. An alternative is nasotracheal intubation. Wire reinforced tubes are not risk-free in the postoperative period. These tubes are indented permanently if the patient bites on them. Needless to say, this is a life-threatening situation that one needs to deal with promptly. If prolonged postoperative intubation is needed, we recommend changing the wire-reinforced tube to a regular endotracheal tube at the conclusion of surgery. If this is not possible because of airway and tongue swelling, we do not attempt to change the wire-reinforced tube (even over a tube changer). Use of

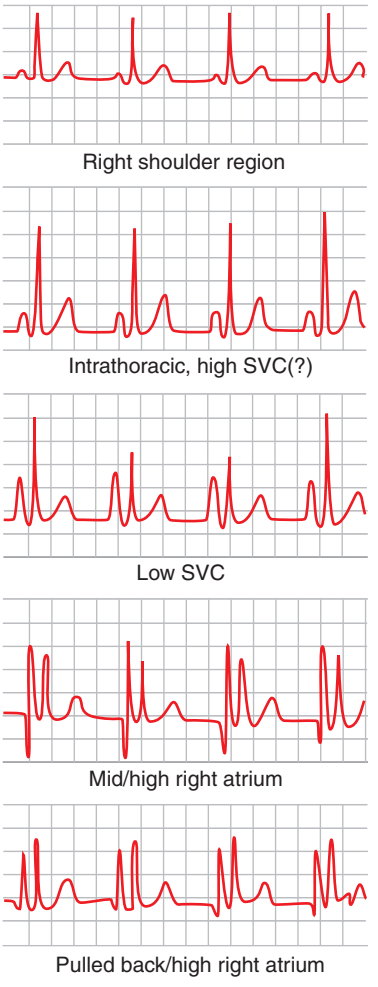

FIGURE 50–19. Typical catheter tip electrocardiograph (ECG) signals obtained during placement of a right atrial catheter for a sitting position procedure. The right-arm lead (+) was attached to the catheter, and a lead 2 configuration was used. In the *top panel*, a typical lead 2 pattern is seen with the catheter tip in an extrathoracic position near the shoulder. As the catheter enters the thorax, the amplitude of all ECG components increases. As the tip nears the right atrium, there is a selective increase in P-wave amplitude, with a relatively sudden change to a biphasic tracing in the high/mid atrium. The bottom tracing was obtained after the catheter was withdrawn 1–3 cm from atrial location and was left to reside in the high atrium or low superior vena cava. (Reprinted from Todd MM. Monitoring in neuroanesthesia. In: Saidman L, Smith NT, eds. Monitoring in Anesthesia. 3rd ed. Boston: Butterworth, 1992: 183, with permission from Elsevier.)

bite-blocking devices, good communication with the patient, and vigilance by intensive care personnel is important in preventing this complication.

Some comments on ventilatory management are appropriate. In the early days of posterior fossa surgery, spontaneous ventilation was used as a monitor of brainstem function. This has been supplanted by the use of better hemodynamic monitors combined with controlled ventilation. Most anesthesiologists choose to modestly hyperventilate their patients. However, Zettner et al. argue that the risk of VAE may be reduced by modest hypoventilation,[833] and Gelb et al. have data indicating that respiratory changes can be observed in unparalyzed patients before (or in the absence of) hemodynamic changes.[426] We are still uncomfortable with allowing patients in the sitting position to breath spontaneously because VAE can trigger a strong inspiratory effort (which can increase the amount of air entrained). However, a reasonable argument can be made for spontaneous ventilation in horizontal patients, at least after the skull is open and any brainstem compression or hydrocephalus has been relieved.

Positioning and the Response to VAE

We have discussed some of the potential complications of positioning. However, another aspect of positioning may be more important. When a major VAE is encountered, the initial response is to ask the surgeon to flood the wound or pack it with wet gauze, discontinue N_2O, and aspirate from the right atrial catheter. Two additional maneuvers can be performed to slow air entry. These are the addition of PEEP and/or bilateral jugular compression.[404,568,573] In both cases, the goal is to increase venous pressure in the head. There are problems with both. Jugular compression is effective and may help to identify venous bleeders in the surgical field that might have been the source of air entrainment. However, this occupies both hands of the anesthesiologist, and the anesthesiologist cannot do anything else. High levels of PEEP (10–15 cm H_2O) are required to elevate venous pressure at the head to values greater than zero,[219] but some feel this will facilitate the right-to-left passage of air through the heart.[568] This is disputed,[94,564] and many are uncomfortable with applying PEEP in the face of hemodynamic instability.

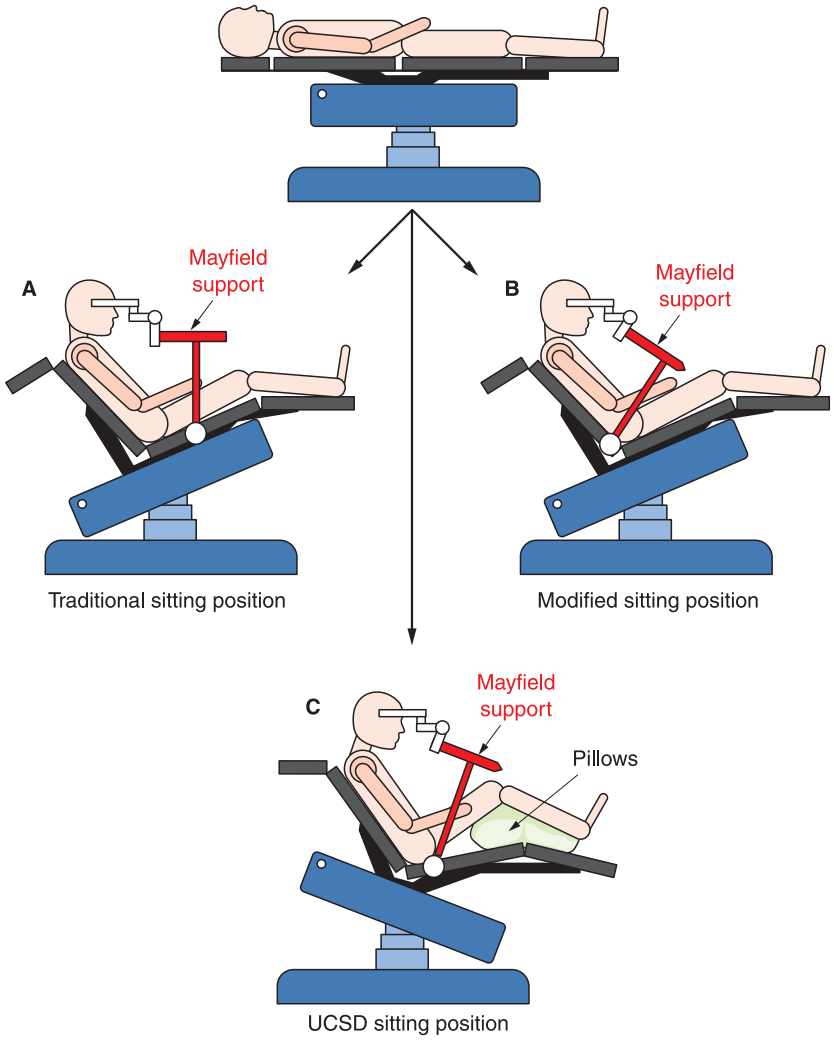

FIGURE 50–20. Three variations of the sitting position. **A.** In the "traditional sitting position," the table is placed in steep Trendelenburg, the back elevated, and the Mayfield support attached to the midsection of the table. It is possible to return the patient to a horizontal position after a severe VAE without removing the head from pin fixation. To facilitate a return to a horizontal position, two alternatives are suggested. **B.** In the first (modified sitting position), the same table position is used, but the Mayfield support is attached to the back section of the table. The horizontal position can now be achieved simply by lowering the back. **C.** In the "UCSD (University of California at San Diego) position" the table base is placed in reverse Trendelenburg, the back elevated, and the legs supported on pillows. In the event of a serious VAE, the horizontal position can be achieved simply by placing the table in the Trendelenburg position.

If air entrainment continues, or hemodynamic deterioration occurs, the patient must be moved into a horizontal position. With the traditional sitting position (Fig. 50–20A), this can be accomplished only by removing the patient from pin fixation. Because this is time-consuming and difficult to do without contaminating the wound, we believe that the only acceptable sitting position is one that allows the patient to be easily moved. There are two major ways to accomplish this. In the first, described by Dr. Shapiro at University of California at San Diego, the primary axis of the operating room table is placed in reverse Trendelenburg, and the legs are supported on pillows (Fig. 50–20B). A horizontal posture then can be achieved simply by moving the table into a head-down position. An alternative is to place the main axis into steep Trendelenburg, raise the back, and attach the over-bed support arch and pin-fixation device to the back portion of the table, rather than to the bottom (Fig. 50–20C). A supine position is achieved simply by lowering the back.

Emergence

In a routine, uncomplicated procedure, the patient can be awakened and

extubated at the end of the case. However, two situations alter this.

Air Embolism and Pulmonary Edema On occasion, a large air embolism will precipitate pulmonary edema. The etiology is unknown, but the condition is usually self-limited. However, if a patient has suffered a major embolus and has a persistent, large shunt, we prefer to continue mechanical ventilation until a more complete evaluation can be carried out.

Cranial Nerve Dysfunction As noted previously, a major complication of posterior fossa surgery (regardless of position) is damage to those cranial nerves that control airway function (i.e., CN IX, X, and XI). There is no reliable intraoperative method for assessing the function of these nerves (although CN VII and VIII can be monitored using facial nerve stimulation and brainstem auditory evoked responses, respectively). In all cases, patients must be carefully monitored after emergence to verify that function has been maintained. In our practice, patients who have suffered more than two or three transient, sudden hemodynamic or respiratory events during surgical dissection (e.g., hypertension–tachycardia, hypertension–bradycardia, inspiratory effort) are left intubated after awakening. The concern is that these hemodynamic events reflect brainstem injury. These individuals are sedated with fentanyl/droperidol and are generally extubated 24–36 hours postoperatively.

There is a small incidence of neurogenic pulmonary edema after posterior fossa surgery, particularly when surgery is performed on the floor of the fourth ventricle. Unlike edema encountered after head trauma, respiratory failure can occur suddenly in fully awake patients. We believe that such an event is most likely to occur in those patients in whom we have seen hemodynamic evidence for brainstem injury, and this provides another reason to be extremely cautious about extubation.

Anesthesia for Infratentorial Craniectomy: The Horizontal Position

The use of horizontal positions (prone or lateral) generally avoids the problems of massive VAE (although Black et al. showed that Doppler ultrasound-detected VAE occurs in up to 12% of these cases, although apparently without important consequences.[96] The remaining problems are similar, except for positioning. There is reason to believe that the prone, lateral, and park bench positions are associated with a higher incidence of positioning related injuries such as the following:[96,456]

- *Brachial plexus injuries* are a particular problem in the lateral/park bench positions when the "up" arm is pulled caudally to improve access to the retromastoid area, or when the head/neck is excessively rotated. A similar problem can occur in the prone position if the arms are pulled down with excessive force.
- *Ulnar nerve injury.*
- *Pressure blisters/skin necrosis* of the face caused by inadequate weight distribution on a horseshoe headrest.
- *Blindness* caused by pressure on the eyes in the prone position.
- *Quadriplegia* associated with extreme flexion of the neck (quadriplegia has been described in the prone position as well sitting).

These problems are all avoidable but only by careful attention to position, nerve stretch, padding, and so forth. It has been argued that because these problems are unlikely to be fatal, these alternative positions are "better" than the sitting position. However, because VAE/PAE-related fatalities are so rare in the hands of experienced teams, we believe that morbidity is the more important factor. These positioning problems make it likely that the overall morbidity of horizontal approaches is no better than with the sitting position.

Anesthesia for Intracranial Vascular Procedures: Aneurysms

Aneurysmal SAH strikes ≈30,000 people a year in North America.[91,351] Only 17,000–20,000 patients are admitted to the hospital, and only 70% of these will come to the operating room. Of patients entered into the International Cooperative Aneurysm Study, only 58% of individuals admitted to the hospital within 3 days after hemorrhage had a "good" outcome; if analysis is restricted to patients who actually undergo surgery, a "good outcome" is seen in approximately 68%, with death occurring in ≈14%.[356,357]

The most common presenting symptom is severe headache, with or without a loss of consciousness. The cause of both the headache and the initial neurologic deterioration is a sudden, severe increase in ICP (Fig. 50–21).[776] If ICP does not rapidly normalize, the patient will die. Severe ischemia that results from shorter or less-severe increases in ICP is a major cause of neurologic deficit among survivors. After a patient reaches a medical facility, the patient faces three major problems: (a) "vasospasm," (b) recurrent hemorrhage, and (c) hydrocephalus (we do not discuss this problem).

Vasospasm

Strictly speaking, vasospasm is an angiographic diagnosis. Arteries constrict in response to extravascular blood, but this is transient. By contrast, clinical "vasospasm" typically occurs several days after the initial hemorrhage.[180,356,357,801] Acute vasoconstriction is easily reversed by vasodilators (e.g., nitroprusside, nitro-

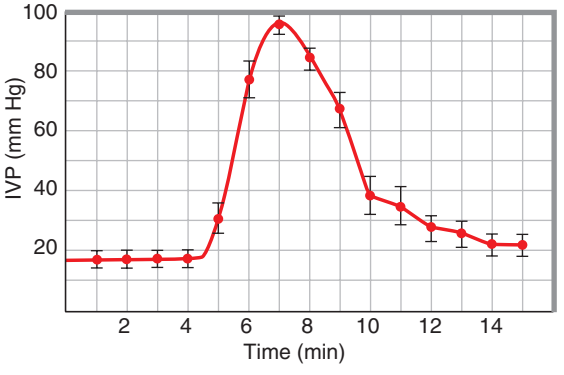

FIGURE 50–21. ICPs recorded during and after recurrent subarachnoid hemorrhage. Data represent the average from seven patients. Note the abrupt increase to near systemic levels (90 to 100 mm Hg) and the rapid decline. (Reproduced with permission from Voldby B, Enevoldson EM. Intracranial pressure changes follow aneurysm rupture: recurrent hemorrhage. J Neurosurg 1982; 56:784.)

TABLE 50–6.

Neurologic Grading System for Patients with Subarachnoid Hemorrhage

Grade	Criteria
Hunt and Hess	
Grade I	Asymptomatic or minimal headache and slight nuchal rigidity
Grade II	Moderate-to-severe headache, nuchal rigidity, no neurologic deficit other than cranial nerve palsy
Grade III	Drowsiness, confusion, or mild focal deficit
Grade IV	Stupor, moderate-to-severe hemiparesis
Grade V	Deep coma, decerebrate rigidity, moribund appearance
World Federation of Neurologic Surgeons	
Grade I	GCS (Glasgow Coma Scale) 15, no motor deficit
Grade II	GCS 14–13, no motor deficit
Grade III	GCS 14–13, any motor deficit
Grade IV	GCS 12–7, with or without motor deficit
Grade V	GCS 6–3, with or without motor deficit

glycerin), but delayed vasospasm is not. This had led to the hypothesis that vasospasm is actually a form of vessel injury or vasculopathy. Other work indicates that either endothelial relaxing factor or endothelin (a constricting factor) play an important role in this disorder.[142,146,620] In view of uncertainties concerning the etiology of this disorder, many clinicians prefer the term "delayed cerebral ischemia" to define the development or worsening of focal neurologic deficits in patients with SAH. Such an event occurs in roughly 30–40% of patients admitted with SAH.[356,357]

Recurrent Hemorrhage

Without therapy, 20–30% of patients hospitalized after SAH will rebleed within 2 weeks (≈7% of patients rebleed within 48 hours).[355–357] It can be prevented only by clipping the aneurysm. To reduce the presurgical risk, patients are treated with bedrest, sedation, antihypertensives, and antifibrinolytic drugs. These are "two-edged swords" that increase the risk of respiratory complications and deep vein thrombosis. Antifibrinolytics can also increase the incidence of vasospasm. Given these problems, surgeons have long been interested in early, definitive surgery. Data obtained in the early 1980s indicated little difference in morbidity or mortality between patients operated on early or late,[356,357] with patients undergoing early surgery succumbing to more frequent vasospasm. However, the subsequent introduction of more effective treatments for vasospasm (nimodipine and hypertensive/hypervolemic therapy) has convinced most surgical teams to operate early, at least in good-grade patients.

Preoperative Evaluation

Special areas of concern in these patients include the assessment of (a) neurologic status, (b) cardiac dysrhythmias and other ECG abnormalities, (c) intravascular volume status, and (d) the use of calcium entry blockers for the prevention of vasospasm.

Neurologic Status All patients suffering aneurysmal SAH are assigned a clinical "grade" that provides prognostic information and allows better communication between clinicians. The most widely used system was proposed by Hunt and Hess,[323] although the World Federation of Neurologic Surgeons (WFNS) scale may be more objective (Table 50–6).[183] Other grading systems have been proposed, but all follow the same general pattern: The greater the numerical score, the more severely ill the patient.

There are three reasons for the anesthesiologist to be aware of the patient's neurologic status. These patients may deteriorate rapidly, and the anesthesiologist may be the first to identify such a change. Second, the failure of a patient to return to his/her baseline status upon emergence from anesthesia requires that a distinction be made between residual anesthetic effects and surgical concerns. Finally, clinical grade correlates well with alterations in intracranial physiology.[777,778] As grade deteriorates, autoregulation and CO_2 responsiveness become progressively disordered, and the incidence of intracranial hypertension increases. Grades I and II patients typically have near-normal ICP values and normal vascular responsiveness. Such patients can be approached differently by the anesthesiologist in terms of premedicants, the use of volatile agents and N_2O, the limits of hypotension, and so forth, than can grades III through V individuals.

Cardiac Dysrhythmias and Other ECG Abnormalities SAH is associated with an increased incidence of dysrhythmias and ECG morphologic abnormalities.[168,434] Holter monitoring reveals rhythm disturbances in as many as 91% of patients, although retrospective analysis of multiple studies suggest an incidence of ≈40% is more accurate.[168,175,393] The most frequent abnormalities are prolongation of the Q-T interval, flattened or inverted T waves, S-T segment depression, and prominent U waves. These may occur in combination or sequentially (Fig. 50–22). The mechanism of these changes remains controversial. Elevated catecholamines, hypercortisolism, and hypokalemia have all been implicated, and evidence also exists that incriminates a hypothalamic neurogenic mechanism. Studies of myocardium-specific enzymes are inconsistent, but postmortem studies show evidence of subendocardial injury. However, noninvasive studies of myocardial perfusion (thallium scans) and LV function (echocardiography) show a high incidence of abnormalities, at least in patients with ECG abnormalities.[167,720]

The patient with serious dysrhythmia requires prompt treatment, and patients with SAH should have continuous ECG monitoring throughout the perioperative period. The most difficult dilemma is the patient with ECG changes suggestive of myocardial injury, particularly when the clinical grade is good and early surgery is contemplated. If there is no evidence of congestive heart failure or angina, and serial enzymes are negative, surgery should proceed. The greater problem is the individual with enzymatic evidence of myocardial damage. Which represents the greater risk: anesthesia and surgery in the face of a recent myocardial infarction, or rebleeding because the aneurysm is not clipped? This problem has not been studied systematically. Furthermore,

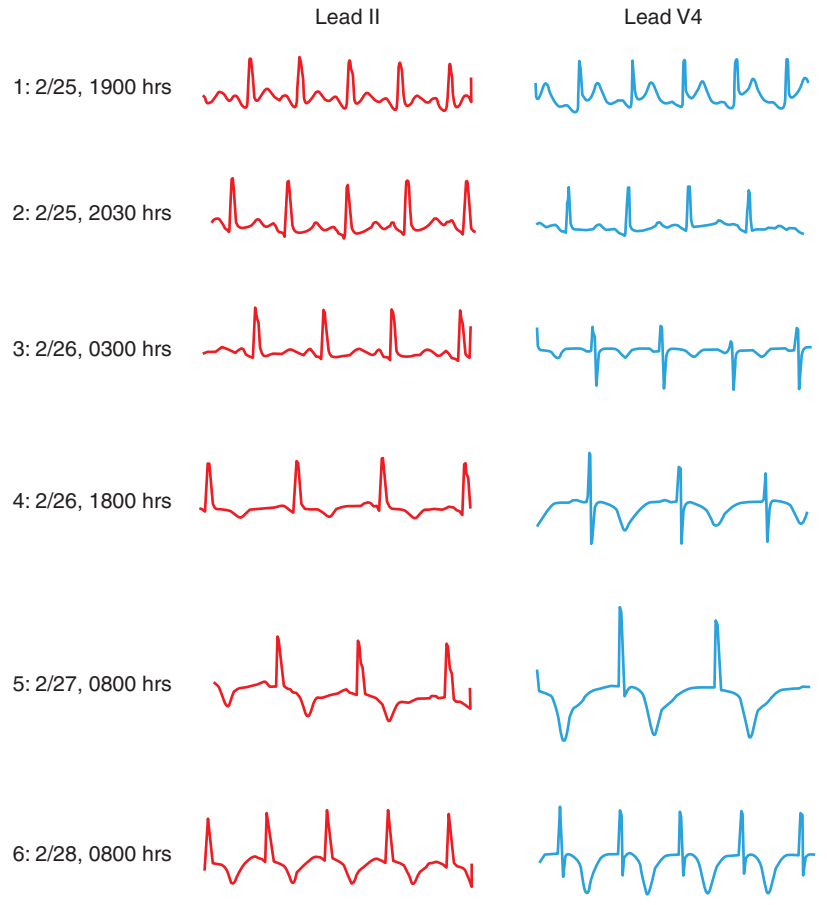

FIGURE 50–22. Serial electrocardiogram tracing obtained in a young woman with a subarachnoid hemorrhage. The first tracing was obtained at about 30 minutes after the onset of headache. Note the sequential appearance of ST-segment elevation, QT prolongation, T-wave inversion, and QRS axis changes. There were no changes in serum creatine kinase isoenzymes at any time.

the prognostic implications of a myocardial infarction precipitated by an SAH are unknown, and cardiovascular diseases are a relatively minor cause of death among patients with SAH.[356,357] In the cooperative study, overall hospital mortality from recurrent hemorrhage was 236 of 3521 (6.7%), and the risk of hemorrhage was generally judged to be 1–2% per day. In addition, 15–20% of patients suffer some degree of serious morbidity caused by vasospasm, which might be alleviated by early surgery combined with aggressive therapy. We believe that there is little justification for delaying surgery for anything other than an obvious myocardial infarction with serious LV dysfunction.

Intravascular Volume Status The preoperative volume status of untreated patients with SAH is often abnormal. In earlier days, patients were relatively hypovolemic because of bedrest, negative nitrogen balance, decreased erythropoiesis, iatrogenic blood loss, and dysregulation of the autonomic nervous system; this has become less common because of the frequent use of hypervolemia to treat/prevent vasospasm. Hyponatremia is also occasionally observed, caused by either a central salt-wasting syndrome or true syndrome of inappropriate antidiuretic hormone.[690]

Calcium Antagonists Although multiple methods have been used for the treatment of vasospasm, most recent work has centered on the calcium antagonists, with nimodipine being the first drug released for the specific prophylaxis of vasospasm.[316,614] Like every new drug, nimodipine initially raised concern about whether its preoperative use would make anesthesia more dangerous or difficult. Fortunately, these fears are unfounded. While patients taking nimodipine have lower blood pressures (as well as lower systemic vascular resistances and higher cardiac outputs), there are no clinical management difficulties as long as anesthetic agents are carefully titrated. An alternative calcium blocker, nicardipine, was initially evaluated as an antivasospastic agent, but trials were halted with the introduction of nimodipine.[273] The drug is now approved only for blood pressure control.

Another drug under evaluation for the treatment/prevention of vasospasm (or its ischemic consequences) is the 21-aminosteroid tirilazad.[274,275] This compound is chemically related to methylprednisolone, but has glucocorticoid activity. Its primary mode of action appears to be as a free-radical scavenger. Clinical trials in Europe suggest some benefit in men only; US trials are ongoing.[352] The drug appears to pose no anesthetic problems.

Premedication

The choice of premedication must balance two factors: (a) the risk of anxiety-related hypertension and aneurysmal rerupture, and (b) the chance of respiratory depression that may exacerbate intracranial hypertension. Fortunately, it is possible to generate some guidelines. Voldby et al. demonstrated a good relationship between clinical grade and ICP, with patients in grades I and II almost uniformly having near-normal ICP values (Table 50–7).[778] As clinical grade deteriorates, the incidence of intracranial hypertension increases. Consequently, there is little reason to avoid modest sedation (e.g., with benzodiazepines) in grades I and II individuals, particularly several days after the initial hemorrhage. By contrast, patients who are somnolent or who have focal deficits (grades III through V) are transported to the operating room without premedication. If premedication is needed, it should be given intravenously with the anesthesiologist in attendance.

Routine Monitoring

Given the potential risks associated with rapid swings in blood pressure (e.g., aneurysmal rupture, profound hypoperfusion) and the need for very accurate beat-to-beat control during profound hypotension, direct arterial cannulation is mandatory (although this can be deferred until after induction if it results in patient agitation). Urinary bladder catheterization yields information on fluid balance, but the routine use of mannitol or furosemide limits the value of urine output as an index of intravascular volume. To improve our assessment of volume status,

TABLE 50–7.

ICP and Vascular Responsiveness after Subarachnoid Hemorrhage

Grade	ICP (mm Hg)	CO_2 response $\Delta CBF/\Delta PCO_2$	Autoregulation Δ CBF/Δ % MABP
II	10 ± 3	1.61 ± 0.67	−0.042 ± 0.194
III	18 ± 6	1.02 ± 0.5	−0.230 ± 0.514
IV–V	29 ± 6	0.61 ± 0.42	−0.334 ± 0.219

CBF, cerebral blood flow; ICP, intracranial pressure; MABP, mean arterial blood pressure. Data are all mean [+/-] standard deviation (SD). Units for CO_2 response are all mL/100g/min change in CBF/mm Hg change in CO_2. Autoregulation is expressed as mL/100g/min change in CBF/% change in MABP (a value of 0.000 would be perfect autoregulation, and a more negative number indicates progressive autoregulatory impairment). Note that the clinical grading was not consistent between the two reports, and hence the first column was constructed to the best of our ability. Data from Voldby B, Envoldsen EM, Jensen FT. Cerebrovascular reactivity in patients with ruptured intracranial aneurysm. J Neurosurg 1985;62:59, and Voldby B, Envoldsen EM. Intracranial pressure changes following aneurysm rupture. Part I: clinical and angiographic correlations, J Neurosurg 1982;56:186.

we lean toward the placement of central venous or pulmonary artery catheters, in those with preoperative ECG changes that cannot be readily distinguished from myocardial ischemia and in patients with large or relatively inaccessible aneurysm (i.e., where "excess" blood loss is anticipated). Note that this is perhaps the only surgical procedure where pharmacologic hypotension must be maintained in the face of active arterial hemorrhage (from a ruptured aneurysm). Other than central vascular cannulation, there are no reliable methods for rapidly distinguishing normovolemic hypotension from shock in such situations. We recognize that there are risks associated with central catheter placement, and we also realize that many experienced centers do not employ central catheters, particularly those that have abandoned induced hypotension. Pulmonary artery catheterization is reserved for patients with known preexisting cardiac disease, or perhaps for cases where surgery is anticipated to be difficult or prolonged.

Specialized Monitoring: EEG and Evoked Potentials

Because the most feared immediate complication of surgery is a misplaced clip or tissue injury caused by excessive retraction and/or hypotension, many groups have attempted to improve their ability to detect ischemic changes before they become irreversible. Nevertheless, the value of electrophysiologic monitoring remains unclear. EEGs recorded from the perimeter of the craniotomy have yielded contradictory results.[340,729] Because of the uncertainly, most centers probably only use EEG monitoring to facilitate drug administration (e.g., barbiturates). Greater attention has been directed at somatosensory evoked potentials (SEPs), because the conduction pathways pass through areas at greatest risk. Symon et al. have presented extensive data relating changes in central conduction time with outcome.[228,719] A correlation with outcome need not necessarily mean that monitoring can prevent a deficit, but several groups have now used SEP monitoring to define the limits of temporary vessel occlusion during surgery.[428,499] Hence, although SEP monitoring has not yet been established as a routine, it may offer some benefits.

Induction and Maintenance

We believe that the principal risk is rebleeding. Four papers have shown that the incidence of hemorrhage on induction ranges from 1% to 2%.[243,357,715,758] In one of these studies, hemorrhage was associated with airway difficulties encountered during induction that presumably led to hypertension and coughing. Given these considerations, induction is designed to avoid sudden hypertensive events, particularly during laryngoscopy and intubation. We tend to carry patients "deeper" at the time of intubation, using volatile agents, larger doses of opioids (e.g., fentanyl 12–15 μg/kg), or additional thiopental or lidocaine. Arterial pressure is continuously monitored; if blood pressure or heart rate starts to rise with laryngoscopy alone, the laryngoscope is removed and additional anesthetic given. In general, we are far more tolerant of hypotension during induction than we are of hypertension.

Subsequent management is directed at ensuring adequate surgical conditions. Because aneurysms are located around the base of the brain, exposure may be a challenge, particularly in the face of cerebral swelling. This is clearly much worse during "early" surgery (Fig. 50–23).[357] If exposure cannot be facilitated, then the risk of tissue injury from excessive retractor pressures[18,587]

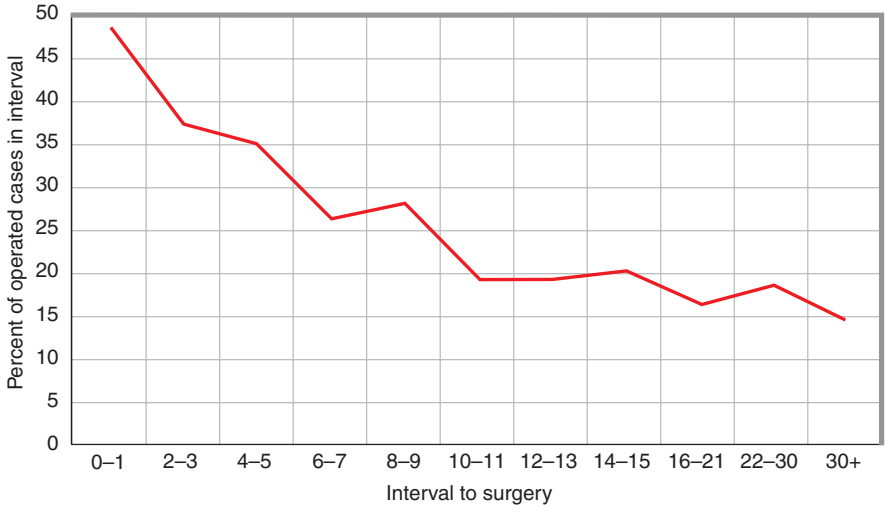

FIGURE 50–23. The incidence of subjectively "tight" brain at craniotomy, relative to the time of surgery after subarachnoid hemorrhage. There is clearly a far greater likelihood of difficult operating conditions with acute aneurysm surgery. (Reproduced with permission from Kassel NF, Toner JC, Jane JA, et al. The international cooperative study on the timing of aneurysm surgery surgical results. J Neurosurg 1990;73:37.)

or uncontrolled aneurysmal hemorrhage is high. For these reasons, patients may have spinal drains placed, receive mannitol, and be aggressively hyperventilated ($Paco_2$ ≈25 mm Hg).

Induced Hypotension versus Temporary Occlusion

To minimize the risk of aneurysmal rupture during dissection, one of two interventions is employed: induced hypotension or temporary vessel occlusion (trapping). In both cases, the goal is to reduce intraluminal pressure. In the case of hypotension, a secondary goal is to slow the rate of hemorrhage in the event that rupture occurs.

Hypotension Induced hypotension has long been a standard component of surgery. Most surgeons believe it to be of value, although this is impossible to "prove," particularly because most surgery performed before the introduction of hypotensive techniques was also done before the use of the operating microscope. The argument against hypotension is that SAH and vasospasm may disrupt cerebral autoregulation, particularly in lower-grade patients.[216,777] As a result, the lowest safe MAP that can be employed is unknown, particularly in the face of retraction pressure. Hypotension also poses a risk of myocardial ischemia especially in patients with coronary artery disease. Nevertheless, most centers are willing to reduce MAP to values of 70 mm Hg during initial dissection, and to pressures as low as 50 mm Hg during direct manipulation of the aneurysm.

Considerable effort has been directed toward determining the ideal agent to produce the hypotension. These efforts have not succeeded. The three agents in most common use are sodium nitroprusside, nitroglycerin, and isoflurane. Isoflurane has gained some popularity because it is well tolerated, and some believe it to have some protective effects. Unfortunately, there have been no prospective studies demonstrating an improved (or worsened) neurologic outcome or altered complication rate with any agent. The picture is even more complex because polypharmacy is the rule, and these drugs are combined with long-acting nitrates (e.g., hydralazine), β-blockers, calcium antagonists, preoperative clonidine, and so forth.

Regardless of the agent used, several points from the earlier discussion of basic physiology/pharmacology should be remembered. Autoregulation is not instantaneous and abrupt decreases or increases in pressure may lead to transient hypoperfusion during the induction of hypotension and hyperperfusion upon its discontinuation. Hypotension increases several humoral factors, including norepinephrine, epinephrine, and renin–angiotensin. Recovery from hypotension then may be followed by rebound hypertension that can persist for several hours unless treated. Finally, because hemostasis must be verified before dural closure, blood pressure should be allowed to gradually rise to values on the "high end" of normal (e.g., 140–160 mm Hg systolic) during the completion of the intracranial portion of the procedure.

Temporary Occlusion Hypotension has become far less common in recent years, being replaced by the placement of temporary clips on the parent artery (which effectively produces "regional hypotension"). This avoids many of the systemic problems associated with hypotension and also prevents rupture. However, if temporary occlusion is prolonged (i.e., >10–20 minutes), it may increase the risk of focal ischemic deficits.[499,632] Despite this risk, the approach is gaining in popularity. In most centers, blood pressure is modestly reduced during initial dissection, and then normalized after temporary clip placement. In some cases, barbiturates are administered to protect the brain, although we reserve this for procedures where the duration of occlusion is prolonged.

Emergence and Early Postoperative Care

A rapid return to consciousness permits early clinical assessment and the detection of unexpected neurologic deficits (e.g., caused by a clot or misplaced clip). This can lead to either a diagnostic procedure (e.g., angiography and/or reoperation) or the institution of hypertensive–hypervolemic therapy. This emphasis on rapid emergence makes the maintenance of hemodynamic stability a bit more difficult. Kalfas and Little demonstrated a 2.3% incidence of postoperative intracranial hemorrhage among patients undergoing aneurysm clippings.[347] Their data implicate uncontrolled hypertension as a causative factor. We believe the arterial pressure should be monitored without interruption in these patients, including during transportation from the operating room to the recovery room, and from the recovery room to the surgical intensive care unit. Obviously, if such monitoring is to be useful, the patients must be accompanied at all times in the early postoperative period by an individual able to administer the pharmacologic agents needed to control hypertensive events.

Treatment of Delayed Ischemic Deficits/Symptomatic Vasospasm

In spite of the use of calcium antagonists, vasospasm remains a major cause of morbidity and death even after an otherwise successful clipping. Although there is growing interest in the use of endovascular therapy (e.g., balloon angioplasty) or fibrinolytics (e.g., tissue plasminogen activator),[180,533] the only widely accepted acute therapy is hypervolemia–hypertension.[50,180,354,698] The patient with a new focal deficit or decrease in level of consciousness is first scanned to rule out an infarct, clot, or hydrocephalus. An angiogram may be carried out to verify clip placement. Patients then are moved to an ICU where arterial and central venous/pulmonary artery pressure monitors are placed, if not already in place. Albumin and/or crystalloids are infused to increase CVP to values of 10–12 mm Hg, or pulmonary capillary wedge pressure (PCWP) to 15–18 mm Hg. (*Note:* Initial volume loading can obviously be started before monitoring catheters are in place. However, continued therapy is dangerous without such monitors [see following discussion].) Hetastarch is avoided because large doses (>1–1.5 L) are associated with coagulation deficits and intracranial hemorrhage.[160,165] If these measures fail to reverse the neurologic deficit, blood pressure is elevated pharmacologically. There are no good guidelines concerning the target blood pressure, but most groups will increase systolic pressure to values as high as 160–200 mm Hg if tolerated. The most common drug used is dopamine, but other agents or combinations of agents seem equally efficacious. Many groups think that hematocrit can be modestly decreased (i.e., 33–36%), but there is little current enthusiasm for more profound hemodilution.

The major complications are cardiovascular, with a reported incidence of pulmonary edema ranging from 7% to

17%.[50,354,822] Cerebral edema has also been reported.[680] One must beware of the urge to "keep pushing" when initial volume expansion fails to resolve the deficit. Severe pulmonary edema with resultant acute respiratory distress syndrome has been seen. Also, increasing and maintaining an elevated PCWP and blood pressure is strikingly difficult in some patients, particularly the young. They will mount a brisk diuresis in response to volume loading and may be refractory to vasopressors. Vasopressin or DDAVP (1-deamino-8-D-arginine-vasopressin) can be used in such cases, along with more potent α- and β-adrenergic agents, but these, in turn, further increase the risk of fluid overload, tachyarrhythmias, or myocardial ischemia.

Special Problems

Intraoperative Hemorrhage Intraoperative aneurysmal rupture is a potentially catastrophic event occurring in 15–20% of patients.[61] However, hemorrhagic shock and death are not the most important consequences. Instead, one sees cerebral ischemic damage. When brisk bleeding occurs deep within the cranium, the operator is blinded. Ischemia results from efforts to slow this bleeding. This may stem from excessive hypotension (elective or otherwise), more vigorous retraction, or from clips placed on major cerebral vessels (either intentionally or unintentionally).

This is not a rare event and some kind of plan should exist. First, do not panic! The rate of blood loss is usually slow enough to be handled. Our first response is to increase the rate of IV fluid administration. If bleeding is not stopped within a few minutes, blood pressure is progressively (and smoothly) reduced to mean values as low as 40–50 mm Hg (measured at the head). This can be accomplished by any method desired as long as normovolemia is maintained. Manual compression of the carotid arteries in the neck is also effective but it leaves the anesthesiologist unable to perform other tasks. The goal is to slow the rate of hemorrhage so that the source can be found or a feeding vessel identified. If the aneurysm can be directly clipped, there are few problems. More commonly a clip is temporarily applied to a feeding vessel. (*Note:* There is some evidence that prolonged hypotension in the face of ruptures may be more dangerous than temporary clipping.[243] Consequently, it is probably reasonable to keep the duration of hypotension as short as possible.)

Intraoperative Protection Barbiturates are the only drugs shown to be useful in situations of temporary intracranial vessel occlusion (albeit in repeated animal studies).[527,701,795] Contrary to popular belief, they need not be given before occlusion but can be administered up to 30–60 minutes after occlusion and still be beneficial. Hence there is no need to subject a hypovolemic patient to the hemodynamic risks of "emergency" barbiturate loading. Our practice is to ensure adequate vascular volume and hypotension and then to begin barbiturate administration with small (100–200-mg) boluses of thiopental. Other anesthetics are progressively reduced as the dose increases. Our goal is to administer a dose of ≈15–30 mg/kg of drug over a 30-minute period. If vessel occlusion persists, a dose of 5–6 mg/kg/h of thiopental will maintain a reasonable degree of EEG and metabolic suppression. Note, however, that while the traditional goal is EEG burst suppression or isoelectricity, there are data suggesting that even lower doses are equally effective.[68,793]

Etomidate is also advocated as a protective agent, based on its ability to reduce CMR.[62] However, because two animal studies failed to demonstrate protective efficacy,[184,634] we do not believe this is reasonable, other than in the context of a clinical trial.

Renewed interest in the use of hypothermia has been generated by the recent demonstration of the protective value of relatively mild hypothermia 89.6–93.2°F (32–34°C). Some have argued that patients should simply be allowed to spontaneously cool (as they always do) rather than be actively warmed. This may prove to be reasonable, but in view of the problems associated with awakening a hypothermic patient, as well as the risk of myocardial ischemia,[226] we believe that some concrete demonstration of efficacy is needed before this is done routinely.

Anesthesia for Intracranial Vascular Procedures: Arteriovenous Malformations

Although the care of these patients has many things in common with the care of those undergoing aneurysm clippings, certain differences exist. First, the risk of recurrent hemorrhage is much lower than with an aneurysm (and hence surgery for definitive excision is rarely emergent). Second, hypertension-induced hemorrhage appears to be almost nonexistent,[721] and hence blood pressure control during induction is probably not as crucial. Because vasospasm is rare, there is little need for calcium antagonists or hypervolemic–hypertensive therapy. The major risks are intraoperative hemorrhage—which can be torrential—and a disorder called reperfusion breakthrough.[8,51,506] Hemorrhage is handled by transfusion and induced hypotension; reperfusion breakthrough, however, is a much more difficult problem.

An AVM represents a low resistance pathway shunting blood directly from arteries to veins. The result is that perfusion pressure to adjacent normal tissues may be very low, and these tissues may therefore be maximally dilated. If the AVM is suddenly obliterated, the perfusion pressure to these tissues may rise dramatically. For example, AVM flow rates in excess of 1 L/min have been estimated, and 50–75 mm Hg increases in collateral perfusion pressures have been seen with AVM occlusion.[538] This can lead to either the rapid formation of cerebral edema or the physical disruption of vessels with intraparenchymal hemorrhage. The result is a phenomenon often called malignant brain swelling or "reperfusion breakthrough," where the brain begins to rapidly herniate out of the craniotomy site.

To date, the only successful therapy for this disorder is a combination of induced hypotension (to reduce perfusion pressure) and very high doses of barbiturates.[170,439] The doses used are governed by the patient's response, not by some theoretical "EEG-suppressant" dose of barbiturate. Thiopental (or pentobarbital) loading is continued until the swelling is controlled or cardiovascular toxicity occurs. Barbiturate-induced hypotension may actually be beneficial. Of equal importance is the realization that this therapy, particularly the control of blood pressure, may need to be continued for several days postoperatively. This necessitates pulmonary artery catheterization, mechanical ventilation, heavy sedation, ICP monitoring, and a very skilled ICU team.

There is a theoretical risk that hyperventilation will increase flow throughout the AVM because only normal vessels are responsive. However, although

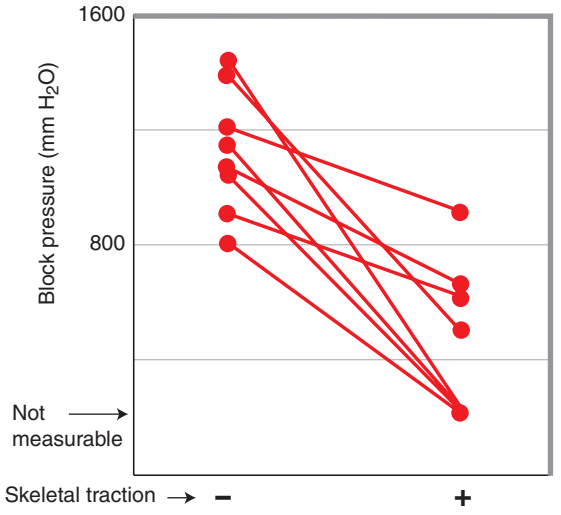

FIGURE 50–24. Changes in cervical "block pressure" (*y*-axis) during laryngoscopy before and after the application of neck traction. Data were obtained from 8 patients with cervical stenosis. Note that "block pressure" is measured by placing a catheter in the lumbar subarachnoid space and then measuring CSF pressure during a controlled infusion of fluid. With cervical cord compression, lumbar CSF pressure rises rapidly until it exceeds that needed to force fluid around the area of compression, at which point a plateau appears in the pressure trace. Less compression results in lower block pressures. (Reproduced with permission from Magnaes B. Clinical recording of pressure on the spinal cord and cauda equina. Part 3. Pressure on the cervical spinal cord during endotracheal intubation in patients with cervical spondylosis. J Neurosurg 1982;57:64.)

there is some experimental support for this idea,[505,833] there is little clinical reason for concern at present.

Anesthesia for the Patient with Cervical Spine Disease

The care of patients with cervical spine disease does not involve much "neuroanesthetic" physiology or pharmacology and is well reviewed elsewhere.[152,285] However, a few comments are in order.

Our greatest fear in patients with cervical spine disease is that we may permanently injure the spinal cord in the process of induction, intubation, and positioning. This is not a trivial concern. Neck extension can compress the cervical cord, at least in patients with cervical stenosis.[422] More importantly, quadriplegia/paresis following anesthetic induction has been reported in at least 3 patients, and for obvious medicolegal reasons, this is almost certainly only the tip of the proverbial iceberg. There is no doubt that these patients can be managed safely,[152] but only if we understand the diseases involved and the consequences of our various interventions.

This fear has led some to conclude that all patients with any form of cervical spine disease require awake fiberoptic intubation and awake positioning. This is clearly an excessively dogmatic—and unthinking—approach. It is far preferable to make some assessment of spinal column stability and/or spinal cord compression. Usually this determination will have already been made in the course of diagnostic workup. In many cases, however, the information is not present in the chart, and there are no obvious clues, such as Gardner-Wells tongs or a halo-fixation device. In these cases the anesthesiologist must make an evaluation. The first step is a history, and next is examination of the patient's *active* range of motion. (The patient is allowed to do the moving, do not move the neck for the patient!) If the patient has a full range of motion, an otherwise normal airway, and no displacement on flexion–extension films, general anesthesia can probably be induced in a routine manner, followed by direct laryngoscopy. Axial traction (perhaps applied manually) is probably a reasonable supplement in the patient with a normal airway and a stable cervical spine whose only complaint is mild pain on rotation or extension, particularly if the disorder is some form of spondylolisthesis or spinal stenosis. The role of traction in decompressing the cervical cord in such situations has been demonstrated by Magnaes (Fig. 50–24).[422] However, if a difficult intubation is anticipated, if there is any radiologic evidence of instability (even if the patient can move), if there is a serious preexisting neurologic deficit (even if partially resolved), or if neck movement is accompanied by severe pain, we believe that some alternative approach is indicated. Our preference remains an awake fiberoptic intubation, followed by awake positioning. Alternatively, one of the alternate airway management devices (e.g., Bullard laryngoscope, light wand, Augustine intubating airway) can be used. In some cases, it may be reasonable to perform the intubation after the induction of general anesthesia, at least if the patient can be easily ventilated by mask. Any of the above noted devices can then be used to facilitate intubation. A suggested compromise is the use of the laryngeal mask airway, a device that can serve as both a means of ventilation and a guide for the fiberoptic scope. The exact method chosen is often a matter of personal choice; regardless of technique, the obvious goal is to avoid marked extension (or flexion) of the cervical spine.

What is the approach for the patient with a truly unstable neck who will not cooperate with an awake intubation? Some might insist on an awake approach, but we disagree; does it matter whether the cervical cord is injured by the intubation or by a thrashing patient? Another factor that plays a role in decision making is the location of the injury. The bulk of cervical spine movement during direct laryngoscopy occurs between the occiput and C2.[286,638] If the airway is determined to be normal, it may be more acceptable to perform direct laryngoscopy with manual stabilization (perhaps after placement of Gardner-Wells tongs) in a patient with a subaxial injury than someone with a C1-C2 fracture/instability. Note that the goal is not to apply traction (which, if applied with excessive vigor, may produce vertebral seperation[92]) but to simply prevent extension of the neck. To further avoid extension, we rarely attempt to obtain full exposure of the glottis, preferring instead to carry out a "directed but semiblind" intubation. On the other hand, if the airway is judged to be "difficult" (where more movement may occur at lower segments), this may be dangerous—although there maybe little choice. An alternative may be a fiberoptic intubation after the induction

of anesthesia, a "blind" nasal intubation, or the use of the alternate intubating devices mentioned above.[286] If an awake intubation is deemed impossible, if the airway is truly difficult (e.g., massive facial trauma) and if general anesthesia before intubation is felt to be dangerous (e.g., a truly full stomach), there may be little choice but to proceed with tracheostomy (although doing this in an awake, combative patient may not be "ideal"). Note that if neurologic assessment after intubation is critical, it is possible to induce anesthesia using thiopental or propofol and a short-acting relaxant, maintain anesthesia with N_2O or propofol, and then reawaken the patient to assess motor function.

One issue we have not discussed concerns the quadriplegic patient with spinal shock. The physiology of this disorder is well described and is very similar to the hypotension seen during high spinal anesthesia. Usually such patients are already intubated and should have arterial and central venous/pulmonary artery catheters in place. The keys to successful care are the maintenance of normal intravascular volume without overload and the judicious use of vasopressors (ephedrine, dopamine, phenylephrine).

Transsphenoidal Hypophysectomy

This operation revolutionized the surgical approach to the sella turcica and to the immediate suprasellar region, turning a difficult subfrontal craniotomy into a relatively simple operation. Nevertheless, there are a few major problems.

First, the airway is shared with the surgeon, and the endotracheal tube must be secured to the lower jaw. There is also the danger that blood, tissue, and bone fragments can fall into the posterior pharynx. A throat pack minimizes the chance of their being swallowed, but we believe that laryngoscopy should be performed before extubation, simply to ensure that the pharynx is clear.

Second, typical neuroanesthetic maneuvers designed to reduce ICP can be counterproductive in these cases because they make the pituitary retreat upward out of the sella. In contrast, many surgeons request that the patient be hypercapnic or that a Valsalva maneuver be performed to "deliver" the gland down into the surgical field.

Third, the carotid arteries lie just lateral to the surgical site, particularly in the suprasellar area. If they are damaged, blood loss can be torrential (and, because the bleeding site is often intracranial, usually fatal).

Fourth, these patients are at risk for developing diabetes insipidus, particularly when the resection involves the suprasellar regions. The diagnosis is usually straightforward (i.e., sudden onset of diuresis). The best course is to initially decrease the IV rate to a minimum and wait. If the diuresis persists in the face of such restriction, the diagnosis becomes easier; it becomes certain if hypovolemia develops in the face of continuing urine output. If in doubt, paired urine and serum osmolalities will help although again these may be erroneously "normal" if the patient has received a large volume of IV fluids. In the event that diabetes insipidus does develop, the temptation to reach for an antidiuretic hormone replacement should probably be resisted, at least initially. Most cases are transient and require no therapy other than fluid replacement. We treat only when the volume of urine output begins to exceed 1 L/h or if it persists for more than a few hours. The drug choice is largely personal, although pitressin in oil is probably obsolete. Intravenous DDAVP is available and is both safer than aqueous pitressin (which can produce intense coronary vasoconstriction) and longer acting.

Cardiac anesthesia remains one of the more dynamic subspecialties within the clinical practice of anesthesia. Continuing innovation in pharmacologic development, technology and surgical interventions have had a significant impact on the core body of knowledge and experience required by perioperative intensivists who practice cardiac anesthesia. Furthermore, over the past several years, the risk profile of cardiac surgical patients has shifted towards higher risk populations predisposed to increased perioperative morbidity and mortality, thus further contributing to the increasing complexity and specialization of the techniques required for monitoring, anesthetizing, and managing these patients. This chapter will review the basic fundamental principles which remain the core body of knowledge required for the perioperative anesthetic management of patients undergoing cardiac surgery.

CARDIOPULMONARY BYPASS: PATHOPHYSIOLOGY AND PATIENT MANAGEMENT CONSIDERATIONS

Despite the introduction and perseverance of off-pump coronary artery bypass graft surgery (OPCABG), cardiopulmonary bypass (CPB) remains an essential technique for the vast majority of cardiac surgical patients.[1] A comprehensive understanding of the CPB circuit, pathophysiology, and important patient management issues is essential for anesthesiologists responsible for the perioperative care of these patients.

Fundamental Components of a CPB Circuit

Traditionally, the CPB circuit removes blood from the body via the venous circulation and returns blood to the

KEY POINTS

1. Initiation of cardiopulmonary bypass initiates an extremely complex and multifactorial response involving activation of complement, platelets, neutrophils, monocytes, and macrophages, thus initiating the coagulation, fibrinolytic, and kallikrein cascades. The systemic inflammatory response to cardiopulmonary bypass is further amplified by subsequent stimulated release of various endotoxins and cytokines, including interleukins and tumor necrosis factor, which further promote endothelial cell permeability.
2. Preparation for separation from cardiopulmonary bypass must be based on a clear understanding of the patient's preoperative condition and events of the operative course. Weaning from cardiopulmonary bypass is initiated after review and adjustment of numerous physiologic and technical variables, including temperature, laboratory data, heart rate and rhythm, myocardial contractility, and mechanical ventilation.
3. The anesthetic management of patients undergoing coronary artery bypass graft surgery requires an understanding of myocardial oxygen supply and demand, patient monitoring, and the anesthetic techniques that provide myocardial protection and favor oxygen supply over demand.
4. Patients with coronary artery disease presenting for coronary artery bypass graft surgery require special considerations in their anesthetic management. First and foremost are techniques that minimize myocardial oxygen demand while maximizing myocardial oxygen delivery. These considerations include preoperative preparation, intraoperative monitoring, and the use of anesthetic agents with hemodynamic effects that favor oxygen supply over demand and allow for myocardial protection. Postoperative management that provides particular attention to pain management, temperature control, and hemodynamic monitoring to avoid tachycardia, hypotension, and hypertension also must be considered.
5. Modern practices that focus on early extubation and "fast-tracking" cardiac surgical patients through the postoperative period use smaller narcotic doses, with supplementation by short-acting hypnotic agents.
6. Patients at risk for increased mortality after coronary artery bypass graft surgery are identified by preoperative factors. The most significant risk factors that increase mortality are age >80 years, emergent surgery, prior cardiac surgery, and renal failure.
7. The unifying concept in all valve surgery includes the principles of preserving myocardial function and the influence of preload, afterload, inotropy, rate, rhythm, and diastolic function on myocardial performance and mechanics.
8. Intraoperative transesophageal echocardiography is an essential diagnostic tool and monitor of cardiac performance for patients undergoing heart valve procedures.
9. Cardiac anesthesia for heart valve surgery is associated with a number of special considerations not found in other aspects of cardiothoracic anesthesiology. Among these considerations is familiarity with the type of repair technique or prosthetic valve used.
10. The process of repairing or replacing a portion of the thoracic aorta typically requires the temporary or permanent interruption of blood flow through the aorta or its major branch vessels, creating the potential for ischemia or infarction of almost any major organ system. Techniques to protect organs during temporary interruption of blood flow in the thoracic aorta include deep hypothermic circulatory arrest, selective antegrade cerebral perfusion, retrograde cerebral perfusion, and partial left heart bypass for distal aortic perfusion. Intraoperative neurophysiologic monitoring and lumbar cerebrospinal fluid drainage are recognized techniques commonly used for repairs involving the descending thoracic or thoracoabdominal aorta to decrease the risk of spinal cord ischemia and infarction.

Continued

Key Points—continued

11. Preoperatively, the anesthesiologist must identify any neurologic deficits and ascertain the extent of major organ dysfunction, including renal or hepatic insufficiency, which are common in patients undergoing placement of a ventricular assist device. Any further deterioration in the perioperative period may prevent a full recovery and eliminate the possibility of a patient qualifying for a subsequent heart transplantation at a later date.
12. Right heart failure is one of the most important causes of perioperative death in patients undergoing placement of a left ventricular assist device. Right ventricular dysfunction and failure may develop in up to 20–30% of patients implanted with an isolated left ventricular assist device. β-Adrenergic agonists, phosphodiesterase inhibitors, as well as nitric oxide should be initiated to improve right ventricular contractility and decrease right ventricular afterload in an attempt to improve transpulmonary blood flow. A supplemental temporary right ventricular assist device may be necessary if right ventricular dysfunction persists.

body via the arterial circulation.[2] Thus, CPB must function "physiologically" as the patient's heart and lungs. Most commonly, blood is drained by gravity via cannulas in the superior and/or inferior vena cavae and then similarly returned by a cannula in the ascending aorta. Although the CPB circuit consists of many important components, the two most important components are the pump, which functions as the patient's heart, and the oxygenator, which functions as the patient's lungs.

The two most common types of pumps used are roller pumps and centrifugal pumps. Roller pumps induce blood flow by compressing the tubing via rollers, thereby pushing the blood ahead through the tubing. Flow rate depends upon the size of the tubing, length of the roller track, and rotation rate of the rollers (i.e., revolutions per minute). Alternatively, centrifugal pumps induce blood flow by either a vaned impeller or a group of cones that reside inside a plastic housing. The impellers or cones are magnetically coupled with an electric motor and, when rotated rapidly, generate a pressure differential that may cause movement of blood though the tubing. Thus, unlike roller pumps, centrifugal pumps are afterload dependent, such that increases in resistance decreases forward flow delivered to the patient.

The two most common types of oxygenators used are membrane oxygenators and bubble oxygenators. Membrane oxygenators attempt to achieve separation between blood and gas in a manner analogous to the natural lung. Bubble oxygenators physically mix blood and gas, allowing sufficient time for adequate gas exchange to occur prior to defoaming and delivery to the patient. A heat exchanger usually is an integral part of the oxygenator. The type of oxygenator used influences the configuration of the CPB circuit. Membrane oxygenators typically are positioned after the pump because the resistance in most membrane oxygenators requires blood to be pumped through them. Thus, a venous reservoir collects venous return from the patient before delivery to the pump, followed by the membrane oxygenator, then back to the patient. Alternatively, bubble oxygenators typically are positioned before the pump because they do not require blood to be pumped through them, and they contain a reservoir of oxygenated blood that supplies the pump before it directly delivers blood back to the patient.

Over the past four decades, CPB technology has undergone a dramatic metamorphosis and can no longer be simply viewed as "the pump."[3] Additional vital components of the CPB circuitry include the arterial line filter, bubble detector, cardioplegia lines, suction lines, temperature monitor, arterial line pressure monitor, anesthetic vaporizer, and oxygen monitor, among others. Needless to say, the perfusionist plays an important role in intraoperative patient management during cardiac surgery.

Pathophysiology of CPB

Substantial controversy surrounds questions regarding "optimal" flow and pressure during CPB. Each patient must be individualized, with specific goals determined by numerous factors, including age, comorbidity, temperature, and body mass. However, most clinicians aim for flows in the range from 2.4–2.8 L/min/m^2 and pressures in the range from 50–80 mm Hg. It has been known for many years that CPB induces a systemic inflammatory response syndrome (SIRS) in patients following cardiac surgery that can lead to major organ injury and postoperative morbidity.[4–7] Initiation of CPB initiates an extremely complex and multifactorial response involving activation of complement, platelets, neutrophils, monocytes, and macrophages, thus initiating the coagulation, fibrinolytic, and kallikrein cascades. The SIRS response to CPB is further amplified by subsequent stimulated release of various endotoxins and cytokines, including interleukins (ILs) and tumor necrosis factor (TNF), which further promote endothelial cell permeability. Transvascular migration of activated leukocytes into tissues associated with SIRS results in the release of various proteases and neutrophil elastases, which cause additional vascular and parenchymal damage that can exacerbate ischemia–reperfusion injury associated with CPB and cardiac surgery.[8]

The basic physiologic insults caused by CPB have been associated with major postoperative morbidity, including neurologic dysfunction, pulmonary dysfunction, renal dysfunction, and/or hematologic abnormalities. Additional clinical manifestations associated with SIRS include increased metabolism and fever, fluid retention, myocardial edema, and detrimental hemodynamic alterations. Recent controversies surrounding clinical management of patients exposed to CPB have focused on the potential detrimental physiologic effects of hemodilution[9,10] and hyperglycemia[11] on postoperative morbidity. Over the years, a wide variety of antiinflammatory treatment options have been used in patients subjected to CPB in hopes of attenuating the SIRS, including leukocyte depletion techniques, neutrophil adhesion molecule blockade, heparin coating of CPB circuitry, and use of monoclonal antibodies directed specifically against various inflammatory mediators. Although results from animal work appear promising, the demonstration of a definite clinical benefit in humans has not been consistent.[12–16]

Management of Anticoagulation

Heparin Dosing

Anticoagulation is used during cardiac surgery to prevent thrombosis of the

CPB circuit and to minimize excessive CPB-related activation of the hemostatic system. Heparin is used routinely because it is effective, immediately reversible, generally well tolerated, and inexpensive.[17,18] Heparin induces anticoagulation primarily by potentiating the activity of antithrombin III. Most heparin preparations are "unfractionated," meaning that the heparin compound isolated from animal tissues, including porcine intestine and bovine lung, contains heparin molecules of various lengths. Because the relationship between mass (milligrams) and potency (units) varies among heparin preparations, most clinicians record heparin doses in units rather than milligrams. The anticoagulant effect of an intravenous dose of heparin occurs within minutes, and the intravenous heparin bolus dose administered prior to initiation of CPB may decrease arterial pressure and/or systemic vascular resistance.

Much controversy surrounds appropriate heparin dosing and monitoring of anticoagulation in patients exposed to CPB. Somewhat surprisingly, the literature does not consistently support the importance of anticoagulation monitoring techniques during CPB.[19] However, bleeding and transfusion outcomes likely can be improved by refining heparin monitoring techniques, either by sustaining better anticoagulation during CPB or by optimizing reversal of anticoagulation with protamine. Most clinicians administer an initial dose of 200–400 units/kg and maintenance doses determined by the particular laboratory test used for assessment of anticoagulation. The activated clotting time (ACT) is perhaps the most widely used method, and most clinicians administer additional heparin periodically in order to maintain the ACT >400–480 seconds. However, numerous other clinical conditions can affect the ACT, including hypothermia, hemodilution, thrombocytopenia, and aprotinin administration. Heparin concentration measurement techniques also are commonly used. Whatever laboratory test is used, most clinicians assess anticoagulation every 30 minutes during CPB.

Protamine

Protamine neutralizes heparin-induced anticoagulation. Salmon milt provides the pharmaceutical source of protamine, which neutralizes the antithrombin III effect of heparin by forming large complexes with heparin's sulfate groups. Protamine may exhibit antihemostatic properties by affecting platelets and by releasing tissue plasminogen activator from endothelial cells.

Much controversy surrounds the recommended dose of protamine to adequately neutralize heparin. Questions regarding the optimal ratio of milligrams of protamine to units of heparin, and how much heparin is actually left in the patient, are central to this controversy. Most clinicians use protocols that call for administration of protamine in slight excess doses of the usual ratio of 1 mg of protamine to 1 mg of heparin in order to assure return of normal coagulation. Subsequent postoperative administration of protamine may be required to prevent "heparin rebound."[20]

A spectrum of adverse reactions may be associated with protamine use; the most important is hypotension and/or anaphylactoid/anaphylactic reaction.[21] Hypotension following administration of protamine is fairly common and may be related to rate of injection, subsequent decreased systemic vascular resistance, and perhaps myocardial depression. True anaphylactoid/anaphylactic reactions to protamine are rare. Patients receiving protamine-containing insulins and/or previously exposed to protamine may be at slightly increased risk of developing anaphylactic reactions. Pulmonary vasoconstriction causing pulmonary hypertension may be associated with protamine use. Heparin–protamine complexes and complement activation may be the primary mediators of these adverse reactions. Slow administration of protamine may limit adverse reactions. If sudden hypotension and/or pulmonary hypertension occur, protamine administration should immediately cease. Heparin may be considered in order to reduce heparin–protamine complex load. Hemodynamic support with vasopressors and inotropes may be required in addition to reinitiation of CPB. Milder cases may resolve without intervention.

Heparin-Induced Thrombocytopenia

Unfractionated heparin given during CPB is remarkably immunogenic. In fact, as many as 25–50% of cardiac surgical patients develop heparin-dependent antibodies postoperatively over the first 5–10 days after exposure. This immunogenic response can strongly activate platelets and coagulation, causing the prothrombotic disorders known as heparin-induced thrombocytopenia (HIT).

HIT is defined as thrombocytopenia with a potential for associated thrombosis (HITT). A definitive diagnosis usually requires one or more positive tests for HIT antibodies.[22] An otherwise unexplained perioperative platelet count fall ≥ 50% from baseline or any thrombosis that occurs 5–14 days after cardiac surgery is suggestive of HIT, even when heparin is not still being given (i.e., delayed-onset HIT). Regarding laboratory testing, commercially available enzyme immunoassays and washed platelet activation assays (i.e., platelet serotonin release or heparin-induced platelet activation) are highly sensitive for detecting HIT antibodies such that a negative test result essentially rules out HIT. Antibody seroconversion of no clinical consequence is common following cardiac surgery. Thus, the presence of HIT antibodies in the absence of thrombocytopenia or thrombosis does not indicate HIT. However, patients with acute HIT usually have strong positive HIT antibody results. In general, the greater the magnitude of a positive HIT antibody test result, the greater the likelihood the patient has HIT. In patients following cardiac surgery, the frequency of HIT is approximately 2%. Although HIT antibodies are transient, at least half of patients with HIT develop thrombotic complications. Porcine intestine heparin has been associated with a lower risk of HIT than with bovine lung heparin.

If high suspicion of HIT exists, all heparin should be discontinued. In general, HITT should be treated with one of the following alternative anticoagulants: lepirudin, argatroban, danaparoid, or bivalirudin.[22] Warfarin and other oral anticoagulants are generally contraindicated during acute HIT and should be delayed pending substantial recovery of the platelet count. The alternative anticoagulant should be stopped only when platelet count recovery is complete and therapeutic oral anticoagulation is achieved. For patients strongly suspected of having HIT but without clinical evidence of thrombosis, an alternative anticoagulant in therapeutic doses is recommended because of the high risk of developing thrombosis.

Standard anticoagulation with heparin is recommended for cardiac surgical patients with previous HIT in whom HIT antibodies are no longer detectable (or only weakly detectable) by enzyme immunoassay. In patients with acute or subacute HIT who require cardiac surgery and yet in whom the platelet count has recovered yet HIT antibodies remain detectable, two general approaches are available. One approach is administration of an alternative anticoagulant (i.e., lepirudin, argatroban, danaparoid, bivalirudin) and avoidance of heparin exposure. The other is administration of standard heparin anticoagulation along with a platelet antagonist, including epoprostenol or tirofiban. Given the absence of prospective comparative studies, no single option can be generally recommended in these patients.

Antifibrinolytics

Antifibrinolytic agents, including the lysine analogues e-aminocaproic acid and tranexamic acid, and the serine protease inhibitor aprotinin have become mainstay prophylactic therapies for reducing bleeding and blood product transfusions for cardiac surgical patients.[23] Although many studies have demonstrated beneficial effects of these agents in reducing perioperative bleeding and morbidity,[24] others have reported adverse side effects associated with multiorgan dysfunction and prothrombotic outcomes,[25] especially among patients with a genetic predisposition to a hypercoagulable state.[26] Thus, similar to all pharmacologic agents, the decision to administer any antifibrinolytic should include a thorough risk-to-benefit consideration that is individualized to each patient.

Management of Patients during Weaning and Separation from CPB

Weaning from CPB should represent a smooth transition from the mechanical pump back to the patient's heart and lungs as the source of blood flow and gas exchange. The process should always be conducted in a coordinated fashion with all members of the team, including the surgeon, anesthesiologist, and perfusionist.[27] Preparation for separation from CPB must be based on a clear understanding of the patient's preoperative condition and events of the operative course. Weaning is initiated after review and adjustment of numerous physiologic and technical variables, including temperature, laboratory data, heart rate and rhythm, myocardial contractility, and mechanical ventilation, among others. The patient should be normothermic (>97°F 36°C]) and demonstrate normal laboratory values for hemoglobin, potassium, calcium, and acid–base balance. Myocardial function, including heart rate, cardiac rhythm, myocardial contractility, and preload, should be optimized, which may require administration of intravenous medications, depending on the desired goal (Table 51–1). Many patients usually require medications that increase myocardial contractility during separation from CPB. In extreme cases, mechanical devices may be required (intraaortic balloon pump [IABP], ventricular assist device [VAD]). It now is clear that information obtained from transesophageal echocardiography (TEE) is far superior in quality and quantity to that obtained from a pulmonary artery catheter (PAC) and may be very helpful in guiding therapy toward optimizing hemodynamics and guiding de-airing procedures during weaning from CPB. Furthermore, TEE has proved invaluable in assessing the quality of surgical procedure following separation from CPB, especially among patients with significant ventricular dysfunction and those undergoing valve procedures, congenital heart surgery, and aortic surgery.[27–30]

Vasodilator Agents
Nitroglycerin
Nitroprusside

ANESTHETIC MANAGEMENT DURING CORONARY ARTERY BYPASS GRAFTING

The anesthetic management of patients undergoing coronary artery bypass graft surgery (CABG) requires an understanding of myocardial oxygen supply and demand, patient monitoring, and the anesthetic techniques that provide myocardial protection and favor oxygen supply over demand. Myocardial ischemia results as an imbalance between the oxygen supply of the coronary circulation and the metabolic demand of myocardial tissue. Ischemia initially causes contractile dysfunction. However, if ischemia is severe or prolonged, it can lead to cell death, tissue necrosis, and permanent loss of contractile function of the affected myocardial region. This section reviews the basic pathophysiology of myocardial ischemia, the anesthetic management of patients at risk for developing myocardial ischemia, and anesthetic considerations during CABG surgery.

Coronary Artery Anatomy

Coronary artery anatomy is particularly relevant to the anesthesiologist caring for patients with coronary artery disease. The severity of the blockages correlates with the margin of reserve for tolerating tachycardia and hypotension. Patients with coronary lesions obstructing 99% of the lumen (subtotal occlusion) may not tolerate even mild degrees of tachycardia and hypotension, whereas patients with lesions in the 70–75% range may tolerate some degree of hemodynamic compromise without causing ischemia. Knowledge of specific coronary lesions also allows for focused monitoring of targeted myocardial regions at increased risk for developing myocardial ischemia.

The two major coronary arteries are the first arterial branches of the aorta, which arise from two of the three sinuses of Valsalva in the aortic root (Fig. 51–1). The right coronary sinus is anteriorly located, although the left coronary sinus is located laterally and slightly posterior. The left coronary artery (LCA) divides into the left anterior descending coronary artery (LAD) and left circumflex artery (LCx). The LAD gives rise to the diagonal branches and supplies the anterior wall of the right ventricle (RV), the anterior two thirds of the interventricular septum, the anterior wall of the left ventricle (LV), and the ventricular apex. The LCx gives rise to the obtuse marginal branches and supplies the left atrium (LA), and the posterior and lateral

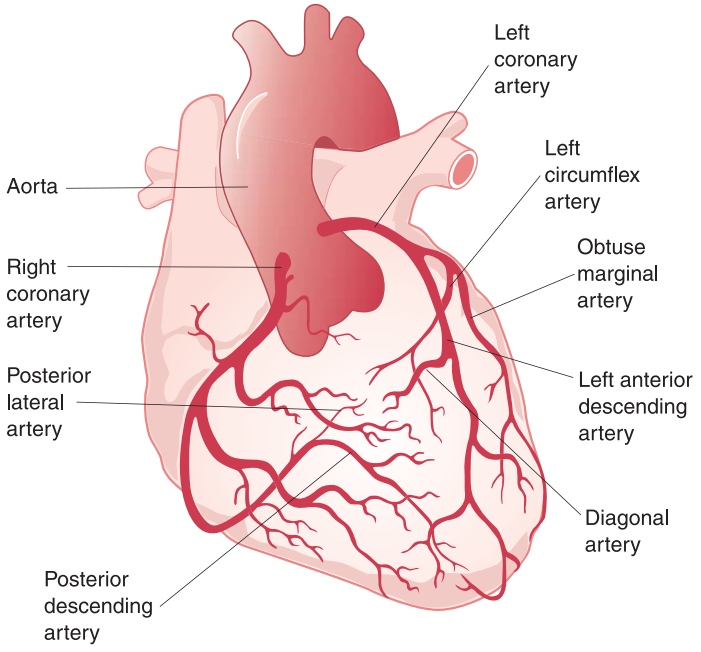

FIGURE 51–1. Coronary anatomy. (From www.bph.co.th/heartcenter/heartCardiacCatheterization.html with permission.)

walls of the LV. Patients described as having "a left main" have a significant lesion in the LCA and are at particular risk for developing ischemia that affects a large portion of the LV, which would cause rapid hemodynamic compromise and cardiac arrest. Patients described as having a "left main equivalent" have high-grade obstructions in both the LAD and LCx arteries. These patients potentially have the same risk of coronary ischemia and rapid hemodynamic compromise as do patients with left main disease.

The right coronary artery (RCA) supplies blood to the lateral and posterior walls of the RV, the inferior wall of the LV, and the posterior third of the interventricular septum. The RCA terminates as the posterior descending artery (PDA) in 85–90% of the population. The blood supply of the PDA determines the pattern of coronary dominance: RCA for right dominant and LCx for left dominant. Most patients have an RCA dominant or balanced pattern of blood supply to the PDA. A balanced pattern is used to describe coronary anatomy with no particular dominance in terms of the blood supply to the PDA. The presence of a right dominant or balanced system during OPCABG frequently leads to bradycardia and hypotension during RCA occlusion because it supplies blood to the sinoatrial node in 55% of patients, whereas the PDA supplies the atrioventricular node in right dominant patients.

Myocardial blood collects in the coronary veins, which drain into the coronary sinus, and subsequently the right atrium (RA). The coronary sinus is often used as a conduit for the delivery of cardioplegia to the myocardium in a retrograde fashion. This is possible because the coronary veins lack valves, allowing blood to flow in either direction. Retrograde cardioplegia is used in patients with aortic insufficiency (AI), during aortic valve (AV) surgery, in the presence of high-grade coronary obstructions, and in patients with previous CABG who have a patent internal mammary artery graft. All of these situations limit the antegrade delivery of cardioplegia to the myocardium from the aortic root. Retrograde delivery of cardioplegia via the coronary sinus also has limitations. A coronary sinus catheter inserted beyond the small cardiac vein will prevent delivery of cardioplegia to the RV. Subsequently, the right heart may be poorly protected from myocardial ischemia during aortic cross-clamping.[31] Coronary sinus catheters that are directed into the small or middle cardiac vein may cause coronary sinus rupture.

The LAD is positioned on the anterior aspect of the heart. The obtuse marginal branches of the LCx and diagonal branches of the LAD are located on the lateral or posterior aspect of the heart (Fig. 51–1). The surgeon must rotate or lift the heart to gain access to these vessels, causing hemodynamic compromise if the cardiac chambers are compressed. The pulmonary outflow tract also may be compressed with cardiac rotation, again resulting in severe hypotension by dramatically reducing preload. Additionally, the electrocardiographic (ECG) axis changes during cardiac manipulation and may change the ECG–coronary artery anatomic relationship, limiting the ability to use ECG for ischemia monitoring. Use of TEE for ischemia and ventricular function monitoring may be compromised when the heart is lifted or manipulated within the surgical field. The PAC may be malpositioned during these maneuvers, providing erroneous data regarding cardiac output and filling pressures.

Coronary Blood Flow Physiology

The physiology of coronary blood flow is based upon the assumption that coronary arteries are nondistensible tubes, and that blood is a homogeneous fluid. Blood flows from a region of higher pressure (aorta) to one of lower pressure (capillaries). The rate of flow is dependent on the pressure gradient that moves red blood cells through the coronary arteries in a laminar flow pattern. Flow is most dependent on the radius of the blood vessel, which is why coronary arterioles maximally dilate in response to coronary arterial stenosis.[32] Coronary stenosis causes the vessel to maximally dilate distal to the stenosis, creating a vessel with a fixed radius. Manipulation of the coronary perfusion pressure then becomes the most important factor that determines coronary blood flow and the most important physiologic parameter manipulated by the anesthesia provider in the setting of coronary ischemia. Exercise-induced ischemia causes a compensatory increase in heart rate, α_1-adrenergic–induced vasoconstriction, and increased LV filling pressure, all of which reduce coronary blood flow.[33] Adequate coronary perfusion pressure is the most important factor in the prevention and treatment of myocardial ischemia, both in the operating room and during exercise.

A second important factor is blood viscosity determined rheologically as the concentration or suspension of erythrocytes within the blood. Patients

with coronary artery disease (CAD) have disturbed blood flow patterns that create an increased tendency for coronary arterial thrombosis.[34] These abnormal flow patterns underscore the importance of aspirin therapy in the medical management of patients with CAD by reducing platelet adhesion and aggregation at the site of coronary stenoses.

Coronary blood flow has a characteristic phasic perfusion pattern, 70–80% of which occurs during the diastolic phase of the cardiac cycle. Cardiac contraction during systole impedes myocardial perfusion by increasing intraventricular cavitary pressure and coronary artery resistance, thus producing a nonlinear relationship between heart rate and diastolic time.[35] β-blockade is a very effective medical therapy for patients with CAD by preventing even small increases in heart rate during the perioperative period, reducing mortality with heart rate reduction, and improving outcome.[36]

Heart rate reduction improves subendocardial coronary artery blood flow,[37,38] allowing for better matching of myocardial oxygen supply and demand (myocardial perfusion–contraction coupling), thus preserving regional myocardial contractility.[39] Recovery of stunned or hibernating myocardium in patients with ischemic heart disease occurs with restoration of myocardial perfusion–contraction coupling.

Myocardial Oxygen Delivery

Myocardial oxygen delivery depends on the oxygen content in the blood and is composed of hemoglobin-bound oxygen and dissolved oxygen. Hemoglobin-bound oxygen composes most of the blood's carrying capacity. However, delivery of oxygen to myocardial cells is dependent on release of oxygen from hemoglobin and is represented by the oxygen–hemoglobin dissociation curve. A leftward shift of this curve from normal indicates a greater affinity of oxygen by hemoglobin, which has the effect of drawing more oxygen into the blood as it passes through the lungs but reducing oxygen release at the cellular level. A leftward shift is caused by alkalosis (both metabolic and respiratory), hypothermia, carboxyhemoglobinemia, methemoglobinemia, and decreased red blood cell 2,3-diphosphoglycerate (DPG), which may be observed after transfusion of a large volume of old blood stored in acid-citrate-dextrose. A rightward shift indicates less affinity of the red cells for oxygen, which has the effect of greater oxygen release to the tissues but at the expense of drawing less oxygen into the blood as it passes through the lungs. A rightward shift is caused by acidosis (both metabolic and respiratory), hyperthermia, and increased 2,3-DPG in the red blood cells.

Although anemia clearly reduces the oxygen carrying capacity of blood, clinical studies have not determined the lowest acceptable level of anemia that does not produce myocardial ischemia. The degree of anemia that produces myocardial ischemia is dependent on factors that are specific for each patient and the loading conditions of the ventricle. Factors include the severity of CAD, myocardial wall thickness and tension, heart rate, and perfusion pressure. Isovolemic reduction of hemoglobin to 4.6–5.3 mg/dL in healthy volunteers produced ST-segment changes on Holter monitoring in two of 11 subjects, whereas hemoglobin levels of 5.0 mg/dL led to myocardial ischemia infrequently.[40] In another investigation, ECG ST-segment changes suggestive of ischemia occurred in only three of 55 subjects during acute reduction of hemoglobin concentrations to 5 g/dL. These authors attributed the imbalance of myocardial oxygen supply and demand to tachycardia.[41] No adverse outcomes were found in healthy children undergoing scoliosis surgery who experienced acute intraoperative, normocarbic, normovolemic, hemodilution to 3.0 g/dL.[42]

Patients with ischemic heart disease require a higher hemoglobin concentration to minimize perioperative complications. A higher incidence of postoperative mortality was found in cardiac surgical patients older than 75 years whose preoperative systemic oxygen delivery was < 320 mL/min/m^2 and who had anemia on the second postoperative day.[43] Bracey et al.[44] found no increase in morbidity, mortality, or patient self-assessment of fatigue when the hemoglobin threshold for red cell transfusion was lowered to 8.0 g/dL after CABG. Therefore, the lower limit of hemoglobin concentration depends on multiple factors, such as the patient's age, heart rate, perfusion pressure, clinical evidence of myocardial ischemia, and success of coronary revascularization.

Myocardial Oxygen Demand

Myocardial oxygen demand is primarily determined by heart rate, ventricular wall tension, and myocardial contractility. Acting on the myocardial β-receptors, β-blockers decrease heart rate and reduce contractility and thus are primary treatment for patients with CAD at risk for myocardial ischemia. Although treatment with atenolol in the perioperative period does not significantly alter the neuroendocrine stress response,[45] perioperative β-blockade reduces mortality and myocardial infarction (MI) among patients undergoing noncardiac surgery.[46–48] Patients treated with metoprolol and for whom ventricular filling pressures were unchanged had an up to 40% reduction in myocardial oxygen consumption.[36] Metoprolol also improves survival, patient well-being, and New York Heart Association (NYHA) functional class in patients with congestive heart failure (CHF).[49,50] β-Blockade and subsequent heart rate reduction clearly decrease myocardial oxygen consumption and increase oxygen supply in patients with CHF. Although most anesthesiologists recognize the benefits of perioperative β-blockade, few institutions have formalized protocols for administering β-blockers to surgical patients.[51]

Preload

Preload is the ventricular volume at end-diastole that determines myocardial fiber length, which in part determines the force of ventricular contraction. Manipulation of preload is an important therapeutic option in the care of patients with myocardial ischemia. Nitroglycerin is commonly used for treatment of myocardial ischemia, primarily exhibiting its antianginal effect by preload reduction through venodilation and coronary vasodilatation. Morphine also is useful for treating myocardial ischemia by causing vasodilatation (preload reduction) and providing pain relief, thereby leading to reduced heart rate. Furosemide reduces preload through both its diuretic action and venodilation.[52]

Determination of end-diastolic volume is problematic in the clinical arena. Pulmonary artery occlusion pressure (PAOP) is commonly used for approximating LV end-diastolic volume (LVEDV), but multiple assumptions must be made in order to use PAOP to estimate preload. Use of a pressure

measurement to estimate volume must take into account LV compliance, which is the change in unit pressure for each change of unit volume. Both LVEDV and the compliance of the myocardium determine the LV end-diastolic pressure (LVEDP). Myocardial ischemia decreases ventricular compliance, thereby increasing LVEDP for the same LVEDV. This change may be reflected in PAOP measurements, allowing use of PAOP as an ischemia monitor.

Other factors that affect the relationship between PAOP and LVEDP are mitral stenosis (MS), LA compliance, and intrathoracic pressure. Although the severity of MS does not change over the course of an anesthetic or surgical procedure, the pressure gradient between the LA and LV is dynamic, dependent on the cardiac output, heart rate, and flow though the mitral valve (MV) during the diastolic phase of the cardiac cycle. Tachycardia decreases diastolic time, thereby increasing flow through the MV during diastole and hence increasing the pressure gradient between the LA and LV. An increase in PAOP in this circumstance is due to an increase in the pressure gradient across the MV rather than an increase in preload. Actual LV preload may be reduced because tachycardia impedes LV filling in patients with MS. When PAOP is used for ischemia monitoring, trends in pressure changes must be taken in the context of these other hemodynamic variables in patients with MS.

Fig. 51–2 shows a normal central venous pressure waveform and the relationship of the waveform with the ECG. PAOP appears similar but reflects LA pressure rather than RA pressure. The presence of large prominent V waves is indicative of mitral regurgitation (MR), which can occur with ischemic papillary muscle dysfunction. This acute increase in LA volume decreases the compliance of the LA and pulmonary veins.

Large changes in intrathoracic pressure also affect PAOP.[53] During spontaneous inspiration, mean PAOP declines because of the decrease in intrathoracic pressure. Positive-pressure ventilation causes increased intrathoracic pressure, which is reflected in the pulmonary venous pressure. Measurement of PAOP is made at the end of expiration to minimize the effects of inspiration on intrathoracic pressure and the pulmonary vasculature.

Afterload

Afterload is impedance to ventricular ejection and is best described with pressure–volume loops. The ratio of end-systolic pressure to stroke volume defines the elastance of the arterial tree. In the absence of aortic stenosis (AS), this is primarily determined by arterial vasculature tone. Afterload conditions that allow more fiber shortening allow greater metabolic efficiency and reduced oxygen consumption.[54] The clinician can manipulate afterload by changing the size or radius of the LV through preload manipulation or more commonly by affecting systemic vascular resistance or blood viscosity. Although systemic vascular resistance is only one component of afterload, it is the only factor that is easily measured and readily changed clinically.

Contractility

Inotropy describes the contractile state of the ventricle and is measured using either the ejection or isovolumic phase of ventricular contraction. Pressure–volume loops consisting of ejection, relaxation, and isovolemic pressure are drawn under different loading conditions. The slope of the serial end-systolic pressure–volume relationship describes the myofibril contractile state independently from preload or afterload (Fig. 51–3). Simple clinical tools for measuring contractility independent of preload and afterload do not exist; however, some investigators have used simultaneous pressure and echocardiography area relationships to provide measurements of contractility.[55]

Anesthetic Considerations for Patients Undergoing CABG Surgery

Patients with CAD presenting for CABG require special considerations in their anesthetic management. First and foremost are techniques that minimize myocardial oxygen demand while maximizing myocardial oxygen delivery, as described in previous sections. These considerations include preoperative preparation, intraoperative monitoring, and the use of anesthetic agents with hemodynamic effects that favor oxygen supply over demand and allow for myocardial protection. Postoperative management that provides particular attention to pain management, temperature control, and hemodynamic monitoring to prevent tachycardia, hypotension, and hypertension also must be considered. Many of these considerations apply to patients undergoing CABG surgery, with or without CPB. However, certain considerations apply to patients who undergo CABG with CPB, although others apply if coronary revascularization is performed without CPB (i.e., OPCABG).

Preoperative Evaluation

Most patients presenting for CABG surgery undergo extensive preoperative testing of their cardiac disease and other medical problems. Medical conditions that predispose patients to the development of CAD also affect other organ systems. They include smoking, hypertension, hypercholesterolemia, diabetes, obesity, and advanced age. It is particularly important to identify comorbidities that may prolong or complicate the patient's postoperative course. One comorbidity that deserves particular attention is respiratory insufficiency. Patients with CAD often complain of dyspnea due to ventricular dysfunction caused by myocardial

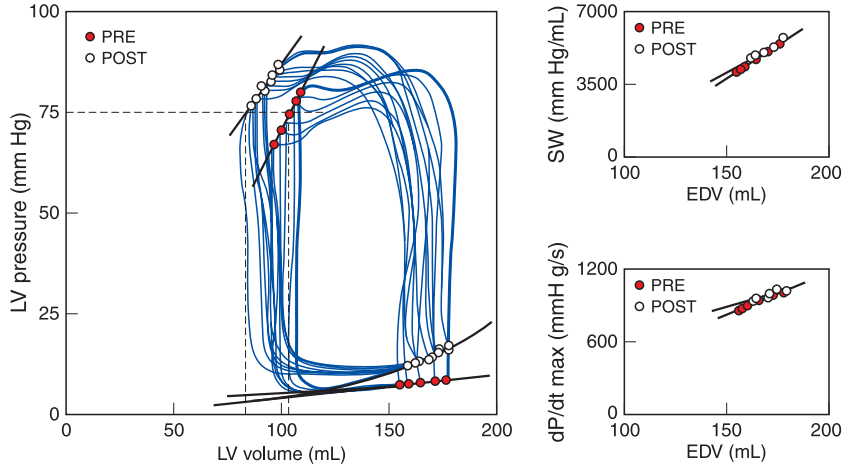

FIGURE 51–3. Example of end systolic pressure–volume relations (ESPVRs) derived by caval vein occlusion before and after cardiopulmonary bypass (CPB). The ESPVRs (left) show the increased contractile performance after CPB in this patient. Although the slope of the ESPVR (Ees) is slightly decreased, the position of all end-systolic pressure–volume points to the left and above the pre-CPB ESPVR suggests higher contractility. Dotted lines indicate the position of the ESPVR at 75 mm Hg. The same holds for the preload recruited stroke work (PRSW) relation (upper right) and the dP/dt_{max}–end-diastolic volume (EDV) relation (lower right), although the differences are much less pronounced. The EDPVRs (left panel) provide clear evidence for a substantial increase in chamber stiffness after CPB, as observed in all patients. (From Tulner SA, Klautz RJ, van Rijk-Zwikker GL, et al. Perioperative assessment of left ventricular function by pressure–volume loops using the conductance catheter method. Anesth Analg 2003; 97:950–957, with permission.)

ischemia. Dyspnea related to myocardial ischemia should resolve with adequate revascularization. However, patients with a long-standing smoking history who develop underlying pulmonary disease may not derive the same benefit after CABG surgery, but instead experience exacerbation of their pulmonary disease and require prolonged postoperative mechanical ventilation and suffer pulmonary complications after surgery.

Diabetes is a progressive metabolic disorder that leads to the development of CAD, cerebral vascular disease, neuropathy, nephropathy, and retinopathy. An important aspect of diabetes in the patient with CAD is that myocardial ischemia may occur in the absence of classic symptoms. Patients may suffer from ischemic episodes without therapy, leading to potentially irreversible cardiac damage. They may have prolonged recovery from CABG surgery because of the increased need for inotropic support. Tight control of glycemic blood levels during the perioperative period is important for reducing the incidence of wound infection following cardiac surgery.

Hypertension is another medical condition common in patients with CAD. It also is a risk factor for cerebral vascular disease, renal failure, and CHF. This condition may be asymptomatic, yet it carries the risk of end-organ damage if untreated for prolonged periods. Patients with uncontrolled hypertension often are more difficult to manage because of wide swings in blood pressure associated with events such as sternotomy and pericardotomy. Their vasculature is more responsive to catecholamines causing an exaggerated response, while the relatively volume contracted state leads to exaggerated hypotension in response to vasodilator therapy.

Renal disease is associated with cardiac surgical patients, especially in those with hypertension and diabetes. Development of renal failure after cardiac surgery is a concern, which occurs in 0.9% of CABG patients and 2.0% of patients undergoing valve procedures. More importantly, operative mortality has been reported to be 63.7% in patients who develop acute renal failure versus 4.3% for patients who did not develop renal failure.[56] The risk of postoperative MI, reoperation for bleeding, and mediastinitis is higher in patients who develop postoperative renal failure.[57]

Monitoring

Continuous ECG monitoring, along with blood pressure measurement, pulse oximetry, and end-tidal carbon dioxide (CO_2) analysis are standard monitors for all anesthetized patients. For the cardiac surgical patient, a display monitor that allows viewing of two ECG leads simultaneously, with automated ST-segment analysis, is preferred. Limb leads II and V_5 of the ECG allow for monitoring of myocardial regions supplied by the RCA and LAD coronary arteries, respectively. Automated ST-segment trending has only moderate sensitivity and specificity (75% for both) in detecting changes found by off-line Holter monitoring[58] but is a marked improvement over the observation of the clinician, whose attention must also be directed at providing anesthetic care. Monitoring two ECG leads simultaneously increases the sensitivity of detecting ischemia to 80% if leads II and V_5 are monitored, 82% if leads II and V_4 are monitored, and 90% if leads V_4 and V_5 are monitored (Fig. 51–4).[59] Factors such as LV hypertrophy, cardiac conduction changes, electrolytes, and drugs such as digitalis all can affect the interpretation of ST segments,[60] but the primary concern is acute ST-segment changes that occur during the perioperative period (Fig. 51–5).

All cardiac surgical patients require invasive arterial blood pressure monitoring. Although the radial artery is used at many institutions, consideration must be given to the possibility of harvesting the radial artery as a conduit for CABG. When used, the radial artery is harvested from the patient's nondominant hand, so radial artery cannulation should be performed in the dominant hand. Femoral artery cannulation can be used and is preferred by some clinicians and institutions. The benefits of using femoral artery cannulation include a better correlation with mean arterial pressure in the immediate post-CPB period and access to the femoral artery if an IABP must be inserted. The intraarterial catheter can be placed prior to or immediately after induction, but preinduction placement allows the clinician to respond more rapidly to the changing hemodynamic conditions often present during induction of anesthesia. If a potential difficult airway is anticipated or if the patient has a greater risk of rapidly changing hemodynamics (left main disease or severe ventricular dysfunction), then preinduction placement of the arterial catheter is preferred.

All cardiac surgical patients should have central venous access for the

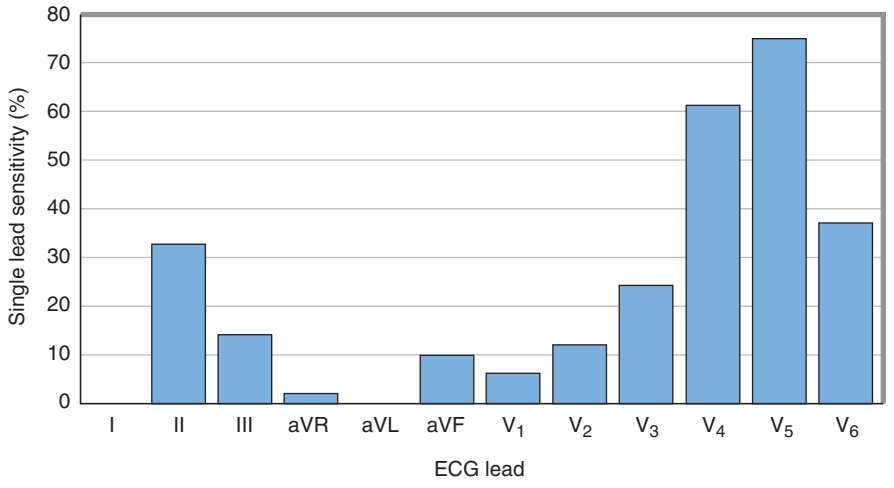

FIGURE 51–4. Distribution of ischemic ST-segment changes in each of the 12 ECG leads of 105 patients with known or suspected coronary artery disease undergoing noncardiac surgery with general anesthesia. Sensitivity was calculated from the number of changes in a single lead as a percentage of the total number of episodes obtained with continuous intraoperative recording. purpose of administering important vasoactive medications into the central circulation and for assessing volume status. The issue of whether to place a central venous pressure (CVP) catheter versus a PAC is controversial. A PAC measures pulmonary artery (PA) pressure and provides a means for sampling mixed venous oxygen saturation (SvO_2). PA pressure is not easily obtained with TEE, and SvO_2 cannot be obtained with a CVP catheter or by TEE. Some studies suggest that use of a PAC does not improve outcome in cardiac surgery.[61] However, prolonged pre-CPB pulmonary hypertension and post-CPB elevation of PA diastolic pressure are predictors for the development of perioperative MI.[62] Early treatment of pulmonary hypertension is presumed to improve outcome.

The American Society of Anesthesiologists (ASA) Task Force on Pulmonary Artery Catheterization has provided practice guidelines for PAC insertion (Table 51–2).[63] PA pressure monitoring is indicated based on the medical condition of the patient or the nature of the surgery (Table 51–3) but is not recommended when the patient, procedure, and practice setting each poses a low risk for hemodynamic complications.[63] Cardiac surgical patients with unstable angina, recent MI, active CHF, severe CAD or valvular heart disease, and severe pulmonary or renal disease should have PA pressure monitoring. However, routine PA catheterization is not necessary in all patients undergoing CABG. Outcome after CABG is not influenced by routine use of a PAC, suggesting its use can be delayed until a clinical need develops.[61]

Right bundle-branch block occurs in approximately 3% of patients undergoing PA catheterization.[64] For this reason, placement of a PAC in patients with a previous left bundle-branch block is not recommended unless precautions are taken for managing the patient should complete heart block occur. A decision-making algorithm for inserting a PAC in patients with a preexisting left bundle branch block is shown in Fig. 51–6.

American Society of Anesthesiologists Task Force on Pulmonary Artery Catheterization Practice Guidelines[63]

- Indications Related to the Patient
  - Clinical evidence of significant cardiovascular disease
  - Pulmonary dysfunction
  - Hypoxia
  - Renal insufficiency
  - Other conditions associated with hemodynamic instability (e.g. advanced age, endocrine disorders, sepsis, trauma, burns)
- Indications Related to Surgery
  - Surgical procedures associated with an increased risk of hemodynamic changes, including damage to the heart, kidneys, lungs, or brain
- Indications Related to Practice Setting
  - Physician skills
  - Duration of procedure
  - Technical support
  - Training and experience of nursing staff
  - Ability to manage potential complications

Data from American Society of Anesthesiologists Task Force on Pulmonary Artery Catheterization. Practice guidelines for pulmonary artery catheterization: an updated report by the American Society of Anesthesiologists Task Force on Pulmonary Artery Catheterization. Anesthesiology 2003;99:988–1014.

TABLE 51–3.

Indications for Pulmonary Arterial Pressure Monitoring

- Indications Related to the Patient
  - Right heart failure
  - Pulmonary hypertension
  - Pulmonary embolism
  - Unstable angina
  - Recent myocardial infarction
  - Acute congestive heart failure
  - Severe coronary artery disease
  - Shock (cardiogenic, septic, or hemorrhagic)
  - Massive trauma
  - Severe lung disease
  - Severe renal disease
- Indications Related to Surgery
  - Major organ transplantation
  - Aortic cross-clamping procedures
  - Large fluid shifts
  - Massive blood loss
  - Implantation/explantation of ventricular assist devices

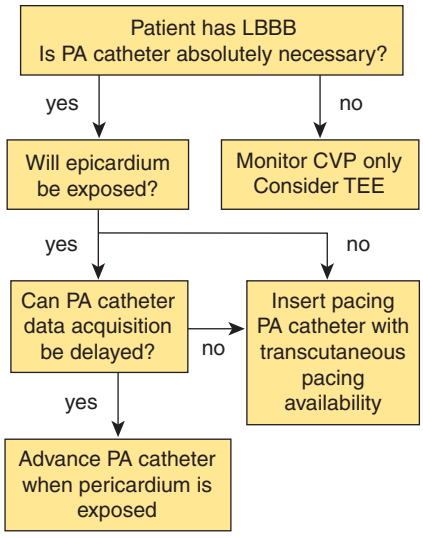

FIGURE 51–6. Algorithm for pulmonary artery (PA) catheter insertion in patients with left bundle-branch block (LBBB). TEE, Transesophageal echocardiography. (Reprinted from Troianos CA. Intraoperative monitoring. In: Anesthesia for the Cardiac Patient. St. Louis: Mosby, 2002: 106, with permission from Elsevier.)

TEE can be used to assess global and regional myocardial contractility, volume status, and valvular function during cardiac surgery. Although TEE has revolutionized the intraoperative assessment and management of patients undergoing cardiac surgery, few data suggest that routine use of TEE for all patients with normal ventricular function undergoing elective CABG improves outcome. Regional wall-motion assessment by qualitative inspection of radial shortening and wall thickening is subjective. Accurate diagnosis is dependent on observer experience and having the ischemic myocardial segment in the imaging plane during the ischemic episode. More sophisticated techniques such as computerized digitations, color kinesis, and tissue Doppler imaging may allow for better assessment, but these techniques are not readily available or familiar to all users. Nonetheless, information obtained from TEE is far superior in quality and quantity to that obtained from a PAC and may be very helpful in guiding therapy toward optimizing hemodynamics in the perioperative period. Furthermore, TEE has proven invaluable for assessing the quality of the surgical procedure following separation from CPB, especially among patients undergoing CABG surgery who have significant ventricular dysfunction and those undergoing concurrent valve procedures, congenital heart surgery, and/or aortic surgery.[27–30]

Near-infrared reflectance spectroscopy has been used to demonstrate a correlation between low bifrontal regional cortical oxygen saturation and cognitive dysfunction, prolonged hospital stay, and perioperative stroke. Thus, some clinicians have advocated monitoring of cerebral oximetry in CABG patients as a technique for preventing profound cerebral desaturation and associated morbidity.[65]

Anesthetic Induction

Induction of general anesthesia for CABG surgery patients can be accomplished using a variety of medications, provided the goals of preventing tachycardia, hypotension, and hypertension are achieved. The worst combination is tachycardia and hypotension. Although hypertension increases ventricular wall tension and therefore myocardial oxygen demand, it also increases coronary perfusion pressure. Myocardial depression and the vasodilating effects of the anesthetic agents are most important considerations in patients with severely impaired ventricular function or valvular heart disease. Laryngoscopy and intubation are the first intraoperative events after induction of anesthesia that test the effects of the anesthetic technique used. Coincident with these events is the institution of positive-pressure ventilation, which may result in hypotension among hypovolemic patients or in patients with air trapping due to pulmonary disease.

Patients with CAD benefit from a narcotic-based technique because of the lack of myocardial depression, a tendency for decreased heart rate, and an attenuated response to laryngoscopy and intubation. Fentanyl probably is the most frequently used opioid in cardiac surgery, although sufentanil is a reasonable choice. Use of remifentanil and sufentanil during induction has been associated with a high incidence of bradycardic/asystolic complications in patients who have been treated with β-blockers and calcium channel blockers.[66,67] Many patients with CAD are likely to be taking one or both types of drugs. A nondepolarizing muscle relaxant devoid of cardiovascular side effects is used to facilitate intubation. Pancuronium can be used with a large dose of narcotic because the tachycardic side effects of pancuronium are balanced by the bradycardic side effects of the large-dose narcotic. Use of vecuronium or rocuronium is prudent when the initial narcotic dose is smaller because the bradycardic effects of the narcotic are not as pronounced. Pancuronium use with only a small narcotic bolus may result in undesirable tachycardia.

Modern practices that focus on early extubation and "fast-tracking" the patients through the postoperative period use smaller narcotic doses, with supplementation by short-acting hypnotic agents, such as midazolam. Use of an intraoperative awareness protocol is prudent in these patients to minimize the incidence of intraoperative recall, which is more of a concern with a primarily narcotic-based anesthetic technique. The anesthetic technique usually will use a low concentration of a potent inhalational agent or intravenous propofol for hypnosis and amnesia. Reduced doses of opioids often are administered with small doses of hypnotic drugs such as benzodiazepines, thiopental, propofol, or etomidate to promote early postoperative extubation. Care must be taken when hypnotics are administered concomitantly with opioids. Mean arterial pressure can drop precipitously in hypovolemic patients. Midazolam significantly decreases blood pressure and increases heart rate when used as an induction agent.[68] Propofol causes venodilation and can profoundly decrease blood pressure.[69] A vasoactive drug such as ephedrine or phenylephrine should be readily available to treat hypotensive episodes during the induction of anesthesia. Although regional anesthesia for cardiac surgery may provide superior postoperative analgesia, shorter postoperative ventilation, reduced incidence of supraventricular dysrhythmias, and lower rates of perioperative MI,[70] most clinicians use general anesthesia during CABG procedures.

The same hemodynamic goals must be achieved for the patient with a difficult airway who requires an awake/sedated fiberoptic intubation prior to general anesthesia. The patient's airway should be well anesthetized with local anesthetics and the patient sedated with short-acting intravenous agents that blunt the response to laryngoscopy and intubation. An inhalational induction also might be considered in some patients. Alternatively, an intubating laryngeal mask

airway can be used to secure the difficult airway under general anesthesia. The particular technique or approach is individualized to the patient's anatomy and medical condition and the experience of the clinician in using one or more of these techniques.

Pre-CPB Management

Once the airway is secured and general anesthesia induced, anesthesia care is directed toward maintaining a stable blood pressure and heart rate. If access to the central circulation was not obtained before induction of anesthesia, cannulation of the internal jugular or subclavian vein is performed, and a PAC is inserted if indicated. The right internal jugular vein is often used because of its predictable location, accessibility, and direct route into the RA. The patient is placed in the Trendelenburg position during central venous cannulation, which increases preload and helps maintain blood pressure at an acceptable range following the induction of anesthesia, in the absence of surgical stimulation. Use of surface ultrasound for guiding the insertion and placement of central venous cannula has become more popular.[71] As the operating room table is leveled following cannulation, the blood pressure frequently declines. A fluid bolus or small doses of vasoactive drugs may be required.

Additional tasks for the anesthesia provider before surgical incision include placement of a TEE probe, antibiotic administration, determination of a baseline ACT, and infusion of antifibrinolytic drugs. Although many studies have demonstrated the beneficial effects of antifibrinolytic agents in reducing perioperative bleeding and morbidity[24] others have reported adverse side effects associated with multiorgan dysfunction and prothrombotic outcomes,[25] especially among patients with a genetic predisposition to a hypercoagulable state.[26] Thus, similar to all pharmacologic agent, the decision to administer any antifibrinolytic should include a thorough risk-to-benefit consideration that is individualized to each patient.

Patients must be anesthetized to a depth that avoids a tachycardic and hypertensive response to surgical incision. Small doses of short-acting agents such as esmolol (50–100 mg) or nitroglycerin (50–100 μg) can be administered, or the anesthetic depth can be deepened with additional narcotic or potent inhalational agent. The patient's response to skin incision is a gauge to his or her subsequent response to the more stimulating event of median sternotomy. If the anesthetic depth was not adequate for skin incision, then additional narcotic or a bolus of esmolol should be administered before sternotomy. The lungs typically are deflated during sternotomy to prevent the sternal saw from cutting the lung parenchyma. Another complication that can occur during sternotomy is accidental tearing of the innominate vein or the RV. Sternotomy is especially hazardous during repeat CABG surgery, where adhesions from previous surgery placed the heart immediately posterior to the sternum. Banked packed red blood cells must be immediately available at the time of sternotomy, particularly for patients at increased risk for this complication.

Maintenance of anesthesia during the pre-CPB period can be accomplished with a variety of techniques. Isoflurane–fentanyl anesthesia and propofol–fentanyl anesthesia both are acceptable techniques for maintaining anesthesia during CABG surgery.[72] Use of sevoflurane and desflurane has been shown to result in shorter intensive care unit (ICU) and hospital length of stay.[73] This finding seemed to be related to better preservation of early postoperative myocardial function. Considerable research has recently focused on the myocardial protective effects of potent inhalational anesthetics. Isoflurane protects the myocardium during ischemic episodes in an experimental model.[74,75] Isoflurane and other volatile anesthetics may mimic the protective effects of a process called *ischemic preconditioning*.[76] Brief periods of ischemia activate the protein kinase C–mediated pathway that confers cardioprotection during subsequently longer periods of ischemia.[77] Sevoflurane decreases the inflammatory response after CPB, as measured by the release of IL-6, neutrophil β-integrins (CD11b/CD18), and TNF-α. Myocardial function after CPB, as assessed by regional wall motion and LV stroke work index, also is improved with sevoflurane.[78] Both halothane and isoflurane have been shown to provide significant preservation of adenosine triphosphate (ATP) levels during ischemia, but this preservation did not improve hemodynamic recovery.[79] In a comparative study in which patients received either propofol or inhalational anesthesia during CABG surgery, patients who received inhalational anesthesia (sevoflurane or desflurane) but not propofol had preserved LV function after CPB, with less evidence of postoperative myocardial injury.[80] The cardioprotective effects are clinically most apparent when the inhalational agent is administered throughout the operation.[81]

Important activities that occur during the pre-CPB period include surgical dissection of the left internal mammary artery, opening of the pericardium, and placement of the aortic and venous cannulas in preparation for CPB. Sternal retraction that exposes the internal mammary artery may affect the function of intravenous and arterial catheters placed in the ipsilateral arm. This most commonly affects the left arm with harvesting of the left internal mammary artery. Papaverine is commonly injected into the ligated internal mammary artery to prevent vasospasm but may cause hypotension. This decrease in blood pressure usually is brief but may require treatment with a small dose of phenylephrine. Hypertension may develop during surgical manipulation of the pericardium and aorta as a result of sympathetic activation. A small bolus of narcotic or esmolol can blunt this hypertensive response.

Heparin is administered prior to ligation of the internal mammary artery (if used) and cannulation of the aorta to prevent thrombus formation. Heparin is a polyanionic mucopolysaccharide that increases the rate of anticoagulant effect of antithrombin III on factors II, X, XI, XII, and XIII. It usually is given in a dose range of 300–400 units/kg to achieve ACT >400 seconds. The adequacy of anticoagulation must be determined prior to initiating CPB. For patients undergoing OPCABG, some surgeons administer a smaller dose of heparin, with the goals of achieving ACT >300 seconds.

CABG without CPB

CABG without CPB (OPCABG) was first reported during the 1960s and 1970s.[82,83] Advancements in the safety of CPB with better equipment and techniques allowed surgical access to more distal coronary target sites and a quiet surgical field, thereby eliminating the need for CABG without CPB.[1]

Developments in mechanical stabilization devices during the 1990s renewed the interest among surgeons to return to this technique in order to avoid the deleterious effects of CPB, particularly in elderly patients with calcified aortas. OPCABG also allowed faster recovery and fewer ICU days, providing an economic incentive to using this technique.

The anesthetic management of patients undergoing OPCABG encompasses the same hemodynamic goals as the pre-CPB management of patients undergoing CABG with CPB, but the goals are more difficult to achieve, particularly when distal coronary anastomoses are being performed. Myocardial protection with the use of inhalational agents remains an important consideration. Compared to patients who receive propofol, patients receiving sevoflurane have less myocardial injury in the first 24 postoperative hours.[84] OPCABG requires more attention, vigilance, and intervention on the part of the anesthesia provider while the surgeon is performing the distal coronary anastomoses. Maintenance of perfusion pressure, cardiac output, and normothermia, while avoiding profound myocardial ischemia, is challenging during surgical manipulation that produces ventricular compression and temporary coronary occlusion. Ischemia monitoring is compromised by cardiac displacement that alters ECG polarization and affects the anatomic relation with a TEE probe. Vasoactive medications and the Trendelenburg position are used to maintain blood pressure and cardiac output. Despite the best efforts, however, decreases in cardiac output with elevations in central venous and PAOP are commonly observed during surgical manipulation. Cardiac dysrhythmias are not uncommon and are treated by increasing the perfusion pressure and with use of medications such as lidocaine, amiodarone, and magnesium. Malignant dysrhythmias that are not corrected by medications or electrical cardioversion may prompt the need for CPB. Temporary cardiac pacing may be required in patients with right coronary dominant anatomy because of bradycardia or cardiac arrest during right coronary occlusion. Upon successful completion of all distal coronary anastomoses, the blood pressure is lowered before application of the partial aortic clamp for the proximal anastomoses. Release of this clamp after all of the proximal grafts are completed may produce reperfusion dysrhythmias or send air through the coronary grafts, if they were not adequately de-aired by the surgeon.

Anticoagulation is reversed with protamine after the surgeon is satisfied with the grafts and the absence of surgical bleeding. The surgical wound is closed, and the patient is transported to the ICU. Some patients may be candidates for extubation immediately after surgery, but this should be individualized according to the patient's temperature, need for inotropic and mechanical support of the circulation, coexisting medical problems, and degree of mediastinal bleeding.[85] Extubation within 2–4 hours after surgery is a reasonable goal for most patients undergoing OPCABG.

CABG with CPB

For patients undergoing CABG with CPB, a two-stage cannula is placed in the RA to direct blood away from the patient to the CPB circuit and a cannula is placed in the aorta to return oxygenated blood to the patient's circulatory system. The patient must be fully heparinized before cannulation to avoid thrombus formation. The arterial blood pressure is lowered to 85–90 mm Hg systolic pressure prior to aortic cannulation to reduce aortic wall tension and minimize the risk of aortic dissection as the aortic wall is punctured. The surgeon may request hand-bag ventilation to provide better visualization of the RA for insertion of the venous cannula. Atrial fibrillation may develop during placement of the venous or coronary sinus catheters. Cardioversion with internal paddles may be required if the patient becomes hypotensive prior to CPB.

Some institutions "retrograde prime" the CPB circuit by allowing the patient's blood to displace the clear fluid priming volume from the aortic and venous lines to the CPB machine. This process nearly always causes hypotension due to volume depletion and requires vigilance and treatment by the anesthesia provider to avoid profound hypotension. Small boluses of phenylephrine are effective for raising blood pressure during this process. Once the retrograde priming is complete, pump volume is infused through the aortic cannula and the venous cannula is unclamped, thereby initiating CPB.

Cardiopulmonary Bypass

Mechanical ventilation is discontinued when a calculated circulation flow is reached. The surgical field is observed for evidence of venous obstruction, aortic dissection, and cardiac distension. Anesthesia is maintained by volatile anesthetics administered through a vaporizer on the CPB machine or by continuous infusion of hypnotic drugs such as propofol, titrated according to mean arterial blood pressure and readings on the awareness monitor. Some clinicians routinely administer hypnotics with initiation of CPB and during rewarming to reduce the incidence of intraoperative awareness. Additional muscle relaxation helps reduce oxygen consumption by minimizing shivering as the patient is cooled. ECG, systemic and pulmonary pressures, urine output, and temperature are monitored. PA pressure may increase with cardiac distension or because the PAC has migrated to more peripheral regions in the lung during cardiac manipulation. In the absence of cardiac distension, the PAC should be withdrawn until the pressure measured in the distal port decreases.

The clinician should use the CPB time to prepare for post-CPB events. Most patients with good ventricular function do not require inotropic support following successful coronary revascularization. However, patients with poor preoperative ventricular function and those who undergo complicated surgical procedures and prolonged prebypass ischemia often require inotropic or IABP support in the postbypass period. Prior to termination of CPB, the surgeon places epicardial atrial and ventricular pacing leads, to be used as needed to establish an adequate cardiac rhythm and rate.

Post-CPB Management

The patient is rewarmed to normothermia with CPB as the surgeon completes the coronary anastomoses. The rewarming process may take longer in patients with a higher body mass index and after more profound hypothermia. Mechanical ventilation is resumed upon the surgeon's request, after inspection of the anastomotic sites reveals the absence of a surgical cause for bleeding. If inhaled anesthetics are being used in the CPB circuit, their delivery should be continued via the anesthesia machine. The dose of the potent inhalational agent used should

be minimal to avoid myocardial depression. Vasoactive infusions should be started or maintained. Communication should take place between the surgeon and the anesthesiologist to confirm that both are ready to begin the process to separate the patient from CPB. Venous drainage to the pump is reduced, and the patient's heart begins to receive more blood from the circulation. Preload is adjusted by observing mean arterial pressure, cardiac distension, and PA or central venous pressure. The physician performing TEE provides information to the surgeon regarding volume status and contractility, which also aids the separation from CPB. A cardiac index is determined if a PAC is used. The venous cannula is removed from the RA with satisfactory separation from CPB. The surgeon, perfusionist, and anesthesiologist all must be aware when protamine is administered to reverse the anticoagulant effects of heparin. With adequate neutralization of the heparin, the surgeon inspects the surgical field for bleeding and closes the surgical wound with adequate hemostasis. The patient is transported to the ICU for postoperative care.

Postoperative Complications

Postoperative myocardial ischemia occurs in up to 48% of cardiac surgical patients and is associated with adverse cardiac outcomes.[86] Thirty-eight percent of ischemic episodes occur during the first 2 postoperative days and peak within the first 2 hours of revascularization. These findings have important implications for monitoring, diagnosis, and treatment. Treatment of myocardial ischemia is directed toward adjusting the factors that determine myocardial oxygen supply and demand. Ischemia that develops immediately upon termination of CPB usually is related to air or particulate emboli in the bypass grafts. Elevation of mean arterial pressure and incremental increases in boluses of nitroglycerin are effective for treating ischemia caused by air in the venous grafts. The surgeon should confirm graft patency with Doppler flow probes or palpation. Persistent myocardial ischemia is treated with placement of an IABP. "Stunned myocardium" may be the result of reperfusion injury or intraoperative MI. These patients will require support of cardiac function until myocardial function improves.

Patients at risk for increased mortality after CABG are identified by preoperative factors. The most significant risk factors that increase mortality are age >80 years, emergent surgery, prior cardiac surgery, and renal failure.[57,87] Cerebral vascular events are more common among elderly patients. Mediastinitis is more common among patients with chronic obstructive lung disease, severe obesity, diabetes, renal failure, emergent surgery, and preoperative ejection fraction <40%.[57,87] Renal failure is associated with advanced age, history of CHF, and preexisting renal disease.[57,87]

CARDIAC ANESTHESIA FOR VALVE SURGERY

Whereas the number of CABG procedures in the United States has decreased over the past several years, operations for heart valve disease are increasing. More than five million people have moderate-to-severe valvular regurgitation in the United States alone.[88] Our aging population, expanding indications for surgery, improvements in valve repair techniques and replacement construction, and reduced patient morbidity and mortality after surgical intervention all suggest that valve surgery likely will increase in coming years.

The two most common valves requiring surgical intervention are the MV and AV. Most patients in the United States undergo MV procedures for MR because of annular dilation, leaflet prolapse, or leaflet tethering (Fig. 51–7). Myxomatous MV disease is the most common cause of isolated MR.[89] The defect usually is associated with advancing age and degenerative changes. The pathophysiology includes elongated and/or ruptured chordae with generous leaflet tissue, dilated annulus, and severe regurgitation. The defect is associated with increased mortality, even in asymptomatic patients.[90] A majority of these patients are amenable to valve repair rather than valve replacement. AV disease is a common indication for surgery. Calcific AS is seen in elderly patients, whereas a bicuspid AV is common in younger patients. Bicuspid AVs are found in approximately 0.5% of the population.[91] The bicuspid AV is a heritable condition, associated with a defect in fibrillin and matrix metalloproteinase-2, which leads to weakening an aneurysm formation (Figs. 51–8 and 51–9).[92,93] These patients often present for AV replacement with an ascending aortic root replacement requiring deep hypothermic circulatory arrest (DHCA).

The spectrum of valve surgery extends well beyond this limited review. There are both regurgitant and stenotic

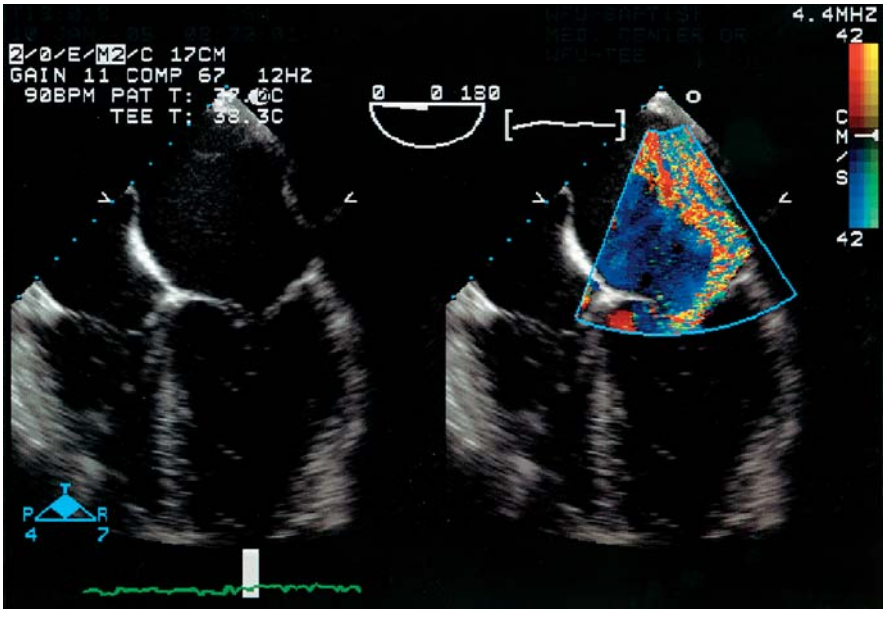

FIGURE 51–7. Midesophageal transesophageal echocardiographic two-dimensional (**left**) and color flow Doppler (**right**) views showing mitral regurgitation associated with posterior leaflet tethering secondary to left ventricular dilation after a myocardial infarction. A coronary artery bypass grafting procedure was performed, and the valve was repaired with a ring annuloplasty.

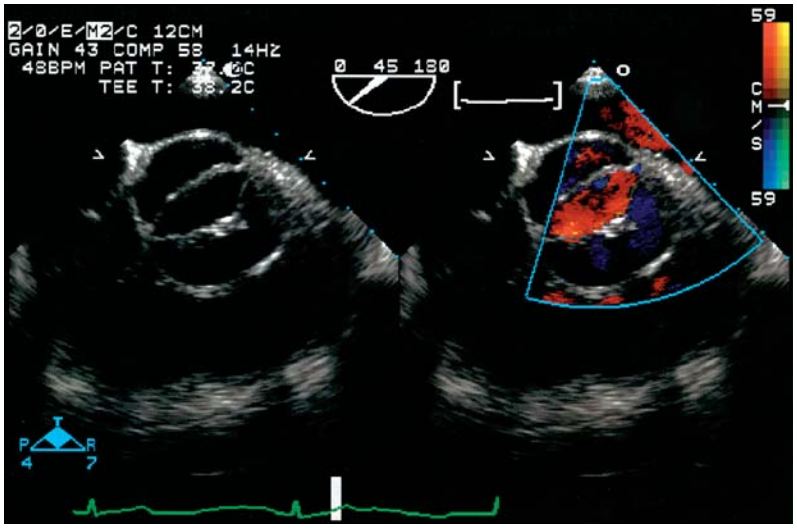

FIGURE 51–8. Transesophageal midesophageal aortic valve short-axis two-dimensional (**left**) and color flow Doppler (**right**) views showing a bicuspid aortic valve.

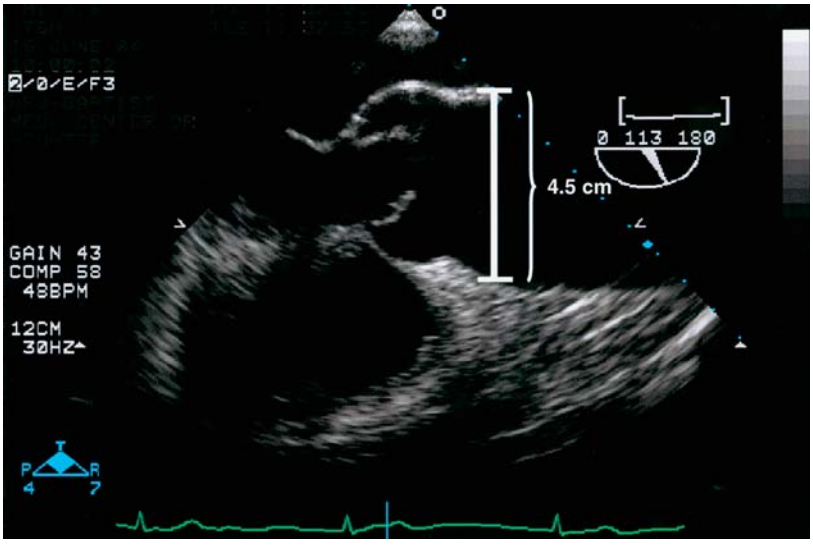

FIGURE 51–9. Transesophageal midesophageal ascending aortic long-axis view demonstrating a bicuspid aortic valve and a dilated aorta measuring 4.5 cm just beyond the sinotubular junction. Aortic dilation is commonly associated with a bicuspid aortic valve defect.

lesions of all heart valves. The etiology varies widely from congenital birth defects, senile calcific stenosis, infective endocarditis, rheumatic disease, trauma, and other causes. The unifying concept in all valve surgery, however, remains the principles of preserving myocardial function and the influence of preload, afterload, inotropy, rate, rhythm, and diastolic function on myocardial performance and mechanics (Table 51–4). In pathologic conditions that acutely affect valve function, such as endocarditis or chordal rupture, the compensatory reserve of the heart and vascular system are limited. Alternatively, in more chronic conditions including myxomatous MR or senile or calcific AS, compensatory reserve can be significant. Perioperative anesthetic management of these patients requires a comprehensive appreciation of myocardial performance, the acuity of the defect, the extent and mechanism of compensation, and the interplay of anesthetic drugs and surgery on the patient's condition.

Valve surgery will remain a mainstay in the practice of contemporary cardiothoracic anesthesiology. This section reviews the preoperative evaluation of patients presenting for heart valve surgery, perioperative management techniques, and special considerations relating to the anesthesiologist's management of these complex patients.

Preoperative Evaluation

In valvular heart disease, a number of questions that will directly influence anesthetic management must be answered. Many procedures are sched-

TABLE 51–4.

Valve Abnormalities and Hemodynamic Goals

	Preload	Afterload	Contractility	Heart Rate	Diastolic Function[a]
Aortic stenosis	↑	↑	↔	↓	Impaired relaxation

HOCM; Hypertrophic obstructive cardiomyopathy with systolic anterior motion of the mitral valve.
[a]Typical transmitral Doppler flow velocity profile pattern.
[b]Augmentation of preload usually is required to maintain forward stroke volume. However, excessive preload can induce further left ventricular dilation and exacerbate mitral regurgitation and left atrial hypertension.

uled only as "aortic valve replacement" or "mitral valve replacement," with little information pertaining to the etiology or mechanism of valve dysfunction, associated collateral cardiac dysfunction, or patient comorbidity. Understanding the specific valve pathology preoperatively is essential in preparing to achieve the hemodynamic goals for the induction, maintenance, and postoperative care of these patients.

Additional information unrelated to the valve pathology is important to obtain. For example, will other procedures or interventions be performed during this repair (e.g., carotid endarterectomy, CABG, septal myomectomy, maze procedure for atrial fibrillation procedure)? What is the clinical condition of the patient? Is the patient in a compensated or uncompensated state? In the patient with AS, the timing of surgery will have a great impact on outcome depending on the patient's condition. For example, a patient in the early to middle stages of AS will have a hyperdynamic, hypertrophied heart that likely will perform well after CPB. In contrast, a patient with chronic AS may have CHF, with reduced ejection fraction, and likely will require extensive inotropic support after CPB.

A number of essential imaging and laboratory studies should be reviewed preoperatively. Preoperative echocardiography will establish the type of lesion (stenosis versus regurgitant), extent of valve disease, and cardiac function. The valve area is of critical importance in assessing stenotic lesions. In patients with normal LV function, gradients associated with severely stenotic lesions may be very high (Figs. 51–10 and 51–11). Patients with poor ventricular performance may have anatomically critical lesions (AV area < 0.7 cm^2) and a relatively low gradient. These patients are especially prone to intraoperative instability with induction of general anesthesia and may require significant inotropic support post-CPB. Other important imaging modalities include coronary angiography to rule out concurrent CAD, a chest x-ray film, and perhaps thoracic CT or MRI to evaluate thoracic anatomy. A chest x-ray film is essential for "redo" operations involving the heart and mediastinum. The heart may be adherent to the posterior margin of the sternum, rendering sternotomy quite hazardous. All precautions, including

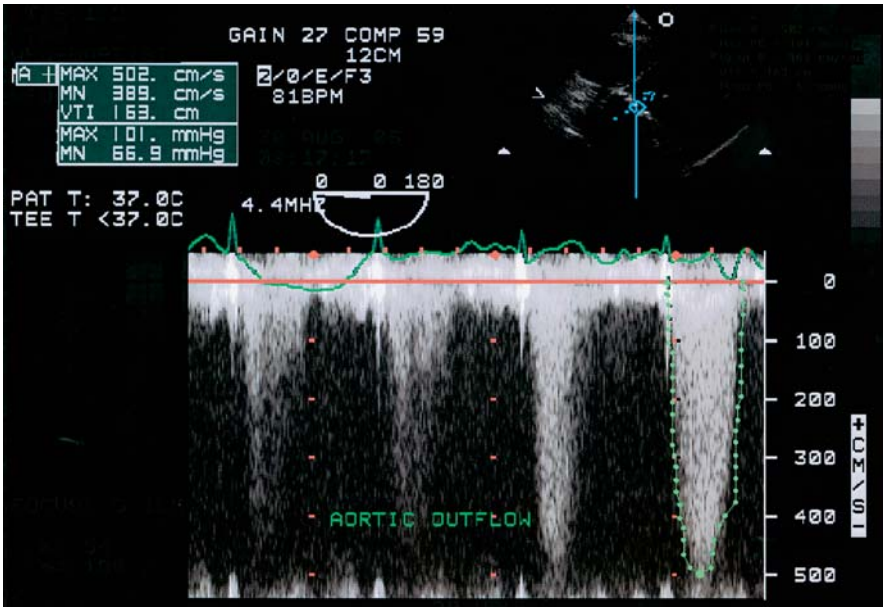

FIGURE 51–10. Intraoperative transesophageal deep transgastric long-axis view using continuous-wave Doppler obtained prior to cardiopulmonary bypass in a patient with aortic stenosis scheduled for an aortic valve replacement. Peak (101 mm Hg) and mean (66.9 mm Hg) transaortic valve (AV) pressure gradients (ΔP) are shown. ΔP is obtained from the peak velocity (V = 502 cm/s) using the simplified Bernoulli equation: $\Delta P = 4V^2$.

adequate venous access, immediate availability of blood products, and intraoperative vigilance by the entire operating room team, are required in these situations (Fig. 51–12).

Atrial natriuretic peptides are useful markers for evaluating CHF due to valvular pathology. In 130 patients with severe AS followed for 377 ± 150 days, the natriuretic peptides increased with increasing NYHA functional classes and decreasing LV ejection fraction.[94] Asymptomatic patients who later became symptomatic had higher levels of B-type natriuretic peptide (BNP) and N-terminal BNP (NtB-

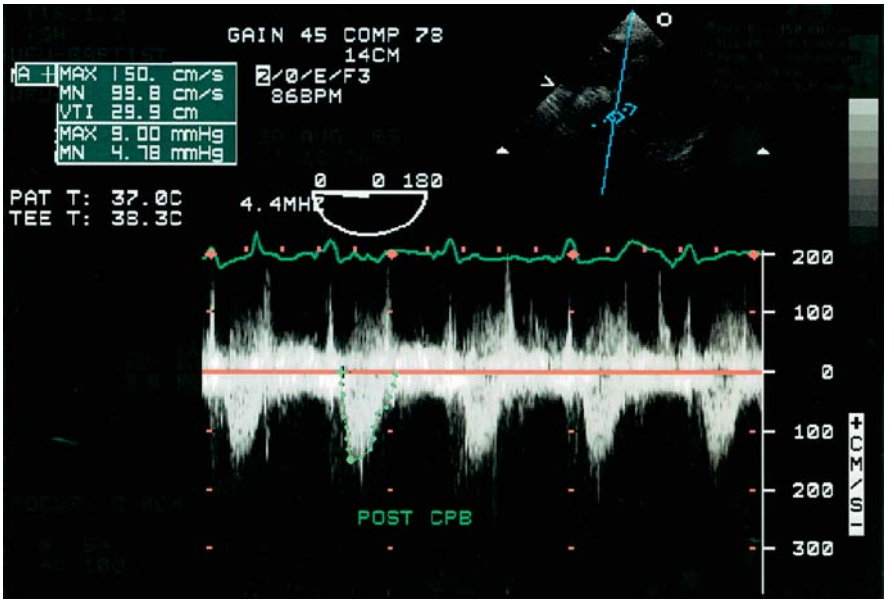

FIGURE 51–11. Intraoperative transesophageal deep transgastric long-axis view using continuous-wave Doppler obtained prior to cardiopulmonary bypass in the same patient shown in Fig. 51–10 after aortic valve replacement for aortic stenosis. Peak (9 mm Hg) and mean (4.78 mm Hg) transaortic valve (AV) pressure gradients are significantly reduced and consistent with a normal prosthetic valve area.

FIGURE 51–12. Preoperative MRI showing the close proximity of the aorta (Ao) to the sternum in a patient scheduled for a fourth reoperation for mitral regurgitation. Sternotomy in this patient poses extreme risk for aortic trauma and hemorrhage. Consequently the surgical approach was via a right thoracotomy to avoid this complication.

NP) at baseline. Following AV surgery, BNP levels decreased.

Monitoring

Consideration for monitoring during heart valve surgery varies little from monitoring required during CABG and other cardiac procedures. In addition to the standard monitors recommended by the ASA, an arterial line and a central venous line are essential. Many institutions routinely use PACs to monitor cardiac output, mixed venous oxygenation, PA pressures, and PAOP. Although this is standard practice by many clinicians, outcome data supporting PA catheterization are lacking.

Intraoperative TEE is an essential diagnostic tool and monitor of cardiac performance for patients undergoing heart valve procedures.[29,30,95,96] Extensive preoperative evaluation by TEE often reveals previously unknown structural or functional defects. In addition, TEE can provide instant assessment of the status of a valve repair or replacement, including the presence of perivalvular leaks or persistent valve dysfunction. TEE may assist in identifying the presence of left-sided intracardiac air and guide de-airing procedures. TEE is helpful in guiding post-CPB hemodynamic intervention and treatment. In recognition of this tool's utility in cardiac surgical procedures, the ASA, Society of Cardiovascular Anesthesiologists (SCA), American Society of Echocardiography (ASE), American College of Cardiology (ACC), and American Heart Association (AHA) all strongly recommend use of intraoperative TEE for heart valve surgical procedures.[97,98]

Assessment of diastolic dysfunction by TEE is important in all patients presenting for cardiac surgical procedures. Dourvas et al.[99] reported 40 consecutive cases of RV diastolic dysfunction in patients with significant AI, LV ejection fractioni >55%, LV end-diastolic pressure <15 mm Hg, RV systolic pressure <30 mm Hg, and normal coronary arteries. The pathophysiology of this defect may be related to rapid LV dilation in early diastole, a bulging septum, and interference with RV filling. On examination, these patients show a small RV and a large RA.[100] An awareness of diastolic dysfunction may guide intraoperative and postoperative hemodynamic therapy.[101,102]

Other special monitoring devices in heart valve surgery include processed electroencephalographic (EEG) monitoring either for patient awareness or to monitor activity during procedures in which stoppage of all electrical activity is desired (i.e., circulatory arrest). Cerebral oximetry and transcranial Doppler ultrasound also have also been advocated by some as potential efficacious monitors.[103]

Induction of Anesthesia

Extraordinary care and vigilance are required by the cardiac anesthesiologist during the induction of general anesthesia of patients with heart valve disease. The clinician should have a clear understanding of how preload, afterload, inotropy, heart rate and rhythm, and diastolic function interact during this critical time of induction.

Table 51–4 outlines several basic considerations regarding these parameters. On occasion, a patient will present with a constellation of disease processes. For example, the patient may have concurrent severe AS with moderate-to-severe AI and CAD. How should the information in Table 51–4 be applied to such a patient? There are two approaches. One approach identifies the lesion that poses the greatest proximate risk. For example, a patient with AS and tricuspid regurgitation (TR) most likely will be symptomatic from the effects of the AS rather than the low-pressure, high-volume TR lesion. When caring for this type of patient, it is sometimes best to apply the hemodynamic recommendations according to the AS algorithm. Another approach is to maintain the hemodynamic parameters for a patient's most compensated condition. For example, for a patient who presents with compensated AI, it may be most optimal to maintain preload, afterload, inotropy, rate, and rhythm unchanged from the patient's conscious condition.

No induction agents are specifically indicated in any of the heart valve conditions. More important than a specific agent is the adherence to identifying and maintaining clear hemodynamic goals. In certain disease states, an abrupt alteration of a particular hemodynamic parameter can lead to catastrophic results. For example, in patients with severe LV hypertrophy, AS, and CAD, a drop in arterial blood pressure may lead to significant myocardial ischemia and cardiovascular collapse. These patients with a relatively fixed outflow obstruction are unable to alter ejection; therefore, any drop in preload and afterload may reduce both stroke volume and coronary perfusion. Furthermore, the hypertrophied heart is especially subject to increased myocardial oxygen demands; therefore, the consequences of

ischemia will be magnified in severity and hastened in onset.

Maintenance of Anesthesia

No agents or techniques are indicated for maintenance of anesthesia in any specific valve disease condition. Again, adherence to the hemodynamic goals outlined in Table 51–4 will provide appropriate guidance when maintaining anesthetic depth. The sound principles of anesthesia apply, including loss of consciousness, muscle relaxation, and hemodynamic stability (i.e., blunting of the autonomic nervous system).

Patient awareness during cardiac surgical procedures requires special attention. Awareness, especially auditory recollection, may occur in up to 6% of patients requiring CPB.[104] Sebel et al.[105] reported a 0.13% incidence of operative awareness in a broad population of 19,575 surgical patients. Multivariate logistic regression identified increasing ASA status and type of procedure as risk factors for recall. For cardiac surgical procedures, the odds ratio for recall was 3.58 with a 95% confidence interval of 0.72–17.9. As with any procedure, attention to hemodynamic signs, depth of anesthesia, use of benzodiazepines, and inhalational agents likely will reduce the risk of operative recall.

Good data support the concept of "fast-track" or early extubation protocols in the care of patients presenting for CABG.[106] Benefits include reduced hospital stay, ICU stay, and reduced cost of care. Data on early extubation protocols in valve surgery are less common, although one might expect similar benefit as observed in CABG surgery.[107] One should be aware, however, that many valvular procedures are complex in nature, requiring extended CPB time, potential DHCA, and increased requirements for blood and blood product transfusion. All of these factors may limit the opportunity for early extubation protocols.

Reports of regional anesthesia for heart valve surgery are limited. Canto et al.[108] reported a series of 305 patients undergoing heart valve surgery managed with general anesthesia and thoracic epidural anesthesia. Sixty-five percent of these patients were extubated in the operating room. An epidural catheter was placed at T1–3 on the day of surgery, a rigid anticoagulation protocol was followed both before and after surgery, and no neurologic complications from epidural hematomas occurred. Hemmerling et al.[109] found similar benefit with rapid extubation, lower postoperative pain scores, and no epidural hematomas with high thoracic epidural anesthesia after AV surgery in 45 patients. There are case reports of AV replacement in conscious patients under regional anesthesia without intubation.[110,111] Nonetheless, it is unlikely that regional anesthesia techniques will replace more traditional general anesthetics for heart valve surgery.

Weaning from Bypass and the Postbypass Period

Once a dysfunctional valve has been adequately repaired or replaced, the hemodynamic goals of the patient may be fundamentally different from the pre-CPB period. A more normal hemodynamic profile usually is immediately observed while in the operating room. The anticipation is that the heart will now perform normally, but this frequently is not the case. The heart suffers an acute insult from the surgical intervention, aortic cross-clamping, and the myocardial depressant effects of the various anesthetic agents. As with any cardiac surgical procedure, evidence of new regional wall-motion abnormalities, global cardiac dysfunction, and peripheral vascular dysfunction may be seen. Thus, in patients with valvular heart disease, the heart will require some time to remodel before significant improvement is observed.

In some patients, hemodynamics may be greatly improved after CPB. In simple, compensated AS, the patient may be hyperdynamic and hypertensive after weaning from bypass. However, it also may be possible that, because of LV hypertrophy, cardioplegia was incomplete for total myocardial protection, and the patient emerged from CPB with transient myocardial dysfunction. In complex repairs or multiple valve surgery, an extended CPB period may be required, thereby increasing the risk of immediate postoperative cardiac dysfunction and the requirement for inotropic or even IABP support. Ejection fraction and LV function may decline after surgery for MR, commonly thought to be caused by the new loading conditions of the heart after removal of the "pop-off" MR flow. This likely is not true, as emerging data on MV repair procedures with sparing of the valve apparatus show little alteration in ejection fraction.[112] This preservation of mitral annular integrity stabilizes LV shape and contractility, thereby preserving function. The diminished performance likely is secondary to other factors, including extended cross-clamp time, inadequate myocardial protection, and myocardial stunning. Combined CABG and valvular heart surgery is associated with inotrope use during separation from CPB.[113] In a retrospective study of 1009 consecutive patients undergoing either CABG or CABG with valve surgery and CPB, multivariate risk analysis revealed extended cross-clamp time, worsening wall-motion score index, reoperation, combined procedures, severe MR, and low ejection fraction as predictors of inotrope use during separation from CPB.

TEE is especially useful in the immediate post-CPB period.[29,30] TEE facilitates the assessment of myocardial function and filling parameters, providing important information that will affect decisions about inotropes and volume management. TEE also can assess the condition of the valve repair or replacement. On every case in which TEE is used and images can be obtained, complete evaluation of the valve is required, including assessment of its structure and function, degree of residual regurgitation or stenosis, and any collateral injury. Following a valve repair or replacement, documentation of any perivalvular or central regurgitation and a gradient across the valve should be obtained. In addition, after MV repair, assessment for systolic anterior motion should be obtained. Finally, it is important that the anesthesiologist have a comprehensive understanding of the echocardiographic "signatures" of the most commonly used prosthetic valves, including their expected normal washing jets, closing jets, and transvalvular gradients.

The post-CPB period may be a time of hemodynamic instability. The heart is adjusting to new preload, afterload, and inotropic conditions, often in the presence of ongoing bleeding. Constant vigilance regarding hemodynamics, blood volume, blood gas chemistry, and metabolic state (i.e., ionized calcium, glucose concentrations, and urine output) are required. In addition, there may be new rhythm disturbances. Patients with preoperative atrial fibrillation now may be converted to sinus rhythm after MV repair

and a surgical maze procedure. Other patients may suffer from third-degree heart block, bradycardia, tachycardia, or other rate and rhythm abnormalities, making management difficult.

Special Considerations and Long-Term Prognosis

Cardiac anesthesia for heart valve surgery is associated with a number of special considerations not found in other aspects of cardiothoracic anesthesiology. Among these considerations is familiarity with the type of repair technique or prosthetic valve used. There are a number of valve types, including mechanical and bioprosthetic valves. The choice of valve is up to the surgeon; however, the anesthesiologist may be asked to provide a comprehensive TEE assessment that may guide the surgeon in valve selection. For example, measurement of AV annulus size is important when determining the size of a prosthetic valve. In the assessment of a patient for a possible Ross procedure, pulmonary annulus size and degree of pulmonary insufficiency are important factors before committing to the procedure. After valve replacement, the anesthesiologist should have a comprehensive understanding of the echocardiographic "signatures" of the most commonly used prosthetic valves, including their expected normal washing jets, closing jets and transvalvular gradients. Bioprosthetic and mechanical valves all come with a complete hemodynamic profile in their package insert, and this information should be consulted when rendering a decision on the function of a new valve. Sometimes the expected gradients are higher, and the calculated valve area may be less than expected. The impact of valve prosthesis–patient mismatch (VP-PM) on mortality is as high as 25% in patients with a severe VP-PM mismatch.[114] In a followup study of 1563 patients undergoing AV replacement, the adjusted hazard ratio (95% confidence interval) at 5 years for heart failure with a VP-PM mismatch was 1.64 (1.01–2.56; P = .047) and for heart failure deaths was 2.09 (1.03–4.27; *P* = .043).[115] Referring to the package insert will help guide the clinician in deciding whether intraoperative gradients and calculated valve areas are acceptable.

Valve repair for patients with endocarditis presents all of the hemodynamic considerations in addition to the frequently septic condition of the patient (Fig. 51–13). Patients with endocarditis usually have acute regurgitant lesions and present in CHF. The in-hospital mortality for acute endocarditis is 20%, and 82% of patients have endocarditis of a native heart valve.[116] The early predictors of in-hospital mortality include embolic events, diabetes mellitus, *Staphylococcus aureus* bacteremia, and Acute Physiology and Chronic Health Evaluation (APACHE) II score. Use of intraoperative TEE is especially helpful in the diagnosis of endocarditis and quantification of the valve defect. Valve surgery reduces 6-month mortality. In a study by Iung et al.,[117] 513 patients with complicated left-sided infective endocarditis were treated with antibiotics, 45% underwent valve surgery, and 55% received medical therapy alone. The 6-month mortality was 16% in the surgery group compared to 33% in the medical group ($P < .01$). Patients with the most severe CHF demonstrated the greatest reduction in mortality with surgery (14% vs. 51%, $P = .001$).

Significant data support valve repair and replacement in patients with heart valve disease over medical management.[118,119] After surgery for AS, there is initial remodeling of the heart with subsequent LV mass reduction.[120] Between 1986 and 2001, 1410 patients underwent surgery for severe AI, of whom 160 (11%) had valve repair.[121] One operative death (0.6%) occurred, and two patients required early re-repair. Seven years after repair, the survival rate was 89%, and the reoperation rate on the AV was 15%. Patients with MR receive symptomatic relief and improvement in LV ejection fraction following valve surgery.[122] Although early mortality is associated with heart valve surgery, the long-term benefit remains superior to medical management even among asymptomatic patients.[123] As the population extends longevity, more patients will present for valve procedures. Although advancing age is associated with poor outcome, there is no upper limit of age at which time valve surgery is contraindicated. In summary, these and other data show that surgery offers an opportunity for improved mortality, symptomatic relief, and hemodynamic improvement in nearly all patients with valve dysfunction.

The impact of percutaneous valves and other unconventional surgical valve repair procedures on the volume of heart valve surgery is unknown.[124] However, patients undergoing percutaneous valve procedures likely will require anesthesiologists to provide sedation and/or general anesthesia. In addition, comprehensive TEE imaging inevitably will be essential for the appropriate positioning of these devices and perioperative hemodynamic monitoring of these patients.

ANESTHETIC CONSIDERATIONS FOR AORTIC SURGERY

Thoracic aortic diseases are generally surgical problems (Table 51–5).[125] The most common operations performed on the thoracic aorta are repair of aortic dissection, aortic aneurysm, traumatic aortic injury, and aortic coarctation. Operative repair involving the aortic root, ascending aorta, or transverse aortic arch typically is approached through a median sternotomy. Operative repairs involving the distal aortic arch or descending thoracic and thoracoabdominal aorta typically are approached through a left thoracotomy or thoracoabdominal incision. endovascular stent graft techniques for repair of descending thoracic aortic aneurysm (TAA) and dissection have been developed that are accomplished by access through the femoral or iliac arteries.[126]

The anesthetic management of patients undergoing thoracic aortic operations has contributed to the overall success of these operations and requires specialized knowledge of several unique techniques that are practiced routinely in few other areas of medicine. Clinical application of TEE and ultrasound imaging performed by the anesthesiologist provides a means to emergently diagnose acute aortic syndromes, identify associated life-threatening complications, and detect cerebral malperfusion, permitting early surgical intervention and treatment.[127] The process of repairing or replacing a portion of the thoracic aorta typically requires the temporary or permanent interruption of blood flow through the aorta or its major branch vessels, creating the potential for ischemia or infarction of almost any major organ system. Techniques to protect organs during temporary interruption of blood flow in the thoracic aorta include DHCA, selective antegrade cerebral perfusion, retrograde cerebral perfusion, and partial left heart bypass for distal aortic perfusion. Intraoperative neurophysiologic monitoring and lumbar cerebrospinal fluid (CSF) drainage are recognized techniques commonly used for repairs involving the descending thoracic or thoracoabdominal aorta to decrease the risk of spinal cord ischemia and infarction.

Thoracic Aortic Aneurysm

Aortic aneurysm is a dilation of the aorta containing all three layers of the vessel wall that has a diameter of at least 1.5 times that of the normal diameter of the corresponding aortic segment. TAAs are common. They are detected in 10% of autopsies, have an incidence of 5.9 per 100,000 person-years, and are the most common reason for thoracic aortic operation.[128] TAAs can be characterized by etiology, location, diameter, and extent of aortic involvement. Aortic pseudoaneurysms are caused by a contained rupture of the aorta or arise from intimal disruptions, penetrating atherosclerotic ulcers, or partial dehiscence of the suture line at the site of a previous aortic vascular graft. Aortic aneurysms can be associated with dissection of the vessel wall.

Surgical repair of TAAs is performed for acute rupture, AI, or refractory pain, or to prevent eventual rupture. Rupture of the aortic root or proximal ascending aorta will cause cardiac tamponade because the first several centimeters of the ascending aorta lies within the pericardial sac. Dilation of the proximal ascending aorta may cause AI by distortion of the aortic root and outward tethering of the AV cusps.[128,129] Because the risk of aortic rupture is associated with aneurysm size, aortic diameter is commonly used as a clinical indication for elective repair (Table 51–6). For the ascending aorta, aneurysm diameter ≥ 4.5 cm in patients with Marfan syndrome, collagen vascular disease, bicuspid AV, or a family history of aneurysm, ≥ 5.0 cm in patients requiring AV replacement, or ≥ 5.5 cm in any patient is generally considered an indication for operative repair.[130–132] Because the operative risks associated with open repair of the descending thoracic aorta is greater, repair usually is not performed until an aneurysm size 6.5 cm is reached.[131,132] Very large aneurysms of the ascending aorta, aortic arch, or descending thoracic aorta may produce a mediastinal mass effect, causing extrinsic compression of the trachea, left

mainstem bronchus, right PA, RV outflow tract, or esophagus (Fig. 51–14). In contrast to patients with collagen vascular or familial aortic aneurysms, patients with atherosclerotic aneurysms generally are elderly and have more comorbid conditions and peripheral vascular disease.

Ascending Aorta and Aortic Arch Aneurysm

Aortic aneurysms limited to the aortic root and proximal ascending aorta can be repaired using standard CPB with cannulation of the aneurysm, ascending aorta, or femoral artery and cross-clamping of the distal ascending aorta. Based on assessment of the AV, the AV may be replaced, resuspended, or reimplanted within the prosthetic vascular graft. Replacement of the aortic root requires reimplantation of the right and left coronary arteries. Intraoperative TEE is useful for evaluating the native AV prior to repair and for determining if the presence of residual AI after valve-sparing operations.

Operative repair of aortic aneurysms that extend into or involve the aortic arch require temporary interruption of cerebral perfusion. The primary technique used to protect the brain from ischemic injury in the absence of cerebral blood flow is DHCA. In the conduct of DHCA, achieving a satisfactory level of hypothermia is considered the most important intervention for brain protection, but the optimal temperature for DHCA, best site for temperature measurement, and safe duration of DHCA have not been established. EEG during the conduct of DHCA has demonstrated that the average nasopharyngeal temperature required to produce electrocortical silence was approximately 18°C, but a nasopharyngeal temperature of 12.1°C or cooling on CPB for at least 50 minutes was necessary to achieve electrocortical silence in 95% of patients (Fig. 51–15).[133] Clinical studies indicate that the cerebral metabolic rate decreases by a factor of approximately 2.6 for each 10°C decrease in temperature (Q_{10} ratio for adults).[134] Assuming the brain can tolerate an ischemic period of approximately 3–5 minutes at 37°C, the reduction in cerebral metabolism at a temperature of 17°C would predict that the brain should tolerate approximately 20–34 minutes of ischemia. Clinical studies support this prediction and have detected the onset of neuronal ischemia at approximately 18 minutes after DHCA (Fig. 51–16).[135] Other studies have indicated that postoperative neurocognitive dysfunction was more frequent when DHCA duration exceeded 25 minutes.[136]

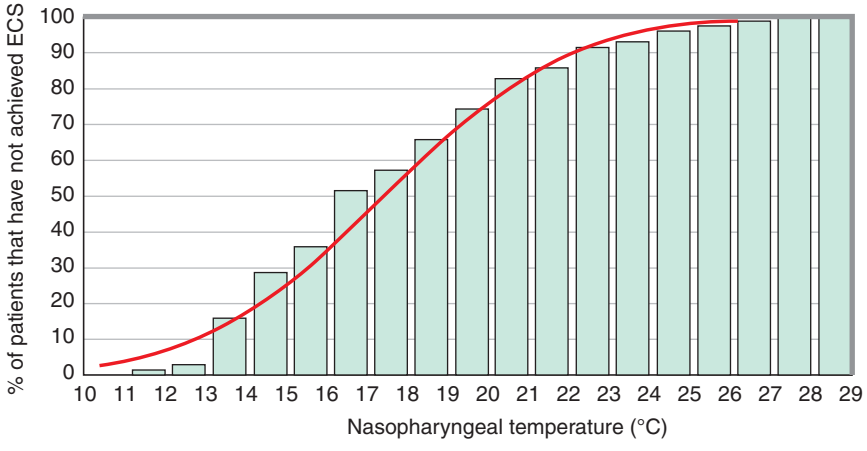

FIGURE 51–15. Relationship between electroencephalographic (EEG) activity and nasopharyngeal temperature prior to deep hypothermic circulatory arrest in 109 patients undergoing thoracic aortic operations requiring circulatory arrest. Electrocortical silence (ECS) was achieved by EEG in all patients after 50 minutes of cooling or at a nasopharyngeal temperature of 12.5°C. At a nasopharyngeal temperature of 18°C, only 50% of patients had electrocortical silence by EEG. This article was published in and adapted from Stecker MM, Cheung AT, Pochettino A, et al. Deep hypothermic circulatory arrest: I. Effects of cooling on electroencephalogram and evoked potentials. Ann Thorac Surg 2001;71:14–21. Copyright Elsevier 2001.

Strategies for improving the safety of DHCA to facilitate operations requiring temporary interruption of blood flow in the aortic arch include techniques to provide retrograde cerebral perfusion or selective antegrade cerebral perfusion. Retrograde cerebral perfusion (RCP) can be provided immediately after initiation of DHCA by infusing cold oxygenated blood into the superior vena cava at flow rates averaging 150–250 mL/min.[137] During RCP, the pressure within the superior vena cava is generally maintained ≤ 25 mm Hg to decrease the risk of cerebral edema, the aortic arch is opened to atmospheric pressure to prevent pressurization of the arterial system, and the patient is positioned in 8–10° Trendelenburg to prevent air entry into the aortic arch branch vessels. Experimental and clinical studies have demonstrated that RCP via the superior vena cava provides perfusion to the brain, but existing evidence indicated that the flow achieved with RCP was insufficient to prevent cerebral ischemia.[137] Nevertheless, advocates of RCP argue that even some substrate delivery increases the margin of safety of DHCA, that cerebral hypothermia is maintained with RCP, and that RCP decreas-

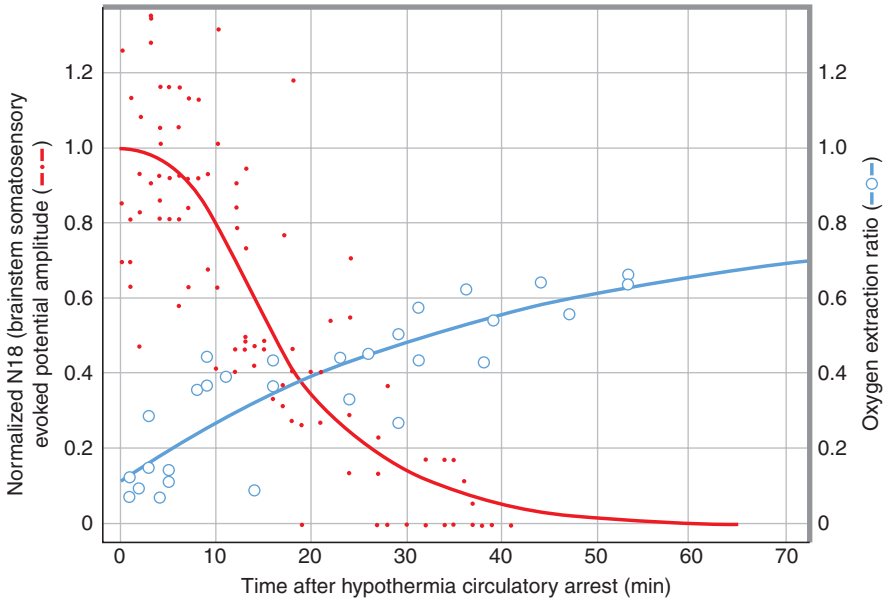

FIGURE 51–16. Changes in brainstem (N18) somatosensory evoked potential amplitudes after initiation of deep hypothermic circulatory arrest with retrograde cerebral perfusion superimposed on the change in brain oxygen extraction ratio (OER) in patients during retrograde cerebral perfusion (O; n = 19). The N18 somatosensory evoked potential decayed to half its original amplitude at 16 minutes after interruption of antegrade cerebral perfusion. OER decreased to half its maximal value of 0.66, also at 16 minutes after interruption of antegrade cerebral perfusion. (Adapted from Cheunget al.[135] with permission.)

es the risk of cerebral embolization by flushing out particulate matter in the cerebral arteries prior to resumption of antegrade cerebral perfusion.

Selective antegrade cerebral perfusion can be accomplished by arterial cannulation and perfusion of the axillary artery, innominate artery, subclavian artery, or even the internal carotid arteries.[138] Antegrade perfusion into a single arch branch vessel provides flow to the contralateral cerebral hemisphere through a functional circle of Willis. Selective antegrade cerebral perfusion is generally performed in combination with deep hypothermia for operations where the duration of DHCA is anticipated to exceed 30 minutes. Flow rates for antegrade cerebral perfusion typically range from 400–1000 mL/min at radial artery pressures of 50–80 mm Hg. Clinical studies supporting the efficacy of antegrade cerebral perfusion demonstrated acceptable morbidity despite antegrade cerebral perfusion duration times as long as 75–235 minutes.[138]

Attempts to further improve the safety of DHCA by manipulating pH, blood viscosity, or hemoglobin concentration or by administration of pharmacologic agents often are practiced, but no clinical evidence has supported the efficacy of these other interventions. Barbiturates or other central nervous system depressants are sometimes administered in an effort to decrease cerebral oxygen demands. Glucocorticoids, magnesium sulfate, lidocaine, and mannitol are sometimes administered in an effort to protect against cerebral and end-organ injury. In general, the existing evidence suggests that pharmacologic neuroprotection is unproven and should not be considered a substitute for hypothermia to protect against cerebral ischemia in the setting of hypoperfusion.

Descending Thoracic and Thoracoabdominal Aortic Aneurysm

Classification of TAAs and thoracoabdominal aortic aneurysms (TAAAs) according to anatomic extent provides a useful guide to surgical approaches, anesthetic management, and estimate of perioperative mortality and postoperative paraplegia associated with operative repair (Table 51–7).[139] In the Crawford classification, extent I TAAA involves the entire descending thoracic aorta from the origin of the left subclavian artery to the level of the diaphragm, extent II TAAA involves the entire descending thoracic aorta with extension across the diaphragm through the abdominal aorta to the aortic bifurcation, extent III TAAA involves the distal half of the descending thoracic aorta and most of the abdominal aorta, and extent IV TAAAs are confined to the upper abdominal aorta (Fig. 51–17). Isolated TAAs are those confined to the descending thoracic aorta between the origin of the left subclavian artery and the diaphragm. TAAAs can be further distinguished into those with dissection and those without dissection. Operative repair of TAAA with an interposition tube graft is approached through a left thoracoabdominal incision and requires single-lung ventilation. Repairs originally were accomplished by cross-clamping the thoracic aorta proximal to the aneurysm. Modifications of this technique included passive arterial shunting (Gott shunt) or partial left heart bypass using extracorporeal circulation to provide distal aortic perfusion while the proximal descending thoracic aorta was cross-clamped.[140] CPB with DHCA may be necessary for aneurysms that extend into the distal aortic arch.[141] Endovascular stent graft repair has become an option for repair of isolated TAAs.[126] One of the major complications of operative repair is spinal cord ischemia or infarction resulting in postoperative paraplegia.

TABLE 51–7.

Mortality and Paraplegia after Thoracoabdominal Aortic Aneurysm Repair in 1,220 Consecutive Patients

TAAA Extent	Number of Patients	30-Day Mortality	Hospital Mortality	Paraplegia/ Paraparesis
I	400 (35.1%)	20 (5.0%)	30 (7.5%)	16 (4.1%)
II	343 (30.1%)	18 (5.2%)	29 (8.5%)	28 (8.2%)
III	184 (16.1%)	9 (4.9%)	9 (4.9%)	7 (3.8%)

Strategies to Decrease the Risk of Paraplegia from Spinal Chord Ischemia after Thoracic or Thoracoabdominal Aortic Procedures

- Distal Aortic Perfusion
  - Passive shunt (Gott)
  - Partial left heart bypass
  - Partial cardiopulmonary bypass
  - Minimize aortic cross clamp time
- Deliberate Hypothermia
  - Mild-to-moderate systemic hypothermia (32°–35°C)
  - Deep hypothermic circulatory arrest (14°–18°C)
  - Selective spinal cord hypothermia (epidural cooling, 25°C)
- Increase Spinal Cord Perfusion Pressure
  - Re–implantation of critical intercostal and segmental arterial branches
  - Lumbar cerebrospinal fluid (CSF) drainage (CSF pressure ≤10 mm Hg)
  - Arterial pressure augmentation (mean arterial pressure ≥85 mm Hg)
  - Avoid hypotension
- Intraoperative Monitoring of Lower Extremity Neurophysiologic Function
  - Somatosensory evoked potentials
  - Motor evoked potentials
- Postoperative Neurologic Assessment for Early Detection of Delayed-Onset Paraplegia
  - Serial neurologic examination
- Pharmacologic Neuroprotection
  - Glucocorticoid
  - Barbiturate or central nervous system depressants
  - Magnesium sulfate
  - Mannitol
  - Naloxone
  - Lidocaine
  - Intrathecal papaverine

The risk of spinal cord ischemia is a consequence of interruption of distal aortic perfusion or the sacrifice of intercostal, lumbar, and sacral artery branches that provide collateral flow supplying the spinal cord. Strategies to prevent, detect, and treat spinal cord ischemia are important aspects in the anesthetic management of patients undergoing TAA and TAAA repair. Spinal cord protection strategies include deliberate hypothermia, surgical techniques to minimize ischemia time, arterial pressure augmentation, avoiding hypotension, lumbar CSF drainage, and perioperative neurophysiologic monitoring of spinal cord function. Deliberate hypothermia is an established technique to protect against neuronal ischemia and can be accomplished by passive cooling to 3°C, active cooling using extracorporeal circulation, or selective cooling by infusion of cold saline into the epidural space (Table 51–8).[142,143] Passive arterial shunting using an ascending aorta to distal aortic shunt or partial left heart bypass using extracorporeal circulation to direct blood from the LA to the femoral artery can be used to provide distal aortic perfusion during construction of the proximal aortic anastomosis and decreases the duration of lower body ischemia. While the descending aorta is cross-clamped, spinal cord perfusion via the vertebral arteries can be augmented by maintaining the proximal aortic pressure ≥ 90 mm Hg. Intraoperative neurophysiologic monitoring of somatosensory evoked or motor evoked potentials from the posterior tibial nerves has been advocated for detection of spinal cord ischemia during operation in the anesthetized patient to permit early intervention or to prompt the reattachment of intercostal artery branches.[144] Pharmacologic agents such as glucocorticoids or even naloxone have been administered for spinal cord protection, but their efficacy remains unproven. Patients with delayed-onset paraplegia or paraparesis after TAA, TAAA, or endovascular stent graft repair often respond to strategies to improve spinal cord perfusion by increasing the arterial pressure and drainage of CSF.[142,143] One rationale for the routine use of lumbar CSF drainage is that the lumbar CSF pressure may increase during repair as a consequence of aortic cross-clamping or spinal cord edema during reperfusion. Hypotension associated with spinal cord ischemia may be a consequence of general anesthesia, regional anesthesia, blood loss, vasodilatation, or even neurogenic shock from spinal cord ischemia and requires prompt treatment. The effectiveness of lumbar CSF drainage for treatment of spinal cord ischemia may be improved when combined with arterial pressure augmentation. Interventions to increase spinal cord perfusion pressure appear to be most effective when applied immediately upon detection of spinal cord ischemia. Although the routine use of lumbar CSF drainage remains controversial, its effectiveness has been demonstrated in randomized controlled trials and case series.[145] Complications of lumbar CSF drainage are uncommon and include intracranial hypotension, subdural hematoma, catheter fracture, meningitis, and hemorrhagic complications.[146,147] Precise monitoring of CSF pressure, controlled drainage of CSF to maintain a lumbar CSF pressure of at least 10 mm Hg, and supervised insertion and removal of catheters may decrease the risk of complications. Considering the

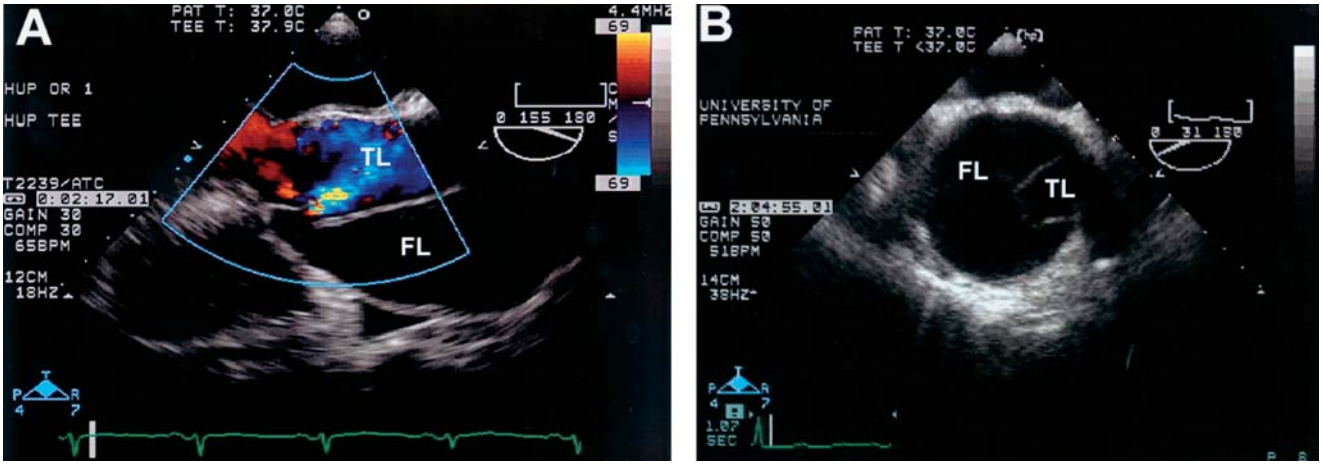

FIGURE 51–18. Transesophageal midesophageal long-axis view of the aortic valve (**A**) and short-axis views of the ascending aorta (**B**) in a patient with a type A aortic dissection. An intimal flap separating the true lumen (TL) of the aorta from the false lumen (FL) was shown in the aortic root and ascending aorta. Extension of the dissection into the aortic root may cause aortic regurgitation or coronary insufficiency.

morbidity associated with paraplegia, the application of lumbar CSF drainage, arterial pressure augmentation, and neurophysiologic monitoring can be justified in patients at risk for postoperative spinal cord ischemia.

Aortic Dissection

Aortic dissection evolves from a tear in the intima that allows blood to enter the medial layer of the vessel, causing the intima to separate or dissect circumferentially and longitudinally within the aorta. Aortic dissection is diagnosed by emonstrating a true and a false lumen separated by an intimal flap within the vessel (Fig. 51–18).[148,149] Aortic intramural hematoma is a variant of aortic dissection characterized by hemorrhage into the medial layer producing circumferential thickening of the vessel wall.[150] Aortic dissection affects a wide demographic population and age range. The most common associated diseases are hypertension, atherosclerosis, and cystic medial degeneration. Other associated conditions include collagen vascular disease, familial aortic dissection, bicuspid AV, aortic coarctation, pregnancy, cocaine abuse, arteritis, and aortic trauma. Early complications of aortic dissection include dissection into aortic branch vessels causing malperfusion, resulting in myocardial, cerebral, mesenteric, or limb ischemia (Table 51–9). Dissection into the aortic root may cause acute aortic regurgitation. Rupture of the proximal ascending aorta causes cardiac tamponade. Dilation and expansion in the diameter of the aorta over time as a consequence of a weakened vessel wall is a long-term complication of aortic dissection. Aortic dissection is classified according to location. Dissections involving the ascending aorta and aortic arch are classified as Stanford type A or DeBakey type I or II. Dissections confined to the descending aorta are classified as Stanford type B or DeBakey type III (Fig. 51–19). Aortic dissections involving the ascending aorta (Stanford type A or De-

TABLE 51–9.

Complications of Acute Stanford Type A Aortic Dissection (N = 513)

Complications	Percent
All neurologic defects	18.0%
Coma/altered consciousness	14.0%
Myocardial ischemia/infarction	10.0%
Limb ischemia	10.0%
Mesenteric ischemia/infarction	4.0%
Acute renal failure	6.2%
Hypotension	26.0%
Cardiac tamponade	17.0%
Mortality	30.0%

This article was published in and adapted from Bossone E, et al. Usefulness of pulse deficit to predict in-hospital complications and mortality in patients with acute type A aortic dissection. Am J Cardiol 2002;89:851–855. Copyright Elsevier 2002.

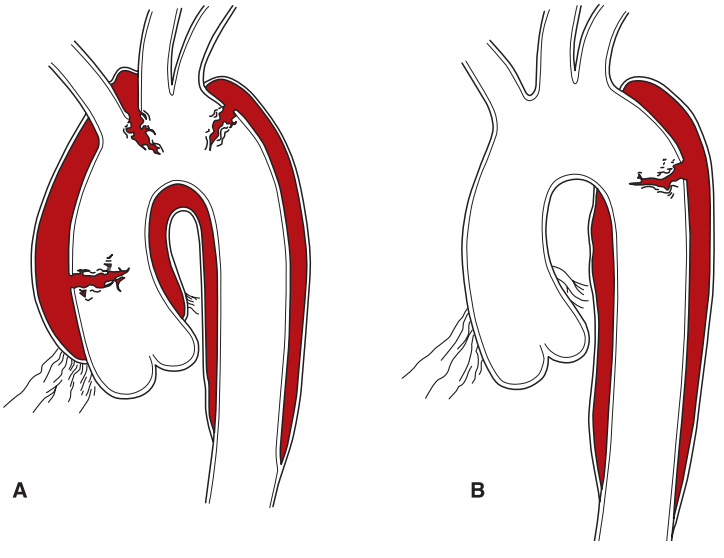

FIGURE 51–19. Stanford classification of aortic dissection. In type A aortic dissection, the ascending aorta is dissected regardless of the location or number of intimal tears (**A**). In type B aortic dissection, the dissection is limited to the descending aorta (**B**) distal to the origin of the left subclavian artery. Bakey type I or II) are considered surgical emergencies. According to an international registry for acute aortic dissection, mortality rates for patients with Stanford type A aortic dissection managed without surgery was approximately 1–2% per hour following the initial symptom onset for the first 48 hours, 60% by day 6, 74% by 2 weeks, and 91% by 6 months.[151] When managed with surgery, the mortality rate for type A aortic dissection was 26% (Fig. 51–20).[151] Aortic dissections confined to the descending thoracic aorta (Stanford type B) are considered surgical emergencies only if there is evidence of a life-threatening complication such as malperfusion or aortic rupture. Mortality in patients with acute type B aortic dissection managed surgically was 31.4% at 30 days compared to a mortality rate of 10.7% at 30 days in medically managed patients (Fig. 51–20).[151] Acute management of patients with suspected aortic dissections requires establishing the diagnosis, distinguishing Stanford type A from Stanford type B aortic dissection, and detecting malperfusion or rupture. In an international registry of aortic dissection, the initial diagnosis was established by computed tomography in 61% of patients.[149] Echocardiography was used as the initial diagnostic technique in 33% of cases but was used as a secondary diagnostic technique in 56% of cases.[149] TEE is useful for intraoperative diagnosis and classification of dissection in unstable patients. Intraoperative TEE also is useful for detecting AI, cardiac tamponade, and myocardial ischemia. Surgery for type A aortic dissection involves replacement of the ascending aorta or aortic arch together with AV repair or replacement. Patients with type B aortic dissection are preferentially managed medically unless they have evidence of aortic rupture or malperfusion. Endovascular stent graft repair has become an alternative to open repair in patients with type B aortic dissection complicated by malperfusion or rupture. The anesthetic management of operations for the repair of type A aortic dissection is similar to the management of patients undergoing repair of ascending aortic and arch aneurysms and typically requires temporary interruption of cerebral perfusion and DHCA. A rare but lethal complication of CPB in patients with aortic dissection is acute cerebral malperfusion caused by inadvertent cannulation of the false lumen of the aorta or compression of the true lumen by expansion of the false lumen.[152] This complication can be detected by intraoperative TEE evaluation of blood flow in the aorta and ultrasound confirmation of carotid artery flow during initiation of CPB. Treatment consists of immediate discontinuation of CPB, cannulation of the contralateral femoral artery for CPB, or open fenestration of the intimal flap within the aorta. The anesthetic management of operations for type B aortic dissections require the same strategies and techniques used for patients undergoing TAA and TAAA repair.

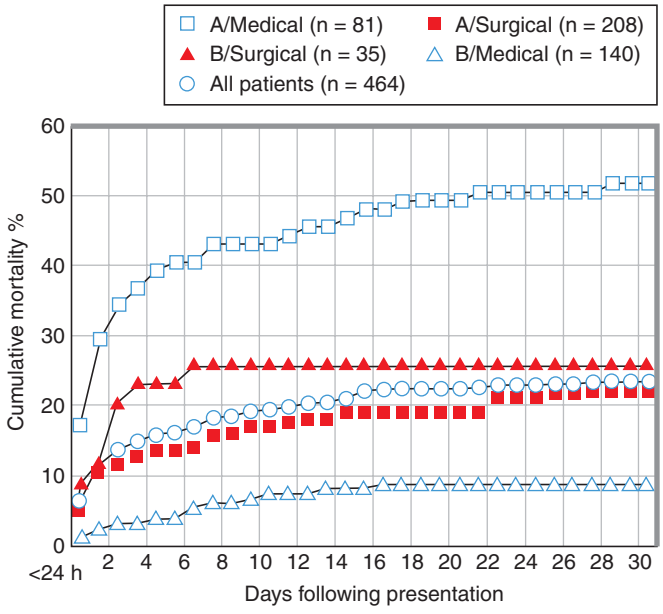

FIGURE 51–20. Thirty-day mortality in 464 patients from the International Registry of Aortic Dissection (IRAD) stratified by medical and surgical treatment in both type A and type B aortic dissection. (From Nienaber and Eagle[148] with permission.)

ANESTHETIC MANAGEMENT FOR VADS

The first left ventricular assist device (LVAD) was implanted by DeBakey in 1966 as a "bridge to recovery" in a patient suffering from postcardiotomy cardiogenic shock (PCCS).[153] The decompressed and rested native LV recovered after 6 days of support, and the device was explanted. Barnard performed the first orthotopic cardiac transplantation 1 year later. During the 1970s, the development of heart transplantation as a viable therapy for end-stage CHF was hindered by the use of nonspecific immunosuppressive agents that resulted in patient deaths from opportunistic infections. By the early 1980s, with the introduction of cyclosporine, a specific T-cell inhibitor, heart transplantation became a viable therapy for end-stage CHF, with risk-adjusted survival rates of 50% at 10 years.[154] VADs subsequently took on a new role as a "bridge to transplant."[155] End-stage CHF patients on transplant waiting lists who are supported by a VAD prior to transplantation could wait longer, recover secondary organ function, be discharged to home, and enjoy improved survival after transplantation.

More than 500,000 Americans are diagnosed each year with CHF, but only 2000 donor hearts become available each year worldwide for transplantation. In the late 1990s, the REMATCH (Randomized Evaluation of Mechanical Assistance for the Treatment of Congestive Heart Failure) trial showed that the HeartMate (Thoratec Corporation, Pleasantville, CA, USA) LVAD could be used as an alternative to transplantation as "destination therapy" in end-stage CHF patients who were not candidates for transplantation.[156] Use of the device conferred a survival benefit compared to optimal medical therapy. Data suggest that long term VAD patients are at risk for three major complications: infections, thromboembolic events, and device malfunction.[157] These are the current challenges for today's physicians caring long term for assist device patients.

Heart transplantation remains a viable option for a relatively small percent of the population of patients with CHF who remain symptomatic despite medical therapy. However, considering the wider availability and recent success of VADs for this population, cardiac anesthesiologists are more likely to encounter patients with CHF who require VAD placement. Therefore, a review of the perioperative anesthetic considerations for this procedure probably is more relevant.

Fundamental Components of a VAD

VADs are pumps that collect blood returning to the heart and eject it downstream of the failing ventricle. VADs differ from CPB and extracorporeal membrane oxygenation devices in that they do not provide any respiratory function. The goal of VAD implantation is to decompress the acutely ischemic and failing, or chronically failing, ventricle by diminishing the radius, wall tension, and oxygen consumption. The ventricle may rest and recover while perfusion to the body is maintained by the VAD. For LV support, the inflow cannula is placed in either the LA or LV and drains into the device. Optimal drainage and decompression occur when the cannula is placed in the ventricular apex; however, sutures may not be well supported by infarcted ventricular tissue.[158] The outflow cannula is generally placed in the ascending aorta. A notable exception is the Jarvik 2000 (Jarvik Heart, Inc., New York, NY, USA), in which the outflow cannula is sutured to the descending aorta.[159] For RV support, blood is drained from the RA or RV to the pump and returned to the main PA.

Determinants for Ventricular Device Selection

The duration of support, patient body habitus, ventricle(s) to be supported, and surgical preference are the main determinants in choosing a particular VAD. Some devices, such as the Tandem Heart Percutaneous VAD (pVAD; Cardiac Assist, Pittsburgh, PA, USA) and the Impella Recover LP 5.0 LV system (ABIOMED, Inc., Danvers, MA, USA), are designed for short-term LV support (days) and can be implanted percutaneously in the cardiac catheterization laboratory or operating room. The Tandem Heart pVAD is a low-speed centrifugal, continuous flow pump inserted percutaneously through the femoral vessels. The Impella Recover LP 5.0 LV system is a miniaturized impeller, microaxial pump located within a catheter that is placed percutaneously through the femoral artery and positioned in the LV. These devices provide time to transfer the patient to a tertiary center and can be considered a "bridge to a bridge" or a temporary means of support until another longer-term VAD can be implanted. The ABIOMED BVS 5000 provides an intermediate duration of support, from 10–14 days. It can support the RV, LV, or both ventricles. It is most often implanted in the stunned ventricle, after an MI or for PCCS, in which recovery is expected. It also can be used to assist the failing RV after heart transplantation or LVAD implantation. Because only a small incision is made in the ventricle or atrium and a pursestring suture is used to secure the inflow cannula, insertion of ABIOMED cannulas is less traumatic to the tissue and explantation is much easier compared to the Thoratec Ventricular Device System and HeartMate LVAD in which the LV apex must be cored out in order to accommodate the inflow cannula and therefore requires a patch repair of the apex upon explantation. The Thoratec Ventricular Device System is the only FDA-approved device that can provide long-term (months to years) biventricular support to serve as a bridge to transplant. It can be used to support the RV, LV, or both ventricles. The Thoratec HeartMate provides only LV support and provides long-term support as either a bridge to transplant or as destination therapy. Because the Thoratec HeartMate is implanted intracorporeally in the left upper quadrant of the abdomen in the preperitoneal or intra-abdominal compartment, it is suitable only for patients with a body surface area $>1.8\ m^2$.

Modes of VAD Operation

Most VADs operate in a "volume mode" in which the VAD ejects as soon as the chamber is filled. VADs function best with slightly increased intravascular volume and slightly decreased intravascular resistance. Hypovolemia slows the rate of filling, thereby decreasing the number of pump cycles per minute and overall VAD output. Increased vascular resistance may impede VAD ejection, resulting in prolonged ejection or decreased chamber emptying and decreased pump output. Incomplete chamber emptying may result in blood stasis in the pump chamber, with resultant risk of thromboembolism. In the case of the LVAD, systemic vascular resistance is the main component of afterload, whereas for an RVAD pulmonary vascular resistance is the major determinant of afterload.

The ABIOMED BVS 5000 pump fills by continuous gravity drainage. The pump automatically ejects when full. It is preprogrammed to deliver approximately 5 L/min of flow. There are no dials to adjust. Anticoagulation with heparin is mandatory to prevent thrombus formation on the mechanical valves in the pump. The goal ACT is between 180–200 seconds. Filling of the ABIOMED BVS 5000 is independent of the underlying cardiac rhythm. Patients with malignant arrhythmias with biventricular support will remain hemodynamically stable.

The Thoratec VAD pump is filled by vacuum-assisted drainage. The pump can operate in one of three operating modes. In "volume mode," the pump ejects as soon as it is full, similar to the ABIOMED. In "asynchronous mode," the device operates in a fixed manner according to defined variables. The "external synchronization mode" is used to provide counterpulsation during device weaning. The Thoratec HeartMate LVAD has an extremely sophisticated control algorithm that adjusts device output to the patient's needs. As long as intravascular volume and the RV are functioning properly, there is no need to adjust the control settings. Anticoagulation initially is achieved with heparin, with a goal ACT between 180 and 200 seconds, but once the patient can tolerate oral medications, anticoagulation can be maintained with warfarin (Coumadin) with a goal international normalized ratio of 2.5–3.5.[160]

Preoperative Anesthetic Considerations

Most patients presenting for VAD implantation are critically ill and often arrive from an ICU or the cardiac catheterization laboratory, or they have developed PCCS in the operating room. When indicated, VAD insertion should be performed early in the setting of PCCS. If a patient is weaned from CPB on significant doses of two inotropes, hospital mortality is 42% and increases to 80% if three inotropes are used to

separate from CPB.[161] If these patients undergo VAD insertion within 3 hours of the first attempt to wean from CPB, a VAD wean rate of 60% and a hospital discharge rate of 43% can be achieved. If VAD insertion is delayed, a wean rate of 27% and hospital discharge rate of 7% are expected, along with an increased risk of end-organ damage and decreased survival.[162]

Preoperatively, the anesthesiologist must identify any neurologic deficits and ascertain the extent of major organ dysfunction, including renal or hepatic insufficiency, which are very common in this patient population. Any further deterioration in the perioperative period may prevent a full recovery and eliminate the possibility of the patient qualifying for a subsequent heart transplantation at a later date.[160]

Strict sterile technique for all invasive procedures and appropriate antibiotic prophylaxis is mandatory in this high-risk population. Antibiotic therapy is ineffective in treating assist device infection once it occurs. CVP monitoring may be of questionable accuracy in patients with an RVAD. However, central access still may be useful for drug and volume infusions. PACs may provide little useful information in the patient with an LVAD that displays real-time cardiac output. However, PACs may be useful in patients with pulmonary hypertension at risk for developing RV failure after LVAD implantation but should not be placed in patients with a functioning RVAD.

CAD is common in LVAD candidates. Adequate preoperative evaluation of CAD is important to ensure the best outcome after VAD implantation. RCA bypass grafts may be particularly necessary to support RV function after LVAD implantation. If RCA bypass grafts are to be performed, placement of the proximal anastomosis site should take into account the LVAD outflow cannula anastomosis site. The lesser curvature of the aorta has been suggested as a good location for the proximal anastomosis site if the VAD outflow cannula is to be sutured to the anterolateral aspect of the ascending aorta.[163]

Pre-CPB Intraoperative TEE Examination

Intraoperative TEE is the monitor of choice for patients undergoing VAD placement. It may be particularly useful in identifying anatomic and physiologic abnormalities in an attempt to preempt possible complications or VAD malfunction.[164]

Valve Pathology

Over 20% of patients scheduled for LVAD insertion have some degree of AI.[164] Persistent AI following LVAD implantation results in high pump flow rates secondary to increased LVAD preload from the regurgitant volume and decreased systemic blood flow. Hypotension, organ hypoperfusion, and metabolic acidosis may occur despite high VAD output. Some centers recommend oversewing, repairing, or replacing the AV if AI ≥ 2+. Oversewing also may be considered if the LVAD is being implanted as a bridge to transplant. However, the outcome of LVAD failure in the setting of an oversewn AV is ominous. If the valve cannot be repaired and must be replaced, bioprosthetic valves are preferred to mechanical valves because of their lower thrombotic potential. After LVAD implantation, AI severity may worsen when the aortic to LV pressure gradient is increased as the device ejects blood into the aorta at arterial pressures while diastolic pressures in the LV remain subphysiologic. In addition, unloading of the LV by a properly functioning LVAD may distort the AV and induce AI.

TR is commonly found in patients scheduled for VAD placement. However, unless ascites is present, no benefit has been found in repairing this lesion.[163] As LV failure improves with device support, so too will RV failure and associated TR tend to improve. MS can compromise device inflow and should be corrected at the time of implant. MR generally has little effect on pump flow rates and often improves with LVAD activation and prolonged support.[164,165]

Patent Foramen Ovale and Atrial Septal Aneurysm

A patent foramen ovale (PFO) may be found by pre-CPB intraoperative TEE in >9% of patients undergoing VAD placement.[164] Under normal physiologic conditions, LA pressure is greater than RA pressure, and flow through the defect is left to right. Arterial saturation remains normal. However, with initiation of LVAD inflow, LA and LV pressures fall dramatically and frequently become lower than right-sided pressures, thus promoting right-to left-shunting through the PFO. Undiagnosed or unrepaired PFOs may result in significant arterial hypoxemia during separation from CPB and LVAD device activation (Fig. 51–21)[166] and pose an increased risk for paradoxical embolism.

Atrial septal aneurysm is defined echocardiographically as a protrusion of the aneurysm at least 10 mm beyond the plane of the atrial septum. According to one study, as many as 85% of patients with atrial septal aneurysms have a coexisting PFO.[167] Atrial septal aneurysms may be a cardiogenic source of thromboembolus.[168] In addition, obstruction of an RVAD inflow cannula by an atrial septal aneurysm has been reported.[169] A "bubble test" in which 10 mL of agitated saline is injected into the RA immediately after the release of positive pressure during a Valsalva maneuver is considered the gold standard for PFO identi-

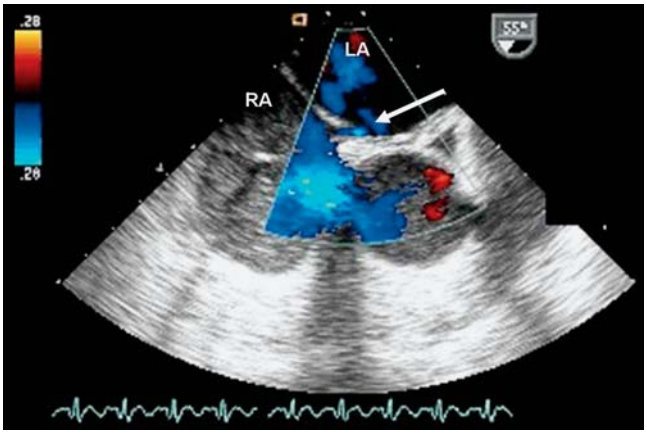

FIGURE 51–21. Transesophageal echocardiographic view showing an undiagnosed patent foramen ovale (*arrow*), which can result in arterial hypoxemia and paradoxical embolus following left ventricular assist device activation. LA, left atrium; RA, right atrium.

fication. However, even this test occasionally fails to identify a PFO, and only after VAD insertion may the PFO become identifiable.[164] Correction of a PFO or atrial septal aneurysm requires dual cannulation and necessitates prompt identification and communication with the surgical team. A PFO identified post-CPB necessitates a return to CPB for repair.

Right Heart Failure

RV dysfunction and failure may develop in up to 20–30% of patients implanted with an isolated LVAD.[170] Decompression of the left side of the heart after LVAD activation can lead to altered RV geometry. A leftward shift of the interventricular septum after LV decompression may result in increased RV compliance and decreased RV contractility.[170] Additionally, although an LVAD should decrease RV afterload and thereby improve RV function in patients with normal pulmonary vascular resistance, patients with fixed pulmonary vascular resistance may actually experience an increase in RV afterload as increased left-sided output from the VAD increases venous return and flow through the pulmonary vasculature.

Right heart failure is one of the most important causes of perioperative death in LVAD patients.[163,171] Blood flow into the LVAD is dependent on adequate pressure gradients to drive blood flow between the LV and the device reservoir and pump. Right heart failure leads to diminished transpulmonary flow and decreased left-sided heart pressures, thus reducing the driving force for LVAD filling.

Acoustic quantification can be used to measure the RV fractional area of change. A preoperative RV fractional area of change $< 20\%$ is associated with RV failure upon LVAD device activation.[164] Low preoperative mean PA pressures and RV stroke work index also can be used to identify patients at risk for developing RV failure after LVAD implantation.[172]

Thrombus

In addition to sepsis and device malfunction, neurologic dysfunction including stroke and transient ischemic attacks remains one of the most common adverse events following VAD implantation.[157] Intracavitary thrombus has been identified as a thromboembolic risk factor in patients with VADs (Fig. 51–22).[173] LV or LA thrombus has been diagnosed by intraoperative TEE in 9.4% and 3%, respectively, of patients prior to LVAD insertion.[164] Intracavitary thrombus can lead to VAD inflow cannula obstruction and mechanical pump failure.[174]

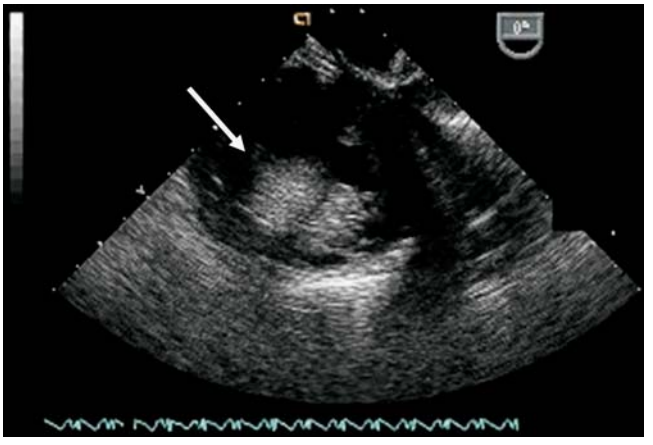

FIGURE 51–22. Large left ventricular thrombus (*arrow*) identified during precardiopulmonary bypass intraoperative transesophageal echocardiographic examination in a patient about to receive a left ventricular assist device.

Thrombus formation in the LV occurs under conditions of blood stasis or low-velocity flow. Apical akinesis, ventricular aneurysm, or diffuse ventricular dysfunction (ejection fraction $< 20\%$) may promote thrombus formation. The sensitivity of echocardiography for detecting LV thrombi is operator dependent. Even when an LV thrombus is not identified on echocardiographic exam, the likelihood of thrombus formation remains high in the aforementioned patient population. Evidence of apical flow stasis or continuous swirling of flow around the apex identifies patients at risk for thrombus. Certain clues should help the operator identify apical thrombus and distinguish it from apical trabeculations. A thrombus is somewhat more echogenic than myocardium, has a distinct contour from the endocardial border, and is located in a region of wall-motion abnormality.[175]

Weaning from CPB and Initiating LVAD Operation

De-Airing

Before the LVAD is activated, the outflow graft is slowly unclamped and the pump is hand cranked. A modified TEE midesophageal AV long-axis view at 130° can be used to monitor air efflux from the outflow graft into the ascending aorta (Fig. 51–23). If large quantities of air are observed, the hand cranking is stopped, the outflow graft is reclamped, and the aorta is

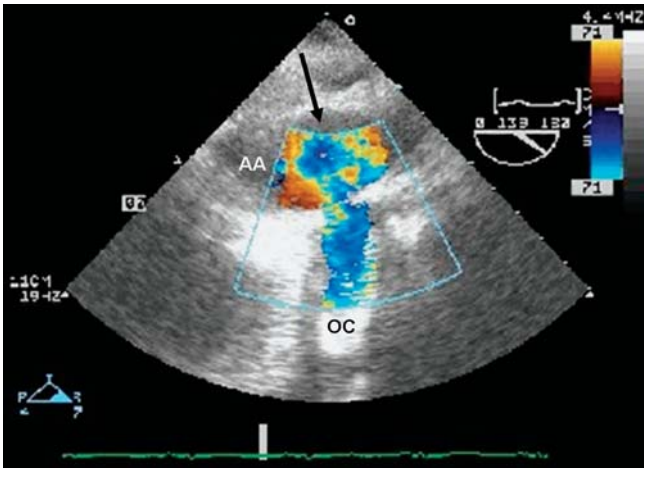

FIGURE 51–23. Transesophageal midesophageal ascending aortic long-axis view showing a normal color flow Doppler jet (*arrow*) at the anastomotic site between a left ventricular assist device (LVAD) outflow cannula (OC) and the ascending aorta (AA). This same view can be used to monitor air efflux from the outflow graft into the ascending aorta prior to full activation of the LVAD.

vented. This process is repeated until minimal air is observed. The pump then is activated at a low rate, approximately 4 L/min.

Assessing RV Function

In the early minutes after LVAD pump activation, determination of RV function is critical. Acute RV failure usually is associated with dilation, global dysfunction, and TR. If transpulmonary blood flow does not improve and the device continues to function, the left-sided chambers will collapse and potentially lead to obstruction of the inflow cannula. If the device pump continues to operate, air may be entrained from the sewing ring or the inlet cannula connections and ejected systemically in large quantities into the aorta.[164] If these conditions exist, the device should be turned off and the patient returned to CPB. β-Adrenergic agonists, phosphodiesterase inhibitors, and nitric oxide should be initiated to improve RV contractility and decrease RV afterload in an attempt to improve transpulmonary blood flow. After a period of several minutes, the LVAD can be restarted. If the same hemodynamic conditions persist, a supplemental temporary RV assist device should be implanted.

LVAD Inflow Cannula Position

Inflow cannula patency is essential for adequate stroke volume and device output. Ideally the LVAD inflow cannula orifice should be directed toward the MV opening and located in the center of the apex (Fig. 51–24).[159] In practice, the inflow cannula often is misdirected anteroseptally (Fig. 51–25). Apical trabeculations, thrombi, papillary muscles, and surgical misplacement can lead to cannula obstruction and LVAD stroke volume reduction. Inflow cannula obstruction can be assessed using color flow Doppler, looking for turbulent flow. In addition, continuous-wave Doppler in the TEE midesophageal four-chamber view can be used to identify inflow cannula obstruction by demonstrating peak velocities >2.5 m/s. Significant obstruction requires repositioning of the inflow cannula.[164]

Hypotension and Low LVAD Pump Flow Rates

Hypovolemia, RV failure, inflow cannula obstruction, pulmonary embolus, and cardiac tamponade are the most frequent causes of hypotension associated with low LVAD pump flow rates.

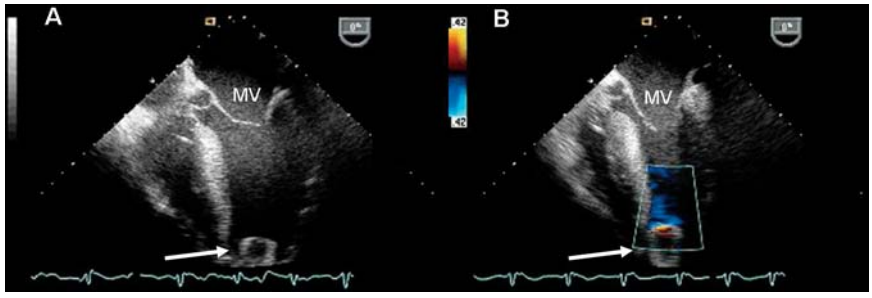

FIGURE 51–24. Transesophageal midesophageal four-chamber two-dimensional (**A**) and color flow Doppler (**B**) images showing correct positioning of the inflow cannula (*arrows*), with the orifice directed at the mitral valve (MV) orifice.

TEE clues to pericardial tamponade include pericardial effusion, systolic collapse of the RA, and diastolic collapse of the RV. Correlation with a low QRS voltage on the ECG and equalization of chamber pressures by catheterization may be helpful in making the diagnosis.[176] Pulmonary embolus may be difficult to distinguish from acute RV failure because both result in RV dilation and severe TR. However, in patients with a pulmonary embolus, an echogenic density may be identified in the main or proximal branch right PA. Hypovolemia is best assessed by TEE. End-diastolic area is a more accurate measure of LV preload than is PAOP; however, the range of normal values for the end-diastolic area is wide.[177]

Device malfunction is the third most common cause of death in long-term Thoratec HeartMate VAD assisted patients.[178] Device malfunctions leading to hypotension with decreased pump flow rates include inflow cannula obstruction and outflow cannula kinking. Clues to inflow conduit obstruction can be acquired by assessing color flow Doppler of the normal laminar diastolic filling pattern into the apical cannula. In cases of cannula obstruction, the flow pattern is intermittently interrupted. Pulse-wave Doppler of the inflow cannula also may indicate periods of obstruction to flow. The most common cause of inflow cannula obstruction is deviation of the inflow cannula toward the interventricular septum (Fig. 51–25). Outflow graft obstruction may occur and is best diagnosed using contrast angiography, which will demonstrate an acute angle bend or "kinking" if obstruction is present.

Hypotension and High LVAD Pump Flow Rates

Hypotension and high LVAD pump flow rates may present either in the immediate post-CPB period or after patients have been discharged from the hospital and the natural course of assist device decline and malfunction occurs. In LVAD patients who are hypotensive and demonstrate high flow rates, it is important to determine whether the right- and left-sided cardiac outputs are

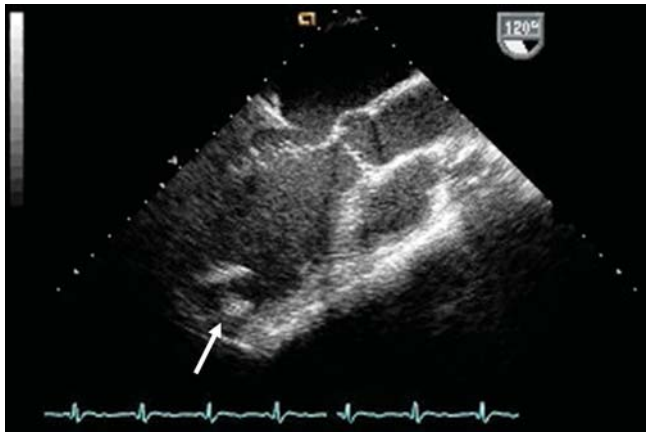

FIGURE 51–25. Transesophageal midesophageal long-axis view showing anteroseptal malalignment of a left ventricular assist device (LVAD) inflow cannula (*arrow*), which can cause obstruction and hypotension associated with low LVAD output.

equal. This may require placement of a PAC to determine the right-sided cardiac output or performance of a TEE or transthoracic echocardiographic examination with calculation of right-sided cardiac output. High biventricular flow rates suggest sepsis. However, if left-sided significantly exceeds right-sided cardiac output, one of the following three etiologies must be ruled out: AI (Fig. 51–26), inflow valve regurgitation, or outflow valve regurgitation. In one prospective study, 26% of Thoratec HeartMate LVAD patients discharged from the hospital developed inflow valve regurgitation, 32% developed new AI, and 0% were identified as having outflow valve incompetence.[179]

AI develops in LVAD patients secondary to native valve distortion after LV decompression and diminished ejection through the native valve. LVAD inflow valve incompetence may be caused by endocarditis, a torn cusp, or commissural dehiscence of the LVAD prosthetic. Although the inflow valve cannot be directly viewed by TEE, clues to incompetency may be acquired by placing the color flow Doppler sector over the orifice of the inflow cannula during device systole. Backflow into the ventricle during device systole suggests inflow valve incompetence[180] (Fig. 51–27). AV opening may be a clue that inflow valve regurgitation exists, as up to 65% of LVAD patients with inflow valve regurgitation have been shown to demonstrate frequent AV opening versus only 19% of patients without inflow valve regurgitation.[179] In addition, echocardiographically acquired outflow graft velocity, velocity–time integral, and stroke volume all are significantly diminished in patients with inflow valve regurgitation.

Anesthetic Management of VAD Patients for Noncardiac Surgery

As the population of patients with VADs increases, we can anticipate a greater number of these patients presenting for noncardiac surgical procedures that require perioperative anesthetic management. Because infection and thromboembolic events are the two most common causes of morbidity in long-term VAD-assisted patients, every effort should be made to correctly manage antibiotic prophylaxis, ensure the strictest sterile technique for invasive procedures, and manage anticoagulation therapy appropriately.

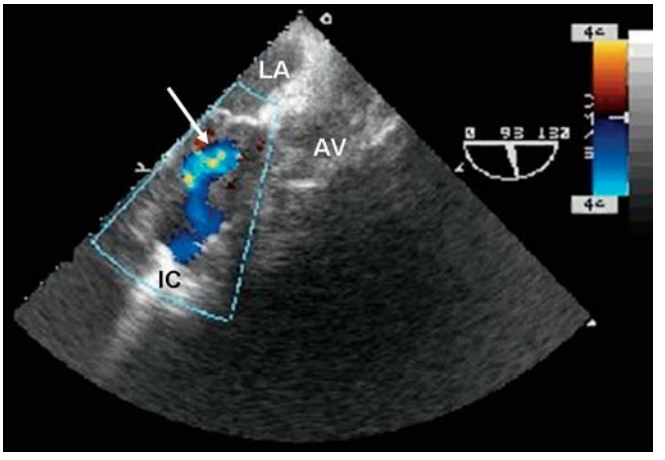

FIGURE 51–26. Transesophageal midesophageal aortic valve (AV) long-axis view showing a color flow Doppler jet of aortic regurgitation (AR; *arrow*) directed apically toward the inflow cannula (IC) of a left ventricular assist device (LVAD). AR in LVAD patients may lead to hypotension and increased output. LA, Left atrium.

Patients with long-term intracorporeal devices, such as the Thoratec HeartMate, suffer from delayed gastric emptying and early satiety because of the proximity of the device to the stomach. Cricoid pressure and a rapid sequence induction should be performed for these individuals if general anesthesia is desired. With the exception of patients with the Thoratec HeartMate, which has a titanium-covered pump chamber and requires only aspirin for anticoagulation, patients with most other VADs will require maintenance of some level of anticoagulation to prevent thromboembolic complications. Increased intraoperative bleeding should be anticipated. The surgeon and the anesthesiologist should discuss coagulation management prior to surgery. Giving small amounts of fresh-frozen plasma to achieve the lower limits of anticoagulation recommended by the device manufacturer may help control excessive blood loss. Regional techniques usually are contraindicated secondary to the need for anticoagulation maintenance.

Fundamental anesthetic principles regarding decisions to intubate and extubate patients also apply in VAD-assisted patients. Although positive-pressure ventilation may affect venous return to the left heart and diminish LVAD filling, in most circumstances this is only a minor consideration, and mechanical ventilation should be implemented if needed. In addition, the VAD should be set on a "volume mode" prior to general anesthesia induction. Slight increases in preload and small decreases in afterload will optimize VAD filling and output.

Invasive monitoring is generally not necessary because the VAD control console continuously displays the device output. An arterial line can be inserted under strict sterile precautions if frequent blood gasses will be needed or if large alterations in blood pressure are anticipated. Otherwise, a

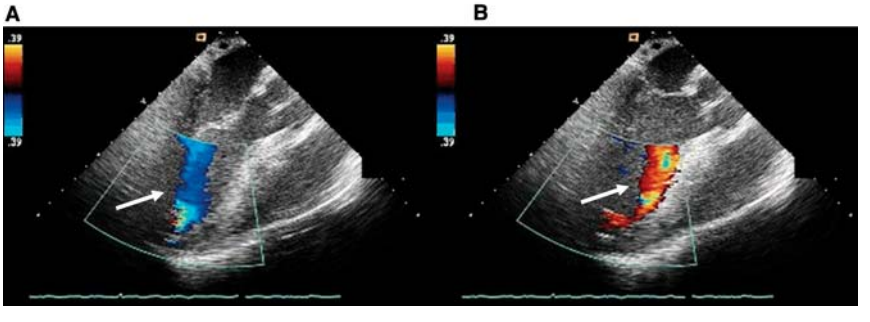

FIGURE 51–27. Transesophageal midesophageal long-axis views demonstrating normal laminar diastolic left ventricular assist device inflow (**A;** *arrow*), and a high-velocity jet of inflow valve regurgitation seen during device systole (**B;** *arrow*). Inflow valve regurgitation is the most common form of malfunction in HeartMate VE and XVE devices.

noninvasive blood pressure cuff usually is adequate. Finally, because the VAD-assisted patient likely was transported to the operating room on battery-assisted power, it is important to remember to reconnect the VAD to the power supply in the operating room to prevent battery failure.

CHAPTER 52

Anesthesia for Surgical Treatment of Congenital Heart Disease: A Problem-Oriented Approach

James S. Harrington, MD, Avinash C. Shukla, MBBS, and Paul R. Hickey, MD

The goal of anesthetic management in the treatment of patients with congenital heart disease (CHD) is maintenance of circulatory homeostasis despite the destabilizing events accompanying therapeutic procedures. Anesthesia for management of CHD is complicated by the diversity of lesions and the variety of therapeutic approaches. Congenital cardiac defects vary widely in severity, anatomic combinations, and pathophysiologic conditions. Complex cardiovascular pathophysiologic conditions change dynamically with time and with organ development and therapeutic interventions. In these circumstances, simple formulas for anesthetic management are not valid. The pathophysiology of each lesion and its alteration by previous medical and surgical treatment and by the proposed procedure should be individually considered in planning anesthetic management. Major interventional procedures in the catheterization laboratory are increasingly replacing or supplementing surgical procedures. Their anesthetic management also should be considered. Such transcatheter procedures can cause profound changes in homeostasis and often require anesthesia, particularly in children. Thus, anesthetic considerations for these transcatheter interventional procedures have been included. Anesthetic management of CHD is first approached by focusing on common pathophysiologic problems related to specific cardiac defects and previous therapeutic interventions. Understanding these problems is critical for determining anesthetic management priorities. Knowledge of the effects of anesthetics, manipulations, and ad-

KEY POINTS

1. Congenital heart diseases that decrease cardiopulmonary reserve include intracardiac shunting, hypoxemia from inadequate pulmonary blood flow or intracardiac shunting, congestive failure from volume or pressure overload, vascular obstructive disease from excessive pulmonary blood flow, various kinds of stenoses, and occasional coronary ischemia.
2. Many of the determinants of shunting (its magnitude and direction) may change considerably during anesthesia and operative manipulations.
3. There are simple shunts, bidirectional shunts, and occasionally complex shunts. The key for anesthesia providers is understanding the effects of vasodilators, cardiac depressants, and surgical manipulation on these various shunts.
4. "Bubble discipline" is an important concept in dealing with anesthesia administration for patients with congenital heart disease.
5. Chronic hypoxia leads to polycythemia, which, in turn, leads to dramatic increases in blood viscosity.
6. The anesthesia provider should understand the hemodynamic consequences of pulmonary vascular hypertrophy, the end stage of which is the Eisenmenger syndrome.
7. Even though a child with congenital heart disease may not have frank failure, cardiac reserves may be dramatically decreased, especially if episodes of prolonged congestive failure have been a part of the patient's history and have resulted in cardiomegaly or ventricular hypertrophy.
8. "Transitional circulation" keeps neonates with severe life-threatening congenital heart disease alive. In this context, therapy with prostaglandin E_1 infusion should be understood, especially the possibility of side effects such as apnea and major vasodilatation.
9. The functional capacities of the immature heart should be of particular interest to anesthesia providers. The immature noncompliant ventricle is extraordinarily sensitive to increases in volume and is considerably restricted in its ability to respond to same by increasing stroke volume. The Starling curve plateau in neonates is reached at left ventricular end-diastolic pressures of 4 mm Hg. Therefore, cardiac compliance values in neonates do not correspond to values for adult patients.
10. Adult arterial pressures, especially during bypass, do not apply to neonates and infants.
11. The procedures for weaning from bypass and using deep hypothermic circulatory arrest or low-flow hypothermic bypass are important and should be reviewed in detail.
12. The anesthesia provider should fully understand the hemodynamic consequences and purpose of various pulmonary artery banding procedures and various kinds of transcatheter management of congenital lesions. Transcatheter procedures require anesthetic care in the interventional cardiac catheterization laboratory.
13. Halothane has been a successful induction anesthetic in children with various kinds of transcatheter treatment of congenital lesions.
14. Transcatheter procedures require anesthetic care in the interventional cardiac catheterization laboratory.
15. Intravenous anesthetics, including high-dose opioids and ketamine, may provide increased margins of safety in some infants with congenital heart disease. Intravenous agents, however, have the possibility of very high transients after intravenous bolus doses because of inadequate mixing or shunting.
16. Intramuscular ketamine 3–5 mg/kg is reasonably well tolerated, even in sick children with cyanotic congenital heart disease.
17. Manipulation of pulmonary and systemic vascular resistance described in this chapter is worth reviewing for anesthesia providers engaged in the practice of anesthesia for congenital heart disease.
18. Inhaled nitric oxide is now a clinically useful and efficacious selective pulmonary vasodilator for many, but not all, patients with congenital heart disease.

junctive agents on the pathophysiologic and therapeutic procedure is essential for anticipating the responses of any patient.

SPECIFIC PROBLEMS RESULTING FROM CHD

Although many different lesions in varying combinations occur in patients with CHD, problems that decrease cardiopulmonary reserve include (1) intracardiac shunting with increases and decreases in pulmonary blood flow, (2) hypoxemia from inadequate pulmonary blood flow or intracardiac shunting, (3) congestive heart failure from volume or cardiac pressure overload, (4) pulmonary vascular obstructive disease (PVOD) from excessive pulmonary blood flow and pressure, (5) obstruction to left or right heart outflow from stenosis at various sites, and (6) coronary ischemia from congenital defects and iatrogenic intrusions. Of the eight of 1000 live births with CHD, one third have critical diseases requiring catheterization or surgery in the first year, so anesthetic management for CHD frequently involves immature neonatal circulatory and pulmonary physiology.[1,2] Physiologic limitations of the immature heart, circulation, and lungs are superimposed on CHD problems. Table 52–1 shows problems encountered with CHD patients usually seen in the operating room or catheterization laboratory and frequencies of occurrence. In long-standing or particularly severe lesions, problems may occur more frequently than indicated in Table 52–1.

Intracardiac Shunting

Shunting within the heart and between the great vessels gives rise to many of the problems seen in patients with CHD. These include hypoxemia, excessive pulmonary blood flow, high volume loads, and CHD. Thus, control of intracardiac shunting is a central issue in CHD and its anesthetic management. The hemodynamics of intracardiac shunts are complex and depend on numerous factors determining shunt magnitude and direction (Fig. 52–1). Complete description of the dynamics of a particular shunt requires more data than are ordinarily clinically available.[3] The determinants of shunting, such as ventricular compliance, may change considerably during anesthesia and operative manipulations, but the changes may not be readily measurable. A simplified view of shunt hemodynamics is useful in clinically assessing the hemodynamic importance of shunts and their probable alterations during therapeutic procedures.

Shunt orifice and outflow resistance are important determinants of shunting. By considering outflow resistance and the size of the shunt orifice, intraoperative changes in shunt magnitude and direction can be predicted for simple and complex shunts. Manipulation of pulmonary or systemic outflow resistances can alter shunt directions and magnitudes, depending on the type of shunt. Influences of cytokines, activated complement, and other endogenously released humoral agents such as nitric oxide also are important in determining pulmonary vascular resistance (PVR) and systemic vascular resistance (SVR). Local and circulating levels of such agents can be profoundly altered by surgical procedures and cardiopulmonary bypass (CPB).[4] Effects of such agents on vascular resistances may overwhelm clinical efforts to manipulate vascular resistances.

Simple Shunts

In simple shunts (without associated obstructive lesions), outflow resistance is equivalent to PVR on the right and SVR on the left. The effects of shunt orifice and vascular resistances on simple shunts are schematically shown in Fig. 52–2. Shunts with small orifices are relatively fixed in magnitude and are restrictive by definition. As the communication becomes larger and nonrestrictive (equal to or exceeding the aortic valve area), shunt direction and magnitude depend more on the ratio of outflow resistances, that is, the relative resistances of the pulmonary versus systemic vascular beds (PVR/SVR)[5].

In many forms of CHD, hypoxemia requires additional pulmonary blood flow from surgically constructed aortopulmonary anastomoses. Aorta-to-pulmonary artery flow through a small diameter (restrictive) Blalock-Taussig shunt increases moderately with elevations in systemic arterial pressure when PVR remains constant or alternatively by decreasing PVR with a constant systemic arterial pressure. These changes increase pulmonary blood flow and arterial oxygen saturation (SaO_2) and probably are beneficial in increasing tissue oxygen delivery when oxygen saturations are very low (>70%). In contrast, when SaO_2 values are greater (e.g., 85–90%, approaching the plateau of the oxyhemoglobin dissociation curve), further increases in SaO_2 require high levels of pulmonary blood flow and may not improve tissue oxygen delivery because of concomitant decreases in systemic flow (Fig. 52–3). High pulmonary flow through large, unrestrictive shunts is required for greater levels of SaO_2, and it increases cardiac volume loading. This volume loading often may exacerbate congestive heart failure, producing a net decrease in systemic cardiac output and net oxygen delivery despite the small increases in SaO_2 produced by increased pulmonary flow. Thus, the same relative changes in SVR and PVR could be detrimental with a large, nonrestrictive aortopulmonary shunt. Also, with large, nonrestrictive ventricular septal defects (VSDs), the same relative changes in PVR/SVR can increase left-to-right shunting, subjecting the heart to further increased volume loads, worsening congestive heart failure.

In contrast, with tetralogy of Fallot, because pathophysiology consists of right-to-left complex shunt flow through a VSD, the same changes, namely, increasing SVR and decreasing or holding PVR constant, decrease right-to-left shunting and improve the clinical picture. SaO_2 increases by decreasing systemic venous blood shunted into the left atrium and mixing with pulmonary venous blood, improving the patient's clinical condition. Relative levels of PVR and SVR needed to optimize the patient's clinical status with an intracardiac shunt become clearer when the pathophysiologic condition of the defect is detailed. Characteristics and examples of simple shunts of various sizes are listed in Table 52–2.

Mixing

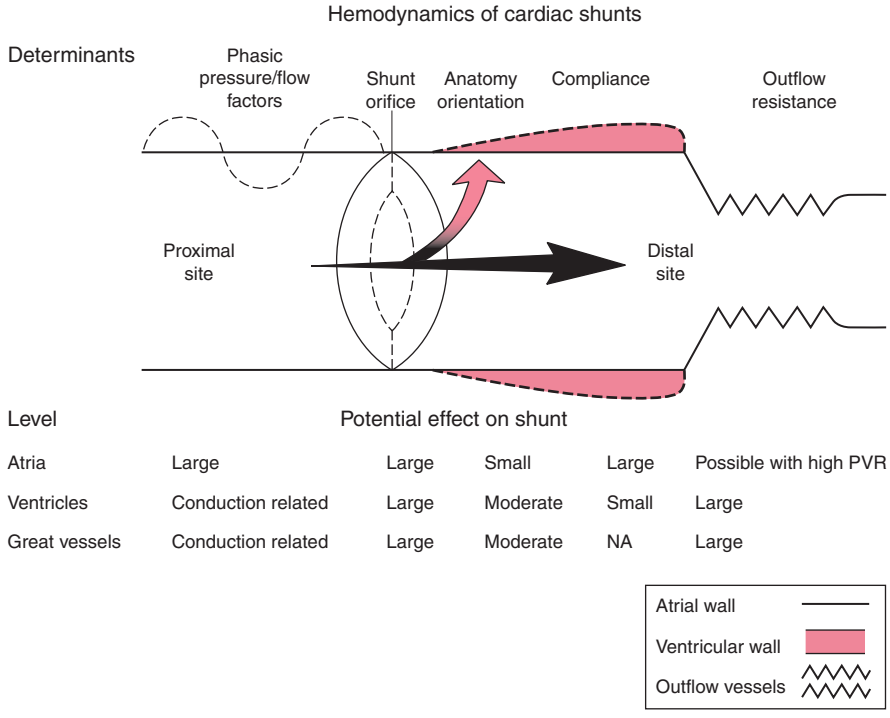
If the intracardiac communication is sufficiently large, the two cardiac chambers or great vessels effectively become a common chamber. More or less complete mixing (bidirectional shunting) occurs. This usually causes some degree of hypoxemia, despite normal or increased pulmonary blood flow. Mixing implies equal shunting in both directions for any period greater than a few cardiac cycles. If shunting is bidirectional but quantitatively unequal for any long period, there is a net transfer of blood into the pulmo-

TABLE 52–1.

Frequency of Hemodynamic Problems in Various Forms of Congenital Heart Disease

Lesion	Hypoxemia	Intracardiac Shunting	Excessive Pulmonary Blood Flow	Congestive Heart Failure	Left-Sided Obstruction	Coronary Ischemia	Immature Circulation	Obstruction to Pulmonary Flow
Atrial septal defect	Rarely	Always (L → R)	Usually	Rarely	Not seen	Not seen	Not seen	Rarely
Patent ductus arteriosus	Rarely	Always (L → R)	Usually	Sometimes	Not seen	Not seen	Sometimes	Rarely
Ventricular septal defect	Rarely	Always (L → R)	Usually	Often	Not seen	Not seen	Often	Late (PVOD)
Tetralogy of Fallot	Often	Always (L → R)	Rarely	Sometimes	Not seen	Rare	Occasionally	Usually
Atrioventricular canal (partial or complete)	Rarely	Always (L → R)	Usually	Often	Not seen	Rare	Often	Late (PVOD)
Transposition of the great arteries	Always	Always (mixing)	Sometimes	Sometimes	Rare	Sometimes	Often	Rarely
Coarctation of aorta	Not seen	Occasionally (through PDA)	Not seen	Rarely	Always	Occasionally	Sometimes	Not seen
Interrupted aortic arch	Always (in lower half of body)	Always (through PDA)	Not seen	Rarely	Always	Rarely	Usually	Not seen
Pulmonary atresia	Always	Always (L → R)	Sometimes	Sometimes	Rare	Occasionally	Usually	Always
Truncus arteriosus	Usually	Always (mixing)	Usually	Often	Rare	Sometimes	Usually	Late (PVOD)
Anomalous of original coronary artery	Not seen	Not seen	Not seen	Often	Not seen	Always	Occasionally	Not seen
Single Ventricle	Usually	Always (mixing)	Often	Often	Occasionally	Sometimes	Usually	Occasionally
Aortic stenosis	Not seen	Not seen	Not seen	Occasionally	Always	Not seen	Occasionally	Sometimes
Critical aortic stenosis	—	Usually (PDA)	Not seen	Usually	Always	Not seen	Frequently	Always
Pulmonic stenosis	Occasionally	Not seen	Not seen	Occasionally	Not seen	Always	Not seen	Sometimes
Critical pulmonary stenosis	Always	Usually (PDA)	Not seen	Usually	Not seen	Always	Not seen	Always
Tricuspid atresia	Always	Always	Frequently	Occasionally	Not seen	Always	Rarely	Frequently
Total anomalous pulmonary venous return	Occasionally	Always	Sometimes	Frequently	Not seen	Frequently	Rarely	Always

L, left; PDA, patent ductus arteriosus; PVOD, pulmonary vascular obstructive disease; R, right.



Level	Potential effect on shunt				
Atria	Large	Large	Small	Large	Possible with high PVR
Ventricles	Conduction related	Large	Moderate	Small	Large
Great vessels	Conduction related	Large	Moderate	NA	Large

FIGURE 52–1. Effects of the many determinants on central cardiac shunting at various levels. PVR, Pulmonary vascular resistance. (From Berman[3] with permission.)

nary or systemic circulation. Continued for more than a few minutes (several hundred cardiac cycles in the infant), this theoretically puts the patient's entire blood volume on one side of the circulation. However, this does not occur because changes in compliance resulting from large shifts of blood tend to counteract shunt inequality. Thus, for periods longer than a few cardiac cycles, shunting is equal in both directions.

With complete mixing in a common chamber and with no outflow obstruction, the amount of pulmonary and systemic blood flow depends on PVR/SVR. Because normal PVR often is much less than SVR (as little a $^1/_{20}$ of SVR in older children and adults), pulmonary blood flow can become large with a nonrestrictive simple shunt, even in neonates. In these situations, it can become important to limit pulmonary blood flow because pulmonary volume overload can lead to congestive heart failure, inadequate systemic flow, and progressive acidosis. With mixing, SaO_2 is determined by the relative amount of pulmonary blood flow and systemic blood flow (Qp:Qs). Because of the shape of the oxyhemoglobin dissociation curve, increasingly large amounts of pulmonary blood flow are required to further increase SaO_2 as it increases. This is shown in Fig. 52–3 and explains why high $SaO_2 \geq 90\%$ when CHD is present with mixing physiology can occur only with very high pulmonary blood flows. This high flow frequently leads to congestive heart failure from volume overload, which in turn results in net decreased systemic cardiac output.

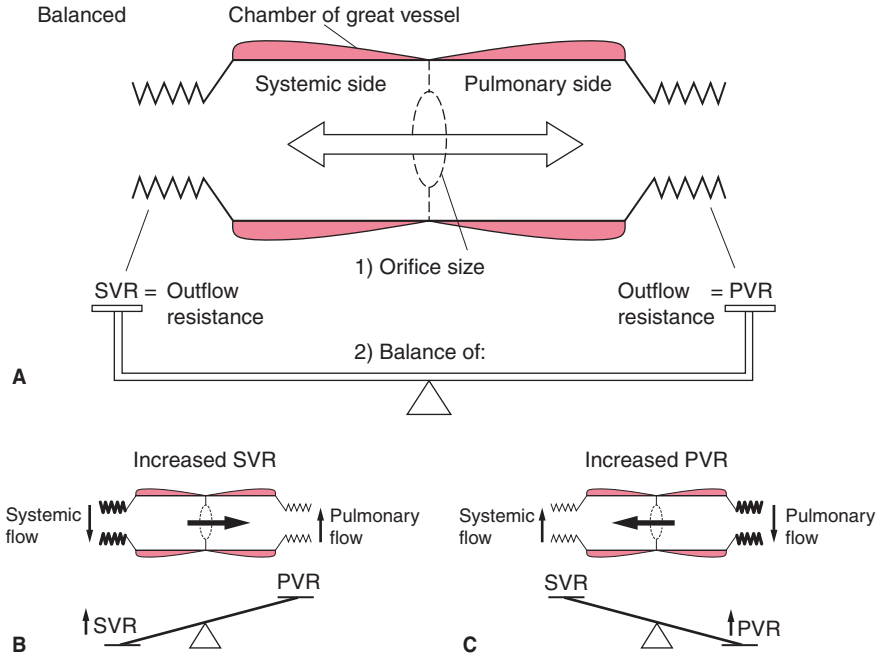


FIGURE 52–2. Determinants of magnitude and direction of simple central shunts. (1) Orifice size is important in determining magnitude of shunting and pressure gradient across the shunt and is generally fixed. (2) Balance of pulmonary vascular resistance (PVR) and systemic vascular resistance (SVR) is dynamic and determines the direction of shunt and variations in magnitude around limits fixed by orifice size. **A.** Balanced PVR/SVR. **B.** Increased pulmonary flow with increased SVR. **C.** Increased systemic flow with increased PVR. (Reprinted from Hickey PR, Wessel DL. Anesthesia for treatment of congenital heart disease. In Kaplan JA, ed. Cardiac Anesthesia. 2d ed. New York: Grune & Stratton, 1987, with permission from Elsevier.)

Complex Shunt Lesions

In complex shunts (Fig. 52–4), fixed central outflow obstruction is present at some level on one or the other side of the circulation. Fixed resistance additively increases downstream vascular outflow resistance, which increases shunting to the opposite side. When the fixed resistance is high, it largely dictates total shunting; only part of shunt flow in complex shunts is related to relative resistances in the distal pulmonary and systemic beds. As outflow obstruction increases and becomes a greater component of total resistance to flow, changes in ipsilateral vascular resistance (PVR or SVR) become progressively less important in determining flow because they become smaller components of total resistance. This is particularly true on the right side, where normal PVR is only a fraction of the resistance offered by most right-sided obstructive lesions seen in CHD. In contrast, changes in vascular resistance (PVR or SVR) contralateral to the fixed obstruction become relatively more impor-

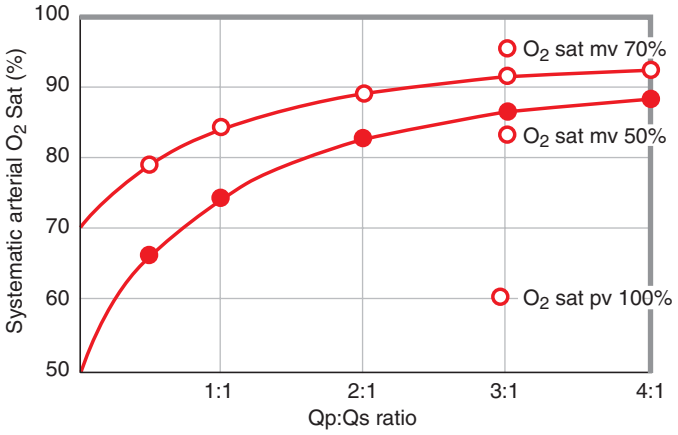

FIGURE 52–3. Changes in systemic arterial O_2 saturation with mixing lesions as the ratio of pulmonary flow to systemic flow (Qp:Qs) changes, assuming different levels of mixed venous (mv) O_2 saturation. This assumes a pulmonary venous (pv) O_2 saturation of 100%.[5]

tant in determining shunting in complex shunts. For example, in tetralogy of Fallot with severe pulmonic stenosis, a large component of the right-to-left VSD shunting is caused by fixed pulmonary valve stenosis. An additional variable aspect of shunting may be caused by variations in PVR or dynamic right outflow infundibular obstruction. Dynamic changes in variable portions of the total right ventricular outflow obstruction may increase or decrease total right-to-left shunting, thereby increasing or decreasing hypoxemia. At baseline, when dynamic obstructive components are minimal, right-to-left shunting is determined largely by this large, fixed pulmonic obstruction. This presumes constant SVR and cardiac output; large changes in SVR markedly change shunting by altering the balance contralateral to the final obstruction (Fig. 52–4). Characteristics and examples of complex shunts are listed in Table 52–3.

Complete Obstruction

When obstruction to central outflow becomes complete, as in patients with tricuspid atresia, pulmonary atresia, or aortic atresia, shunting across communications proximal to the obstruction becomes total and obligatory and can be considered an extreme type of simple shunt, as listed in Table 52–3. This should be associated with another downstream shunt that provides flow to the obstructed side of the circulation. The associated shunt can be a patent ductus arteriosus (PDA), which provides pulmonary blood flow in pulmonary valvular atresia or provides systemic blood flow in aortic valvular atresia. Downstream shunting variably depends on PVR/SVR, depending on the restrictive nature of the "compensatory" shunt, that is, a small patent ductus constitutes most of the resistance when the ductus is the site of the compensatory shunt in pulmonic atresia. In this situation, the small ductus limits pulmonary blood flow.

Intracardiac Shunting and Air Emboli

Systemic air embolus is a constant danger in patients with CHD regardless of nominal left-to-right shunting patterns because anesthetic and surgical manipulations can dynamically alter shunts. Air traps are advisable for all intravenous (IV) lines but are not substitutes for meticulous attention and constant vigilance in the purging of air bubbles.

Systemic air emboli are a relative contraindication to use of nitrous oxide in patients with CHD. Right-to-left shunts may occur during some portions of the cardiac cycle or during straining or coughing in patients with open communications and nominal left-to-right shunts because normal transatrial pressure gradients are transiently reversed.[6–8] Right-to-left shunting may occur even across functionally "closed" communications. A "probe patent" foramen ovale is common in children (and adults) with and without CHD. Transient right-to-left shunting across such a foramen ovale has even been documented in a healthy child during emergence from anesthesia.[9] In many patients with CHD, direct shunting of microbubbles and macrobubbles of air into the systemic intracerebral arterial circulation from multiple IV lines and injections can be readily documented with transcranial Doppler (TCD). "Bubble-free" room temperature solutions may "rain out" bubbles at 37°C. The cerebral effects of such arterial air emboli have not been ascertained except in patients with massive cerebral arterial air emboli.

Severe Hypoxemia

Severe hypoxemia in patients with CHD results from inadequate pulmonary blood flow or defects that allow mixing as defined previously. Chronic hypoxemia requires adaptations to provide adequate tissue oxygen transport. Although moderate hypoxemia is well tolerated in neonates, hypox-

TABLE 52–2.

Simple Shunts (No Obstructive Lesions)

Restrictive Shunts (Small Communication)	Nonrestrictive Shunts (Large Communication)	Common Chambers (Complete Mixing)
Characteristics		
Large pressure gradient	Small pressure gradient	No pressure gradient
Direction and magnitude more independent	Direction and magnitude more dependent on PVR/SVR	Bidirectional shunting
Less subject to control	More subject to control	Net Qp/Qs totally dependent on PVR/SVR
Examples		
Small VSD, small PDA, Blalock shunts, small ASD	Large VSD, large PDA, large Waterston shunts	Single ventricle, truncus arteriosus, single atrium

ASD, Atrial septal defect; PDA, patent ductus arteriosis; PVR, pulmonary vascular resistance; Qp, pulmonary blood flow; Qs, systemic blood flow; SVR, systemic vascular resistance; VSD, ventricular septal defect.

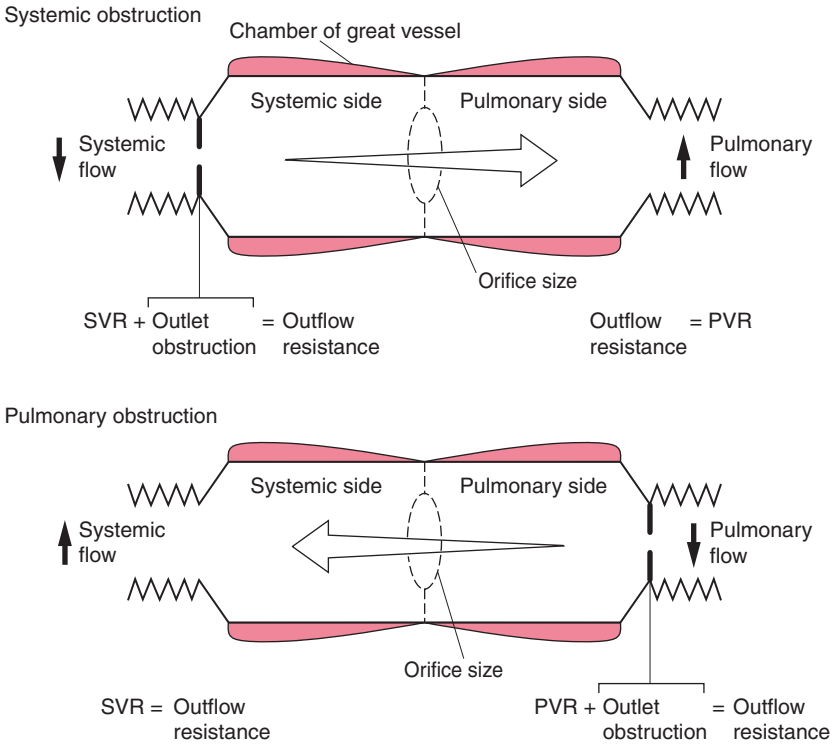

FIGURE 52–4. Determinants of complex shunting with systemic or pulmonary outflow obstruction. Orifice size again limits magnitude, but balance of outflow resistances include outlet obstruction on either side of the circulation in addition to systemic vascular resistance (SVR) or pulmonary vascular resistance (PVR). Addition of outlet obstruction increases flow on the opposite side and decreases flow on the same side. (Reprinted from Hickey PR, Wessel DL. Anesthesia for treatment of congenital heart disease. In Kaplan JA, ed. Cardiac Anesthesia. 2d ed. New York: Grune & Stratton, 1987, with permission from Elsevier.)

emia after infancy produces special problems, including polycythemia; increased blood volume; and vasodilatation, neovascularization, and alveolar hyperventilation with chronic respiratory alkalosis. Chronic hypoxemia and its accompanying adaptive mechanisms may limit cardiac reserve and oxygen delivery during the stress of anesthetic induction and surgery. Additionally, in such patients, the margin for error and tolerance for loss of airway is decreased.[10]

Polycythemia increases blood hematocrit and blood viscosity to dangerously high levels that cause vascular stasis and worsen tissue hypoxia.[11] Although an increased hematocrit improves blood oxygen carrying capacity, resultant increased blood viscosity decreases cardiac output when the hematocrit is >60%. Patients with polycythemia and cyanosis have increased risk for renal or cerebral thrombosis because of increased viscosity, particularly if they become dehydrated.[12] Hematocrits >70% generally are associated with increased risk of cerebrovascular accidents and coagulopathies. These patients may have a history of cerebrovascular accidents and sometimes already have residual neurologic deficits. They require IV hydration starting on the evening before anesthesia and also postoperatively until oral intake is adequate. Some patients may benefit from erythropheresis before surgery if hematocrits are >60–70%. Polycythemic CHD patients also have coagulopathies in part because of decreased levels of platelets and fibrinogen.[13] These coagulopathies increase the risk of excess intraoperative bleeding, and appropriate arrangements should be made for intraoperative transfusion of clotting factors when necessary.

Patients with severe hypoxemia caused by intracardiac shunting generally undergo anesthesia for procedures designed to improve their pulmonary blood flow and SaO_2. Induction of anesthesia itself using a variety of techniques markedly increases arterial saturation.[14,15] This induction-related increase in arterial saturation probably results from greater systemic venous oxygen saturation caused by greater inspired oxygen concentrations plus decreased oxygen consumption with induction of anesthesia and muscle paralysis.[16,17] Systemic venous blood with a greater oxygen saturation is shunted into the systemic circulation, decreasing the degree of hypoxemia seen. Thus, induction of anesthesia itself may be therapeutic for patients with CHD with severe hypoxemia and sometimes can be used to temporize until correction or palliation can be accomplished surgically.

TABLE 52–3.

Complex Shunts (Shunt and Obstructive Lesions)

Partial Outflow Obstruction	Total Outflow Obstruction
Characteristics	
Shunt magnitude and direction largely fixed by obstruction	Shunt magnitude and direction totally fixed
Shunt depends less on PVR/SVR	All flow goes through shunt
Orifice and obstruction determine pressure gradient	Pressure gradient depends on orifice
Examples	
Tetralogy of Fallot, VSD and pulmonic stenosis, VSD with coarctation	Tricuspid atresia, mitral atresia, pulmonary atresia, aortic atresia

PVR, Pulmonary vascular resistance; SVR, systemic vascular resistance; VSD, ventricular septal defect.

Excessive Pulmonary Blood Flow

Excessive pulmonary blood flow is common in patients with CHD and produces cardiac and pulmonary complications. Volume overload always compromises cardiac reserve regardless of the presence of frank congestive heart failure. Increased pulmonary artery (PA) pressure and blood flow can limit gas exchange by several mechanisms. Compression of large

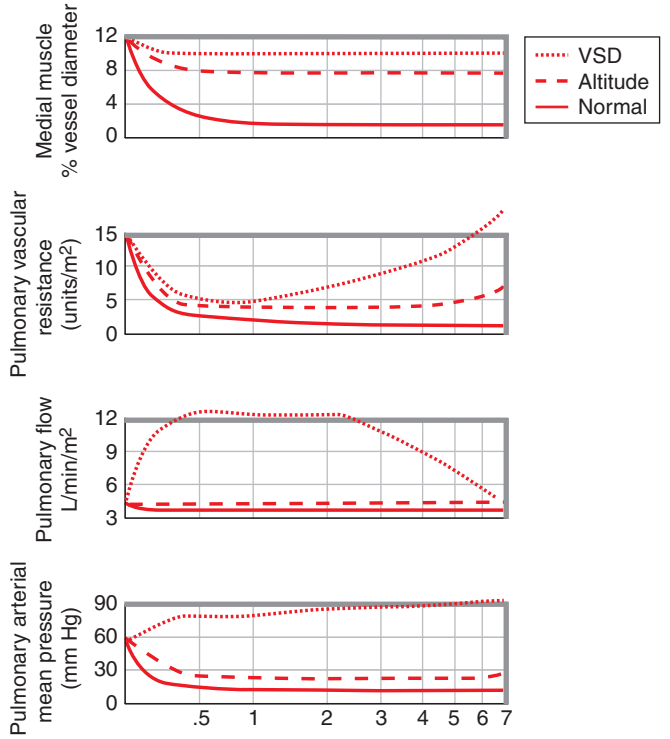

FIGURE 52–5. Normal and abnormal developmental changes in pulmonary arterial tree during the first years of life. Pulmonary vascular resistance, percent of arterial smooth muscle, and pressure normally decrease in the first year of life. A large, nonrestrictive ventricular septal defect with a large left-to-right shunt results in an immediate increase in flow and a later increase in vascular resistance.[5]

bronchi by distended pulmonary vessels may obstruct large and small airways and increase the work of breathing. The increased pulmonary venous return distends the left atrium and may obstruct the left main stem bronchus. Most important, increased pulmonary blood flow and pressure combine with elevated left atrial pressure to produce pulmonary venous congestion and increased interstitial and alveolar lung water. Resultant lung compliance deterioration and increased airway resistance can produce tachypnea and sometimes wheezing. Regions of the lung with atelectasis and intrapulmonary shunt then contribute to systemic arterial desaturation, even in a child with "acyanotic" heart disease and left-to-right shunting.

PVOD is produced by prolonged high pulmonary flows and pressures. The anatomic lesion is hypertrophy of the medial layer of pulmonary arteries and intimal thickening, with resultant increased PVR and reactivity.[18,19] Fig. 52–5 shows normal progression of pulmonary flows, pressures, and vascular resistance during early childhood and alterations in the normal progression with a large VSD. Fig. 52–6 indicates normal evolution of pulmonary arteries during infancy and alteration caused by high pulmonary flows and pressures resulting from left-to-right shunting through a VSD. Smaller pulmonary arteries are anatomic substrates of increased pulmonary vascular reactivity and high PVR seen in patients with PVOD. When PVR eventually equals or exceeds SVR, a left-to-right shunt then becomes a right-to-left shunt (Eisenmenger syndrome). PVOD can occur during the first year of life in patients with some lesions, such as an atrioventricular canal, but may require decades to develop in patients with atrial septal defects (ASDs).[20,21] Depending on the severity and duration of these changes, correction of the underlying lesion may result in varying degrees of reversal of pulmonary vascular changes and decreases in pulmonary hypertension.

In neonates with a widely PDA and a single source of blood supply to the systemic and pulmonary circulations, pulmonary blood flow may become particularly excessive intraoperatively. This is signaled by high systemic arterial saturations (>90%) in these mixing types of pathophysiologic conditions. It occurs in patients with lesions, such as truncus arteriosus or hypoplastic left heart syndrome (HLHS), and results in acute congestive heart failure with ventricular enlargement, low systemic output, high SaO_2, and hypotension. This can produce myocardial ischemia in neonates.[22] The myocardial ischemia seen in this situation can be remedied only by acutely increasing PVR by placing a tourniquet on one of the branch pulmonary arteries or by applying a partially occluding PA clamp. These maneuvers mechanically increase PVR, decrease the excessive pulmonary blood flow and arterial saturation, increase systemic (coronary) perfusion pressure, and decrease cardiac volume load and reduce ventricular diameter. In patients with CHD with tendencies toward excessive pulmonary blood flow and only mild hypoxemia, anesthetic management is planned to avoid major decreases in PVR because such decreases exacerbate the increased pulmonary flow and lead to cardiovascular decompensation.

Congestive Heart Failure

The child with CHD develops congestive heart failure because of increased pressure, volume, or combined pressure and volume loads. Increased volume loads can result from intracardiac shunting or valvular insufficiency. Increased pressure loads can result from valvular obstruction, stenosis of major systemic or pulmonary arteries, or diffuse PVOD. Patients compensate by well-known mechanisms. Increased catecholamine production redistributes cardiac output to favored organs, increases heart rate, decreases skin temperature, and frequently induces a catabolic nutritional state.[23] Pulmonary congestion increases the work of breathing and caloric demand, whereas tachypnea limits intake of calories. Derangements vary with severity of congestive heart failure. In the severe cases, growth is retarded, and body weight is well below the third percentile for age. These patients often are tachypneic, tachycardic, and dusky in room air and may have chest wall retractions, expiratory wheezes, and diffuse rhonchi. Capillary refill may be prolonged and extremities cool to the touch, with palpable hepatomegaly. Preoperative chest radiographs demonstrate cardiac enlargement and increased pulmonary vascular markings with areas of atelectasis despite hyperexpansion of

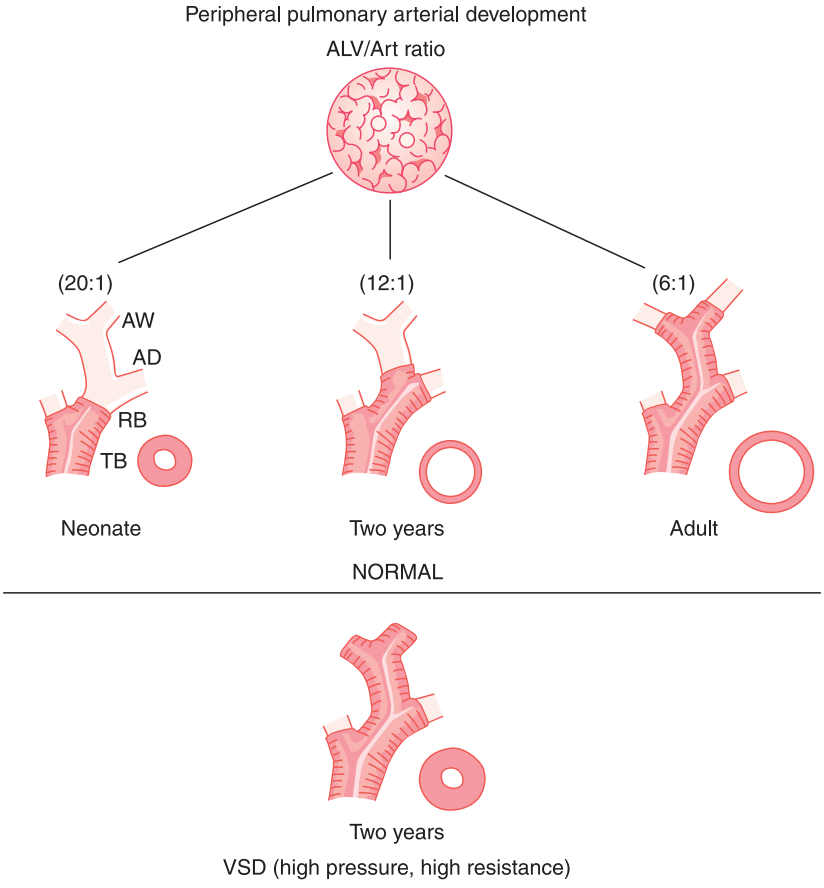

FIGURE 52–6. Developmental changes in peripheral pulmonary arterial tree in normal patients and in the presence of a ventricular septal defect (VSD) with a large left-to-right shunt. Alveolar-to-arteriolar (ALV/Art) ratio decreases with age because of extensive arborization of arterial tree as arteriolar lumen increases and muscle layer thins and spreads distally. Pulmonary hypertension with high flow from left-to-right shunt in a VSD causes pulmonary vascular obstructive disease marked by decreased numbers of pulmonary arterioles (ALV/Art = 25:1), decrease in vessel lumen, increase in muscle thickness, and more distal spread of muscle. Letters indicate arteriole from level of the terminal bronchiolus (TB) to the alveolar wall (AW).[5,19]

the lungs. In severe cases, medical management consisting of administration of digoxin and diuretics is indicated before surgery, which may induce a profound metabolic hypochloremic alkalosis with potassium depletion.

Other children with lesser degrees of congestive heart failure caused by CHD may be only mildly symptomatic but still have substantially decreased cardiovascular reserves. The additional stress of anesthesia and surgery may result in cardiac decompensation, particularly when compensation depends on maximal sympathetic tone. Reversibility of ventricular dysfunction accompanying congestive heart failure in those with CHD varies depending on the severity of the defect, degree of correction, and duration of ventricular dysfunction.

Prolonged congestive heart failure and attendant ventricular dysfunction result in cardiomegaly and ventricular hypertrophy. The amount and location of cardiomegaly or hypertrophy occurring depends on the combination of cardiac pressure and volume loads and intracardiac anatomy. Long-standing cardiomegaly and hypertrophy jeopardize the myocardium in children, particularly in those with chronic hypoxemia. In the young, growing heart, pressure-overload hypertrophy appears to occur in association with myocardial angiogenesis rather than with diminished myocardial capillary density as occurs in adults.[24] Despite the former compensatory mechanism, microscopic areas of myocardial infarction eventually appear in young hearts subjected to chronic overload, particularly in those with chronic hypoxemia.[25] This results in progressive ventricular dysfunction in the affected ventricle, as working muscle mass is depleted and is replaced by fibrous tissue. Some ventricular dysfunction may be reversible, depending on timing of correction of the underlying defect. For example, VSDs and tetralogy of Fallot defects repaired during early infancy before myocardial damage occurs subsequently have better ventricular function than those repaired later in childhood.[26–30]

In patients with any degree of congestive heart failure, anesthetic treatment is planned to avoid large doses of myocardial depressants and alterations of PVR or SVR that exacerbate cardiac failure. The detrimental alterations depend on individual pathophysiology findings. In patients with severe congestive heart failure or in those with detrimental alterations in pathophysiologic conditions that cannot be avoided, appropriate pressor and inotropic support are included in the anesthetic plan.

Obstructions to Systemic Blood Flow

Congenital lesions producing obstruction to left heart outflow include interruption of the aortic arch, coarctation of the aorta, aortic stenosis (subvalvar, valvar, or supravalvar), mitral stenosis and atresia, and HLHS. These patients may have left ventricular hypertrophy, coronary ischemia, and limited systemic ventricular reserve. Systemic perfusion in neonates with these problems often depends on a PDA that may be rapidly narrowing. Such infants usually present with shock and metabolic acidosis, requiring resuscitation with prostaglandin E_1 (PGE_1) preoperatively. Ventricular fibrillation is a distinct risk. Older children with less severe forms of stenosis often are asymptomatic, with only mild hypertension in coarctation of the aorta or mild aortic stenosis. They may have dysrhythmias, syncope, fatigue, or chest pain in various forms of aortic stenosis.

Obstructions to Pulmonary Blood Flow

Pulmonary flow obstructions occur at many levels in the right side of the circulation. Right ventricular hypertension, pulmonary hypertension, and hypoxemia may result, depending on the location of obstructions and the presence of intracardiac shunting. Combinations of these problems are seen in pulmonary valve and subvalvular stenosis, PA stenosis, PVOD, tetralogy of Fallot, and pulmonary atresia. High levels of right ventricular after-

load result in a hypertensive, hypertrophied right ventricle that is prone to myocardial ischemia. As right ventricular intracavitary pressures approach and then exceed systemic arterial pressures, coronary perfusion pressures become inadequate, and right ventricular failure results from myocardial ischemia. Acute therapy is aimed at increasing systemic arterial pressure with α-adrenergic agents, such as phenylephrine, to improve coronary perfusion of the right ventricle.[31] Lowering of PVR also is beneficial if it can be accomplished without decreasing systemic (coronary) perfusion pressure.

Patients with right ventricular hypertension resulting from outflow obstruction or obstruction of the larger pulmonary vessels can be effectively treated with balloon dilation in the cardiac catheterization laboratory or with a surgical procedure. Unilateral or segmental pulmonary edema requiring management may be seen after such procedures. When PVR at the small vessel level is markedly elevated and irreversible, as in patients with end-stage PVOD, therapy frequently is ineffective. Patients with a markedly hypertensive pulmonary circulation of any duration have cor pulmonale or dysrhythmias and are prone to sudden, poorly understood increases in PVR. Such pulmonary hypertensive crises may occur without warning, resulting in refractory acute right ventricular failure and sometimes in death. When systemic levels of pulmonary arterial pressure are encountered in the operating room, despite corrective procedures, every effort should be made to correct this problem because of the associated high risks of sudden decompensation and death.

Coronary Ischemia

Although acquired coronary artery disease is rare in children with CHD, except in those with transplanted hearts, coronary ischemia may occur with left heart outflow obstruction, surgical retraction, "pulmonary steal" in neonates with a single source of pulmonary and systemic flows, or anomalous coronary arteries arising from the PA. In neonates with truncus arteriosus, intraoperative decreases in PVR can lead to decreased systemic flow and diastolic pressure, which produces ST-segment changes indicative of acute myocardial ischemia.

Maneuvers to decrease pulmonary flow, such as temporarily ligating the left or right PA, can increase diastolic pressure and reverse the ischemia and ST-segment changes seen on electrocardiography (ECG).[22] In anomalous coronary arteries, retrograde flow into the PA occurs via anastomotic connection with normal coronary arteries (i.e., those with aortic origin) when flow is "stolen" from the high-pressure origin and diverted to the low-pressure pulmonary circulation. Myocardial infarcts and ventricular dysfunction can result. These problems may be preventable or reversible if the anomalous coronary arteries are detected and corrected early in life.

Rarely, patients have aberrant sinusoidal coronary arteries originating directly from the right ventricular cavity. These arteries provide nutrient, antegrade (albeit hypoxemic) flow into the coronary bed as long as high (systemic) pressures are maintained in the right ventricle. Any intervention that substantially decreases right ventricular intracavitary pressure results in intractable and even fatal coronary ischemia. When perfusion pressure decreases, flow from these vessels becomes retrograde into the right ventricular cavity as flow is "stolen" from adjacent, communicating systemic coronary arterial beds.

Immaturity of Circulation

Transitional Circulation

Transitional circulation consists of a PDA, patent foramen ovale, and high PVR, as shown schematically in Fig. 52–7. In neonates with severe, life-threatening CHD, the transitional circulation plays a major role in maintaining viability because its persistence is required to sustain functional circulation until therapeutic interventions can be undertaken. Particularly important in maintaining an intact circulation is patency of the ductus arteriosus. Before anatomic (as opposed to physiologic) closure occurs at several weeks of age in the normal sequence, the ductus may remain open in response to hypoxemia or PGE_1 infusion.[32,33] Reopening of the ductus has been documented in infants older than 7 days in whom the ductus has been kept open with PGE_1 infusions for many weeks when necessary.[34,35]

The PDA plays a critical role in maintaining life by providing either systemic or pulmonary blood flow in neonates with severe congenital heart lesions (Box 52–1). Acute decompensation occurs in these infants when the ductus closes. When systemic and coronary perfusion depend on a PDA, closure results in reduction of systemic flow, coronary insufficiency, rapidly progressive metabolic acidosis, and death.[36] When pulmonary flow depends on a patent ductus, closure results in acute reduction of pulmonary flow, progressive hypoxemia, and death.[37] In neonates with ductus-dependent lesions who decompensate after closure, therapy with PGE_1 infusion for 24–48 hours provides effective resuscitation and correction of metabolic deficits.[38] Side effects of PGE_1 infusion include apnea and vasodilatation; many neonates receiving PGE_1 infusions need intubation and ventilatory support and supplementation of intravascular volume.[39]

High PVR in the transitional circulation is particularly important when the congenital defect has only a single, nonrestrictive source of pulmonary and systemic blood flow, as in truncus arteriosus, HLHS, or pulmonary atresia. When the ductus arteriosus is kept widely patent with PGE_1 or when no ductus is involved (truncus arteriosus), decreases in high PVR from the immediate postnatal levels produce "pulmonary steal" of systemic blood flow and low diastolic blood pressure. This leads to systemic hypoperfusion, coronary ischemia, and progressive metabolic acidosis despite good SaO_2.[40,41]

The Immature Heart

At birth, the immature heart is markedly different from the mature heart. Right and left ventricles have approximately equal size and wall thickness; the right ventricle is slightly heavier.[42] The increased afterload on the left and decreased afterload on the right, occurring with birth, lead to progressive thickening of the left ventricular wall. By 4 weeks of age, the left ventricle weighs more than the right ventricle.[43] By 3 or 4 years of age, the left ventricle is approximately twice as heavy as the right, the normal adult relationship. These changes are accompanied by myocyte ultrastructural development. Small immature myocytes with chaotically arranged myofibrils accounting for 30% of gross muscle mass evolve into larger mature myocytes with organized, longitudinally oriented myofibrils that make up 60% of muscle mass.[44,45] The larger mass of noncontractile elements in immature myo-

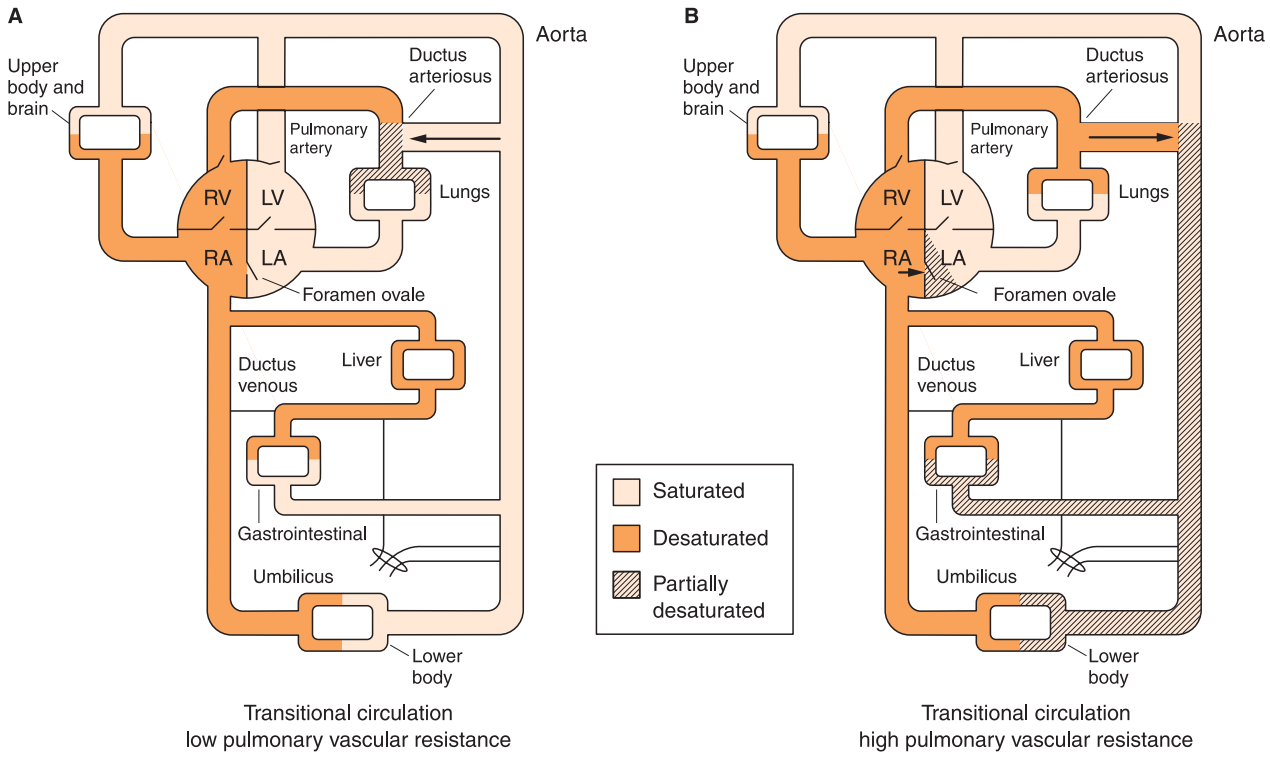

FIGURE 52–7. Schematic diagram of central shunting and blood saturations that occur normally in the transitional circulation in the first few hours and days after birth. **A.** In the first few hours, the foramen ovale is widely patent and pulmonary vascular resistance is high, leading to right-to-left shunting. **B.** Later stage of transitional circulation when pulmonary vascular resistance decreases and the ductus remains patent, resulting in left-to-right shunting. Foramen ovale is functionally closed. (Reprinted from Hickey PR, Crone RK. Cardiovascular physiology and pharmacology in children. In Ryan JR, Todres PS, Coté C, et al., eds. A Practice of Anesthesia for Infants and Children. New York: Grune & Stratton, 1986, with permission from Elsevier.)

cytes results in noncompliant cells with diminished contractile capacity. Myocardial contractility and compliance increase with development; immature myocardium develops less force during contraction than does adult myocardium, and velocity and magnitude of shortening also are less in immature myocytes.[45,46]

Other changes include development of the transverse tubular system, essentially absent in the neonatal heart, and development of sarcoplasmic reticulum, increasing its capacity to store and release calcium.[47,48] Contractile proteins, namely, myosin, tropomyosin, and troponin T, required for myocardial contraction also change their isoforms during this period.[49] These changes, taken together, may explain increased sensitivity to inhalational anesthetics seen in the immature heart.[50–53] Ultrastructural changes occurring in maturing myocytes result in improved myocardial function, but until myocytes fully mature, cardiac reserve is limited. This should be appreciated in anesthetic treatment of infants with CHD, who have additional sources of decreased cardiac reserve in addition to immaturity. Despite these factors, immaturity confers some "advantage" for cardiac function during hemodynamic stress because during acidosis contractile function is less affected[54,55] and intracellular myocardial pH is better maintained.[46]

Functional capacities of the immature heart are well defined. The immature, noncompliant ventricle is highly sensitive to increases in filling volume and is relatively restricted in its ability to respond with increased stroke volume. Although stroke volume improves with increased filling pressure, the range over which this occurs is narrow. The Starling curve is reached at filling pressures of 4 mm Hg, and stroke volume actually decreases at filling pressures near 7 mm Hg.[56] This Starling plateau may be a result of increased afterload effects as mean arterial pressure increases with increased preload.[57] The immature ventricle is highly sensitive to increased afterload. With constant afterload, stroke volume improves with progressive increases in left atrial pressure from 5–10 mm Hg. Because the immature heart is noncompliant, small increases in intravascular volume rapidly increase filling pressures to the plateau of the Starling curve where stroke volume is fixed. At the level of filling pressure where stroke volume is fixed, cardiac output becomes rate dependent. Additional increases in volume push filling pressures to the descending portion of the curve, and the ventricle begins to fail. Although the Starling curve of the neonate is clearly shifted to the left compared with the curve of older children and adults, it still does apply.[58,59] Be-

BOX 52–1.

Ductus-Dependent Neonatal Congenital Heart Defects

PDA Provides Systemic Flow
- Critical coarctation of the aorta
- Interrupted aortic arch
- Hypoplastic left heart syndrome
- Critical aortic stenosis

PDA Provides Pulmonary Flow
- Pulmonary atresia
- Critical pulmonic stenosis
- Severe subpulmonic stenosis with ventricular septal defect
- Tricuspid atresia with pulmonic stenosis

PDA, Patent ductus arteriosus.

cause of this, cardiac output is not entirely rate dependent at lesser filling pressures and rates within neonatal physiologic range. Increases or decreases in heart rate within physiologic ranges result in changes in stroke volume without major changes in cardiac output in the term human fetus and in the lamb.[60,61] It is only when the plateau of the Starling curve is reached that the immature heart becomes truly rate dependent.

Reduced compliance and similarity in size and wall thickness of the ventricles during the first month lead to an intimate interrelationship between right and left ventricular function.[58] Failure of one immature ventricle quickly causes septal shift, and, in contrast to adults, congestive heart failure quickly becomes biventricular. This has important implications for ventilatory management, namely, the fact that inadequate ventilation in infants rapidly leads to increased right ventricular afterload and biventricular failure because of the muscular, hyperreactive pulmonary circulation. This also applies to small infants with CHD. As a result of the poor tolerance of the immature heart for increased afterload, right ventricular failure of some degree may result, which, in turn, rapidly compromises function of the left ventricle. Thus, adequacy of ventilation in the infant frequently determines cardiac function even if severe hypoxemia has not yet occurred.

In summary, functional capacity of the immature infant heart and cardiac reserve improve with age. Increasing preload or afterload results in ventricular failure sooner in neonates and infants than in adults, and failure quickly becomes biventricular. By 3 or 4 years of age, adult levels of systemic arterial pressure and PVR are achieved, and the previously mentioned functional limitations probably no longer apply. Additional stresses and loads placed on the immature heart by various forms of CHD further reduce cardiac reserves in infants, thus reducing their already compromised ability to deal with the stresses of anesthesia and surgery.

Combined Problems

Combinations of the previously mentioned problems are found in many patients with CHD. Excessive flows caused by intracardiac shunting and flow obstruction often lead to congestive heart failure. In older children with long-standing complex lesions that cannot be readily corrected, ventricular function may gradually deteriorate because of long-standing ventricular pressure or volume overload. Chronic volume loading is seen in those with aortic or mitral valve regurgitation or in patients with long-standing pulmonary-to-systemic arterial shunts. The latter patients may have only mild-to-moderate hypoxemia despite complete mixing when there is a large shunt and excessive pulmonary blood flow.

The price paid for near-normal levels of SaO_2 is chronic ventricular dilation and potential development of PVOD. These patients may have combined problems of hypoxemia and mild cyanosis, some degree of PVOD, and left ventricular dilation with progressively decreasing ejection fractions.

In infants and especially neonates, problems of transitional circulation and limited functional capacity of the immature heart are invariably added to physiologic problems created by the CHD itself. Because the most severe forms of CHD generally are present in neonates, such congenital heart problems are complicated by physiologic limitations of the immature heart and lungs.

In patients with complex congenital disease in whom a number of previously discussed problems are present, assessment should be directed at myocardial performance and reserve, quantification of pulmonary blood flow, degree of cyanosis, and evaluation of PVR. For example, a patient with a long-standing Waterston shunt who is only mildly cyanotic but easily fatigued and who has a heaving precordium with bounding pulses may be expected to have a high normal hematocrit with oxygen saturation in the upper 80s. Pulmonary blood flow is torrential, and PVR is elevated. This patient may not be a candidate for reparative cardiac procedures because of high (and irreversible) PVR resulting from progressive PVOD.

INTRAOPERATIVE PROBLEMS FROM SPECIFIC PROCEDURES OR TECHNIQUES

Complex intracardiac anatomy, incomplete or misdiagnosis of specific lesions, limitations of currently available procedures, and technical errors combine to result in hemodynamic problems in an appreciable fraction of patients who require surgical or transcatheter treatment of CHD. These problems often present as hemodynamic instability, low cardiac output, or hypoxemia in the operating room or in the catheterization laboratory immediately after the cardiac repair or later in the intensive care unit. Causes may not be readily apparent and may require intraoperative pressure measurements, intraoperative or postoperative echocardiography, and sometimes early postoperative cardiac catheterization before the cause is clearly established and before therapy can be properly directed.

Specific Surgical Procedures

The anesthesia care team should deal with *intraoperative problems* until their causes are discovered and corrected. Primary pump failure is only infrequently the cause of difficulties seen in this setting. In the majority of patients, a specific mechanical problem in the circulation system is responsible. Table 52–4 lists the incidence of different problems commonly seen with specific surgical procedures.

Excessive Pulmonary Flow

In addition to its occurrence in lesions described previously, excessive pulmonary flow may be a result of operative procedures. A surgically created aortopulmonary shunt, such as a Blalock-Taussig shunt, can be too large, with excessive pulmonary blood flow and low systemic cardiac output. Residual intracardiac left-to-right shunt can produce excessive pulmonary blood flow as a result of incomplete repair or undiagnosed and unsuspected defect. Increased volume load may result in low cardiac output in a heart that has been injured by a period of hypothermic ischemia with cross-clamping during CPB. Measures designed to increase PVR and to provide inotropic support improve the hemodynamic condition temporarily until a specific diagnosis can be made and residual problems corrected (Box 52–2).

Excessive pulmonary flow can result from failure to ligate an aortopulmonary shunt (e.g., PDA or Blalock-Taussig shunt). In some patients, an extensive series of large and small native aortopulmonary collateral vessels from the descending aorta, bronchial arteries, and vertebral arterial system can produce excessive pulmonary flow postoperatively. In the ab-

sence of a few large collaterals that can be easily approached and ligated surgically, this problem is best approached preoperatively or postoperatively in the catheterization laboratory where multiple small vessels can be embolized. Until interruption of collateral supply is accomplished, inotropic support often is needed. Presence of such collaterals can jeopardize cerebral blood flow during CPB, particularly when the pulmonary collaterals originate from vessels also supplying the head. This problem is more likely when α-stat acid–base management is used for hypothermic bypass and low $Paco_2$ levels dilate the pulmonary circulation while constricting the cerebral circulation.

BOX 52–2.

Anesthetic Management of Excessive Pulmonary Blood Flow

Signs
- High arterial saturations in mixing physiology
- Oxygen saturation step-up from right atrium to pulmonary artery
- Elevated pulmonary artery pressures

Therapeutic Maneuvers
- Low fraction of inspired oxygen
- Normocapnia or mild hypercapnia
- Positive end-expiratory pressure
- Mechanical restriction of pulmonary flow (clamp or band)
- Inotropic and pressor support
- Ligation or coil embolization of aortopulmonary shunts and collaterals

Inadequate Pulmonary Flow

Inadequate pulmonary flow occurs in association with surgically created aortopulmonary shunts, such as the Blalock shunt, that are too small, are clotted, or have partially obstructed anastomoses. These patients may become hypoxemic (SaO_2 <70%) immediately after opening the newly constructed shunt after an existing source of pulmonary blood, such as PDA, is ligated. The degree of hypoxemia may not be appreciated until reversal of muscle paralysis and emergence from anesthesia. Increases in oxygen consumption and resultant decreases in mixed venous oxygen saturation accompanying these events can result in substantial decreases in SaO_2 when pulmonary flow through the shunt is marginal. Anesthesia, hypothermia, and paralysis using muscle relaxants improve the situation temporarily until increased shunt flow can be established. PA banding procedures can produce similar results. Inadequate flow and increased right ventricular afterload resulting from excessive tightening usually is immediately apparent as progressive hypoxemia, right ventricular dilation, hypotension, and bradycardia. This is acute right ventricular failure and is managed by immediate loosening of the band.

Inadequate pulmonary flow may occur after a Fontan procedure. This procedure is used when there is no pulmonary ventricle to pump blood through the lungs; pulmonary blood flow depends on a gradient between central venous pressure (CVP) and left atrial pressure. Moderate elevations in PVR resulting from CPB and associated events or mechanical obstruction to blood flow in the Fontan pathway can severely restrict pulmonary flow, resulting in inadequate left heart filling. Low cardiac output is seen with high CVP (>17–20 mm Hg). These patients generally are not hypoxemic. Inotropic support, "pulmonary" vasodilators, and other manipulations to decrease PVR (Box 52–3) are only temporizing measures. Urgent reparations are needed to avoid progressive low cardiac output,

BOX 52–3.

Anesthetic Management of Inadequate Pulmonary Blood Flow

Signs
- Arterial oxygen saturation <75%
- Right atrial pressure >15–17 mm Hg (Fontan)

Therapeutic Maneuvers
- 100% O_2
- Increased systemic perfusion pressure with pressors
- Hypocapnia to $Paco_2$ <25 mm Hg with hyperventilation and alkalinization
- Maintenance of normal functional residual capacity (avoiding hyperexpansion or atelectasis of lungs)
- Trial of positive end-expiratory pressure (low levels 3–7 cm H_2O)
- Reduce oxygen consumption (anesthesia, paralysis, hypothermia)
- Drainage of pleural and peritoneal cavities
- Trial of pulmonary vasodilators, including nitric oxide

BOX 52–4.

Anesthetic Management of Left Heart Outflow Obstruction

- Signs
  - Large inotropic requirement
  - Low cardiac output
  - High left atrial pressure
- Therapeutic Maneuvers
  - High left atrial filling pressures
  - Maintenance of high coronary perfusion pressures
  - Minimization of right ventricular afterload
  - Inotropic and pressor support

multiorgan dysfunction, and death. When fenestrated Fontan procedures are done, shunting through the fenestration maintains cardiac output even when PVR is high; cardiac output is maintained, but hypoxemia results from low pulmonary blood flow. With the fenestrated Fontan, the cardiac output is better maintained, and tolerance for transient increases as PVR improves.

Intracardiac Shunting

Intracardiac shunting occurs intentionally in surgical procedures, such as creation of aortopulmonary shunts and PA bands, because in these palliative procedures no attempt is made to completely correct the anatomy. Residual intracardiac shunting also occurs unintentionally. Residual defects may remain because of inadequacies in the surgical repair or because of undiagnosed additional defects. Whenever an intracardiac patch or baffle is placed, there is potential for residual intracardiac shunting. Such residual shunting usually produces either excessive or insufficient pulmonary blood flow, depending on individual pathophysiology. It is handled by manipulating SVR/PVR to minimize detrimental effects.

Obstruction to Left Heart Outflow or Inflow

When complex reconstructions of the ventricular septum are performed inside the heart near the left ventricular outflow tract, subaortic obstructions to flow may be created, which result in low cardiac output and persistent, large inotropic requirement. This problem should be suspected because of the combination of hemodynamic instability and a complex VSD repair in the subaortic region. Diagnosis can be made using pullback pressure measurements from the left ventricle to the aortic root and by intraoperative echocardiography. Supportive measures, including inotropic support (Box 52–4), in these patients are no substitute for correction of outflow obstruction.

In other ventricular septal repairs, large degrees of obstruction to right heart outflow producing suprasystemic right ventricular pressures may cause bowing and shift of the intraventricular septum into the left ventricular outflow tract and even obstruction. The obstruction to right ventricular outflow should be corrected and usually greatly improves left heart function. Again, inotropic support is only a temporizing measure.

Obstruction to left heart inflow (i.e., pulmonary venous return) may occur with atrial baffle repairs of transposition of the great arteries (Mustard or Senning repair) or occasionally with repair of total anomalous pulmonary venous return. This condition presents as low cardiac output; pulmonary hypertension, and severe, poorly tolerated pulmonary edema. Immediate relief of the pulmonary venous obstruction is indicated.

Obstruction to Right Heart Outflow or Inflow

This occurs most frequently in tetralogy of Fallot repair or other repairs of pulmonic stenosis and PA hypoplasia. Inadequate relief of pulmonary stenosis leads to right ventricular hypertension and often some degree of right heart failure, which may not be tolerated. In the immature heart, right ventricular failure is always accompanied by some degree of left ventricular dysfunction. Moderate outflow obstruction usually does not cause severe problems but often requires inotropic support intraoperatively and postoperatively. Measures used in these situations are outlined in Box 52–5.

Obstruction to right heart inflow occasionally occurs with complex intraatrial baffle repairs of transposition of the great arteries (Mustard or Senning repair). Most common is superior vena cava obstruction, intraoperatively seen as low cardiac output and immediately apparent when surgical drapes are removed and severe head and upper body edema and venous stasis are apparent. Similar problems with inferior vena cava obstruction occur less frequently during Mustard and Senning repairs. These repairs are now infrequently performed because of the superiority of great vessel switch procedures for transposition repairs.

BOX 52–5.

Anesthetic Management of Right Heart Outflow Obstruction

- Signs
  - Inotropic requirement
  - Low cardiac output
  - High right atrial and right ventricular pressures
- Therapeutic Maneuvers
  - Maintenance of high right atrial filling pressures
  - Maintenance of high coronary perfusion pressures
  - Minimization of pulmonary vascular resistance
  - Inotropic support

Coronary Ischemia

Coronary ischemia associated with congenital heart procedures usually has iatrogenic origins. The "switch" operation for transposition of the great arteries entails relocation of the coronary arteries in small infants from the right ventricular outflow tract to the left ventricular outflow tract. Technical errors in transplantation of these small coronary arteries may result in stenosis from excessive tension, anastomotic obstruction, or torsion of transplanted coronary arteries. Coronary ischemia may develop intraoperatively or later. It most often is apparent as ventricular failure and low cardiac output.

In other types of repairs in which dissection and retraction around the aortic root are performed, compression, inadvertent suture ligation, and inadvertent transection of coronary arteries can occur. These events may first be signaled by ST-T wave ECG changes. It is important to continuously monitor two ECG leads in congenital heart surgery, preferably leads II and V_5 or V_6. When ischemia is seen, the measures outlined in Box 52–6 are useful until the cause is found and corrected.

The most frequent type of coronary ischemia seen is simply that associated with inadequate coronary perfusion pressures when weaning from bypass. Even in children with normal coronary arteries, stress of high afterload, dilated ventricles, and tachycardia can result in coronary ischemia, particularly during hypotension. Such ischemia usually is easily managed by increasing systemic arterial pressure using a vasopressor or by increasing CPB flow pump output, slowing heart rate, and

BOX 52–6.

Anesthetic Management of Coronary Ischemia in Congestive Heart Disease

Signs
- ST-T segment changes in electrocardiographic lead II or V_5
- Cyanotic demarcation of epicardial coronary distribution
- Dyskinetic regional myocardial wall motion
- Low cardiac output

Therapeutic Maneuvers
- Checking of surgical retraction
- High coronary perfusion pressures
- Minimization of ventricular distension and heart rate
- Nitroglycerin rarely useful
- Inotropic and pressure support

correcting overdistension of the ventricle. Nitroglycerine is rarely useful because of the etiology of most coronary ischemia in patients with CHD.

Dysrhythmias

Most dysrhythmias seen in patients with CHD are iatrogenic and are related to mechanical or ischemic injury to conduction pathways. Anesthetics can alter or exacerbate existing dysrhythmias but are rarely solely responsible for dysrhythmias seen during cardiac procedures.[62] These dysrhythmias limit cardiovascular reserve and increase operative risk. Some patients with CHD may be receiving antiarrhythmic drugs or have implanted pacemakers. Particular attention should be paid to the patient's intrinsic rate and rhythm plus characteristics of pacemaker function. In patients with surgically induced complete heart block, immediate temporary pacing generally is required. If atrioventricular conduction has not returned in 10 days, permanent pacing is needed because atrioventricular conduction rarely returns after this time.[63]

In patients with CHD and permanent pacemakers undergoing cardiac surgical procedures, asystole often results if pacemaker failure occurs. Although setting the pacemaker to asynchronous mode protects against interference from inappropriate sensing caused by electrocautery, cautery use occasionally has caused complete pacemaker failure in patients with CHD through actual "burnout" of the pacemaker generator from current induced in the pacer lead by high-frequency electrocautery currents. External pacing capabilities or pacing via a temporary wire may be needed. Alternatively, a bipolar cautery can be used until the pacemaker generator is removed. Bipolar cautery does not interfere with normal pacemaker function or damage pacemaker generator circuits, unlike the radiofrequency currents used by electrocautery.

In patients whose conduction systems have been injured intraoperatively and whose cardiac output is marginal after surgery, synchronous atrioventricular pacing may be useful to increase cardiac output. Ventricular extrasystoles are unusual in children with CHD and usually indicate myocardial damage. They are managed conventionally with normalization of electrolytes and acid–base balance, overdrive pacing, and antidysrhythmic agents.

Low Cardiac Output

Low cardiac output is the final common pathway and expression of multiple problems associated with surgical treatment of patients with CHD. Supportive management with inotropic and pressor agents, replacement of intravascular volume, pacing, and other measures should be considered as only temporary therapy for support until the cause can be accurately diagnosed and corrected (Box 52–7). Primary myocardial injury and pump failure should be a diagnosis of last resort. All other possible residual or undiagnosed and correctable lesions should be sought before this diagnosis is accepted. When all other possibilities have been excluded and when a reversible lesion such as myocardial "stunning" or reversible pulmonary hypertension is diagnosed, maximal medical and ventilatory support is instituted. In extreme cases, extracorporeal membrane oxygenation (ECMO) and ventricular assist devices (VADs) have been successfully used for temporary circulatory and ventilatory support.[64]

BOX 52–7.

Anesthetic Management of Low Cardiac Output

Signs
- High filling pressures
- Poor ventricular function
- Progressive metabolic acidosis
- Low urine output

Therapeutic Maneuvers
- Cause should be determined
- Discontinuation of inhalational anesthetics
- Optimizing of ventilatory pattern
- Synchronous arteriovenous pacing
- Elevation of filling pressures
- Period of partial circulatory support on bypass
- Maximization of pressor and inotropic support
- Ventricular assist devices if indicated
- Extracorporeal membrane oxygenation support if indicated

Management of Problems Associated with CPB

Management of CPB in children with CHD differs considerably from treatment of adults with acquired heart disease. Aortopulmonary communications, abnormal intracardiac anatomy, small body size, and immature cardiovascular systems alter CPB management. Historically, the morbidity of CPB in neonates and small infants has been a major limiting factor to surgical treatment.[65] Substantial evidence indicates that nonepithelial surface-induced damage to formed blood elements and blood proteins is proportionally greater in small children and infants, who have large surface area-to-body mass ratios. In recent years, technologic refinements have lowered the contribution of CPB-related problems to pediatric mortality, but CPB remains a substantial issue, particularly in small infants. Growing knowledge about the roles of cytokines, activated leukocytes, platelets, and endothelial cells in the inflammatory response to CPB holds promise for reducing the morbidity rate.[66]

Potential Perfusion Problems

Because of the factors of scale related to surface area and blood volume, substantial hemodilution and multiple exchanges of the entire circulating blood volume are required when conventional pediatric CPB circuits are used in small infants. The minimum pump prime required even by current infant-sized pump oxygenator circuits (250–500 mL) is very large compared with the neonate native circulating blood volume (~300 mL). CPB results in an exchange of one or more blood volumes in neonates and small infants, plus hemodilution to hematocrits of 20%. This extensive dilutional exchange may make postbypass hemostasis difficult without fresh blood products and also imposes large crystalloid and metabolic loads. CPB priming solution has substantial metabolic consequences be-

cause of its large volume. Depending on the constituents of the pump prime solution, large glucose, lactate, and osmotic loads are imposed.[67] These loads can be substantially reduced with modern washing and ultrafiltration techniques.[68] Ultrafiltration techniques likely reduce bypass morbidity in infants by decreasing levels of cytokines and other inflammatory mediators.[4,69]

Pump perfusion in children is regulated primarily by flow rate in most institutions. Because of the greater relative cardiac output of infants and their greater surface area-to-body mass ratio, pump flow rates as high as 150–200 mL/kg/min are used in neonates weighing 2–3 kg to provide normal cardiac output. Despite these high flows, mean arterial pressures during bypass often are approximately 30 mm Hg in infants, particularly during deep hypothermia when hemodilution markedly decreases blood viscosity. In older children, lesser flows are used, and perfusion pressures increase until the standard adult flows (50–70 mL/kg/min) and pressures are achieved in patients weighing >50 kg. Because of the low mean arterial pressures frequently used during bypass surgery in infants, unobstructed venous return to the pump oxygenator reservoir is critically important during bypass surgery, particularly in the superior vena cava. Presence of high venous pressures in the cerebral circulation can markedly hamper cerebral perfusion in children when mean arterial pressures are low during bypass surgery. This is particularly true during deep hypothermia in children when pressure-flow autoregulation of cerebral perfusion may not be present.[70,71] When caval occlusion tapes are tightened around venous cannulae, it is especially important to check for signs of superior or inferior vena caval obstruction or alternatively to monitor pressures in central venous lines positioned superior to the caval tape.

In the absence of inferior or superior vena caval obstructions, with normal venous pressures, low arterial perfusion pressures cause no problem in hemodiluted children receiving adequate flow. However, the margin of error is small for proper positioning of inferior and superior vena cava cannulae in the small infant heart. Obstruction of hepatic or jugular veins can easily occur, so signs of caval obstruction should not be ignored, particularly when venous pump return is inadequate.

The frequent presence of aortopulmonary collaterals in patients with CHD makes the definition of adequate bypass flow rates uncertain. In assessing perfusion during CPB in patients with CHD, the potential effect of aortopulmonary shunts or collaterals on systemic perfusion should be considered. A high perfusion rate may be indicated by pump head revolutions, but unless all sources of aortopulmonary shunting are controlled, much of the aortic perfusion from the pump passes into the lungs through shunts and collaterals and returns to the pump from the pulmonary veins through intracardiac defect to the right atrial venous cannula. Blood traveling this route does not perfuse the systemic circulation and especially does not perfuse brain. This may constitute a large proportion of apparent pump flow. Although well-defined shunts, such as PDA, Blalock-Taussig shunt, or Waterston shunt, may be ligated before bypass, many children with cyanotic disease have extensive aortopulmonary collaterals that are not easily controlled. During these conditions, pump flow rates may bear little relation to actual systemic perfusion.

Abnormally low perfusion pressure during bypass surgery despite high pump flows should suggest open systemic-to-pulmonary shunts. Sources of such shunts should be sought and controlled. Other indices of flow adequacy should be followed to ensure adequate perfusion of vital organs. Evidence indicates, for example, that systemic arterial collaterals to the lungs originating from the vertebral arteries may "steal" flow from the basilar artery and the brain during CPB, causing cerebral ischemia and choreoathetosis.[72]

During bypass cooling and warming, the rate of change recorded from temperature probes placed in various parts of the body provides an index of regional perfusion. Core temperature, measured by distal esophageal temperature, generally changes most quickly, followed by a lag of several degrees for nasopharyngeal or tympanic temperatures, the latter two better indicating brain perfusion. Rectal or extremity skin temperatures lag further because these areas reflect more peripheral perfusion. Temperature gradients between these regional beds decrease as steady state is approached and generally are seen in reverse order during warming. Deviations from normal temperature gradients seen on cooling and warming may indicate perfusion problems. However, such variations from normal temperature gradients do not predict the adequacy of cooling when jugular venous bulb oxygen saturations are measured during bypass cooling in small children.[73] In the absence of bypass warming or cooling, urine output and systemic acid–base balance are reasonable indicators of perfusion. Oxygen saturation of the venous outflow to the pump also is an important indicator of tissue perfusion. This value should be approximately 70% or greater, particularly during hypothermic bypass surgery.

Management of ventilation of the lungs during bypass surgery has been controversial. During partial bypass surgery, some ventilation probably is indicated if the pulmonic ventricle is demonstrably ejecting blood. This serves to oxygenate the small amount of blood being ejected so that the coronary arteries, which receive the bulk of this blood, are perfused with saturated blood. Low flow of 100% oxygen into the lungs should continue, even if no mechanical ventilation takes place, so that apneic oxygenation occurs as long as pulmonary blood flow continues. Frequent visual checks of arterial and venous lines at the pump provide estimates of the arteriovenous oxygen saturation difference and oxygen consumption. These estimates are periodically confirmed by measurement of venous and arterial blood gases, along with electrolytes, glucose, hematocrit, ionized calcium, and activated thromboplastin time (activated clotting time) during bypass surgery. Addition of blood, sodium bicarbonate, calcium, heparin, potassium, and crystalloid solutions to the pump reservoir, along with gas flow through the oxygenator, are guided by these measurements. Instruments that provide continuous Pa_{O_2}, PVO_2, pH, and PCO_2 are available for use during bypass but may not be as accurate as in vitro blood gas analysis.

Brain Damage

The mortality after pediatric cardiac surgery has decreased significantly over the past few decades. As a result, attention has turned to the issue of morbidity, particularly neurologic morbidity. A survey of six major North American hospitals was conducted from 1988–1989. The conclusion drawn from this study was that

the incidence of brain injury in children who had undergone pediatric cardiac surgery ranged from 2–25%.[74] Although significant improvements have been made in the perioperative management of children, the incidence remains significant. The most common problem seen is choreoathetosis, which has been reported with deep and moderate hypothermia, with long and short circulatory arrest, and with low and normal bypass flows.[75,76] Thus, the exact cause of this problem is unclear, but it is almost certainly the result of disturbances of brain perfusion in the basal ganglia. Although it is known that brain blood flow is altered by temperature,[77] $Paco_2$ levels,[78] and use of prolonged circulatory arrest periods,[77] among other factors, how these factors may interact to produce brain damage, such as choreoathetosis, in the isolated cases in which it occurs is not known. Studies have identified cerebral steal from systemic arterial collaterals to the pulmonary arteries originating from the vertebral–basilar artery system and short cooling times as a possible cause, but this remains to be confirmed.[22] In brain damage other than choreoathetosis, a relationship between high cooling rates and short cooling times before circulatory arrest and subsequent decreases in neurodevelopmental test scores in infants has been shown.[79] Even in the absence of overt neurologic injury, studies have shown that periods of hypothermic circulatory arrest >30–40 minutes during bypass repairs of CHD in infants are associated with a greater incidence of postoperative seizures and lesser neurodevelopmental scores at 1 year of age.[79,80] In addition, the etiology of cerebral injury in adults usually is secondary to embolic phenomenon but in children is less clear. Preoperative, intraoperative, and postoperative factors all contribute to the final neurologic insult in children.

Preoperative Factors

Children with CHD may have some preexisting neurologic impairment or neurodevelopmental delay. Such abnormality has been known for some time with regard to the well-known syndromes, such as Down syndrome, Williams syndrome, and trisomy 13, but is being found with increasing frequency in patients with CHD as our ability to detect it improves. Limperopoulos et al.[81] studied 131 newborns and infants before surgery for CHD. This group reported neurobehavioral abnormalities in more than half of the newborns, with >38% of the infants also showing neurodevelopmental abnormalities.

In addition to congenital abnormalities, acquired causes seem to make a significant contribution. The immature brain is extremely susceptible to the cardiorespiratory imbalance that often occurs in the preoperative patient before surgery.[79] Poor cardiac output, elevated CVP, chronic hypoxia, and possible embolic phenomena all put the immature brain at risk. Limperopoulos et al.[81] also noted that infants who had a saturation <85% preoperatively had a significantly greater incidence of neurologic abnormalities than those whose saturation was >85%. In a more recent study of babies with HLHS, 22 full-term neonates were examined by magnetic resonance imaging before surgery. Ischemic lesions were demonstrated in 23% of the patients.[82] Finally, the diagnosis itself has a significant prognostic effect. Patients with single ventricle physiology and arch obstruction have the highest risk of perioperative cerebral injury compared with all other forms of CHD.[83]

Intraoperative Factors

Intraoperative cerebral injury usually is the result of ischemia and associated reperfusion injury. Some degree of inflammatory effect also may play a part. Current evidence suggests that management of the CPB aspect of the operation can substantially influence the outcome.

Deep Hypothermic Circulatory Arrest and Low-Flow Bypass

In an effort to lower the high morbidity rate historically associated with CPB in young children undergoing intracardiac repairs for CHD, deep hypothermia with circulatory arrest or low-flow continuous bypass has been used. Deep hypothermic circulatory arrest (DHCA) with core and cerebral temperatures <20°C in children weighing <10 kg and in selected older patients provides ideal operating conditions for the surgeon, reduces bypass time and blood trauma, and maximizes myocardial protection.[84] These advantages are offset by risk of CNS damage from prolonged ischemic times. Current studies, both animal and human, suggest that arrest times >40 minutes increase the likelihood of severe injury.[77,81,85–87] Some centers have abandoned DHCA in favor of hypothermic low-flow CPB techniques because of concerns about subclinical neurologic damage and impairment of intellectual development, whereas others advocate using shorter periods of arrest interrupted by periods of perfusion to replace cerebral energy stores; however, this technique has not been conclusively proved in human studies.[88]

The potential disadvantages of DHCA are prolonged periods of ischemia to vital organs. As a practical matter in the large clinical experience with DHCA during the past 20 years, the only organ at appreciable risk is the brain. The majority of studies of neurologic outcome with DHCA in children and adults show no overt cerebral damage resulting from DHCA.[89–95] A minority of these studies have shown some evidence of effects on subsequent intellectual development, but usually only at circulatory arrest periods >45 minutes. Neurologic outcome studies of DHCA patients have been criticized as being poorly controlled and nonrigorous in their assessment of neurologic injuries and of combining heterogeneous groups of patients. The most recent study that avoids these problems shows evidence of intellectual impairment at 1-year followup evaluations in infants subjected to DHCA periods ≥ 30 minutes.[79,80] Because mechanisms of ischemic protection of the hypothermic brain are incompletely understood, there are no accepted optimal techniques for cerebral protection and no well-defined "safe" period of circulatory arrest; however, circulatory arrest is being used less frequently in favor of low-flow bypass techniques. DHCA periods >30 minutes are avoided whenever possible.

The alternative to DHCA, low-flow hypothermic CPB, in theory should allow for a reasonable surgical field while still providing adequate tissue perfusion to prevent cerebral injury. This has been demonstrated to be true metabolically, but recent studies in children have shown some significant deleterious effects of low-flow CPB.[96,97] In addition, there is no "standard" for "low-flow" bypass. Experimental studies have established that with decreasing total bypass flow during moderately hypothermic CPB surgery, the brain takes an increasingly larger fraction for itself to preserve normal cerebral oxy-

gen consumption levels. When flow becomes sufficiently low, oxygen consumption decreases because of ischemia.[98,99] Several studies have demonstrated that low-flow bypass resulted in loss of somatosensory evoked-potentials and intracellular adenosine triphosphate (ATP) and was associated with decreased intracellular pH when flow levels were sufficiently lessened.[100–102] In experimental studies measuring brain levels of high-energy phosphates in vivo, very low flows (down to 10 mL/kg/h) maintained normal brain creatinine phosphate and ATP levels in sheep during hypothermic low-flow bypass surgery.[85] In contrast, no middle cerebral artery (MCA) flow has been detected using TCD in clinical studies of infants and using greater levels of flow during hypothermic low-flow bypass surgery in one institution. A clinical study showed inconsistent perfusion of the MCA during hypothermic low-flow bypass surgery in infants in whom flows <30 mL/kg/min were used.[103]

Rossi et al.[104] showed that creatine kinase levels were equally elevated after DHCA and after low-flow hypothermic bypass in infants, suggesting no difference between the two techniques using this measure of brain injury. Thus, without any established "safe" level of low-flow bypass surgery, some degree of cerebral ischemia and damage may occur even when low-flow bypass surgery is used in preference to DHCA. Thus, continuous low-flow bypass surgery may well provide a false sense of security about brain protection. Together with less favorable operating conditions obtained with low-flow bypass surgery, this false security can markedly prolong low-flow bypass time, bypass damage, and potentially cerebral ischemic time that may occur during low-flow bypass surgery. Because the mechanisms of cerebral injury and the physiology of low-flow bypass surgery during hypothermia in infants and children are not well understood, the cerebral protective effects of low-flow bypass surgery may not always be better than DHCA.

Cerebral blood flow studies in children undergoing DHCA and low-flow bypass surgery by Greeley et al.[77] have shown that cerebral pressure-flow autoregulation is lost in children during deep hypothermia but that metabolism-flow regulation is retained. After prolonged circulatory arrest, cerebral blood flow and metabolism subsequently remain depressed during and after bypass compared with more normal recovery of metabolic rate and cerebral blood flow with continuous low-flow bypass.[70,71,76] These findings are consistent with delayed recovery of electroencephalographic (EEG) and somatosensory-evoked potentials after prolonged DHCA.[105,106] Despite delayed recovery of these functional measures and low cerebral blood flow and metabolism immediately after DHCA, gross neurologic deficits are seen infrequently.

DHCA provides optimal conditions for precise surgical repairs of complex intracardiac problems in tiny hearts, minimizes the formidable morbidity of CPB in small infants, improves myocardial protection, and lessens the incidence of cannulation-related problems and obstruction in the inferior and superior venae cavae. Low-flow bypass should provide less cerebral risk, with most of the surgical benefit associated with visualization of anatomy. In the Boston Circulatory Arrest Study, which compared these two support strategies in patients diagnosed with D-transposition of the great arteries, results were less conclusive. The patients in the DHCA group had worse outcome with respect to seizure activity postoperatively, motor skills at 1 year of age, and behavior, speech, and language at 4 years of age. However, at 8-year follow-up, the low-flow CPB group demonstrated more impulsive behavior, and although the DHCA group still fared worse with regard to manual dexterity and speech, IQ was similar across both groups but below the average for the normal population.[80,107,108]

Glucose Management

Evidence suggests that management of glucose levels is important in cerebral protection. Recovery from cerebral ischemia occurring during hyperglycemia is impaired, suggesting that hyperglycemia in the mature brain should be avoided in DHCA.[109] In addition, children often have hyperglycemic responses to the stress of hypothermic CPB surgery, and deep levels of anesthesia can markedly attenuate both the hyperglycemic stress responses and other hormonal and metabolic stress responses seen with CPB in children.[110,111] In a study[112] that attempted to evaluate the effect of glucose levels on children undergoing the arterial switch procedure, patients were randomized to low-flow versus DHCA and a retrospective analysis of glucose versus outcome was performed. This study suggested that lower blood glucose in the early postbypass period tended to predict EEG seizures but was not associated with an increase in clinical seizures. The report concluded that because glucose levels in the perioperative period were not associated with neurodevelopmental outcome at 1, 4, and 8 years of age, perhaps avoidance of hypoglycemia should be more of a priority in the perioperative period than should avoidance of hyperglycemia. Anesthetic management should emphasize use of muscle relaxants, barbiturates, and reduction of stress responses to minimize oxygen consumption and hyperglycemia during the ischemic period, but avoidance of hypoglycemia should remain a priority.[112] Pharmacologic protective agents, such as high-dose steroids and barbiturates, have not been shown to be protective against DHCA-related brain damage despite theoretical support for their use.

Acid–Base Management

Although cogent theoretical reasons exist for why acid–base management, through its influences on cerebral blood flow and cerebral intracellular pH in the brain, may affect such damage, clinical studies of its effects during DHCA have not yet been performed.[101] Acid–base management thus far has not been shown to have an important effect on the incidence of cerebral complications in hypothermic open heart surgery, at least in adults in whom circulatory arrest has not been used.[113] A large prospective trial comparing pH-stat and α-stat strategies for patients undergoing surgery requiring DHCA demonstrated a lower incidence of seizures, shorter time to first EEG activity, lower postoperative morbidity and mortality, and better cardiac output perioperatively in the pH-stat group. Thus, pH-stat is the recommended technique at present.[114]

Temperature Management

Temperature management has the most significant effect on cerebral homeostasis. Decreasing temperature provides for luxury perfusion of the brain. An increase in temperature above normal provides for an equally deleterious medium. Any excess in temperature

increases the release of excitatory amino acids resulting in increased reperfusion injury and apoptosis.

Postoperative Factors

Temperature management, inhibition of inflammatory mediators, and maintaining adequacy of cerebral oxygen delivery remain the mainstay by which cerebral injury is prevented in the postoperative period. As a result of this, the concept of multimodality neurophysiologic monitoring in the perioperative period has emerged.[115] Although none of these modalities has been shown to predict cerebral injury individually, use of a combination may serve as a surrogate marker predictive of injury. The combination required is not yet decided.

Near-Infrared Spectroscopy

Near-infrared spectroscopy (NIRS) is a technique that enables continuous monitoring of regional cerebral oxygenation. Similar to pulse oximetry, cerebral oximetry uses the fact that oxygenated and deoxygenated hemoglobin absorb near-infrared light to differing degrees. With more than one wavelength, the oxyhemoglobin fraction can be determined. Currently two types of monitors are available for NIRS: a concentration monitor that measures the concentration of oxyhemoglobin and reduced hemoglobin and the relative redox state of cytochrome aa3, and the saturation monitor that measures the ratio of oxyhemoglobin and deoxyhemoglobin.

The skull is translucent to infrared light, so intracranial measurement is possible. The device uses a light-emitting diode (near-infrared light 700–1000 nm) and two light sensors placed 3 and 4 cm away from the light source. The diode emits near-infrared light, which passes through a tissue volume to the detectors. The proximal detector detects light absorbed by extracranial tissues and is subtracted from the total signal, thus allowing determination of intracranial absorption.

Although two instruments, the INVOS 4100 (and 5100 for pediatrics; Somanetics, Troy, MI) and the NIRO 300 (Hamamatsu, Hamamatsu City, Japan) are commercially available, only the INVOS has FDA approval. The INVOS is a continuous-wave, spatially resolved spectrometer that measures change in regional oxygen saturation (rSO_2). Although the device appears to provide continuous monitoring of cerebral oxygenation, the technology has some drawbacks. Because the range of values has not been established, only a trend can be followed, and absolute values are not available. Thus, rSO_2 is reported as a percentage on a scale from 15–95%. This in itself may expose the patient to the risk of hyperperfusion at high cerebral rSO_2 values.[116] In addition, the proprietary algorithm used to calculate the rSO_2 value is based on the assumption that 25% of the intracranial blood is arterial and 75% is venous. In attempting to validate this assumption in children, Watzman et al.[117] found a ratio closer to 15:85, with much interindividual variation. Finally, obtaining an estimate of cerebral blood volume is possible but not yet validated, so its accuracy and usefulness remain uncertain. Despite this, the INVOS instrument is increasingly used in the pediatric operating room, with a deviation of 20% from baseline suggestive of an abnormal event.[118,119]

TCD Ultrasound

TCD ultrasound allows noninvasive continuous monitoring of cerebral blood flow velocity and emboli in the proximal segment of the MCA. This artery provides 70% of the blood flow to the ipsilateral cerebral hemisphere.[120] When using this device, the assumption is made that the diameter of the MCA remains constant, and that there is an association between blood velocity and actual blood flow that is independent of variables such as cerebral vascular resistance and temperature.

Comparing TCD with the xenon technique for measuring cerebral blood flow, Bishop et al.[121] found a poor correlation between absolute values of cerebral blood flow velocity and cerebral blood flow. However, a good correlation was found during hypocapnia, leading the authors to conclude that changes in cerebral blood flow velocity expressed as a reactivity index, not an absolute number, should be used as a indicator of cerebral blood flow.[121] A study using TCD to examine the effect of temperature on cerebral blood flow during CPB found that autoregulation was maintained at normothermia, partially lost with moderate hypothermia, and totally lost with profound hypothermia under α-stat conditions.[122] TCD has also been used to detect emboli reaching the cerebral circulation. True emboli are designated high-intensity transient signals and have characteristic audio and visual signals that differentiate them from false-positives. However, distinguishing between true emboli and false-positives is difficult in practice, and the problem remains that detection occurs after the insult and thus does not in itself prevent the incident. Cannula malposition, however, causes a sudden reduction in blood flow velocity and thus is detected very quickly by TCD. Overall, although TCD can provide a gauge by which changes in cerebral blood flow can be monitored, its use as a preventative tool is yet to be determined.

Jugular Bulb Oximetry

The cerebral venous sinuses drain into a venous dilation known as the *jugular bulb.* $SjvO_2$ is thus a monitor of global cerebral oxygenation. Currently, reflectance oximetry has made possible the continuous noninvasive monitoring of $SjvO_2$. Normal $SjvO_2$ values range from 55–75%, with arterial–jugular venous oxygen content difference of 4–7 mL/dL. In general, upon initiation of CPB, $SjvO_2$ increases despite the relative hypotension; however, the saturation may fall upon rewarming, reflecting a global increase in cerebral oxygen consumption.[123] However, studies have shown an association of both an increase and a decrease in $SjvO_2$ during CPB with short-term cognitive impairment.[124,125] This may be explained by the fact that although $SjvO_2$ is a good monitor of global oxygenation, it may not reflect regional ischemia. Thus, its use as a predictor of adverse neurologic outcome currently is limited. In the field of pediatric cardiac surgery, the best monitor of potential cerebral injury is still undecided, and most likely a multimodality plan is required. The exact combination and how significant each monitor is in the overall scheme is yet to be decided. Further studies are required.

Weaning from Bypass

During rewarming, air is vented from the heart before ejection of blood into the systemic circulation is allowed. Arterial blood gases, electrolytes, glucose, and coagulation parameters are checked periodically during bypass surgery, but especially during rewarming. Electrolytes, especially ionized calcium, are adjusted to normal ranges

before separation from bypass. Adequacy of rewarming is judged by temperature recording from multiple sites and is particularly important when deep hypothermia has been used.

The need for vasopressor and inotropic support to accomplish weaning from bypass is first estimated by close observation of the heart's behavior during rewarming. Dysrhythmias, coronary perfusion problems, and state of myocardial contractility can be estimated from the appearance of the heart. Separation from bypass should be accomplished in close concert with the surgical team using all available sources of information about hemodynamic status. Monitoring appropriate intracardiac and intraarterial pressures and waveforms and transesophageal echocardiogram may provide good information about the adequacy of the operative repair, myocardial preservation, ventricular function, and the state of the pulmonary circulation.[126] Slavish adherence to numbers produced by intracardiac catheters and pressure monitoring systems without visual confirmation of cardiac performance can lead to numerous errors. Small size and presence of unsuspected congenital defects make interpretation of pressures from monitors difficult.[127–129] When rewarming is complete and cardiac function is judged adequate, weaning from extracorporeal circulation is accomplished by slowly allowing the heart to fill and eject while reestablishing ventilation. Optimal ventricular filling pressures are estimated using filling pressures from preoperative catheterization data, appearance of the heart, and infusion of small volume increments while watching filling and systemic arterial pressures. Using this latter technique, a mental Frank-Starling curve can be constructed.

If systemic arterial pressure or gas exchange is inadequate, CPB is reinstituted while problems are analyzed. Problems with oxygenation after bypass surgery are caused as frequently by deficiencies in pulmonary blood flow as by deficiencies in ventilation. With low Pa_{O_2}, adequacy of pulmonary blood flow and ventilation should be critically assessed. Analysis of problems with weaning should start with reassessment of surgical repair, adequacy of ventilation, and verification that inotropic support is reaching the heart. Measurement of PA and atrial and intraventricular pressures often is helpful, along with pullback pressure gradient measurement across aortic and pulmonic valves if indicated.

In patients who are doing poorly after the bypass period, missed or residual lesions are likely. This possibility should be carefully considered before committing the child to prolonged inotropic support postoperatively. Residual defects are by far the most frequent cause of immediate hemodynamic problems and instability after repair, even in institutions with superb diagnostic and surgical expertise in CHD.

Questions of inadequate repair should be resolved using intraoperative echocardiography, including Doppler assessment of intracardiac shunts, with either epicardial or transesophageal approaches.[130–132] In complex CHD, a physician specially trained and expert in the echocardiographic assessment of CHD should interpret such studies. When the problem is identified, appropriate corrective measures are taken, and weaning is again attempted. If no anatomic problems are readily apparent and if the difficultly with weaning appears to be a result of reversible myocardial dysfunction or reversible pulmonary hypertension that cannot be adequately managed, use of a left or right VAD or ECMO should be considered.

Anesthetic Problems during Closed Cardiac Procedures

Anesthesia for closed cardiac procedures may be more demanding than for those involving CPB because bypass support can temporarily solve many hemodynamic problems that otherwise cause intraoperative deterioration. Monitoring requirements are just as stringent, and venous and arterial access are even more important. Pulse oximetry is invaluable to help evaluate the infant's condition. PDA and coarctation of the aorta are the only lesions corrected with closed surgical procedures; ductus ligation and other closed procedures now can be performed using video-assisted thoracoscopic surgery. Closed palliative procedures are used in patients with hypoxemia to increase pulmonary blood flow by constructing surgical shunts, to decrease excessive pulmonary blood flow using a PA band, and to improve atrial mixing of pulmonary and systemic venous return (Blalock-Hanlon atrial septectomy) in transposition of the great arteries. Palliative surgical procedures now are performed less frequently because early correction of many severe cases of CHD has become possible with accompanying low mortality rate and because of the efficacy and safety of interventional cardiac catheterization. Such palliative procedures, when used in preference to reparative procedures, have appreciable mortality and morbidity rates of their own.[133] Reparative operations that correct the intracardiac pathophysiologic conditions are increasingly feasible and preferable even in newborns.[134–137]

Acid–base and electrolyte balance are meticulously maintained throughout closed procedures. When these procedures are performed via thoracotomy, the operative field is rarely visible to the anesthesia care team. Marked deterioration in cardiopulmonary status may result from surgical manipulation and retraction. Any deterioration of the infant's condition should be immediately communicated to the surgical team, which has a better view of the surgical field. Serious deterioration should prompt solicitation of surgical help. Release of retraction usually results in return to hemodynamic stability. Some compromise of ventilation and pulmonary blood flow inevitably occurs in these procedures, sometimes with severe decreases in SaO_2. Inadvertent compression of coronary arteries during these procedures may cause severe cardiac ischemia and dysfunction, which is readily correctable by adjustment of retraction. Anesthetic management using deep levels of anesthesia that minimize oxygen consumption and support cardiovascular stability usually minimizes intraoperative problems but may prolong postoperative ventilation. In extreme cases, periods of inotropic and pressor support may be required intraoperatively.

Ductus Arteriosus and Vascular Ring Interruption

PDA ligation and other procedures, such as interruption of vascular rings, now can be performed thoracoscopically, with either one-lung anesthesia or two-lung anesthesia with lung retraction.[138] In either case, transient decreases in SaO_2 that may occur can be managed with brief reexpansion of the collapsed lung. Visualization of the operative field is superior when thoracoscopy is used. Conversion to open

thoracotomy occasionally is required if exposure is not adequate or if bleeding occurs. Transesophageal echocardiographic confirmation of interruption of flow is useful to ensure complete closure of the vessel.[139]

Surgical Shunts

Severe hypoxemia occurring in the operating room during or after creation of the shunt implies inadequate pulmonary blood flow. Intrapulmonary shunting should be considered in lungs that are retracted, but mechanical obstruction of flow into the PA because of retraction or actual shunt obstruction (kinking or thrombosis) is the usual cause. Reinflation of the retracted lung segment eliminates intrapulmonary shunting. If hypoxemia persists, hyperventilation can minimize PVR and optimize gas exchange until pulmonary blood flow can be improved. Systemic-to-PA shunts are inherently inefficient, recirculating oxygenated blood into the lungs and placing a volume load on the heart.

Pulmonary blood flow should be several times greater than systemic flow to substantially reduce hypoxemia (Fig. 52–3). When the surgically created shunt is too large, pulmonary flows are excessive. This is manifested by pulmonary edema (sometimes unilateral) on chest radiography obtained postoperatively. Intraoperatively, large pulse pressures, excessively low diastolic arterial pressures, and sometimes inadequate systemic output result in children whose SaO_2 is relatively high despite complete mixing of systemic and pulmonary venous return. Maneuvers to increase PVR can compensate for excessive pulmonary flow to a limited degree, but early or late shunt revision often is necessary. Other reported acute complications of systemic-to-PA shunts include Horner syndrome, chylothorax, and acute ischemia of the ipsilateral arm when the subclavian artery is sacrificed.

The Glenn shunt (superior vena cava to right PA with no pump in between) is limited to patients with low PVR because venous pressure is used to provide pulmonary blood flow. Consequently, its use in newborns and infants is excluded. Other problems with Glenn shunts include thrombosis, occlusion, and elevation of PVR leading to superior vena cava syndrome. The Glenn shunt is more efficient than an arterial shunt and is useful in patients who have congestive heart failure stemming from volume overload. In general, for other patients, the Blalock-Taussig shunt has proven the most reliable of the surgical shunts, with good long-term patency rates regardless of age. Early mortality and the incidence of late postoperative complications are lesser than for alternative shunt procedures.[140]

PA Banding

When pulmonary blood flow is excessive and high pressure is communicated to the pulmonary vasculature, surgical intervention may be necessary to prevent progressive PVOD or to lessen symptoms of high-output congestive heart failure and inadequate systemic output. When early complete repair is not possible, pulmonary blood flow is restricted by banding the PA. This adds pulmonary outflow resistance, which converts simple, nonrestrictive shunting situations into complex shunts with limited pulmonary flow. During induction of anesthesia before the band is applied, PVR occasionally may decrease enough to result in massive pulmonary flow and systemic hypotension ("pulmonary steal"). In this case, a partial occlusion of the PA with a clamp aids in maintaining hemodynamic stability until the band can be applied.

However, the banding procedure is unsatisfyingly crude, and results are hemodynamically unpredictable.[133] Adequacy of the band in the operating room is assessed by observing an increased systemic blood pressure and an acceptable decrease in systemic oxygen saturation. Direct measurement of PA pressure beyond the band is made, and the pressure is adjusted to approximately half the systemic arterial pressure. Continuous monitoring of SaO_2 is helpful in rapidly assessing critically low levels of pulmonary blood flow that may occur during band tightening.

Transcatheter Management in the Cardiac Catheterization Laboratory

Congenital heart problems are frequently managed today by transcatheter interventions in the catheterization laboratory.[141,142] Physiologic derangement and complications during such interventions may approach that seen in the cardiac operating room.[143] Anesthesia is often advisable for patient comfort and safety and for monitoring and management of complications.[144] Table 52–5 lists the lesions currently managed using interventional cardiac catheterization, the procedures used, and their effects and complications.

Evolving techniques of nonsurgical management of CHDs have markedly altered pediatric cardiac anesthesia. ASDs, VSDs, PDA, and coarctation of the aorta commonly form the bulk of pediatric cardiac surgery performed in many programs. These lesions now can be managed in the interventional catheterization laboratory using nonsurgical transcatheter techniques.[145–148] A number of these procedures, including closure of ASDs and PDAs, can even be performed on an outpatient basis.[143,148] In centers that perform large numbers of interventional catheterization procedures, these common congenital heart lesions are seen less frequently in the operating room. Transcatheter closures of ASDs have been successfully done in hundreds of patients. Smaller number of VSDs, including multiple VSDs, have been closed with these techniques.[144]

Newer techniques continue to move this field forward. Patients with tetralogy of Fallot (and its subtypes) require relief of right ventricular outflow tract obstruction or restoration of continuity between the right ventricle and the pulmonary arteries. Whether the repair is conducted as a primary neonatal procedure or after a palliative arteriopulmonary connection is largely related to institutional bias. However, the end result appears very similar. In particular, this subgroup progresses very well toward adulthood, but the life span of prosthetic conduits is finite. Conduit stenosis and valve regurgitation appear to be the most problematic, requiring intervention before end-stage right ventricular dysfunction. Because this is difficult to predict, the timing for any intervention is also difficult. Too early results in further reoperation to enlarge the conduit; too late and the right ventricle is unable to remodel. Although many formulations of conduits have been used over time, probably the fresh, autologous pericardial valved conduits are the most promising. A long-term follow-up study showed that inserted conduits ≥ 16 mm had a 100% freedom from operation at 10 years.[149] In this case, provided ventricular function has not deteriorated before the patient has reached a body size that allows insertion of this size of conduit, this might

TABLE 52–5.

Interventional Procedures Performed in the Cardiac Catheterization Laboratory Affecting Pathophysiology of Congenital Heart Disease

Procedure	Structure/Lesion	Effects	Complications
Coil embolization	Aortopulmonary collateral	Reduce pulmonary flow	Hypoxemia, systemic embolization
	Blalock-Taussig shunts	Reduce pulmonary flow	
	Anomalous coronary arteries	Increase coronary flow, reduce pulmonary flow	
Transcatheter device closures	Patent ductus arteriosis	Eliminate shunt, reduce pulmonary flow	Air embolization, device embolization, interference with mitral and tricuspid valve function
	Atrial septic defect	Eliminate shunt, reduce pulmonary flow, prevent paradoxic embolization	
	Ventricular septal defect	Eliminate shunt, reduce pulmonary flow	
Balloon and stent dilations	Pulmonary stenosis	Increase pulmonary flow	Embolization of stent, pulmonary artery disruption, unilateral pulmonary edema, pulmonary insufficiency, aortic insufficiency, mitral insufficiency, tricuspid insufficiency, aortic dissection
	Blalock-Taussig shunt	Increase pulmonary flow	
	Pulmonary valve stenosis	Increase pulmonary flow	
	Tricuspid valve stenosis	Increase pulmonary flow	
	Aortic valve stenosis	Increase pulmonary flow	
	Mitral valve stenosis	Increase systemic flow	
	Aorta (coarctations and others)	Increase systemic flow	
Atrial septostomies (balloon and blade)	Interatrial septum	Increase pulmonary blood flow	Perforation of heart, tamponade
Radiofrequency transcatheter mapping and ablation	Anomalous conduction pathways	Eliminate dysrhythmias, especially supraventricular tachycardia	Complete heart block; supraventricular tachycardia

be an appropriate point at which to consider the final replacement.

Percutaneous stenting is already used as a technique to delay surgical replacement. Further development in this area has included the development of percutaneous pulmonary valve insertion. A biologic valve is harvested from a bovine jugular vein. A section of this vein containing the trileaflet valve is then mounted in a stent for percutaneous insertion. Current studies have successfully demonstrated this technique, with low morbidity and mortality. The long-term durability of this stent and the ability to perform sequential percutaneous pulmonary valve implantation will determine its eventual place in the armamentarium, but at present it certainly should help to delay surgery to such a time that a 16-mm valve can be inserted rather than performing earlier and repetitive surgery with the obvious associated risks.[150,151] Interventional catheterization techniques listed in Table 52–5 also are used increasingly in conjunction with surgical procedures to improve the results of surgical management of CHD and to extend therapy to previously unmanageable lesions.

Anesthetic Care

Catheterization procedures have become more invasive, use larger and multiple catheters, involve greater blood loss, and produce more pain in smaller and sicker patients. The cardiac catheterization laboratory has effectively turned into an operating room in which major problems and complications can result from increasingly invasive procedures.[143] Although many patients seen in the pediatric catheterization laboratory can be adequately sedated by cardiologists, complex procedures in sick children require anesthetic care.[143] Anesthesia, monitoring, and hemodynamic management are needed for many of these invasive procedures performed in children and contribute substantially to a successful procedure.[141,152] Many patients can be treated with monitored IV sedation techniques, but others require general endotracheal anesthesia. Indications for using either technique are not yet well defined but depend on patient condition, procedure, and anticipated complications.

Anesthetic management is handicapped by the catheterization laboratory environment. Problems include poor patient access, poor lighting, radiation hazards, and lack of communication with cardiologists. Independent monitoring, independent IV and sometimes intraarterial access, independent light sources, and adequate access to the patient's airway should be sought. Prevention or prompt management of complications is a major anesthetic task in this setting. Without a thorough understanding of transcatheter procedures, their complications, and their management,

the anesthesia provider is handicapped in coping with accelerating development of these new techniques.

Problems and Hemodynamic Complications

Complications of various interventional procedures are related partly to the type of interventional procedure, but all share risks associated with percutaneous access to major veins and arteries. Specific problems that may occur during various interventional transcatheter procedures are listed in Table 52–5. Many problems are sudden, occur without warning, and are potentially life threatening. As in the operating room, successful management of complications depends heavily on prompt action by anesthesiologists cooperating closely with interventional cardiologists and radiologists.

Loss of control of embolic and closure devices results in systemic and pulmonary arterial embolization. Embolized devices usually can be retrieved using a variety of retrieval catheters, but in a minority of patients, surgical removal is required. If the device is lodged in the heart or a great vessel, CPB may be required for removal. Such device embolizations usually do not cause extreme hemodynamic instability or cardiovascular decompensation requiring emergency surgical removal, but urgent surgical procedures may be necessary. Even after successful transcatheter retrieval, femoral artery and vein reconstructions occasionally are necessary when embolized devices or large dilation balloons are removed through these vessels.[153] When deliberate embolization of aortopulmonary collaterals excessively decreases pulmonary flow and produces severe hypoxemia, general anesthesia and muscle paralysis can increase SaO_2 to acceptable levels by decreasing oxygen consumption, at least until surgical intervention.

Disruption and avulsion of major blood vessels occur, particularly PA disruption during balloon dilation procedures.[154] PA disruption is signaled by hemoptysis or appearance of contrast media in the pleural space or major lung fissures. Substantial hemoptysis calls for immediate endotracheal intubation for airway control and ventilation. Positive end-expiratory pressure (PEEP) may be useful. Intrapulmonary hemorrhage often is self-limited, but hemothorax can be severe and can result in death.[154] Transient unilateral pulmonary edema can occur during PA dilation because of sudden increases in flow after dilation to a previously underperfused lung.[154,155] Unilateral pulmonary edema and disruption of PA integrity can occur abruptly. Both can cause the appearance of frank blood or blood-tinged edema or fluid in substantial quantities in the airway. Management starts with endotracheal intubation and positive-pressure ventilation unless symptoms are only minimal.

Intracardiac air embolization may be a particular problem when clamshell devices are used for PDA, ASD, and VSD closures because the large delivery sheath in the heart is transiently open to atmosphere. Transcatheter closure of an ASD using a clamshell device in shown schematically in Fig. 52–8. In patients with intracardiac shunts, air embolization may be life threatening. The large delivery sheath is a potential space for air accumulation and subsequent delivery into the heart. In addition, when the entry port of the large delivery sheath is open during removal and reinsertion of various catheters and devices, extreme inspiratory efforts may entrain intracardiac air. Air delivered into the right atrium may be shunted across the ASD even in the presence of nominal left-to-right shunting. Left atrial air embolization during these procedures can be seen with fluoroscopy. Resultant ST-segment changes, hypotension, arterial desaturation, and bradycardia generally respond to air aspiration followed by sealing the entry port, along with administration of atropine and inotropic support to maintain coronary perfusion. Meticulous purging of air from

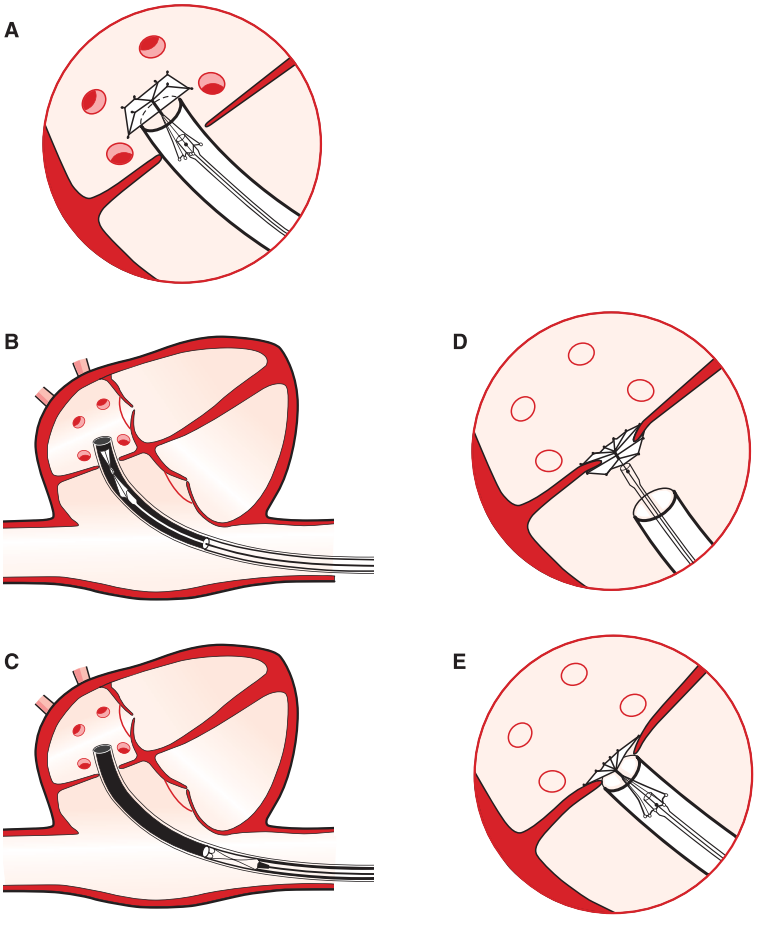

FIGURE 52–8. Technique of transcatheter atrial septal defect closure. **A.** Collapsed clamshell device is through the sheath. **B.** Device and sheath as a unit are positioned on the left atrial side of the defect using previously determined fluoroscopic landmarks. **C.** Sheath is pulled partially back, allowing one set of flexible, spring-loaded arms (covered with Dacron mesh) to spring open in the left atrium. **D.** Sheath, delivery system, and half-opened clamshell device are pulled back as a unit until the open arms engage the left atrial septal surface. **E.** Sheath is pulled farther back to expose the proximal half of the device, allowing it to spring open and engage the right atrial septal surface. Subsequently, the clamshell device is released and the delivery system withdrawn.

the catheter system, with sealing of open ports, should minimize air embolism. Controlled positive-pressure endotracheal ventilation in anesthetized, paralyzed patients may decrease the potential for air entrainment.

Tricuspid or mitral regurgitation with hemodynamic compromise may occur acutely when large catheters impinge on atrioventricular valves. These large catheters can cause dynamic stenosis as they pass across small valves. These problems usually respond to inotropic support and repositioning of the delivery catheter and device. Acute myocardial perforation with tamponade occurs occasionally during the course of interventional cardiac catheterization procedures. Prompt support of the circulation with volume infusions and pressor support, along with immediate catheter drainage of the pericardial space, are essential.

EFFECTS OF ANESTHESIA AND RELATED MANIPULATIONS ON PATHOPHYSIOLOGY

Anesthetics

Individual pathophysiology and the proposed therapeutic procedure largely dictate anesthetic management. Often the skill with which the technique is used determines the success of the anesthesia team in maintaining cardiovascular stability. Several anesthetic techniques provide good cardiovascular stability in children with severe CHD, but cardiovascular stability may not be the only criterion for a successful anesthetic.[156] Stress responses to pain and other noxious stimulation are profound even in the youngest neonates.[157–159] Extreme hormonal and metabolic stress responses during cardiac surgery and CPB can be pathologic in magnitude and are associated with poorer outcome in neonates undergoing cardiac surgery, despite hemodynamic stability.[160,161] Anesthetic techniques clearly have an effect on stress responses—metabolic and hormonal. It is important that children of all ages be given adequate anesthesia for suppression of hormonal and metabolic responses to noxious stimulation and for humane considerations.

Inhalational Anesthetics

Inhalational anesthetics should be used cautiously in children with CHD because of their myocardial and circulatory depression. This is particularly true for induction of anesthesia before adequate access to the circulation and complete hemodynamic monitoring are established. Safe use of conventional inhalation induction with potent anesthetics depends on evaluation of the child's cardiac lesion and understanding the effects in young children with CHD. In children of any age with marginal cardiovascular reserve, myocardial depression caused by potent inhalational agents may produce systemic hypotension, but these agents are still unquestionably useful in small, titrated concentrations to control hypertensive responses after induction when the airway is secure after monitoring and hemodynamic stability is established.

Even in cyanotic children, if they have reasonable functional cardiac reserve, anesthesia can be induced with halothane and oxygen, even with 70% nitrous oxide (the latter relatively contraindicated because of air bubble expansion), without clinically significant decreases in SaO_2.[162,163] Dramatic decreases in arterial pressures occur with these techniques, sometimes to severe degrees. In infants, such induction techniques are of special concern because of the immature circulatory system. Use of these agents may considerably narrow the margin of safety in infants and younger children with severe CHD. At least in those given halothane, the levels tolerated by sick infants provide little suppression of the stress responses to cardiac surgery and CPB.[160]

Numerous studies have shown that even the normal immature cardiovascular system of infants without CHD does not tolerate halothane or isoflurane well; approximately 50% of infants with normal cardiovascular systems develop substantial hypotension and bradycardia during induction with these agents unless cardiovascular function is supported.[32,50,164,165] Ventricular function declines during halothane and isoflurane induction in normal infants; stroke volume and ejection fraction decrease by as much as 38%, although the depression with isoflurane may be somewhat less than with halothane.[166–167]

Sevoflurane is a fluoridated derivative of methyl isopropyl ether and is rapidly becoming the inhalational agent of choice for children. This is largely because it is the only ethereal anesthetic that does not trigger a reflex response or cause airway irritation during inhaled induction. This, combined with its rapid recovery and minimal metabolism, makes sevoflurane an ideal agent in general pediatrics. However, it does cause myocardial depression in children, although stroke volume and ejection fraction are somewhat less depressed with sevoflurane than with other potent inhalational agents.[168–170] In adults, isoflurane appears to decrease SVR more than sevoflurane does. Although this decrease occurs, cardiac index appears to be preserved with both agents, and patients undergoing cardiac or thoracic procedures appear to tolerate either anesthetic safely.[171–175] In one of the few studies comparing isoflurane and sevoflurane in children with CHD, similar results were found. Fifty-four children undergoing cardiac surgery received sevoflurane, isoflurane, halothane, or fentanyl-midazolam. Only sevoflurane and isoflurane maintained cardiac index, with sevoflurane producing less reduction in SVR than any other agent in the study.[176]

Few published studies of desflurane in children with CHD are available, but studies in healthy children suggest that the effects of desflurane on ejection fraction and stroke volume are little different from those of halothane.[177] Isoflurane may be an unwise choice for inhalation induction in cyanotic children because increased airway problems and laryngospasm during induction (because of the agent's pungency) may lead to increases in PVR. Somewhat less myocardial depression occurs in older children.[178] These clinical findings are supported by experimental findings in immature animals, both in vitro with isolated atrial and ventricular muscle and in vivo with some species of young animals.[51–53,179,180]

Halothane can cause loss of normal sinus rhythm because of selective sinoatrial node depression. Because ventricular function depends on normal sinus rhythm in compromised hearts, loss of this mechanism may be especially critical in CHD. This applies to right and left ventricular function in patients in whom right ventricular dysfunction may be expected to be a problem, such as in patients with tetralogy of Fallot.[181] Although greater reductive metabolism of halothane has been demonstrated in cyanotic cardiac patients, no increase in postoperative hepatic and renal derangements has been

documented, and historically "halothane hepatitis" has not been a problem in cyanotic (or other) children.[53]

Sevoflurane

Use of nitrous oxide in children with CHD and shunts is controversial because of its potential for enlarging systemic air emboli. Use of nitrous oxide may cause expansion of intravascular air emboli, exaggerating their circulatory effects, even without additional systemic embolization.[182] In patients with systemic embolization of air to the coronary circulation, nitrous oxide has been shown experimentally to be deleterious.[183] In children with intracardiac shunts, the potential exists for systemic shunting of microbubbles and macrobubbles of air from IV lines and from exposure of the left heart to the atmosphere during open cardiac surgical procedures. Although clinical problems from enlargement of air emboli by nitrous oxide have not been reported in this setting, avoidance of its use is prudent in patients in whom systemic air embolization is a strong possibility.

Nitrous oxide in adults decreases cardiac output, systemic arterial pressure, and heart rate and increases PVR, especially in patients with elevated PVR.[184–186] In children with right-to-left shunts who have decreased pulmonary flow or pulmonary hypertension, increases in PVR with nitrous oxide are detrimental. However, at least in one study, no increase in PA pressure or PVR was observed in infants given 50% nitrous oxide, regardless of preexisting PVR.[187] Mild but notable decreases in cardiac output, systemic arterial pressure, and heart rate were seen in these infants. Inhalation induction with 70% nitrous oxide and halothane in cyanotic children does not decrease SaO_2, suggesting that pulmonary blood flow is not decreased and that PVR is not substantially increased by nitrous oxide.[14,15] Although use of nitrous oxide prevents use of 100% O_2, this may not actually decrease arterial saturation in cyanotic children without lung disease because increases in the fraction of inspired oxygen (FiO_2) have little effect on arterial desaturation caused by large central intracardiac cardiac shunts.[188] The effects of FiO_2 on arterial saturation for different levels of right-to-left shunting are shown in Fig. 52–9.

Use of inhalational agents in children with intracardiac shunting is theoretically complicated by differences in uptake and distribution. A complex computer model suggests inhalation induction is slowed in the presence of central right-to-left shunts, is slowed less in mixed shunts, and is little changed in pure left-to-right shunts, all in proportion to the size of the shunt.[189] These models assume constant cardiac output and are most marked for insoluble gases such as nitrous oxide. In children with left-to-right shunts, speed of inhalation induction actually is altered little clinically.[190] Experimental data in animals with right-to-left shunts confirm slowing of induction, but data in children with right-to-left shunts are not available.[191] Inhalation induction often seems somewhat slow in children with pure right-to-left shunts, but this effect is not marked, probably because of the effects of multiple other variables affecting uptake. Relatively slow induction of anesthesia in children with pure right-to-left shunts is a consideration in deciding how rapidly to increase the inhaled concentrations of potent anesthetics during induction without producing severe myocardial depression.

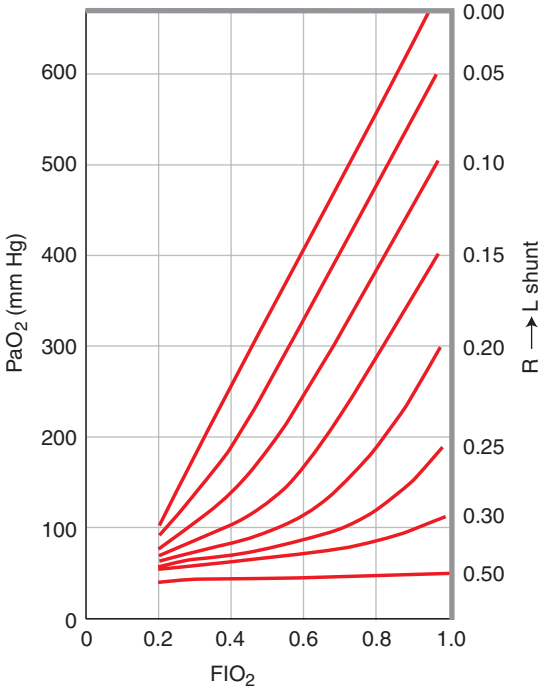

FIGURE 52–9. Iso-shunt graph depicting relationship between fraction of inspired oxygen (FiO_2) and arterial Pao_2 with different amounts of right-to-left shunting. Assumes normal values of pH, $Paco_2$, pulmonary venous saturation, and mixed venous saturation. (Modified from Lawler PG, Nunn JF. A reassessment of the validity of the iso-shunt graph Br J Anaesth 1984;56:1325–1335. © The Board of Management and Trustees of the British Journal of Anaesthesia. Intramuscular and IV Anesthetics

Some IV anesthetics, such as ketamine and high-dose opiates, can provide improved safety margins for induction of anesthesia in the immature and compromised cardiovascular system of neonates and infants with severe cardiac disease and in older children with minimal cardiovascular reserve. Very high transient arterial, cardiac, and brain concentrations of IV agents can result from normal IV doses given as a bolus in children with known right-to-left shunts because mixing, uptake, and pulmonary metabolism are bypassed. For example, IV lidocaine in a 1-mg/kg antiarrhythmic bolus dose administered in dogs with right-to-left shunts resulted in arterial concentrations higher than those reported to cause irreversible myocardial toxicity.[192] The potential for transiently high arterial levels of IV anesthetics in patients with intracardiac mixing and right-to-left shunts should be considered in planning.

Ketamine When IV access is a problem, intramuscular ketamine 3–5 mg/kg is well tolerated in sick children with cyanosis or congestive heart failure.[193,194] In contrast to older literature, experimental studies of isolated ventricular muscle show that ketamine has a positive inotropic effect.[192,195,196] Concomitant intramuscular succinylcholine can be used to facilitate airway control. Atropine or glycopyrrolate given with

ketamine may be helpful to offset secretions produced by ketamine. A small dose of midazolam (0.1 mg/kg) can be used to attenuate ketamine's dysphoric effects. Although increases in PVR have been reported in adults after ketamine administration, in well-premedicated children, ketamine causes no change in PVR when the airway is maintained and ventilation is supported.[163,197,198] In children with CHD, the ejection fraction has been shown to be well preserved during ketamine anesthesia. Our clinical experience with intramuscular ketamine has been excellent with most forms of heart disease, including patients with limited pulmonary blood flow and cyanosis in whom arterial saturation usually improves with ketamine.[14,15] Ketamine has long been used for cardiac catheterization procedures. Ketamine combined with midazolam has been used for interventional cardiac catheterization procedures such as PDA and ASD closures.[141,199]

When IV access is available in patients with marginal cardiac reserve, ketamine (1 or 2 mg/kg IV) is an excellent induction agent in patients with most forms of CHD. Relative contraindications are coronary insufficiency caused by an anomalous coronary artery, severe critical aortic stenosis, and HLHS with aortic atresia and hypoplasia of the ascending aorta. These patients are at risk for ventricular fibrillation because of relative coronary insufficiency; tachycardia and catecholamine release with ketamine may predispose these patients to ventricular fibrillation.

Etomidate This imidazole derivative is being used with increasing frequency in patients with CHD. Studies in children are rare, but one study has examined the use of etomidate as an induction agent in children with limited hemodynamic reserve. The study concluded that etomidate was safe for use in children with limited hemodynamic reserve but suggested the need for studies in neonates and children with substantial ventricular dysfunction.[200] In another study comparing etomidate with ketamine and γ-hydroxybutyrate as the sole anesthetic for cardiac catheterization in children, no difference could be demonstrated among the three groups with regard to hemodynamic or respiratory effects. However, etomidate produced recovery that was more rapid and of a better quality than in either of the other groups.[201] In addition, induction with etomidate is generally as rapid as with thiopental, and with a distribution half-life of 2–3 minutes, recovery is very rapid for procedures such as cardioversions, which are common in this subgroup.

One presumed disadvantage of etomidate is the temporary suppression of adrenocortical function associated with its use, particularly when patients receive a continuous infusion. This is subject to interpretation. One study compared etomidate and ketamine induction with regard to cortisol production in the postoperative period. These investigators demonstrated reduced cortisol levels in the etomidate group but believed that this finding may be beneficial and certainly not detrimental in the context of pediatric cardiac surgery.[202]

Opiates As in adults with severe cardiac disease, high-dose IV opiates, given together with pancuronium and 100% oxygen, or air and oxygen, are excellent as induction agents in very sick children with all forms of CHD. High-dose opiates in infants and neonates provide excellent hemodynamic stability with suppression of hormonal and metabolic stress responses.[159,160] Anesthetic techniques based primarily on high doses of opiates have become standard care for infants and small children with severe forms of CHD, especially if they are critically ill. Hyperglycemic responses to cardiac surgery in children are suppressed by greater doses of fentanyl, so blood glucose measurements are necessary.[203] High-dose fentanyl technique has been reported to be effective in premature neonates undergoing patent ductus ligation and has been shown to effectively attenuate stress responses for this procedure.[159,204] Fentanyl doses as low as 10 μg/kg may be sufficient for effective baseline anesthesia in neonates, but larger doses are necessary for prolonged anesthesia.[205] In high-risk, full-term neonates and older infants with severe CHD, use of high-dose fentanyl in doses up to 75 μg/kg, given with pancuronium, results in minimal hemodynamic changes on induction and intubation; only mild hemodynamic responses to surgical incision generally occur.[206] Additional doses or infusions of potent opiates may be necessary for procedures involving CPB because narcotic levels decrease markedly in children on CPB.[207]

Evidence indicates that suppression of stress responses and amnesia is better if another anesthetic, such as a benzodiazepine (midazolam), is used during high-dose opiate anesthesia. With the use of high-dose opiate anesthetic techniques, oxygen saturation levels are well maintained and may actually improve during induction, intubation, and surgical stimulation even in cyanotic children.[15] Changes in cardiac index, SVR, and PVR in infants given 25 μg/kg of fentanyl have been shown to be minimal.[208]

Use of pancuronium with the high-dose fentanyl technique is recommended; the vagolytic effects of pancuronium offset the vagotonic effects of fentanyl. When other muscle relaxants are used with high-dose opiates, hemodynamic stability may not be obtained.[209] When fentanyl or other opiates are used with nitrous oxide, the negative inotropic effects of nitrous oxide may appear, especially in sicker patients.[210] Sufentanil (5–20 μg/kg) is an alternative to fentanyl and provides roughly equivalent hemodynamic stability, suppression of stress responses, and postoperative analgesia.[211,212] The use of a high-dose fentanyl or sufentanil technique usually necessitates continuous postoperative ventilatory support. Alfentanil, a shorter-acting potent opiate used as a continuous infusion, can be useful for providing hemodynamic stability and stress suppression in children in whom postoperative ventilatory support is not needed. A loading dose of 20 μg/kg and an infusion of 1 μg/kg/min as a supplement to nitrous oxide–halothane has been reported in children undergoing surgery for CHD.[213]

Remifentanil, an ultrashort-acting opiate, has been shown to be a useful agent in patients with CHD undergoing surgical correction, with no clinical differences in hemodynamic and respiratory parameters both intraoperatively and 24 hours postoperatively compared with fentanyl.[214] This opiate has clearly been shown to have no negative inotropic effect on the failing myocardium and has allowed for full response to β-adrenergic stimulation at all concentrations.[215] Remifentanil has been shown to be very predictable in the post-CPB period, with little change in the coefficient of variation despite 20% increased postbypass clearance values.[216]

Propofol Its short duration of action makes propofol attractive for brief procedures in patients with CHD. In the

isolated heart, propofol has myocardial depressant properties somewhat greater than those of thiopental and substantially more than those of ketamine.[217] Its use in patients with CHD should be restricted to those with adequate cardiovascular reserve. For patients with marginal cardiovascular reserve, use of propofol can precipitate cardiovascular decompensation and even collapse.

Successful use of propofol for pediatric patients with CHD undergoing cardiac catheterization and transesophageal echocardiography has been reported,[218] but in one study, a substantial percentage of patients given propofol had decreases in blood pressure >20% from baseline.[219] These mild deleterious effects on blood pressure are confirmed in other studies.[220] Increased incidences of bradycardia and junctional rhythm have been reported in children receiving propofol compared with those receiving barbiturates.[221] In one specific study of propofol's effects on cardiac conduction in pediatric patients, no substantial effects were seen.[58] These data, taken together with clinical experience, suggest that use of propofol in patients with CHD should be restricted to those with good levels of cardiovascular reserve because of the drug's cardiac depressant properties.

Dexmedetomidine Dexmedetomidine is a new α_2-agonist approved by the FDA in 1999 for short-term (<24 hours) sedation and analgesia in critically ill patients. It has been shown to be highly effective for sedating children after cardiac and thoracic surgery who were either ventilated or spontaneously breathing.[222] The infusion rate of 0.3 μg/kg/h (range 0.1–0.5 μg/kg/h) provided mild-to-moderate sedation in 93% of the children for a range of 3–26 hours. Higher mean dosing was required in children younger than1 year, and these children required more rescue medications compared with older children.[222] For painful interventions, adjunct pain medication frequently is required because the sedative properties of this medication are clearly higher than the analgesic effect. However, it is useful for very sick pediatric patients undergoing nonpainful procedures and allows completion of the procedure without subjecting these children to intubation and mechanical ventilation. Finally, increasing evidence indicates that dexmedetomidine may be useful in facilitating acute discontinuation of opioids and/or benzodiazepines in children in the ICU setting.[223]

Thiopental and Other IV Agents IV induction with thiopental generally is not used in patients with severe cardiac defects. However, a reduced dose of thiopental 1 or 2 mg/kg may be safe for induction in patients with moderate defects and may actually result in improved SaO_2 in cyanosis. In pediatric patients with minimal or mild cardiac defects, IV induction with larger doses of thiopental (3–5 mg/kg) usually are well tolerated, provided the patient is not hypovolemic. Rectally administered barbiturates, notably methohexital, may be an acceptable induction technique in an otherwise uncooperative child with less severe CHD and good cardiac reserve, but absorption is variable, and myocardial depression is possible.[224] The experience with etomidate use in CHD has not been sufficiently extensive to determine the drug's effects with certainty, and no studies of the hemodynamic effects in small children are available.

Muscle Relaxants

Pancuronium dosage requirements are unchanged in children with CHD and intracardiac shunts; it produces no heart rate or blood pressure changes when given slowly in these patients.[225] Through its vagolytic effect, a bolus dose of pancuronium can produce tachycardia and hypertension in children, which may be desirable to support cardiac output in infants with relatively fixed stroke volumes.[226] If tachycardia is undesirable, metocurine (Metubine) causes no increase in heart rate, blood pressure, or cardiac rhythm changes in small children, even at doses of 0.5 mg/kg.[227] For patients in whom a short-acting nondepolarizing muscle relaxant is desirable, atracurium, vecuronium, and cisatracurium at the lower end of their dose ranges have few cardiovascular side effects in children.[228,229] Use of the latter two muscle relaxants rather than pancuronium during induction combined with a high-dose opiate anesthetic may produce clinically significant bradycardia, as reported in adults. Bradycardia and even sinus arrest can be problems with use of succinylcholine in children with CHD, particularly those given large doses of opiates. To avoid these problems in vagotonic young children, atropine should be used with succinylcholine. If potent opiates are used at the same time as succinylcholine, severe bradycardia may be avoided by concomitant use of atropine.

Novel Inotropic Drugs

The increased sympathetic drive in these patients inevitably leads to an elevation in catecholamine levels. The continued stimulation of α- and β-receptors by both endogenous and exogenous catecholamines leads to a decreased effect via downregulation and ultimately causes irreversible destruction of receptors. Once this level of desensitization has occurred, recovery requires RNA-directed new receptor synthesis. The options available to support the circulation become limited. Either mechanical support must be initiated or nonadrenergic receptor-mediated inotropic support is instituted. Current therapy is discussed.

Phosphodiesterase Inhibitors

Phosphodiesterase inhibitors are the most commonly used noncatecholamine-mediated inotropic agent. The mechanism of action of these agents is also the most straightforward. Phosphodiesterases degrade cyclic adenosine monophosphate (cAMP) to 5-adenosine monophosphate (5-AMP). Phosphodiesterase inhibitors prevent this degradation, thus allowing the concentration of cAMP to increase. The increased levels of this secondary messenger lead to increased calcium availability and thus increased contractility. Because the response is related to an increase in cAMP and not purely to inhibition of phosphodiesterase, the greatest effect is seen if initial levels of cAMP are higher than normal. Thus, synergy is seen with β-agonists. In addition, phosphodiesterase inhibitors reduce afterload and improve coronary perfusion without any change in myocardial oxygen consumption.

Triiodothyronine

The hormone triiodothyronine (T_3) is essential for maturation of sarcolemmal calcium channels, myosin, actin, and troponin. Hypothyroid rats demonstrate reduced numbers of β-receptors, as well as a reduction in stimulatory secondary messenger protein density with an increase in inhibitory secondary messenger protein density. T_3 is mostly produced by monodeiodination of thyroxine. This process is inhibited by surgery, hypothermia,

catecholamines, propranolol, and amiodarone. Thus, postoperative T_3 levels are reduced.

T_3 replacement acts via two pathways, intranuclear and extranuclear. Intranuclear effects include increased mitochondrial density and respiration, increased contractile protein synthesis, and upregulation in β-adrenoceptors. Extranuclear effects include improved glucose transport, increased stimulation of L-type calcium channels with subsequent calcium mobility, and increased efficiency in calcium reuptake with subsequent improvement in diastolic relaxation.

A randomized, double-blind, placebo-controlled study by Bettendorf et al.[230] examined 40 children undergoing both simple and complex cardiac surgery. Results demonstrated that the group allocated to receive T_3 had better myocardial function with a decreased duration of ICU stay. T_3 provides improved contractility without any associated increase in oxygen consumption. In addition, the Bettendorf group demonstrated no delay in recovery of thyroid function secondary to exogenous administration.

Levosimendan

Levosimendan is a novel drug with a unique mechanism of action. The levosimendan molecule binds to the N-terminal domain of troponin C in cardiac muscle. This process allows for stabilization of the troponin C molecule and maintains tropomyosin in an elevated position. This allows for prolongation of the contractile effect of a set dose of calcium. In addition, levosimendan acts via ATP-sensitive potassium channels, thus causing peripheral vasodilatation, coronary vasodilatation, and myocyte myocardial activation.

Follath et al.[231] reported a multicenter, randomized, double-blind trial comparing levosimendan with dobutamine. Two hundred three patients with severe low-output heart failure were randomly allocated to receive levosimendan or dobutamine. The levosimendan patients reported a significant improvement in cardiac output and subsequent reduction in pulmonary capillary occlusion pressure with an associated reduction in mortality at 180 days. Two other large-scale studies found similar benefits in acute and chronic heart failure patients.[231–233] Levosimendan in adults improves systolic and diastolic function and reduces preload and afterload without any demonstrated increase in myocardial oxygen consumption. Studies in children are required.

Brain Natriuretic Factor and Nesiritide

Brain natriuretic peptide (BNP) is a member of the natriuretic peptide family, which includes atrial natriuretic peptide, BNP, and C-type NP. These peptides together play a large role in maintaining hemodynamic and neurohumoral equilibrium. BNP is secreted from cardiac ventricles in response to increased stimulation of cardiac stretch receptors and increased intraventricular tension and acts mostly via natriuretic peptide receptors (NPRs) present in large vessels and kidneys. Once stimulated, NPRs promote diuresis, natriuresis, and vasodilatation and inhibit the renin-angiotensin-aldosterone system. BNP is used as a marker for heart failure in adults and as a method for monitoring therapeutic progress. Its usefulness in children is less obvious as there is no consensus regarding the normal range. Two studies attempting to determine the predictive value of BNP in acute heart failure in children came to directly opposing conclusions.[234,235]

Nesiritide is the recombinant form of BNP; thus, it acts via the same receptors and has the same end results. Studies suggest that patients with decompensated heart failure may benefit from nesiritide administration, with demonstrated improvement in cardiac output, reduction in pulmonary capillary occlusion pressure, arterial and venous dilation, and minimal associated increase in heart rate or myocardial oxygen consumption. Pediatric studies are awaited.

Nonpharmacologic Support

The failing pediatric heart may require more support than is possible with medical management alone. The need for alternative assist devices is increasing dramatically for two reasons. The chief reason is that increasing numbers of pediatric patients with severe, complicated congenital cardiac anomalies are no longer considered inoperable. As a result, patients now frequently survive long enough to present for surgery and are smaller and much sicker than previously seen. Significant morbidity and mortality in these patients result from postcardiotomy cardiogenic shock, which may necessitate mechanical support of the sick ventricle(s) even if it did not require support preoperatively. Second, heart transplantation in the pediatric population has become much more successful in the past few years as the result of improved pretransplant diagnosis, better rejection prevention, and more sophisticated monitoring of rejection, leading to a vast increase in the potential recipient pool.[236] The donor pool has not increased with the demand, however, and is even more disparate in the pediatric population than in the adult population; therefore, patients are waiting longer for transplants and tend to be much sicker before they receive a new heart.[237,238] The number of pediatric patients that potentially could benefit from VADS as a bridge to transplant has been estimated to be 7,000–30,000 patients per year in the United States alone.[239]

ECMO

ECMO is the most widely used ventricular support modality in the United States. It has been shown to be quite successful and technically easier to initiate and discontinue, and it has the ability to provide oxygenation support in associated pulmonary failure/inadequacy. One study reported that approximately 40% of pediatric patients requiring ECMO for myocardial failure recovered sufficient function to allow them to be discharged from the hospital intact.[240,241] This includes patients with palliative anatomy, such as bidirectional Glenn, and those post Fontan[242]; however, single-ventricle physiology patients have decreased survival to hospital discharge.[243] ECMO use within 24 hours of cardiac arrest suffered in the ICU has been shown to be associated with reduced mortality (odds ratio, 0.8%; confidence interval, 0.04–0.76).[244] ECMO is highly successful and technically feasible for use as a rescue device in patients undergoing interventional cardiac procedures, and successful outcomes have been demonstrated even with extended pre-ECMO cardiopulmonary resuscitation times.[245–247] One center described routine postoperative support of patients after the Norwood stage I procedure with good results,[248] and ECMO has been used and shown to be safe in neonates as small as 1.6 kg.[249] Favorable outcomes as high as 48% for ECMO have been reported when used as a bridge to

transplant.[250,251] Preprimed ECMO circuits may remain clear primed and stagnant for up to 30 days and still be able to far exceed the required minimum of 6 mL O_2/kg /min required by neonates for the first 6 hours of support.[252]

ECMO is associated with multiple, serious potential liabilities that can lead to increased frequency and acuity of complications. The nonpulsatile flow delivered by ECMO is nonphysiologic and associated with slower, more hemodynamically unstable, and longer recovery times. The list of liabilities includes requirement for anticoagulation and associated increased bleeding, embolization (air and/or thromboembolism), need for deep sedation and immobilization, and need for constant sophisticated physiologic and laboratory monitoring. Finally, ECMO cannulation of the carotid vessels is controversial and may lead to increased incidence of neurologic deficits via cerebral infarcts and/or hemorrhage. Venovenous ECMO cannulation is useful when cardiac output support is not required, as pulsatile blood flow is preserved and there is no arterial compromise and no direct route for embolization to the arterial system (barring intracardiac atrial or ventricular right-to-left shunting), all of which may contribute to a lower incidence of neurologic complications.[253] There is also increased oxygen delivery to the myocardium and pulmonary vascular bed with venovenous ECMO, and it may be delivered through a single cannula in tiny neonates.[253] Venovenous ECMO does present the disadvantage of requiring ongoing, possibly intense respiratory/mechanical ventilation support.

The invasive nature of ECMO cannulation increases the risk of potentially fatal infections. The risk of these complications is magnified as the patient's time on ECMO increases, making ECMO generally unsuitable for long-term support (more than a few weeks at most).[254,255] These complex associated difficulties have helped fuel the search for alternative support modalities.

VADs

VADs for pediatric patients have become much more sophisticated and more available in the past few years as their size has decreased, but they still are trailing adult devices in the development process. This is primarily secondary to the smaller number of patients requiring the devices and the historically superior results in pediatric patients, compared with adult patients, treated with ECMO in the United States. Smaller devices operated at low flow rates historically have shown increased propensity for thrombosis and embolus formation[256]; this is improving with better anticoagulation protocols, more postoperative care experience, and improved device materials that are less thrombogenic.[257]

Use of VADs is much more common in Europe than in the United States, and the results have been very encouraging. Multiple new devices are now in common use as the result of these recent successes.[258] The Thoratec VAD (Thoratec Corporation, Pleasanton, CA) is still the most common, having been used in more than 1000 patients worldwide since its launch. Thoratec VADs are paracorporeal devices attached to a large driving console and are less suited to long-term support.[259] They have been used in patients with a body surface area as small as 0.7 m^2. In a large series, survival rates in small patients were higher (~72%) for patients with cardiomyopathy or myocarditis than for patients with congenital cardiac anomalies (~14%).[260] A previous multicenter study showed that 60% of patients survived to transplant, but only 10% survived after recovery of their native heart.[261] The most common complication associated with the Thoratec VAD is infection, and the most common cause of death is multiorgan failure; embolization is always possible.[299] The Berlin Heart VAD and the Medos VAD (MEDOS Medizintechnik AG, Stolberg, Germany) have been used with good results in Europe as a bridge to ventricular recovery and transplantation and are now arriving for use in the United States. They are favorable for use in the pediatric population because they are available in multiple ventricle and cannula sizes.

The Medos DeltaStream DP1 VAD (MEDOS Medizintechnik AG) is an extracorporeal rotary pump with a diagonal flow impeller capable of both continuous and pulsatile blood flow. It has a very small priming volume (~30 mL) and a high pumping capability (≤ 8 L/min).[262] Clinical trials now underway have initially shown faster lactate recovery, reduced need for inotropic support, reduced assistance duration needed in bridge-to-recovery cases, and smoother, more physiologic hemodynamics in patients receiving pulsatile flow delivery.[262]

The Berlin Heart VAD is pneumatically driven, delivers pulsatile flow, and has been implemented in patients as small as 4 kg.[263,264] By 1999, the Berlin Heart VAD had been implanted in more than 350 European patients, and it has been used in patients for as long as 114 days. Overall survival rates have been reported as high as 69% for the Thoratec VAD, 49% for the Berlin Heart VAD, and 36% for the Medos VAD.[265] These numbers are not statistically different from ECMO.[258] When used as a bridge to transplant, the 1-month survival rate for VADs is 72% and, as with ECMO, was higher in patients with cardiomyopathies compared with congenital cardiac defects. Complications associated with VAD use include minor infection at cannula exit sites, generalized sepsis, hemorrhagic events, and thromboembolic events.[258] These complications have been shown to be less common with VADs than with ECMO.[266] Patients with the Berlin Heart VAD consume fewer red blood cell units, platelets, and fresh-frozen plasma compared with ECMO, which decreases exposure to potential blood-borne pathogens.[267] Potential advantages of VADs compared with ECMO are increased patient mobility (possibly even return to home and/or school), increased level of physical activity, and longer complication-free use time. However, use of these devices is just as expensive as ECMO and dramatically increases the cost of hospitalization and the overall costs of cardiac transplantation.

Intraaortic Balloon Pumps

Use of intraaortic balloon pumps (IABPs) in the pediatric patient population has been reported, but in general their effectiveness is limited in this setting. Infants and small children have small vessels for access and exhibit increased aortic elasticity, rapid heart rates (which makes synchronization difficult), and small stroke volumes.[268] They also frequently suffer from right heart dysfunction, which is not supported by IABP.

Conduct of the Anesthetic

Anesthetic Plan and Goals

Virtually all children with CHD tolerate well-managed anesthetics, but their tolerance for events, such as loss of airway patency, hypoventilation, in-

BOX 52–8.

Indices of Critical Impairment in Congenital Heart Disease

- Arterial saturation <75%
- Qp:Qs >2:1
- Left ventricular outflow tract gradient >50 mm Hg
- Right ventricular outflow tract gradient >50 mm Hg
- Pulmonary vascular resistance >6 Woods units
- Polycythemia with hematocrit >60%

Qp, Pulmonary flow; Qs, systemic flow.

appropriate amounts and choices of anesthetics, and major intraoperative surgical insults, often is limited. The anesthetic plan should be aimed at maintaining or improving existing circulatory homeostasis throughout the procedure, but particularly during induction of anesthesia. Because resuscitation may be very difficult in patients with CHD once cardiovascular collapse occurs, prevention of circulatory decompensation is the priority. This makes anticipation of potential problems a particularly important part of the anesthetic plan.

Preoperative Assessment

An important aim of preoperative assessment is identifying those patients with CHD who are likely to develop problems. Cardiac catheterization and echocardiographic data are most useful. Box 52–8 lists the critical indices of severe circulatory impairment in CHD. Patients who have any one of these indices are at risk for perioperative hemodynamic problems. If a patient has two or more of the listed criteria of critical impairment, particular care should be taken with planning the anesthetic. In such patients, depending on the experience of the anesthesia team, consultation with the patient's cardiologist to clarify critical aspects of the patient's pathophysiology may be advisable. In patients who have CHD that does not include any of the criteria listed in Box 52–8, the chances of hemodynamic problems with anesthesia are relatively low. Additional risk factors for patients with CHD undergoing anesthesia are listed in Box 52–9.

Preoperative Preparation and Medication

Before surgery, patients should be in the optimum condition allowed by their underlying disease. Emergency operations in critically ill, severely hypoxemic, and acidotic neonates are rarely necessary because of the advent of PGE_1 treatment of ductus-dependent circulation in those with CHD. A period of 24–48 hours of medical therapy markedly improves the condition of most critically ill children with CHD and lessens perioperative morbidity. Such therapy should be considered part of the preoperative preparation of sick children with CHD.

Patients with more chronic problems, such as congestive heart failure and chronic pulmonary infections resulting from excessive pulmonary blood flow and congestion, should be at their pulmonary baselines if possible. Children taking cardiac medications should continue doing so up to and including the morning of surgery, except for diuretics. Preoperative medication can take many forms. A good preoperative visit may establish sufficient rapport with parents and child to eliminate the need for preoperative medication, whereas relatively large doses of IV sedation may be needed for the extremely anxious child. The goal should be a lightly sedated patient without respiratory depression. In patients with severe hypoxemia and cyanosis or with pulmonary hypertension, premedication should be relatively light to prevent depression of ventilation that may exacerbate their decreased hypoxic ventilatory drive or further increase their PVR. When the anxiety level is high and severe hypoxemia, severe congestive heart failure, or pulmonary hypertension precludes heavy premedication before the patient arrives in the preoperative holding area, intramuscular ketamine and midazolam are given just before the child is taken to the operating room. Such premedication is well tolerated by all but critically ill children and can ease the difficulties experienced by children and parents. Properly monitored transport should be available, with an anesthesia caregiver in constant attendance. This combination of drugs is quickly effective so that a deeply sedated child can be separated from anxious parents. Use of portable pulse oximetry and a precordial stethoscope often are advisable for the trip to the operating room. If there is any question of cardiac stability during this period, an IV line is started immediately after sedation is given or, in extreme cases, even before sedation. With the availability of eutectic mixture of local anesthetics (EMLA) cream, preoperative IV insertion for premedication has become much easier.

BOX 52–9.

General Associated Risk Factors in Congenital Heart Disease

- Severe form of isolated lesion
- Complex lesions
- Concurrent infectious disease
- Metabolic derangements
- Congestive heart failure
- Previous palliative or corrective procedures
- Acute hemodynamic deterioration

Alternatively, oral midazolam at a dose of 0.75–1.0 mg/kg can be given to small children in the presence of the anesthesia provider. This often results in excellent premedication and may be supplemented by intramuscular ketamine, if needed, mixed with atropine or glycopyrrolate.

Induction of Anesthesia

Because of the potential for rapid and dramatic hemodynamic changes in young patients with CHD, especially infants, complete preparation of anesthetic and monitoring equipment and required drugs is essential. Adequate assistance should be immediately available during induction, particularly if the patient meets a number of the criteria of severe disease listed in Table 52–1. Flexibility is needed in the choice of induction techniques because response to premedication and emotional needs of parents and children facing a cardiac procedure can place constraints on choices.

Choice of induction technique is influenced by response to premedication and the parent–child–anesthesia provider relationship and to the anesthetic management plan. In older patients who are not hypoxemic and have minimal compromise of cardiac reserve, choice of induction techniques is large. Rectal, intramuscular, IV, or inhalation induction techniques using various agents can be used with reasonable safety if individual pathophysiologic limitations are respected. Choices decrease for younger, sicker, and less cooperative patients. In older children with only mildly compromised cardiac function, rectal admin-

istration of anesthetics, such as barbiturates, can be a useful technique, but lack of control and potential for circulatory depression make this technique unacceptable for sick infants.

In children with good IV access, quick insertion of a small-bore IV needle for induction can be virtually painless if sufficiently long applications of EMLA cream are used. Cooperative small children who have adequate cardiac reserve but difficult IV access or a morbid fear of needles can be induced cautiously with inhalational anesthetics, even if they are cyanotic. An IV catheter is then inserted expeditiously to facilitate intubation with adjunctive IV agents, avoiding the risk of deep levels of inhalational anesthesia in circulatory systems with little reserve, particularly in the immature circulation of the infant. Such use of an inhalational anesthetic for induction of patients with severe CHD without the presence of a working IV heavily depends on the judgment of the anesthesia provider for safety.

Maintenance of Anesthesia

Maintenance of anesthesia in the pediatric heart patient depends on preoperative status and response to induction and on the surgical procedure and intraoperative events. Whether inhalational agents, additional narcotics, or other IV agents are used for maintenance depends on patient tolerance and postoperative plans for ventilatory management. In children with CHD, intraoperative changes in cardiac shunting are unique problems during maintenance of anesthesia. Whether clinical deterioration is caused by changes in shunting or by primary myocardial depression or dysfunction is not always clear, the intraoperative events and progress of the anesthetic usually suggest a cause. Hypotension and hypoxemia, particularly during induction of anesthesia, should be managed aggressively and immediately. Decreases in arterial oxygenation or systemic blood flow may be caused by alterations in intracardiac shunting in these children and usually can be managed by manipulations of PVR/SVR; however, inotropes are needed in some patients, assuming their circulating blood volume is adequate.

Manipulation of PVR and SVR

Manipulation of PVR/SVR allows some control over shunting, depending on specific pathophysiology. PVR is particularly important because of the frequency of disturbances of pulmonary blood flow and right-sided defects in patients with CHD. Usually the goal is to decrease PVR in order to improve pulmonary flow, right heart function, and oxygenation, but in some lesions, pulmonary flow is excessively high at the expense of systemic output, requiring increases in PVR.[40] Many intraoperative manipulations tend to alter PVR. Manipulations that increase PVR are frequent problems because of the increased reactivity of the abnormal pulmonary vasculature often found in patients with CHD. These manipulations include sympathetic stimulation, encroachments on lung volumes that produce atelectasis (surgical retraction, pleural and peritoneal collections, and abdominal packing), CPB, alveolar hypoxia, and hypoventilation. Manipulations that increase and decrease PVR are listed in Box 52–10. Ventilation is important because it is subject to control by the anesthesia provider and is crucial in attempts to control PVR via airway pressure, lung volumes, alveolar $Paco_2$ and Pao_2, and other, less well-understood variables.

The effects of various anesthetics on PVR are poorly understood. Ketamine and nitrous oxide increase PVR in adults, but studies of ketamine and nitrous oxide in infants with normal or elevated PVR have shown no increase in PVR when ventilation and FiO_2 are constant.[163,187,188] Stress responses in the pulmonary circulation of patients with CHD are a primary concern in some patients. Large doses of potent narcotics, such as fentanyl, attenuate pulmonary vascular responses to noxious stimuli, such as endotracheal suctioning in infants, but they do not change baseline PVR.[269,270] Reactive pulmonary hypertensive responses are partially mediated by the sympathoadrenal axis and thus are attenuated by an adequate depth of anesthesia. CPB increases PVR through activation of the inflammatory response, cytokine release, and ischemia of the endothelium in the pulmonary circulation. After bypass surgery, elevated PVR can be a substantial problem.

PVR can be controlled independently of SVR by manipulating various aspects of ventilation (Box 52–10). Nitric oxide delivered through alveoli has been shown to be a pulmonary vasodilator and to be effective in patients with CHD.[270] In contrast to inhaled nitric oxide, even selective infusions of rapidly metabolized vasodilators (e.g., nitroprusside) into the pulmonary circulation can result in systemic drug concentrations and systemic hemodynamic effects without desired effects on PVR.[270] Nitric oxide has been shown to be effective in selectively reducing PVR in a variety of different CHD lesions accompanied by high PVR; this can be accomplished without altering SVR.[271] Not all patients with CHD and high PVR respond to inhaled nitric oxide, particularly after the neonatal period, but nitric oxide therapy should be tried whenever high PVR is a substantial problem in patients of any age with CHD.[272] High levels of inspired oxygen, especially 100% O_2, also decrease elevated PVR in infants without changing SVR, whereas inspired oxygen levels ≤ 21% increase PVR.[273,274,278,279] Hypoventilation, with associated acidosis and hypercapnia, increases PVR. Hyperventilation to alkalotic pH >7.50 and low $Paco_2$ reliably decreases PVR in infants and improves right ventricular function.[275–278] This maneuver increases pulmonary blood flow and decreases right-to-left shunting in neonates, increasing Pao_2.[279,280] Although prolonged hyperventilation to decrease PVR theoretically may cause problems from decreased cerebral blood flow, clinical and

  - Low hematocrit
  - Inhaled nitric oxide

experimental studies in hyperventilated infants show no evidence of cerebral damage.[278,281,282] The pattern of ventilation and PEEP can alter PVR. PVR is lowest at normal functional residual capacity. At low lung volumes with atelectasis and at high lung volumes with hyperinflation of alveoli, PVR increases.[283] High levels of PEEP increase PVR primarily by hyperinflation of alveoli, but if atelectasis and pulmonary edema are corrected by PEEP, PVR may decrease. Different patterns of ventilation may further reduce PVR by releasing prostacyclin in the pulmonary vasculature.[284,285]

Manipulation of SVR with vasopressors is useful when there is a need for increased coronary perfusion pressure or a need to decrease right-to-left shunting that causes severe systemic hypoxemia. Phenylephrine has been shown effective in reducing right-to-left shunting in patients with tetralogy of Fallot and increasing SaO_2.[286] A mechanical method for increasing SVR to decrease right-to-left shunting in tetralogy of Fallot is compression of the abdominal aorta. This can be done immediately and can be used to gain time while other pharmacologic therapy is started or while the child is prepared for CPB.

CHAPTER 53

Thoracic Anesthesia

Stuart J. Weiss, MD, PhD, and
E. Andrew Ochroch, MD, MSCE

Advances in the management of thoracic disease parallel the advances in thoracic anesthesia and surgery. In the early 20th century, thoracic surgery was limited to rib resection, decortication, and drainage of empyema as management for tuberculosis. During the first part of the 20th century, pulmonary resections were accomplished by tightening a snare or tourniquet around the lesion and subsequently removing the necrotic tissue several days later. These procedures depended on the iatrogenic development of a passive pneumothorax in spontaneously ventilating patients. As expected, the unilateral pneumothorax was poorly tolerated and was associated with mediastinal shift, dyspnea, and rapid ineffective spontaneous respiratory movements. A high incidence of perioperative morbidity resulted from infection, hemorrhage, and air leak.

The period from 1930–1950 saw major advancements in surgery and anesthesia. In the 1930s, Drs. Gale and Waters in the United States and Magill in the United Kingdom developed the techniques of endobronchial intubation and placement of bronchial blockers, respectively, to selectively ventilate one lung. In addition, the introduction of muscle relaxants and controlled ventilation improved patient safety and surgical operating conditions. The development of single-lung isolation techniques accelerated from 1950–1960 with the development of double-lumen endotracheal tubes. In addition, patient safety and anesthetic management were markedly improved by the introduction of halogenated inhalational anesthetics and the dramatically increased use of perioperative physiologic monitoring. More recently, use of the fiberoptic bronchoscope greatly increased the success of single-lung ventilation by facilitating the placement and confirmation of position of double-lumen endotracheal tubes and bronchial blockers.

KEY POINTS

1. Thoracic surgery is being performed on patients with more severe pulmonary disease than performed in earlier years. Previous exclusion criteria for undergoing general anesthesia now are considered overly conservative.
2. Because the mortality rate of untreated lung cancer approaches 100%, assigning definitive exclusion criteria for lung resection is difficult. Parameters used to predict patients at increased risk for postoperative complications include forced vital capacity, forced expiratory volume in 1 second, split lung functions, and exercise tolerance.
3. Patients undergoing thoracic surgical procedures often have preexisting pulmonary and cardiac disease.
4. Preoperative symptoms of dyspnea, shortness of breath, and hoarseness of voice may be related to thoracic tumor pathology. Possible etiologies include superior vena cava obstruction, mediastinal mass, tracheal compression, tracheomalacia, and malignancy.
5. One goal of preoperative preparation is to improve pulmonary function by use of bronchodilators for reactive airway disease, antibiotics for infection, and education to promote the cessation of smoking. Smoking should stop at least 4–8 weeks preoperatively.
6. Routine diagnostic procedures that are performed to confirm and evaluate the extent of pulmonary and thoracic disease include bronchoscopy, mediastinoscopy, and video-assisted thoracoscopic surgery.
7. The anesthetic plan should be coordinated with the surgeon and support staff to limit perioperative risk. In high-risk patients, anesthesia can proceed with a slow, controlled, staged induction that can be stopped if respiratory difficulties ensue.
8. Lateral decubitus position impacts negatively on the physiology of ventilation and circulation and is associated with position-related injuries.
9. Fiberoptic bronchoscopy is the most reliable method for ascertaining correct positioning of the double-lumen endotracheal tube and assuring pulmonary toilet.
10. When using single-lung ventilation, the anesthesiologist should be especially alert to problems with ventilation or oxygenation. The majority of problems are related to malposition of the double-lumen tube. Once proper position of the tube is confirmed, management strategies include (1) increased oxygenation to dependent lung (positive end-expiratory pressure, increased tidal volume, increased fraction of inspired oxygen), (2) increased oxygenation of blood flowing to the nondependent lung (continuous positive airway pressure, intermittent ventilation), (3) decreased blood perfusion to nondependent lung (discontinue drugs that inhibit hypoxic pulmonary vasoconstriction, ligature to pulmonary artery), increased oxygen content of blood (transfusion, improve mixed venous oxygen saturation), and (4) increased perfusion of the dependent lung (increased cardiac output and administration of a pulmonary vasodilator).
11. Hypoxic pulmonary vasoconstriction is a homeostatic mechanism that limits perfusion of unventilated nonoxygenated atelectatic alveoli, thereby decreasing the shunt admixture. Hypoxic pulmonary vasoconstriction is activated by decreased alveolar oxygen tension but is inhibited by certain anesthetic agents and vasodilators.
12. Volume reduction surgery and other sophisticated intrathoracic operations require careful and complex planning and constant vigilance to maintain adequate ventilation, oxygenation, and hemodynamic stability.
13. Postoperative management after thoracotomy or thoracoscopy is directed to the balance between pain relief and respiratory depression associated with opioids. Epidural analgesia represents best practice in these patients.

Thoracic surgery and anesthesia continue to evolve. The development of endoscopic surgery has revolutionized thoracic surgery by providing for relatively noninvasive access to thoracic cavity contents. Although endoscopic surgery has not replaced open thoracotomy for major pulmonary surgical resections, its use has further expanded to nonpulmonary surgery, such as thymectomy, pericardectomy, and sympathectomy. Surgical management of end-stage disease by lung reduction and transplantation are additional current challenges for thoracic anesthesiologists.

This chapter focuses on important perioperative considerations for the patient undergoing thoracic surgery. The initial portion of the chapter presents the relevant anatomy and pathophysiology. The next sections focus on specific anesthetic concerns and perioperative management issues of operative procedures. Our approach to the anesthetic management of these patients should be flexible to allow for either the short diagnostic procedure or the prolonged anatomic tumor resection. Current strategies for staging and management of lung tumors call for sequential bronchoscopy, mediastinoscopy, and pulmonary resection. In addition, nonpulmonary thoracic operations, such as thymectomy, pericardectomy, and sympathectomy, use many of the same techniques and management strategies.

ANATOMY/PHYSIOLOGY

Thoracic Cavity

The thoracic cavity is formed by the ribs laterally, sternum anteriorly, vertebral column posteriorly, and diaphragm and thoracic inlet inferiorly and superiorly. The thoracic cavity encompasses the lungs, which provide oxygenation of venous blood, excretion of carbon dioxide, and metabolism of endogenous compounds.

Airway

The trachea is the initial conduit for air flow. Its cross-section is outlined by the horseshoe shape of the cartilage anteriorly and the membranous portion posteriorly. The membranous portion consists of a fibrous envelope containing smooth muscle and epithelium. The location of the membranous trachea and the vertical orientation of the exposed muscle fibers guide fiberoptic-assisted placement of double-lumen endotracheal tubes into the appropriate side. The innominate artery lies just anterior to the trachea. Tracheal–innominate fistulae are rare but lethal complications of tracheal resection, tracheostomy, and prolonged intubation.

The trachea initially bifurcates into the right and left mainstem bronchi and then into the lobar and segmental bronchi. The right bronchus is shorter, wider, and more in line with the trachea compared with the left bronchus. Because of the more oblique orientation of the left bronchus, inhaled foreign bodies and aspirated fluid are more likely to go into the right bronchus. The right bronchus provides access to three lobes (upper, middle, lower) that are separated by major fissures. On the left, a major fissure separates the lower and upper lobes. The lobes of the lung are subdivided into bronchial pulmonary segments, each of which has its own bronchus, artery, and vein. The movement of air progresses through a series of branching tubes, which become narrower and more numerous as they penetrate deeper into the lung. The conducting airways contain no alveoli and therefore contribute a portion, approximately 50 mL, of the anatomic dead space.

Mediastinum

The mediastinum is the region between the two pleural sacs. It contains the heart, great vessels, and thymus gland. For purposes of description, the mediastinum is divided into four subdivisions (middle, posterior, anterior, superior). The middle mediastinum contains the pericardium with the adjacent phrenic nerves, the heart, and the great vessels emanating to and from it. The superior mediastinum lies between the thoracic inlet and the horizontal plane connecting the sternal angle with the lower border of the fourth thoracic vertebrae. The main contents of the superior mediastinum are the thymus, great vessels, and several nerves. The posterior mediastinum, which is bounded anteriorly by the pericardium and posteriorly by the vertebral column, contains the thoracic aorta, thoracic duct, azygos and hemiazygos veins, esophagus, and bifurcation of the trachea with the two bronchi. The anterior mediastinum, which lies between the sternum and the pericardium, contains lymphatic vessels, lymph nodes, and branches of the internal thoracic artery.

Pulmonary Vasculature

The lungs are blood vessel-rich structures with extensive capillary networks that allow gas exchange. The main pulmonary artery (PA) branches and follows the bronchial tree, decreasing in size with each bronchial generation. The arteries branch to supply the respiratory bronchioles and alveolar sacks, which provide for gas exchange. The vascular endothelial surfaces form boundaries of the capillaries and occupy approximately 50% of the surface of the alveolar wall.

The pulmonary capillary network provides an enormous surface area not only for gas exchange but also for active metabolism, synthesis, and release of stored vasoactive substances. The lung maintains an active role as a biochemical filter, inactivating exogenous and endogenous substances by metabolic elimination or cellular uptake. The release of vasoactive substances can be stimulated either by manipulation during surgery or by hypoinflation or hyperinflation. One example is hypoxic pulmonary vasoconstriction (HPV), which functions in a homeostatic capacity to normalize the perfusion to ventilation inhomogeneity caused by alveolar hypoxia.

The metabolic functions of the pulmonary circulation can trigger pathologic consequences. Anaphylactoid response to protamine is of particular importance to the cardiac anesthesiologist. The biologically active substances [histamine, slow-reacting substance of anaphylaxis, prostaglandin E_1 (PGE_1), prostaglandin E_2 (PGE_2), prostaglandin F_2 (PGF_2), bradykinin] are released in response to specific biochemical and mechanical triggers.

Bronchial Vessels

The bronchial vasculature normally accounts for approximately 1% of the cardiac output, but it may increase its flow in response to acute lung disease or injury. The origin of the bronchial arteries is variable, coming from the aorta or the intercostal, subclavian, or innominate arteries. The bronchial arteries enter the hilus of the lung and form a communicating arc around the main bronchus. The vessels follow the bronchi distally, supplying the vasa vasorum of the PAs and bronchi. The

dominant deep bronchial venous system drains into the pulmonary veins, and the lesser superficial system of bronchial veins drains into the azygos, hemiazygos, and mediastinal veins. The clinical importance of the bronchial vasculature system is appreciated under conditions of acute lung stress or injury. Neovascularization and increased blood flow occur in response to acute and chronic lung disease. This response may help preserve normal pulmonary ventilation-to-perfusion ratio ($\dot{V}/\dot{Q}$) and protect the lung from ischemia. The absence of an intact bronchial arterial circulation in patients receiving a lung transplant place the new lung at increased risk for ischemic injury immediately after surgery.

Lymphatic System

The lymphatic circulation has a major role in maintaining the balance of fluids across the endothelial membrane. Transcapillary flow (F) is proportional to the difference between pulmonary capillary hydrostatic pressure (inside pressure – outside pressure) and the difference between the capillary oncotic pressure and the interstitial oncotic pressure (Fa) [P (inside – outside) – P (capillary – interstitial)]. Transcapillary flow also depends on the capillary filtration coefficient (K), which is a function of the effective capillary surface area and membrane permeability. Any clinical situation that impedes lymphatic flow increases the risk of pulmonary edema and pleural effusion. Abnormal clinical states that increase capillary permeability increase the flow of fluid into the interstitial space and increase the chance of developing pulmonary edema. In addition, pulmonary interstitial edema may result from marked increases in negative pleural pressure. Markedly increased negative pressures can result from upper airway obstruction (tumors, laryngospasm, epiglottis), rapid reexpansion of the lung, and aggressive suctioning.

The lymphatic drainage pattern is from the periphery toward more proximal lymph nodes, which are located at the carina and points of bifurcation of the bronchi and alongside the trachea and great cardiac vessels. The location of the lymph nodes is classified for prognostic assessment of primary pulmonary cancers. The lowest number is assigned to the most central nodes and progresses to greater numbers at the periphery. The pattern of lymphatic drainage impacts on the sensitivity and specificity of mediastinoscopy to diagnose and detect the spread of disease. Malignant disease of the right lung spreads ipsilaterally up the chain from the pulmonary nodes in the periphery to the paratracheal, scalene, or tracheal nodes more proximally. In contrast, disease from the left lung can either spread ipsilaterally or contralaterally up the chain or proceed subdiaphragmatically to the paraaortic lymph nodes. Biopsy of a lymph node unilateral to the lesion may provide false-negative results if spread occurs contralaterally or subdiaphragmatically.

Work of Breathing

During normal spontaneous inspiration, the major contribution to respiratory mechanics is by the contraction and downward excursion of the diaphragm, which increases the vertical dimension of the thorax. The dimensions of the thorax also are increased by the outward and upward swinging movement of the ribs during inspiration. The importance of diaphragmatic excursion and chest wall movement is most easily appreciated in patients with compromised respiratory function related to positioning. The patient in a flexed lateral decubitus or Trendelenburg position experiences increased abdominal pressure, which limits diaphragmatic excursion and chest wall movement. In addition, patients undergoing thoracic operations are at increased risk for phrenic nerve injury or diaphragmatic dysfunction, which may result in postoperative ventilatory compromise.

The mechanics of respiration are divided into the inspiratory and expiratory phases. The work of normal breathing is associated with the inspiratory phase, whereas expiration normally is a passive process related to elastic recoil of the lung and chest cage structures. The work of inspiration depends on overcoming airway resistance and the elastic forces created by the lung and chest wall mechanics. During normal quiet breathing, the work of respiration constitutes only 2–3% of total energy expenditure. During heavy exercise, pulmonary ventilation and total body energy expenditure may increase 15- to 20-fold, but the energy expended for ventilation increases only slightly to 3–4%. Pulmonary disease or dysfunction that alters compliance, airway resistance, or lung or chest wall mechanics can dramatically increase the work of breathing to one third or more of the total body energy expenditure. For example, the patient with preexisting respiratory disease having minimal reserve is at increased risk for postoperative ventilatory failure and may require reintubation because of diaphragmatic dysfunction and atelectasis.

Cough Reflex

A normal cough reflex is critical for maintenance of pulmonary toilet. Afferent impulses from the respiratory passages are conducted centrally by the vagus nerve. Efferent impulses trigger closure of the epiglottis, apposition of the vocal cords, and contraction of abdominal, chest, and diaphragmatic muscles to produce an explosive exhalation of air. Patients having postoperative dysfunction related to recurrent laryngeal or phrenic nerve injury, trauma to the diaphragm, or pain and who cannot cough effectively are at risk for respiratory failure related to aspiration and poor pulmonary toilet resulting in pneumonia. Such patients may benefit from conservative measures, such as breathing humidified gases to prevent inspissated secretions, chest physiotherapy, and nasal tracheal suctioning to clear secretions.

PREOPERATIVE EVALUATION OF THE PATIENT UNDERGOING THORACIC SURGERY

History

Most patients with lung cancer have a history of smoking and therefore have some degree of chronic bronchitis and emphysema. This history is important because the management of infections and reactive airway disease preoperatively will have a positive impact by decreasing the incidence of postoperative complications. Exercise tolerance also should be assessed because it will estimate the patient's cardiovascular and pulmonary reserve.[1–5]

Physical Examination

Along with a routine assessment of the airway and cardiovascular systems, the anesthesiologist should pay particular attention to the respiratory system during the physical examination. Observation of the respiratory rate and pattern may give insight into the

pulmonary reserve of the patient. The auscultation of wheezes, rales, or rhonchi indicates abnormalities that can be managed preoperatively. Clubbing of the fingernails may indicate chronic hypoxia or lung cancer. Deviation of the trachea may indicate a mediastinal mass, hemothorax, pneumothorax, or fibrothorax. The anesthesiologist should assess the patient's ability to tolerate the supine position, because an intolerance to this position may indicate congestive heart failure or major airway obstruction from a mediastinal mass.

Diagnostic Studies

Laboratory tests should be ordered based on positive findings elicited from history and physical examination. The complete blood count may reveal polycythemia, reflecting prolonged smoking and hypoxia, or leukocytosis, indicating an active infection. Liver function studies may be altered, indicating hepatic metastases or drug or alcohol effects.

The electrocardiogram (ECG) should be assessed for the presence of cardiac or pulmonary disease. Signs and symptoms of ischemia may indicate the need for further cardiac workup. Manifestations of cor pulmonale may indicate the presence of pulmonary hypertension, which may alter intraoperative management or portend intolerance to major pulmonary resection.[6] However, the futility of subsequent therapeutic intervention is controversial. Recent research on patients undergoing aortic or peripheral arterial bypass graft surgery indicates that, in some instances, coronary revascularization does not decrease the rate of perioperative myocardial infarction or long-term mortality.[7]

Abnormal chest radiographs frequently antedate the first sign or symptom of lung cancer by many months. The radiograph may reveal tumor, secondary changes in lung parenchyma distal to an obstructed airway, or other abnormalities caused by intrathoracic and extrapulmonary tumor spread. Radiographic findings that may have implications to perioperative anesthetic management are listed in Table 53–1. The tumor may impinge on the trachea or the mainstem bronchi and thus influence the induction of anesthesia or choice and placement of an endotracheal tube (Fig. 53–1). For example, tumor involvement of the trachea would suggest use of awake sedated fiberoptic intubation, whereas isolated impingement of the left bronchus would suggest use of a right-sided, double-lumen endotracheal tube.

TABLE 53–1.

Radiographic Findings with Important Anesthetic Complications

Abnormality	Anesthetic Implication
Tracheal deviation	Difficulty with intubation Identify cause: mediastinal mass, nodal metastasis, thyroid gland, aortic aneurysm, other
Mediastinal mass	Difficulty with intubation Difficulty with ventilation even after successful intubation (see section entitled Anesthesia for Patients with Mediastinal Masses) Possibility of superior vena cava syndrome and obstruction Cardiac and vascular compressions
Pleural effusion	Cor pulmonale congestive heart failure Need for additional monitoring Careful assessment of response to myocardial depression from anesthetic drugs
Bullae	Risk of rupture with positive pressure and creation of pneumothorax Wasted ventilation, increased dead space Compression of healthy adjacent lung
Abscess	Need for separation of two lungs to prevent spillage and contamination of healthy lung
Consolidation and atelectasis	Need to manage infections aggressively with antibiotics Ventilation/perfusion mismatch admixture and hypoxia
Normal chest radiograph	Patient still may have chronic, diffuse infiltrative lung disease with normal chest radiograph Computed tomography is superior to chest radiography in diagnosing diffuse infiltrative lung disease and should be done before lung biopsy

In addition, patients will undergo computed tomographic (CT) scan of the chest, which is helpful in delineating the presence or absence of high-level nodal and extrapulmonary spread of the disease. Further diagnostic workup is guided by these studies. If mediastinal nodes are suspected, mediastinoscopy or parasternal mediastinotomy may be performed to confirm the diagnosis and determine the extent of tumor spread. If clinical manifestations of distant organ involvement are present, appropriate investigations, such as bone scan and scan of the brain, liver, and upper abdomen, also should be performed.

Assessment of Respiratory Function

Preoperative evaluation of pulmonary functional reserve is used to estimate the patient's ability to tolerate thoracotomy and lung resection.[1,6,9–28] Patients undergoing thoracotomy for lung resection usually have a long-standing history of smoking and varying degrees of underlying lung disease. Therefore, they have decreased pulmonary reserve and are at increased risk for operative and postoperative morbidity and mortality. Smokers have a significantly increased risk for postoperative pulmonary complications: 8% for nonsmokers and 23% for smokers.[8] Carcinoma of the lung is associated with an average survival period of 18 months and a mortality rate of 100% after 5 years if not surgically treated. Therefore, every effort should be made to give the patient the benefit of surgical resection. It is difficult to answer the question, "What is an appropriate risk for rendering the patient a respiratory cripple postoperatively when managing a disease with a mortality rate of almost 100%?" Although most patients do not undergo a complete pneumonectomy, they should be evaluated as potential candidates. Not uncommonly, a more extensive resection is needed than initially anticipated. The next section discusses the tests

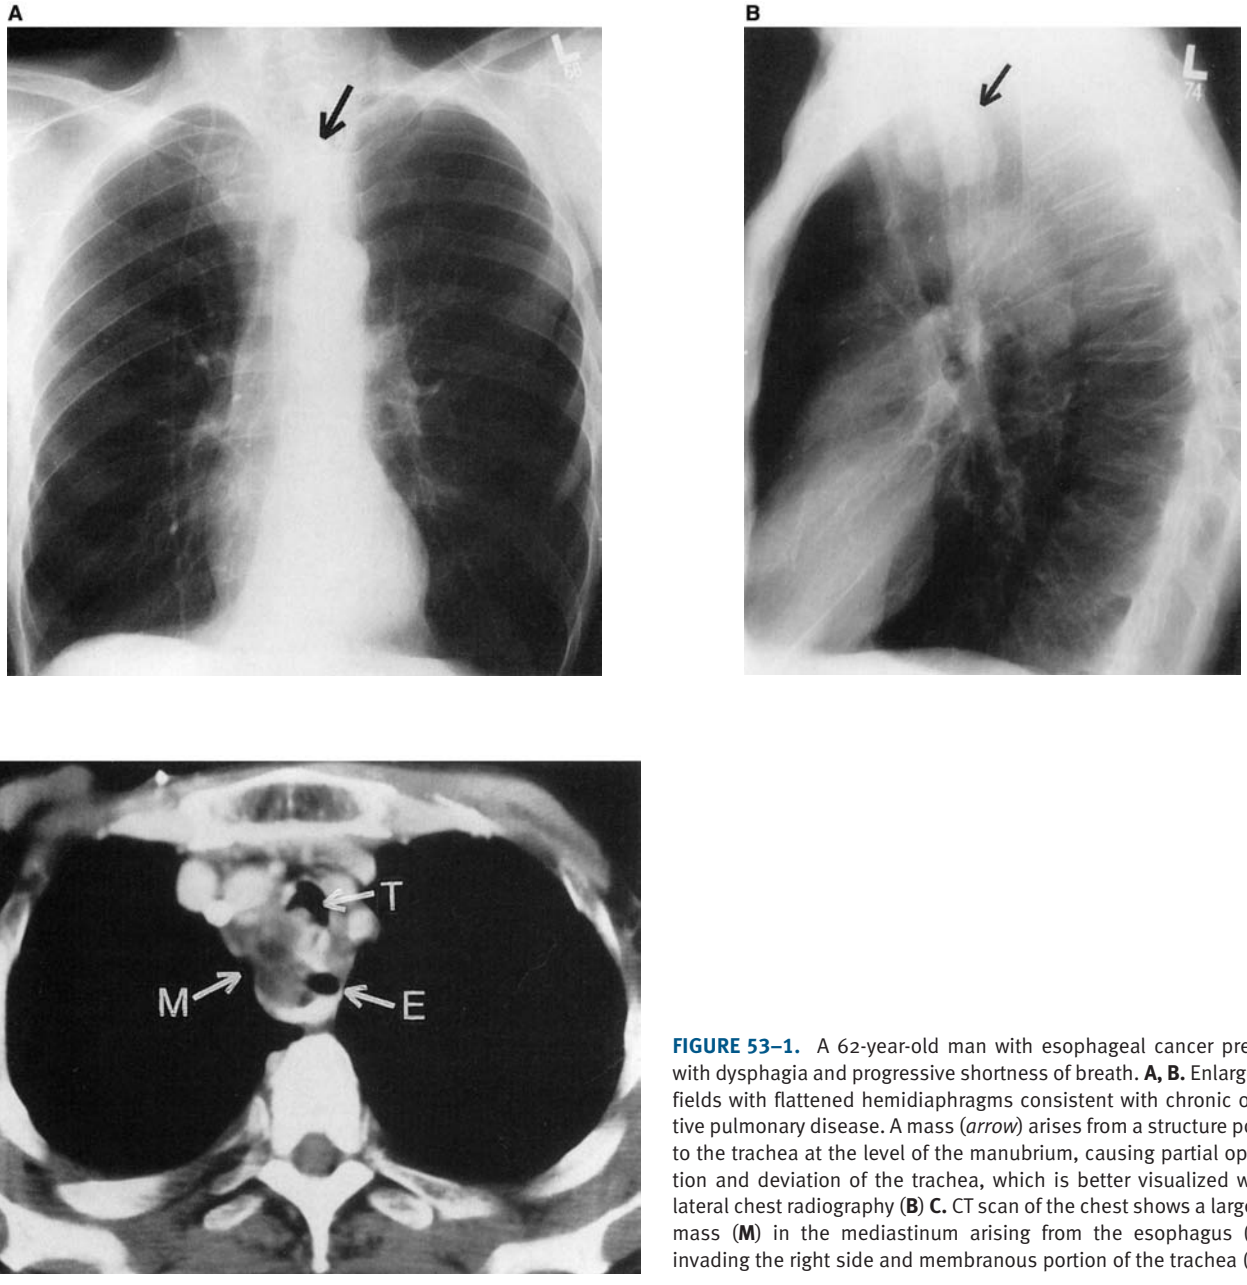

FIGURE 53–1. A 62-year-old man with esophageal cancer presented with dysphagia and progressive shortness of breath. **A, B.** Enlarged lung fields with flattened hemidiaphragms consistent with chronic obstructive pulmonary disease. A mass (*arrow*) arises from a structure posterior to the trachea at the level of the manubrium, causing partial opacification and deviation of the trachea, which is better visualized with the lateral chest radiography (**B**) **C.** CT scan of the chest shows a large tumor mass (**M**) in the mediastinum arising from the esophagus (**E**) and invading the right side and membranous portion of the trachea (**T**).

available for assessing respiratory function and the criteria for eligibility to undergo thoracotomy and pulmonary resection (Fig. 53–2).

Arterial Blood Gas Analysis

Arterial carbon dioxide tension >40 mm Hg suggests increased risk for postoperative complications. Because hypercapnia may be reversible, attempts should be made to correct all potential reversible conditions, such as bronchospasm and infection. In contrast, hypoxemia is not a consistent criterion for increased risk. The change in arterial partial pressure of oxygen (Pao_2) after thoracotomy and lung resection varies. Lung resection beyond the tumor may not be associated with any further decrement in oxygenation, but it may increase oxygenation by improving $\dot{V}/\dot{Q}$ matching. Tumors that have occluded the bronchus and the blood supply have already caused a functional resection.

Spirometry

Spirometry has proved to be an effective, inexpensive, noninvasive way of measuring pulmonary reserve and predicting postoperative pulmonary function. Abnormal spirometry results that suggest an increased risk for postoperative pulmonary complications include forced vital capacity (FVC) <50% of predicted, forced expiratory volume in 1 second (FEV_1) <2 L, and FEV_1/FVC <50%. Other tests of predictive value are the maximum voluntary ventilation (MVV) and the diffusing capacity of lung for carbon monoxide (DLCO). MVV is effort dependent, requiring the patient to breath as quickly and as deeply as possible for 6–12 seconds. This test is similar to an exercise test because it reflects the entire cardiorespiratory system and the patient's cooperation and motivation. DLCO is reemerging as an important predictor of risk in patients undergoing pulmonary resection. Several studies have shown that DLCO is a good predictor of postoperative complications, including death

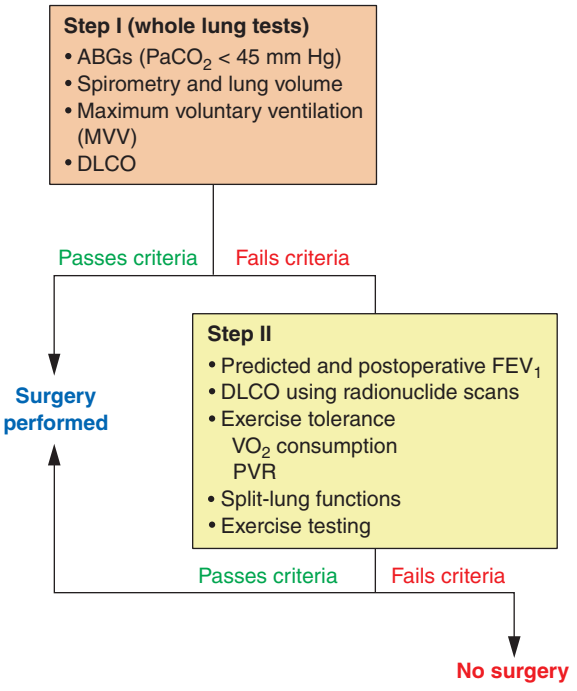

FIGURE 53–2. Sequence of tests for lung resection.

BOX 53–1.

Factors That Predict Increased Perioperative Morbidity and Mortality

$Paco_2$ >45 mm Hg
Pao_2 <50 mm Hg on room air
Inability to walk 2000 feet in 6 minutes
Inability to ascend two flights of stairs
Inability to attain 7.5 mL/kg/min O_2 consumption
Predicted postoperative FEV_1 <30% of expected normal value for patient
Combined predicted postoperative FEV_1 <35% and predicted postoperative DLCO <35% of expected normal value for patient
Measures of right-heart catheterization after balloon occlusion of PA of a mean PA pressure >35 mm Hg, Pao_2 <45 mm Hg, $Paco_2$ >60 mm Hg

DLCO, Diffusing capacity of lung for carbon monoxide; FEV_1, forced expiratory volume in 1 second; PA, pulmonary artery; Pao_2, arterial partial pressure of oxygen; $Paco_2$, arterial partial pressure of carbon dioxide.

and respiratory failure (Fig. 53–3). DLCO < 50–60% of the predicted value is an indication for further testing with split lung function studies before undertaking major pulmonary resection.

Split Lung Function and Ventilation: Perfusion Studies

Patients who are deemed to be at increased risk after the initial phase of the pulmonary function evaluation should undergo additional testing to assess the effect of lung resection. The goal is to predict the impact of resection on postoperative lung function. The involved lung tissue may contribute little to existing lung function, and therefore its removal may not cause further deterioration of pulmonary function. Thus, some patients who would be denied operations based on the initial results may be considered surgical candidates after more specific evaluation.

The effect of anticipated lung resection can be predicted using radioisotope ventilation scans, perfusion scans, or a combination of both. More recently, dynamic perfusion magnetic resonance imaging (MRI)[29] and quantitative CT have been shown to be as accurate as perfusion scintigraphy at predicting postoperative FEV_1.[30] Most authorities consider the minimal predicted postoperative FEV_1 that will be tolerated by a patient is 800 mL (Box 53–1). This is based on the observation that patients with chronic obstructive pulmonary disease (COPD) having FEV_1 < 800 mL had dramatic reduction in their level of daily function.[25] Additionally, patients with COPD start retaining CO_2 and developing hypercapnia when their FEV_1 value is < 800 mL.[31] These previous studies may have been overly conservative.[31,32] Because an absolute value for FEV_1 does not account for persons of different gender, height, and age, some physicians base their decision on FEV_1 > 30–40% of the predicted value.[22]

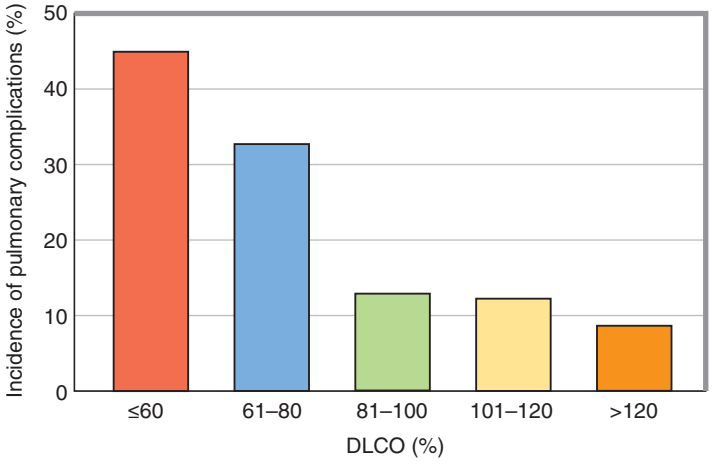

FIGURE 53–3. Prevalence of pulmonary complications after major pulmonary resection versus diffusing capacity of lung for carbon monoxide (%) in 165 patients.

The radioactive technetium-99scan yields data about regional perfusion, and the xenon-133 ventilation scan provides data about regional ventilation and lung volumes. The results allow estimation of the fraction of lung function that is contributed by the lung segments to be removed. The equation for calculating the predicted postpneumonectomy lung function is: Postoperative FEV_1 = Preoperative FEV_1 × Perfusion (%) to the remaining lung. A modification of this equation has been proposed to predict the decrement in lung function after lobectomy: Loss of

BOX 53–2.

Clinical Signs and Symptoms of Pulmonary Hypertension, Right Ventricular Hypertrophy, and Cor Pulmonale

- Patient has prominent neck veins, prominent A waves, and perhaps prominent V waves seen on electrocardiogram.
- Prominent left parasternal heave and rocking motion synchronous with heartbeat may be present.
- Dullness to percussion over left second intercostal space near sternum may be present, indicating dilatation of main pulmonary artery. However, if too much emphysema is present, entire precordium may be resonant because of hyperinflation of lungs.
- On auscultation, pulmonary component of second heart sound increases, with narrowing or loss of normal splitting in second heart sound.
- High-pitched, early systolic ejection click is heard.
- Systolic ejection murmur is present.
- Right-sided atrial S_4 gallop usually indicates increased right ventricular end-diastolic pressure and may coincide with prominent A waves in jugular venous pulse. S_4 gallop usually is not ominous.
- Middiastolic right-sided S_3 gallop usually is evidence of impaired right ventricular function and usually is ominous. Right-sided gallops can be differentiated from left-sided gallops because they increase in intensity with inspiration.
- Early-diastolic, pulmonary regurgitant murmur may indicate functional pulmonary insufficiency caused by dilation of root of pulmonary artery and pulmonic valve.
- Right-sided heart failure with chronic, dependent edema; large, tender liver; ascites; positive, hepatojugular reflex; and dilated, distended, pulsating neck veins are signs.

function = Preoperative FEV_1 × Functional segments in the lobe to be resected/Total number of segments in both lungs.

Exercise Studies

In contrast with some previous studies, preoperative maximal and submaximal exercise testing has been shown to be a good predictor of postoperative pulmonary complications in patients undergoing pulmonary resection.[12,19,28,33] Exercise testing may better predict adverse outcomes by uncovering deficits in O_2 transport or cardiac function. Maximal oxygen consumption <1 L/min is associated with a 75% mortality rate, whereas death is rare if maximal oxygen consumption is >1 L/min. Other exercise-related criteria indicating increased risk for pulmonary resection are (1) pulmonary vascular resistance (PVR) >190 dynes/sec/cm^5 (with exercise), (2) arterial oxygen desaturation >2% with exercise, and (3) maximal oxygen consumption <15 mL/kg/min. Disadvantages of exercise testing are its dependence on patient effort and cooperation and its requirement for special equipment and trained personnel to administer the tests.

Right-Heart Function

Patients who are to undergo thoracotomy and lung resection frequently have a long-standing history of smoking and underlying COPD, which can lead to pulmonary arterial hypertension and its sequelae. Pulmonary arterial hypertension results from an increase in PVR caused by a reduction of cross-sectional area of the pulmonary vascular bed associated with destruction of alveolar septa and hypoxemia-induced pulmonary vasoconstriction. Over time, pulmonary hypertension can lead to right ventricular hypertrophy, cor pulmonale, and right ventricular failure. The normal pulmonary vascular bed can tolerate an increase in cardiac output of 250% without an increase in PA pressure. In contrast, even a small increase of cardiac output causes a large increase in PA pressure in patients with a restricted pulmonary vascular bed. Preexisting impairment of pulmonary vascular compliance associated with congestive heart failure and cor pulmonale may be exacerbated after extensive lung resection, leading to serious pulmonary hypertension and right-sided heart failure. Preoperative evaluation of these patients should assess for signs and symptoms of pulmonary hypertension, right ventricular and right atrial hypertrophy, cor pulmonale, and congestive heart failure (Boxes 53–2 and 53–3). A fixed elevated PVR has been associated with an increased risk for complications.[6] In an attempt to simulate the cardiovascular effects of pneumonectomy, patients can undergo a right-heart catheterization with occlusion of the affected PA. The criteria for inoperability include (1) increase in mean PA pressure to >35–40 mm Hg, (2) increase in $Paco_2$ to >60 mm Hg, and (3) decrease in Pao_2 to <45 mm Hg (Box 53–1).[6,34]

BOX 53–3.

Radiographic Signs of Pulmonary Hypertension

- Dilation of main pulmonary vessels
- Attenuation of peripheral pulmonary vasculature, leading to oligemic peripheral lung zones
- Radiographic findings characteristic of chronic obstructive pulmonary disease, such as hyperinflated lungs and low, flat diaphragms
- Manifestations of right ventricular hypertrophy, clockwise cardiac rotation, and loss of air space behind sternum on lateral chest radiograph

PREOPERATIVE PREPARATION OF THE PATIENT UNDERGOING THORACIC SURGERY

Preoperative preparation of the patient for thoracic surgery should focus on treatable conditions.[2–5,35,36] Stein et al.[36] found that postoperative complications developed in four of 17 well-prepared patients compared with 13 of 17 unprepared patients. Prophylactic measures, such as bronchodilator therapy, hydration, and chest physical therapy, decrease the incidence of postoperative complications and should be started preoperatively and continued postoperatively. In addition, preoperative patient education about the importance of cessation of smoking, incentive spirometry, and bronchodilator therapy are beneficial.

Cessation of smoking for at least 4–8 weeks before surgery is associated with a decreased incidence of postoperative respiratory complications.[8,37] Although cessation of smoking for 12–24 hours preoperatively does not decrease the incidence of postoperative respiratory complications, it still may have a salutary effect by decreasing the concentration of carboxyhemoglobin. Other beneficial effects of stopping smoking several weeks before surgery are decreasing sputum production and improving ciliary activity.[37,38]

Elective operations should be postponed in patients with acute exacerbation until proper management has been instituted. Sympathomimetic drugs can be administered to activate β_2-adrenergic receptors, increasing intracellular cyclic adenosine monophosphate and leading to bronchodilation. Bronchodilation also can be produced by parasympatholytics, such as ipratropium bromide, which inhibit parasympathetic vagal tone of the tracheobronchial tree. Other management for wheezing includes administration of steroids to suppress inflammation and decrease mucosal edema. However, because steroids are slow acting, their benefit in patients with acute bronchospasm is limited.

Mobilization of secretions and improved pulmonary toilet improve perioperative pulmonary function. Mobilization of secretions is achieved by a combination of deep breathing, vigorous coughing, postural drainage, hydration, and chest percussion.[39,40] However, chest physical therapy is relatively contraindicated in patients with lung abscesses, pulmonary metastases, or a history of hemoptysis.

Acute and chronic infection should be managed with antibiotics before operation. A change in the color and quantity of sputum produced by a patient with COPD may indicate infection. One prospective study reported a decreased incidence of postoperative pulmonary complications and mortality rate in patients treated with prophylactic antibiotics before pulmonary operations.[41]

Preoperative pulmonary rehabilitation should be considered for all patients. It typically includes all of the steps reviewed in the preceding three paragraphs along with structured exercise. Compared with education alone, comprehensive pulmonary rehabilitation has produced a significant increase in 6-minute walk test,[42] maximal exercise tolerance,[43] maximal oxygen uptake,[43] and quality of life measures.[42–44] These interventions decrease postoperative pulmonary complications[45]; however, the programs must be initiated 24 weeks before surgery to achieve maximal effectiveness,[42] which typically is not possible in patients with lung cancer.

LUNG CANCER

Classification

Lung cancer is currently the most common cause of cancer mortality in the United States and throughout the world. The World Health Organization (WHO) classification of lung tumors, revised most recently in 2004, remains the foundation for lung carcinoma nomenclature.[46] The characterization of lung carcinomas by histopathologic subtype is the basis of formal classification and has implications to management and prognosis. Lung cancer is divided into several broad categories based on histology: adenocarcinoma (25%), squamous cell carcinoma (≈35%), large cell carcinoma, adenosquamous carcinoma, carcinoid tumors, and carcinomas with pleomorphic elements.

The therapeutic approach to lung cancer depends on the histologic type of tumor and its extent (stage). The most commonly staging classification, the TNM system, is based on cell type (T), extent of lymph node involvement (N), and metastatic spread (M; Box 53–4). The TNM system is used to group patients into subsets or stages that have implications on treatment options, surgical resectability, and prognosis.

The approaches to therapy for small cell lung carcinoma (SCLC) and for non–small cell lung carcinoma (NSCLC) differ. SCLCs account for approximately 25% of all bronchogenic carcinomas and have a strong correlation with cigarette smoking. In general, SCLC has metastasized by the time of diagnosis and are managed primarily by chemotherapy without radiotherapy. NSCLCs often are more localized and thus are better candidates for curative resection. Surgical resection is a standard component of the attempt to cure lung cancer in patients with stage I and II NSCLC. In addition to surgery, adjuvant chemotherapy may be administered for selected patients with stage IB and stage II disease. Although the value of resection has never been established through randomized trials, the favorable results in surgical series and the relative infrequency of long-term survival in patients treated without surgery have established surgery as the treatment of choice.[47]

Lobectomy, the surgical removal of an anatomic lung segment, is generally accepted as the optimal procedure for early-stage NSCLC because of its ability to preserve pulmonary function.[48] Limited (sublobar) resection is increasingly used to treat patients who cannot tolerate a full lobectomy because of severely compromised pulmonary function, advanced age, or other extensive comorbidity. In addition, advances in video-assisted thoracoscopic surgery (VATS) have facilitated the use of limited resections in selected patients.

Intrathoracic Metastatic Manifestations

Clinical manifestations of lung cancer are varied. Common symptoms include shortness of breath, hemoptysis, chest pain, and increasing dyspnea (Table 53–2). Pleural effusions are a common but nonspecific finding observed on chest radiographs. The effusions result from obstruction of lymphatic drainage or malignant extension of the tumor to the lung surface. Chest pain associated with lung cancer usually is dull or mild and nonspecific, occurring ipsilateral to the tumor. Metastasis to the chest wall and ribs can result in local tenderness and pleuritic chest pain. Shoulder pain may result from tumor growth at the lung apex and invasion or encroachment of the brachial plexus (such as in Pancoast tumor). Tumor extension into the pericardium can result in pericarditis, cardiac dysrhythmias, and pericardial effusions that cause tamponade. In addition, superior vena cava obstruction by local growth or lymphatic metastases will impede venous return from the head and upper extremities. Its implications to clinical management are discussed in the section entitled Anesthesia for Patients with Mediastinal Masses.

Other manifestations of lung cancer include neurologic symptoms caused by mechanical encroachment or invasion of the nerve plexus. Involvement of the brachial plexus may result not only in shoulder pain but also in upper arm weakness. Involvement of the phrenic nerve can lead to unilateral diaphragmatic dysfunction, and involvement of the recurrent laryngeal nerve can result in hoarseness of voice.

Extrathoracic Metastatic Manifestations

Common extrathoracic sites of metastases include lymph nodes, brain, bone, liver, skin, and suprarenal glands. The neurologic manifestations of metastatic brain tumors include hemiplegia, personality changes, cerebellar disturbances, seizures, headache, and confusion. Metastases to bone occur primarily in ribs, vertebra, humerus, and femur. Although metastases to the spinal cord and vertebral column are less common, they have implications for positioning and postoperative management of pain.

BOX 53–4.

Definitions for Staging Bronchogenic Carcinoma

To: No evidence of primary tumor
TX: Tumor proved by presence of malignant cells in bronchopulmonary secretions but not visualized radiographically or bronchoscopically, or any tumor that cannot be assessed
TIS: Carcinoma in situ
T1: Tumor 3.0 cm or less in greatest diameter , surrounded by lung or visceral pleura, and without evidence of invasion proximal to lobar bronchus at bronchoscopy
T2: Tumor more than 3.0 cm in greatest diameter or tumor of any size that either invades visceral pleura or has associated atelectasis or obstructive pneumonitis extending to hilar region; at bronchoscopy proximal extent of demonstrable tumor should be within lobar bronchus at least 2.0 cm distal to carina; any associated atelectasis or obstructive pneumonitis should involve less than an entire lung, and no pleural effusion should be present
T3: Tumor of any size with direct extension into an adjacent structure, such as parietal pleura, chest wall, diaphragm, or mediastinum and its contents; or tumor shown bronchoscopically to involve a main bronchus less than 2.0 cm distal to carina; or any tumor associated with atelectasis or obstructive pneumonitis of an entire lung or pleural effusion
No: No demonstrable metastasis to regional lymph nodes
N1: Metastasis to lymph nodes in peribronchial or ipsilateral hilar region, or both, including direct extension
Mo: No distant metastasis
M1: Distant metastasis, such as scalene, cervical, or contralateral hilar lymph nodes; brain; bones, liver; or contralateral lung

Occult carcinoma	Stage 1	Stage 2	Stage3
TX No Mo	TIS No Mo	TS N1 Mo	T3 any N or M
	T1 No Mo		N2 any T or M
	T1 N1 Mo		M1 any T or N
	T2 No Mo		M1 any T or N

Extrathoracic Nonmetastatic Manifestations

The extrapulmonary manifestations of lung cancer affect the metabolic, neuromuscular, skeletal, dermatologic, vascular, and hematologic systems. Although uncommon, the systemic manifestations of such paraneoplastic syndromes can impact on the perioperative treatment. The metabolic and neuromuscular manifestations are more likely to affect perioperative management (Box 53–5). In general, the symptoms resolve, and results of laboratory studies return to normal after a successful tumor resection.

Metabolic manifestations usually result from endocrine secretions by the tumor.

- Cushing syndrome most often is associated with SCLC; it is characterized by increased adrenocorticotropic hormone levels.
- The syndrome of excessive antidiuretic hormone, which is associated with SCLC, may manifest as nausea, vomiting, anorexia, hyponatremia, seizures, or other neurologic disturbances.
- Carcinoid syndrome is associated with production of serotonin; it is diagnosed by elevated 5-hydroxyindoleacetic acid (5-HIAA) levels.
- Hypercalcemia, which is associated with hypophosphatemia, results from a parathyroid hormone-like polypeptide secreted most often by bronchogenic carcinoma.
- Hypoglycemia and ectopic gonadotropin production are rare manifestations.
- Neuromuscular manifestations are the most frequent extrathoracic nonmetastatic effects of lung cancer, most often SCLC.[52] The paraneoplastic myopathy Eaton-Lambert syndrome may appear as a myasthenic-like syndrome characterized by proximal muscle weakness, particularly of the pelvic and thigh muscles. The defect in neuromuscular transmission is a result of an antibody-mediated impairment of presynaptic neurocalcium channel activity, which reduces the release of acetylcholine.[53,54] Patients with this syndrome do not respond as well to anticholinesterase drugs as do patients with myasthenia gravis. In contrast, these patients exhibit increased sensitivity to succinylcholine and nondepolarizing muscle relaxants.
- Other neuromuscular manifestations include subacute cerebral degeneration, encephalomyelopathy, and polymyositis. The cause and pathogenesis of these neuropathies are not completely understood. Immunologic factors are believed to be important because antibody and T-cell responses are directed against shared antigens that are ectopically expressed by the tumor but otherwise exclusively expressed by the nervous system.[55,56]

MONITORING DURING THORACIC ANESTHESIA

The treatment of patients undergoing thoracic surgery is a challenging aspect of anesthesiology. These patients usually have underlying respiratory and cardiac disease that are altered further by surgical manipulations, operative position, and periods of lung collapse and one-lung ventilation, which worsen $\dot{V}/\dot{Q}$ mismatches. Thus, it is important to constantly monitor oxygenation and ventilation. There is disagreement about the need for invasive monitoring in patients undergoing thoracotomy. Monitoring should be individualized, depending on the extent of operation and the

patient's underlying cardiovascular and respiratory condition (Table 53–3).

Monitoring of patients undergoing thoracic surgery includes ECG, pulse oximetry, blood pressure, and capnography. Other noninvasive monitors provide crucial information. Auscultation for wheezing, rales, or rhonchi assist in the diagnosis of endotracheal tube malposition, congestive heart failure, airway disconnect, and bronchospasm. Airway pressures give valuable information about changes in lung compliance, occurrence of bronchospasm, and malposition of the double-lumen endotracheal tube. Perioperatively, pulse oximetry is the most valuable monitor for early diagnosis of problems with oxygenation. Capnography gives a continuous display of the CO_2 waveform and alerts the anesthesiologist to apnea, airway disconnects, and hypoventilation. End-tidal CO_2 usually is 5 mm Hg less than arterial pCO_2; the difference between them will increase as $\dot{V}/\dot{Q}$ mismatching develops, as in the case of one-lung ventilation or pulmonary disease.

The anesthesiologist may require additional monitoring, such as systemic arterial or PA catheters, when caring for patients with a history of pneumonia, cardiac disease, or major anatomic pulmonary resection. Intraarterial catheters are routinely used to monitor arterial blood gases and hemodynamics during major pulmonary resections. However, any monitoring device has risks, and a risk-benefit analysis should always be undertaken.[57]

The PA catheter is used to monitor cardiac output, left ventricular function, PA pressures, and mixed venous oxygenation. It can be used to assess the effect of pulmonary resection on right ventricular function because patients with preoperative cardiac dysfunction are at risk for acute right ventricular failure after a pulmonary resection. A dramatic increase in PA pressures during temporary clamping of vessels might contraindicate such resection. More than 90% of PA catheters end in the right lung.[58] During a right thoracotomy with the patient in the left lateral decubitus position, the PA catheter is in the nondependent lung. Although one study found that the PA catheter in the nondependent lung underestimated measured cardiac output values, other clinical and animal studies found no difference whether the thermistor was located in the main trunk or branches of the PA or in the dependent or nondependent lung.[59–61] Thus, accuracy and clinical interpretation of PA pressures and PA occlusion pressures must account for the location of the PA catheter in relation to patient positioning, mode of ventilation, blood flow, and HPV.

LATERAL DECUBITUS POSITION

The lateral decubitus position (or some variation of it) is nearly universal during thoracic surgery (Table 53–4). It allows for complete access to the hemithorax and permits extending the incision anteriorly and posteriorly. It offers access to the pleural cavity, hilar vessels, lateral pericardium, and descending thoracic aorta. The lateral decubitus position is used for patients undergoing pulmonary surgery, operations on the esophagus, thoracic aorta, thoracic spine, and certain cardiac procedures. This position may affect pulmonary, cardiovascular, and neurologic physiology. Orientation of one lung in a more dependent position alters pulmonary mechanics and increases the risk of contaminating the dependent lung with blood and purulent materials. The dependent lung has decreased functional residual capacity (FRC) and increased airway closure and atelectasis. Increased pulmonary blood flow and reduced ventilation to the dependent lung results in ventila-

Pulmonary artery catheter	Pulmonary hypertension, filling pressures, assess cardiac performance
SvO_2	Adequacy of cardiac output
Transesophageal echocardiography	Ischemia, volume status, right ventricular dysfunction

tion and perfusion abnormalities when both lungs are ventilated, although the increased blood flow to the dependent lung is advantageous during single-lung ventilation.

The lateral decubitus position is associated with hazards (see Chap. 26). To avoid complications, special attention should be given to the orientation of the cervical spine, positioning of the extremities, and placement of straps to anchor the body. A chest roll should be placed under the dependent axilla to prevent compression of neurovascular structures by the head of the humerus. Use of a soft contour bag ("bean bag") is advocated because it not only functions as a chest roll but also supports the patient and decreases the risk of pressure necrosis by molding to the patient's body. Patients often are flexed to open the intercostal spaces and to facilitate the introduction of cameras and surgical instruments. Additionally, slight flexion of the dependent hip and knee help stabilize the patient and decrease stretch of the sciatic nerve. The nondependent leg is positioned on a pillow to avoid pressure on the dependent leg. Positioning of the upper extremities and the head requires special attention to avoid compression and stretch injury to the brachial plexus and peripheral nerves. The cervical spine is placed in a neutral position, and the dependent arm is outstretched (Fig. 53–4). The nondependent arm is elevated superiorly on an arm board to bring the vertebral border of the scapula forward. The decubitus position is further stabilized by placing straps or tape across the table at the level of the hip and across the leg, paying attention to avoid compression of tissue.

The standard lateral decubitus position may be modified to facilitate surgical exposure. Slight rotation of the upper chest from 90° permits better access for more anterior or posterior incisions. Positioning of the nondependent arm in a more cephalad and abducted orientation permit a surgical

TABLE 53–4.

Various Patient Positions Used during Thoracic Surgery

Position	Possible Surgical Incisions	Clinical Application
Supine	Median sternotomy	Cardiac surgery, mediastinal, major liver, vascular trauma
	Bilateral intercostal transverse sternotomy	Repair pectus excavatum, bilateral lung transplant
	Anterior or anterolateral incisions: side to be incised can be slightly elevated	Pericardial tamponade, lung biopsy
Upright	For minor thoracic procedures during local anesthesia	Used in high-risk patients (e.g., open drainage of empyema) and for biopsy of lung or pleura
Lateral decubitus (90° angle to table)	Anterolateral and posterolateral thoracotomy incisions	Standard thoracotomy position
To provide optimal access for cardiac, thoracic, vascular, or gastrointestinal pathology, the obliqueness of the patient's back to the table can vary between 45° and 135°	Anterolateral and posterolateral thoracotomy	To improve exposure in certain cardiothoracic, vascular, or gastroesophageal procedures
	Anterior thoracotomy	Tracheal or esophageal surgery, thyroid or vascular trauma, penetrating neck injuries
	Thoracoabdominal incisions	Thoracoabdominal aortic surgery

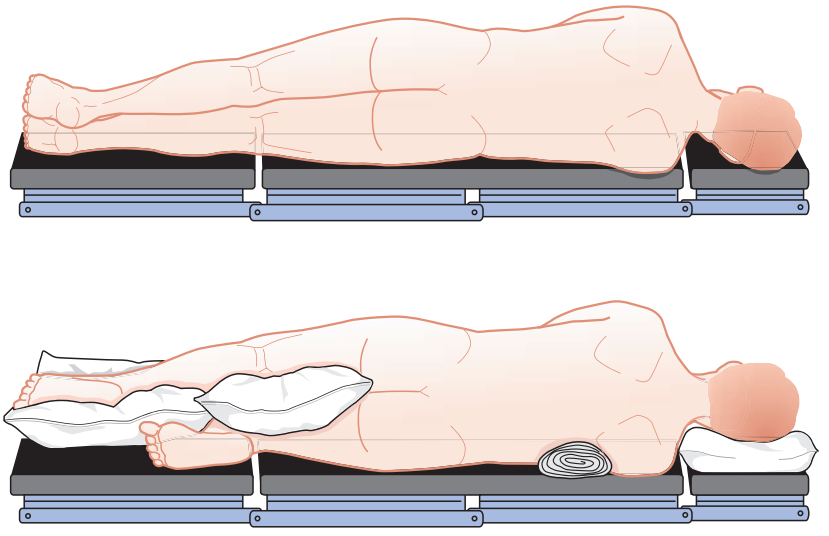

FIGURE 53–4. Standard right lateral decubitus position. Top. Improper head position and inadequate padding. Bottom. Proper padding over bony prominences, chest roll to protect axilla, proper alignment of cervical spine. Flexed lower leg stabilizes torso.

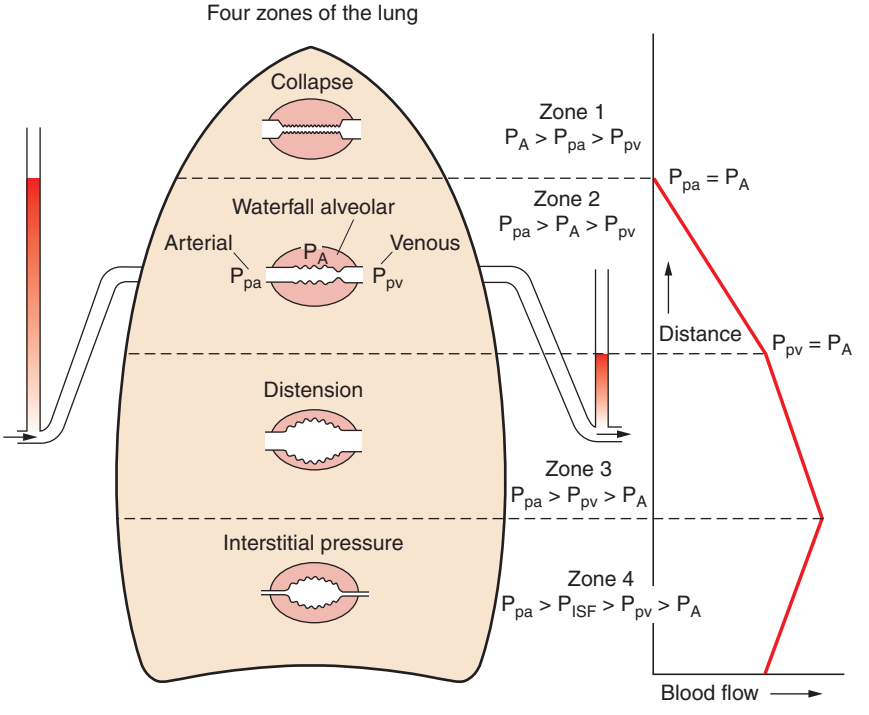

FIGURE 53–5. Schematic diagram showing the distribution of blood flow in the upright lung. In zone 1, alveolar pressure (P_A) exceeds pulmonary artery pressure (P_{pa}), and no flow occurs because the intraalveolar vessels are collapsed by the compressing alveolar pressure. In zone 2, arterial pressure exceeds alveolar pressure, but alveolar pressure exceeds pulmonary venous pressure (P_{pv}). Flow in zone 2 is determined by the arterial–alveolar pressure difference (P_{pa}–P_A) and has been likened to an upstream river waterfall over a dam. Because P_{pa} increases down zone 2 and P_A remains constant, the perfusion pressure increases, and flow steadily increases down the zone. In zone 3, pulmonary venous pressure exceeds alveolar pressure, and flow is determined by the arterial–venous pressure difference (P_{pa}–P_pv), which is constant down this portion of the lung. The transmural pressure across the wall of the vessel increases down this zone so that the caliber of the vessels increases (resistance decreases) and therefore flow increases. Finally, in zone 4, pulmonary interstitial pressure becomes positive and exceeds pulmonary venous pressure and alveolar pressure. Consequently, flow in zone 4 is determined by the arterial–interstitial pressure difference (P_{pa}–P_{ISP}). (Redrawn from West JB. Ventilation Blood Flow and Gas Exchange. 4th ed. Oxford: Blackwell Scientific, 1985, pg. 221, and Wagner PD, Saltzman HA, West JB. Measurement of continuous distribution of ventilation-perfusion ratios: theory. J Appl Physiol 1974;36:588 with permission.)

approach that preserves the integrity of the latissimus and pectoralis muscles—a "muscle-sparing approach."

Proper positioning of the endobronchial tube should be reconfirmed after the patient is repositioned because slight flexion or extension of the neck can displace the endotracheal tube. Flexion of the neck moves the endotracheal tube distally, whereas extension of the neck moves the tube proximally. Confirmation of tube position with fiberoptic endoscopy decreases the incidence of inadequate lung isolation.

Physiology: Principles of Ventilation and Perfusion

Disparity between the greater gravitational pressures at the base and the greater negative intrapleural pressure at the apex are major factors in understanding normal ventilation and perfusion. Gravitational hydrostatic pressure cause distension of vessels and increased perfusion in the more dependent portions of the lung (Fig. 53–5). The apices of the lung may have little or no perfusion. In addition, the effects of gravity tend to collapse the apex of the lung inward and create a negative intrapleural pressure, whereas the lower dependent regions tend to push outward toward the chest wall and create a relatively positive pressure. Because the density of the lungs is 25% that of water and because the height of the upright lung is approximately 30 cm, the difference between the intrapleural pressure at the base of the lung versus the apex is approximately 7.5 cm H_2O.[62] Because the intraalveolar pressure is the same throughout the lung, the transpulmonary distending pressure is greatest at the top of the lung and decreases toward the bottom. Therefore, the alveoli in the apices are largest, and those in the base are the smallest. An approximately 4-fold alveolar volume difference exists between the base and the apex of the lung (Fig. 53–6). The small alveoli in the base of the lung are on the steep portion of their compliance curve, whereas the nondependent alveoli are on the relatively flat, noncompliant portion of the curve. Therefore, in the upright position, the tidal volume is preferentially distributed to the basilar alveoli because they expand more per unit pressure change than do the apical alveoli. These physiologic effects result in greater increases in blood flow ($\dot{Q}$) than the increase in ventilation ($\dot{V}$), and $\dot{V}/\dot{Q}$

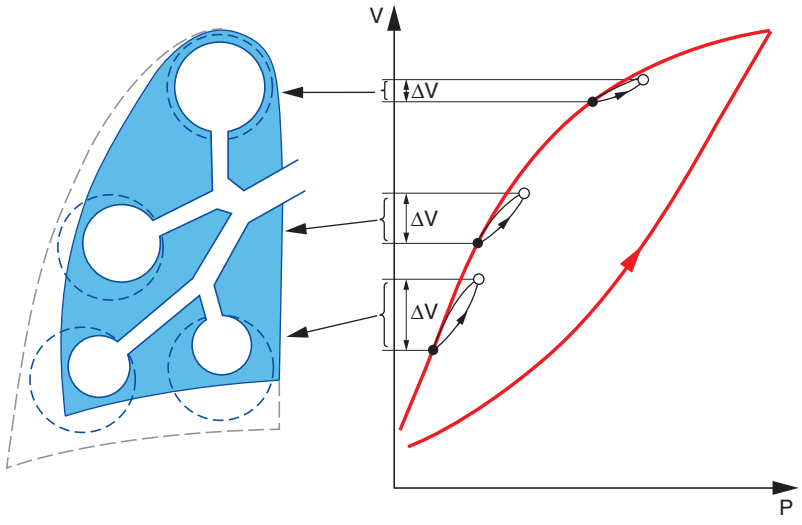

FIGURE 53–6. During quiet breathing, the lower parts of the lung show greater volume changes (ventilation) than do the upper parts. (From Weibel ER, ed. The Pathway for Oxygen: Structure and Function in the Mammalian Respiratory System. Cambridge: Harvard University Press, 1984, with permission.)

decreases from lung apex to base (Figs. 53–7 and 53–8).

Physiology: Lateral Decubitus Position

Patient Awake, Spontaneously Breathing

Gravity causes a vertical gradient in the distribution of pulmonary blood flow in the lateral decubitus position for the same reason it does in the upright position (Fig. 53–9). The vertical hydrostatic gradient is less than it is in the upright position because the distance from the most dependent to the most nondependent part of the lung is less. Nevertheless, blood flow to the dependent lung still is much greater than blood flow to the nondependent lung. Normally, in the upright position, the right lung because of its larger size receives 55% of the total blood flow, whereas the left lung receives 45% of total blood flow.[63,64] When the right lung is nondependent, it receives approximately 45% of total blood flow, whereas the dependent left lung receives 55% of the total blood flow. When the left lung is nondependent, it receives approximately 35% of the total blood flow, whereas the dependent right lung receives 65%. As in the upright position, ventilation is relatively increased in the dependent lung zones (Fig. 53–10).

In addition, in the lateral decubitus position, the dome of the lower diaphragm is pushed higher into the chest than is the dome of the upper diaphragm and therefore is more stretched and sharply curved than is the upper diaphragm. This gives the dependent diaphragm more efficiency during spontaneous ventilation. Thus, in the lateral decubitus position with an awake, spontaneously breathing patient, the dependent lung is better ventilated than the nondependent lung, and $\dot{V}/\dot{Q}$ still is well matched.[65]

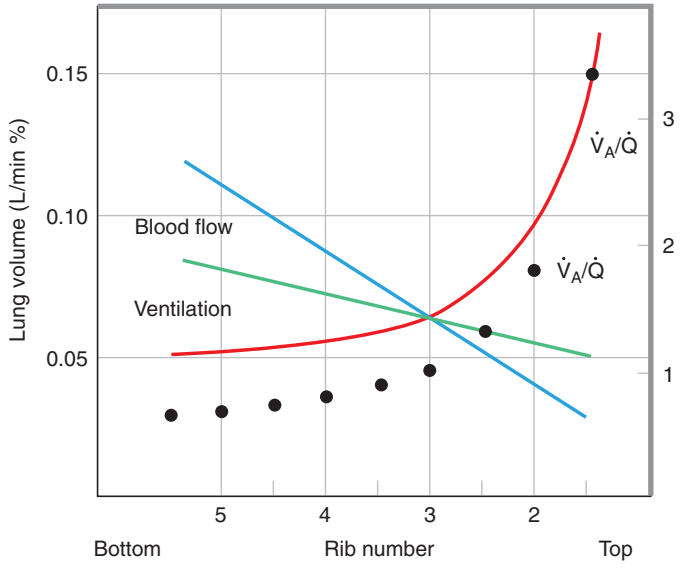

FIGURE 53–7. Distribution of ventilation and blood flow (left vertical axis) and ventilation/perfusion ratio (right vertical axis) in normal upright lung. Blood flow and ventilation are expressed in liters per minute percent alveolar volume and are drawn as smoothed out linear functions of vertical height. Closed circles mark ventilation-to-perfusion ratios of horizontal lung slices (three of which are shown in Fig. 53–8). Cardiac output of 6 L/min and total minute ventilation of 5.1 L/min were assumed. (From West JB. Ventilation: Blood Flow and Gas Exchange. 4th ed. Oxford: Blackwell Scientific, 1985, with permission.)

Patient Anesthetized, Chest Closed

In the anesthetized, spontaneously breathing patient in the lateral decubitus position, the dependent lung continues to receive relatively more perfusion does than the nondependent lung.

The distribution of ventilation changes after induction of anesthesia (Fig. 53–11).[63,66] With the induction of general anesthesia, FRC decreases. Both lungs share in the loss of lung volume and move to a lower location on the pressure–volume curve. The dependent lung now occupies the low flat portion of the curve (i.e., is less compliant). The nondependent lung, initially in the noncompliant part, now moves to the steep compliant part of the curve. Compression by the weight of the mediastinum and the abdominal contents contribute to the decrease in FRC of the dependent lung. Therefore, with induction of anesthesia, little change occurs in perfusion distribution, whereas dramatic change occurs in ventilation distribution. Now the nondependent lung receives most of the ventilation but still is less perfused, whereas the dependent lung receives less ventilation but continues to be more perfused, which leads to an increase in shunt (dependent lung has low $\dot{V}/\dot{Q}$) and dead space ventilation (nondependent lung has $\dot{V}/\dot{Q} > 1$).

Patient Anesthetized, Paralyzed, Mechanically Ventilated

Mechanical ventilation causes further deterioration in the $\dot{V}/\dot{Q}$ relationship.

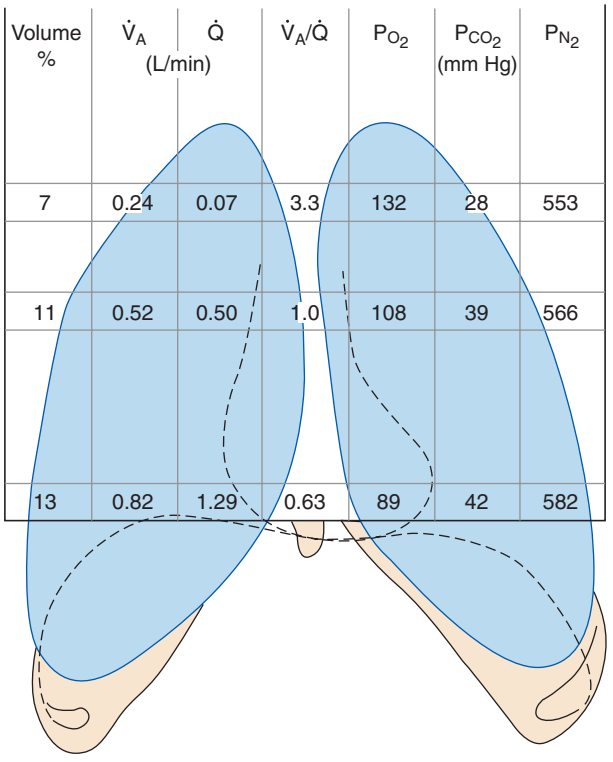

FIGURE 53–8. Ventilation-to-perfusion ratio ($\dot{V}/\dot{Q}$) and regional composition of alveolar gas. Values for regional flow ($\dot{Q}$), ventilation ($\dot{V}_A$), PO_2, and PCO_2 are derived from Fig. 53–7. PN_2 is obtained from what remains of the total gas pressure (which, including water vapor, equals 760 mm Hg). The volumes (vol [%]) of the three lung slices also are shown. Compared with the top of the lung, the bottom of the lung has a low $\dot{V}/\dot{Q}$ and is relatively hypoxic and hypercapnic. (From West JB. Regional differences in gas exchange in the lung of erect man. J Appl Physiol 1962;17:893, with permission.)

Perfusion continues to be greater to the dependent lung because of gravitational effects, but now even more distribution of ventilation goes to the nondependent lung. With the institution of mechanical ventilation, the highly curved diaphragm in the dependent hemithorax no longer confers any advantage in ventilation because it is no longer actively contracting.[67] In addition, the weight of the abdominal viscera physically restricts expansion of the dependent lung, leading to further preferential distribution of ventilation to the nondependent, less-perfused lung. The anesthetized patient in the lateral decubitus position has an unfavorable $\dot{V}/\dot{Q}$ that is worsened by muscle relaxation and controlled ventilation. The application of positive end-expiratory pressure (PEEP) to both lungs restores their FRC and most ventilation to the dependent lung.[63] The lower lung returns to a steeper, more favorable part on the pressure–volume curve, and the upper lung resumes its original position on the flat, unfavorable portion of the curve.

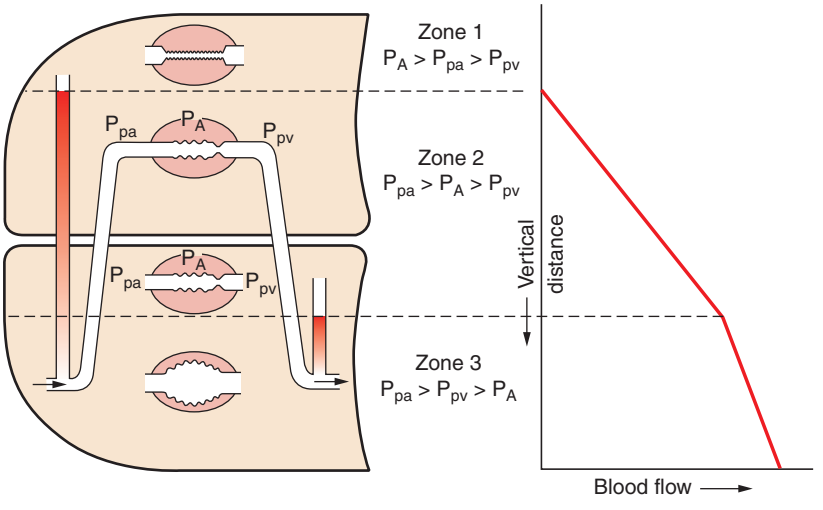

FIGURE 53–9. Schematic representation of the effects of gravity on the distribution of pulmonary blood flow in the lateral decubitus position. Vertical gradients in the lateral decubitus position are similar to those in the upright position and cause the creation of zones 1, 2, and 3. Consequently, pulmonary blood flow increases with lung dependency and is largest in the dependent lung and least in the nondependent lung. (Modified from Kaplan JA. Hemodynamic monitoring.)

Patient Anesthetized, Chest Open

In the spontaneously ventilating patient with an open chest, the inspiratory tidal volume in the dependent lung is decreased by the downward displacement of the mediastinum, which leads to impaired ventilation to the dependent lung and paradoxic respiration. Paradoxic respiration refers to the movement of air between the dependent lung and the nondependent lung during respiration and the ambient atmosphere in and out of the open chest cavity. These physiologic changes can affect circulatory performance by decreasing venous return and triggering associated sympathetic reflexes, resulting in a clinical picture similar to that of shock. The reflex symptoms of hypotension, pallor, cold and clammy extremities, and pupillary dilatation can be lessened by local anesthetic infiltration of the pulmonary plexus at the hilum. Most commonly, the ventilatory and circulatory changes associated with mediastinal shift are abolished by positive-pressure ventilation.

Patient Anesthetized, Mechanically Ventilated, Chest Open

Opening the chest results in a marked increase in the compliance of the upper lung, with a slight but still important increase in the compliance of the dependent lung. Airway pressure decreases in the dependent and the nondependent lungs. As a result, ventilation of the nondependent lung increases further compared with the closed-chest state.[68] The cardiac index increases with opening of the chest

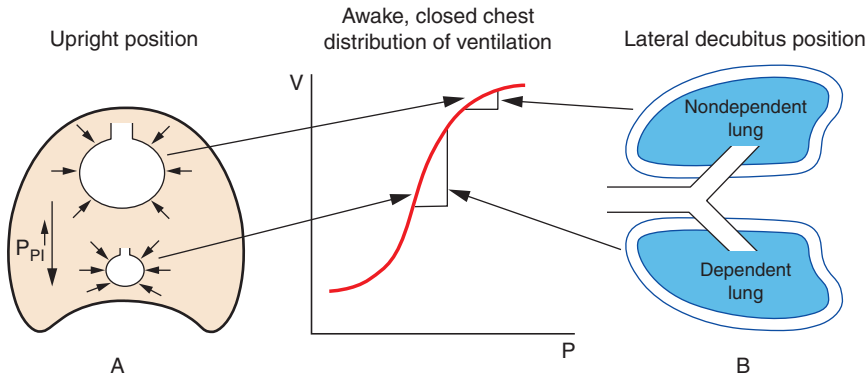

FIGURE 53–10. Pleural pressure in the awake patient (closed chest) is most positive in the dependent portion of the lung; therefore, alveoli in this region are most compressed and have the least volume. Pleural pressure is least positive (most negative) at the apex of the lung; therefore, alveoli in this region are least compressed and have the largest volume. When these regional differences in alveolar volume are translated to a regional transpulmonary pressure–alveolar volume curve, the small dependent alveoli are on a steep (large-slope) portion of the curve, and the large nondependent alveoli are on a flat (small-slope) portion of the curve. In this diagram, regional slope equals regional compliance. Thus, for a given and equal change in transpulmonary pressure, the dependent part of the lung receives a much larger share of the tidal volume than does the nondependent part of the lung. In the lateral decubitus position (*right side of diagram*), gravity also causes pleural pressure gradients and therefore similarly affects the distribution of ventilation. The dependent lung lies on a relatively steep portion, and the upper lung lies on a relatively flat portion of the pressure–volume curve. Thus, in the lateral decubitus position, the dependent lung receives the majority of the tidal ventilation.

and pleura, but mean arterial pressure does not change significantly.[69]

The upper lung eliminates more CO_2 shortly after the pleura has been opened.[69] The increased elimination of CO_2 from the upper lung is proportionately greater than the increase in ventilation. Also, the end-tidal PCO_2 measured from the upper lung increases more than that of the lower lung, which reflects a marked increase in the blood flow to the upper lung. The decrease in airway pressure on opening the pleura, along with the increase in cardiac index, results in increased blood flow to the nondependent lung.

Effect of PEEP

Selective PEEP application to the dependent lung can improve oxygenation by decreasing the shunt fraction. The explanation is that PEEP to the dependent lung increases the FRC of that lung, moving it to a steeper, more favorable portion on its pressure–volume curve and leading to improved ventilation of the dependent lung. Even if the increase in PVR caused by the application of PEEP shifts blood flow from the dependent to the nondependent lung, that portion of the cardiac output diverted to the nondependent lung still participates in gas exchange as long as it is ventilated or exposed to continuous positive airway pressure (CPAP).

Effects of Surgical Manipulation

With the onset of surgical manipulations, compliance and distribution of ventilation to the upper lung decrease dramatically. End-tidal PCO_2 and CO_2 elimination from the upper lung decrease, but changes in $Paco_2$ are minimal.[69]

Summary

The anesthetized, paralyzed patient in the lateral decubitus position with an open chest may have considerable $\dot{V}/\dot{Q}$ mismatch. The nondependent lung receives greater ventilation and less perfusion and has $\dot{V}/\dot{Q} > 1$. The dependent lung has more perfusion and less ventilation (i.e., low $\dot{V}/\dot{Q}$) and therefore acts as a physiologic shunt. The blood flow distribution is mainly determined by the effects of gravity. Causes of poor ventilation of the dependent lung are (1) loss of FRC because of induction of general anesthesia, (2) compression of the dependent lung by the mediastinum, (3) upward shift of the abdominal contents and paralysis of the diaphragm, (4) suboptimal positioning effects, (5) impaired ciliary clearance of mucus, and (6) absorption atelectasis from the use of high fraction of inspired oxygen (FiO_2). Consequently, two-lung ventilation in these patients may result in an increased alveolar-to-arterial PO_2 difference and less than optimal oxygenation.

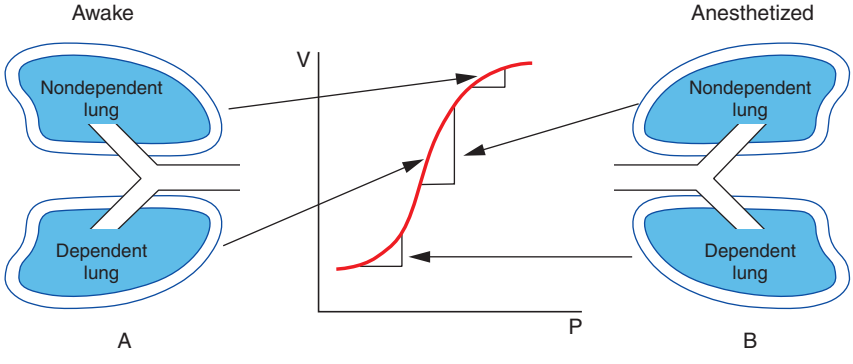

FIGURE 53–11. Schematic diagram showing the distribution of ventilation in the awake patient (closed chest) in the lateral decubitus position (*left*) and the distribution of ventilation in the anesthetized patient (closed chest) in the lateral decubitus position (*right*). Induction of anesthesia has caused a loss in lung volume in both lungs, with the nondependent (*up*) lung moving from a flat noncompliant portion to a steep compliant portion of the pressure–volume curve and the dependent (*down*) lung moving from a steep compliant part to a flat, noncompliant part of the pressure–volume curve. Thus, in the anesthetized patient in a lateral decubitus position, the majority of the tidal ventilation occurs in the nondependent lung (where there is the least perfusion) and the minority of the tidal ventilation in the dependent lung (where there is the most perfusion).

ONE-LUNG ISOLATION

Indications

The techniques of lung isolation are used to selectively ventilate the lung within one hemithorax while the nearly motionless lung is operated on in the contralateral hemithorax. Collapse of the nondependent lung produces less

trauma than surgical retraction and offers better exposure of structures within the hemithorax.[15,16] The airways of the operated lung can be incised while positive-pressure ventilation continues in the other lung. During thoracoscopic surgery, collapse of the operated lung is essential to provide adequate visualization of structures within the pleural cavity. Although many surgical procedures are facilitated by use of isolation techniques, most procedures are feasible without isolation.

Single-lung isolation is indicated under certain clinical conditions. When one lung contains either blood or infectious secretions, isolation of the lungs is imperative to prevent spillage of contents into the unaffected lung. Isolated lung ventilation is essential when a bronchopleural or bronchocutaneous fistula renders positive-pressure ventilation difficult or impossible. Furthermore, directing ventilation toward the healthier lung may result in better oxygenation and ventilation.[70] Some procedures require isolated ventilation, including open procedures on the trachea and mainstem bronchi, such as sleeve and carinal resections, and bronchopulmonary lavage for pulmonary alveolar proteinosis.

Design of Double-Lumen Tubes

Isolated lung ventilation usually is accomplished through a double-lumen endotracheal tube. The central shaft of a double-lumen endotracheal tube is cylindrical and contains a septum that divides it into two symmetric D-shaped lumens. At the proximal end of each lumen is a short length of tubing that creates a Y-shape that permits independent attachment for ventilatory apparatus, clamping, or opening to atmospheric pressure. At the distal end, the shaft is surrounded by an inflatable tracheal cuff. The tracheal lumen terminates just below the tracheal cuff. The other lumen has a cylindrical extension, curved to fit into one of the mainstem bronchi, and carries an inflatable circumferential bronchial cuff. After the double-lumen endotracheal tube has been properly placed within the patient's airway, the bronchial cuff permits use of the bronchial lumen for positive-pressure ventilation or exclusion of the hemithorax in which it resides. The tracheal cuff provides a seal that directs pressurized gas from the tracheal lumen into the other bronchus. Hence, a properly placed double-lumen endotracheal tube permits selective ventilation or collapse of either lung.

Double-lumen endotracheal tubes are manufactured with selective bronchial extensions intended for placement into either the left or right mainstem bronchus. The left mainstem bronchus arises at a more acute angle with reference to the tracheal axis, but it is adequately long to easily accommodate the endobronchial extension with its inflatable cuff. In contrast, the right mainstem bronchus is nearly a direct extension of the trachea, but it contains a branch to the right upper lobe bronchus that arises close to the tracheal bifurcation (Fig. 53–12). A

TABLE 53–5.

Choice of Double-Lumen Endotracheal Tube

Patient Height	Tube Size (Fr)	Depth of Insertion (cm)
136–164 cm 4'5.5"–5'4.5"	37	27
165–179 cm 5'5"–5'10.5"	39	29
180–194 cm 5'11"–6'4.5"	41	31

From Brodsky JB, Benumof JF, Ehenworth J, et al. Depth of placements of left double-lumen endobronchial tubes. Anesth Analg 1991; 73:570–572, with permission.

right-sided double-lumen endotracheal tube has a fenestration within the bronchial extension and an elaborately shaped cuff to permit a seal without airflow obstruction. Because of these considerations, right-sided tubes are more difficult to insert and require more maintenance to ensure continuous ventilation of all lobes of the right lung. In the absence of a specific indication for a right-sided double-lumen endotracheal tube, a left-sided tube is strongly preferred.

Placement of Double-Lumen Tubes

The type of tube is chosen based on the surgical procedure, and its size is based on the patient's body habitus (Table 53–5). Direct laryngoscopy with a curved (MacIntosh) laryngoscope blade is preferred because the glottic opening is better exposed compared with a straight blade. The double-lumen endotracheal tube is held with its bronchial curve oriented anteriorly and its tracheal–pharyngeal curve oriented to the right. The tube is advanced through the glottic opening until the bronchial cuff just passes the vocal cords. If a stylet was used, it is removed.

Two methods are used for cannulation of the desired bronchus: empiric or "blind placement," and direct vision using fiberoptic assistance. In the first method, the tracheopharyngeal curve is rotated anteriorly until the proximal end of the double-lumen endotracheal tube just passes the midsagittal axis. The bronchial curve should now be oriented to the side dictated by the tube selected. It then is advanced until moderate resistance to further insertion is encountered. A bifurcated connector is attached to the two lumens, and the tracheal cuff is inflated. Intubation of the trachea is confirmed by capnography, auscultation, and observation of chest excursion. Once both lungs are determined to be adequately ventilated, it is safe to proceed with confirmation that the tube is positioned to allow isolation of the two lungs. Correct placement can be determined by a series auscultation maneuvers whereby the tracheal and bronchial lumens are ventilated independently. However, this technique is time consuming and may often prove inaccurate. The alternative method uses a bronchoscope to confirm placement. Each lumen of the bifurcated double-lumen endotracheal tube connector is fitted with a fenestrated membrane covered by a removable cap. While the lungs are ventilated with positive pressure, the fenestrated membrane on the tracheal lumen is uncovered, and the bronchoscope is passed through it into the double-lumen endotracheal tube to confirm placement.

The alternative method of tube placement, which uses direct observation via a fiberoptic bronchoscope, is the most efficient method for confirming appropriate anatomic placement. The bronchoscope is steadily advanced through the tracheal lumen until its tip just exits from the distal opening. If the tube is properly positioned, the carina should be seen just beyond the opening, and the medial wall of the endobronchial extension should be seen entering the contralateral bronchus. The bronchial cuff should be entirely contained within the contralateral bronchus, while an unobstructed view of the opening into the ipsilateral bronchus is enjoyed. Disposable double-lumen tubes usually feature a prominent band around the endobronchial extension several millimeters above the endobronchial cuff to facilitate positioning. When ideally positioned, the band should lie at the level of the carina. It may be necessary to slightly advance or withdraw the tube to achieve ideal position. Once anatomically correct tube position has been confirmed, it is secured in place, and the endobronchial cuff is gently inflated under direct bronchoscopic visualization to ensure that the cuff does not herniate into the trachea. Each time the patient is repositioned, the position of the double-lumen endotracheal tube should be verified.

An alternative method of tube placement eliminates the possibility of placing the endobronchial extension in the wrong bronchus. The tube is passed through the cords and rotated as for the first method. It is advanced only until the tip of the bronchial extension is 20–22 cm beyond the central incisors as determined by markings on the shaft. The bronchial cuff is inflated to seal against the wall of the trachea. An anesthetic circuit is attached to the connector for the bronchial lumen, and intubation of the trachea is confirmed. The bronchoscope is passed into the bronchial lumen. After the tip of the bronchoscope has entered the trachea, it is advanced under direct visualization past the carina into the desired mainstem bronchus (Figs. 53–13 and 53–14). After the bronchoscope is advanced as far as possible, the bronchial cuff is deflated. Using the bronchoscope as a directing stylet, the double-lumen endotracheal tube is advanced until gentle resistance is met. The bronchoscope is withdrawn and placed in the tracheal lumen to confirm unimpeded access to the ipsilateral bronchus as in the first method. Once placement is confirmed, the tube is secured.

Occasionally, double-lumen endotracheal tube is malpositioned. Three possible reasons are (1) the tube is inserted so deeply that the tracheal opening is beyond the carina; (2) the tube is not inserted far enough so that the bronchial cuff is above the carina, and (3) the endobronchial extension has entered the incorrect bronchus so that the tracheal lumen opening is trapped against the lateral wall of the trachea on the ipsilateral side (Fig. 53–15). Gently withdrawing or advancing the tube under direct bronchoscopic visualization should reveal and correct either of the first two causes. If the endobronchial extension is not in the correct bronchus, the tube is repositioned by inserting the fiberoptic bronchoscope in the endobronchial lumen and withdrawing the tube and scope until the carina is encountered. The tube and scope then are advanced down the appropriate mainstem bronchus.

Right-sided tubes require more vigilance and confirmation that the fenestration supplying the right upper lobe bronchus is positioned correctly. This is accomplished by passing the bronchoscope into the endobronchial lumen and observing the upper lobe

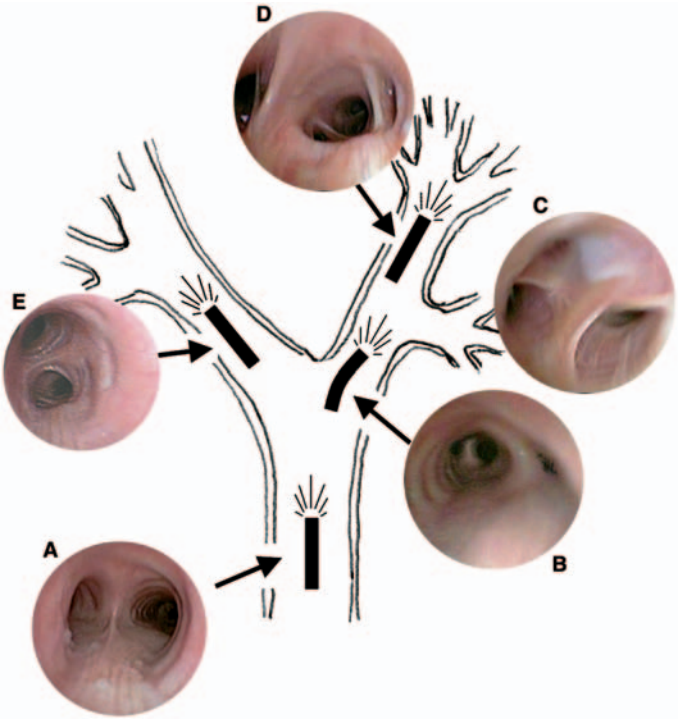

FIGURE 53–13. Bronchoscopic guide for placement of single lung-ventilation devices. **A.** The bronchoscope is situated in the distal trachea. In this view, the carina is clearly visualized along with the anterior cartilaginous rings and the posterior striated membranous portion of the trachea. The takeoff of the right mainstem bronchus is more aligned with the trachea, predisposing to endobronchial intubation of the right mainstem bronchus when an endotracheal tube is advanced too far. The easiest way of absolutely identifying the carina is to locate the right upper lobe. Confirmation of the "true" left and right mainstem bronchi is the best way to ensure proper placement of the selective lung ventilation device. **B.** The bronchoscope is in the right mainstem bronchus, just proximal to the bronchus intermedius, which begins below the origin of the right upper lobe. Origin of the right upper lobe is variable but usually arises 1–1.5 cm past the carina between 2 and 4 o'clock. **C.** The bronchoscope is in the right upper lobe bronchus. The right upper lobe branches into three segments: apical, posterior, and anterior. These three orifices typically are arranged in "V" pattern, but they also can be oriented in a line. **D.** The bronchoscope is in the distal bronchus intermedius. The right middle lobe, which is to the right, immediately splits into the lateral and medial segments. It is possible to advance a double-lumen endotracheal tube distal enough down the right side so that the endobronchial lumen will be in the right inferior lobe and the tracheal lumen will expose the right middle lobe. The right middle lobe's lateral segment orifice could be confused for the right upper lobe orifice, but the right middle lobe's lateral segment does not subdivide like the right upper lobe. **E.** The bronchoscope is in the distal left mainstem bronchus. This view reveals the left upper and lower lobe bronchi. It is important to ensure that left-sided double lumen tubes have not been advanced too far, leading to selective intubation of the left upper or lower lobe.

bronchial orifice through the fenestration in the lateral wall of the endobronchial extension (Fig. 53–16).

Although confirmation of position through direct visualization with a fiberoptic bronchoscope usually is rapid and definitive, it is not always feasible. Furthermore, although it assures anatomically correct position, it does not ensure functional isolation of the left and right lungs. Functional isolation is tested by selectively ventilating one lung while the other is vented to the atmosphere, and unilateral ventilation of the intended lung is confirmed by auscultation and visual or tactile observation. The opposite lung then is ventilated, and the test is repeated. A test for functional isolation should always be used when the double-lumen endotracheal tube is placed to prevent spillage of liquid from one lung to the other.

Complications

Complications associated with double-lumen endotracheal tubes can be divided into two types: those resulting from malposition of the tube, and those caused by trauma to the tracheobronchial tree.

Malposition

Malposition may lead to failure either to ventilate segments of the dependent lung or to collapse the operative lung. Failure to ventilate segments of the ventilated lung can occur if the bronchial lumen obstructs the origin of the upper lobe bronchus, which frequently manifests as hypoxemia and increased peak airway pressures. A common cause of upper lobe obstruction is distal migration of the endobronchial lumen associated with flexion of the neck. Upper lobe obstruction is more common when a right-sided double-lumen endotracheal tube is inserted. Failure to collapse the nonventilated lung may interfere with the operation.

Cephalad migration of the double-lumen endotracheal tube can be caused by surgical manipulation, neck extension, or traction on an inadequately secured tube. As the tube withdraws, the bronchial cuff herniates over the carina into the trachea. When partially herniated, increased cuff pressure may force the cuff further into the trachea. The herniated cuff may partially or fully obstruct the contralateral mainstem bronchus, making that lung difficult or impossible to collapse (or ventilate).

Malposition of the tube should be suspected when peak airway pressure suddenly increases, hypoxemia occurs, or inflation of the nonventilated lung is detected. Vigilance should be heightened immediately after the patient is repositioned and during surgical manipulation near the hilum of the lung. At the first suspicion of a malpositioned double-lumen endotracheal tube, tube position should be confirmed immediately by fiberoptic bronchoscopy. If discerning the anatomy during an open thoracotomy is difficult, the surgeon may be able to manually guide the endobronchial lumen of the double-lumen endotracheal tube into the desired mainstem bronchus.

Traumatic Damage

Trauma to the tracheobronchial tree by double-lumen endotracheal tubes include minor insults, such as ecchymosis of the mucous membranes, and more severe insults, such as arytenoid dislocation and vocal cord rupture. Catastrophic tracheobronchial rupture has been reported.[71–76] The multiple-lumen design and relatively large size of double-lumen endotracheal tubes make them stiffer than conventional endotracheal tubes, thus increasing the risk of damage from forceful ad-

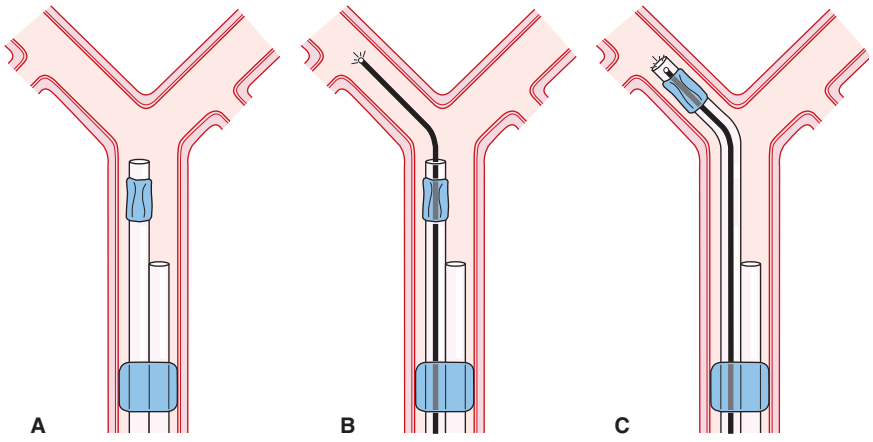

FIGURE 53–14. Schematic diagram portraying use of the fiberoptic bronchoscope to insert a left-sided double-lumen tube. **A.** The double-lumen tube can be put into the trachea in a conventional manner, and both lungs can be ventilated by both lumens. The fiberoptic bronchoscope can be inserted into the left lumen of the double-lumen tube through a self-sealing diaphragm in the elbow connector to the left lumen. This allows continued positive-pressure ventilation of both lungs through the right lumen without creating a leak. After the fiberoptic bronchoscope has been passed into the left mainstem bronchus (**B**), it is used as a stylet for the after-coming left lumen (**C**). The fiberoptic bronchoscope is then withdrawn. Final precise positioning of the double-lumen tube is performed with the fiberoptic bronchoscope in the right lumen.

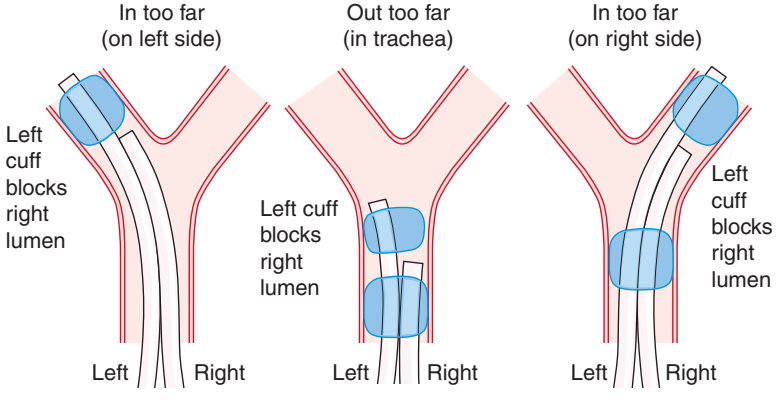

Procedure	Breath sounds heard		
Clamp right lumen (both cuffs inflated)	Left	Left and right	Right
Clamp left lumen (both cuffs inflated)	None or very ↓↓	None or very ↓↓	None or very ↓↓
Clamp left lumen (deflate left cuff)	Left	Left and right	Right

FIGURE 53–15. The three major (involving a whole lung) malpositions of a left-sided double-lumen endotracheal tube. The tube can be in too far on the left (both lumens are in the left mainstem bronchus), out too far (both lumens are in the trachea), or down the right mainstem bronchus (at least the left lumen is in the right mainstem bronchus). In each of these three malpositions, the left cuff, when fully inflated, can completely block the right lumen. Inflation and deflation of the left cuff while the left lumen is clamped creates a breath sound—differential diagnosis of tube malposition (see text for explanation). L, left; R, right; –, decreased.

vancement against resistance. The stiffness is further increased by use of a rigid stylet during tube placement. Therefore, when use of a stylet is required for intubation of the trachea, it should be withdrawn before the bronchial lumen of the double-lumen endotracheal tube is advanced into the mainstem bronchus.

Injuries may result from excessive pressure in either the tracheal or bronchial cuffs, leading to tissue necrosis or rupture. The small size and high pressure of the bronchial cuff increase the risk of tissue injury from overinflation. Cuff pressure should be regularly monitored by palpation of the pilot balloon or by use of a calibrated device.

Failure to obtain a complete seal is especially hazardous when the double-lumen endotracheal tube is used to protect one lung from liquid contents within the other. The leak may allow spillage of liquid into the unaffected lung. Liquids include saline during bronchopulmonary lavage, pus from unilateral empyema, and blood from airway hemorrhage.

Contraindications

The principal contraindication to use of a double-lumen endotracheal tube is the presence of a luminal airway mass that may be dislodged or may prevent passage of the tube. Relative contraindications include critical dependence on bilateral mechanical ventilation in patients unable to tolerate its interruption, patients requiring rapid placement of an endotracheal tube to avoid aspiration of gastric contents, and patients in whom conventional tracheal intubation is judged to be difficult.

Alternative Methods of Lung Isolation

When collapse of the left lung and ventilation of the right are required or use of a double-lumen endotracheal tube is not feasible, a bronchial blocker can be placed in the left mainstem bronchus. This strategy eliminates the risk of losing the airway while changing the endotracheal tube at the end of the case for patients requiring postoperative ventilation. Specific bronchial blockers having a patent central lumen to permit deflation of the distal airway have been developed. The Arndt catheter has a nylon loop that is used to ensnare the distal portion of the fiberoptic scope as it is advanced in the selected mainstem bronchus. The loop

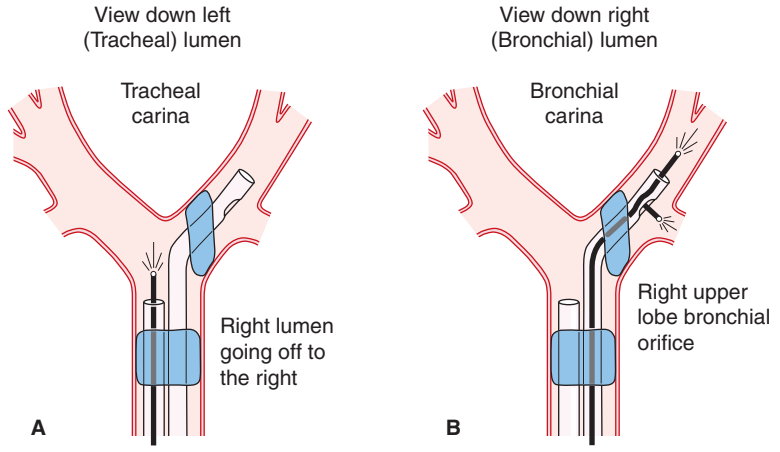

FIGURE 53–16. Schematic diagram portraying use of a fiberoptic bronchoscope to determine precise right-sided double-lumen tube position. **A.** When the fiberoptic bronchoscope is passed down the left (tracheal) lumen, the endoscopist should see a clear straight-ahead view of the tracheal carina and the right lumen going off into the right mainstem bronchus. **B.** When the fiberoptic bronchoscope is passed down the right (bronchial) lumen, the endoscopist should see the bronchial carina off in the distance. When the fiberoptic bronchoscope is flexed cephalad and passed through the right upper lobe ventilation slot, the right upper lobe bronchial orifice should be visualized.

is loosened and advanced distal to the fiberoptic scope. Another variation, the Cohen endobronchial blocker, incorporates a small wheel that is used to deflect the tip of the catheter into the selected bronchus. Under direct vision, the catheter is slowly withdrawn until the inflated balloon is just distal to the level of the carina. In an emergency, an angled Fogarty catheter is inserted through the endotracheal tube under radiographic or fiberoptic guidance into the desired bronchus.[77] Absence of a patent lumen extending below the balloon of Fogarty catheters prevents suctioning or oxygen delivery to the occluded lung segment.

Endobronchial intubation with a single-lumen tube offers an alternative to the double-lumen endotracheal tube, which can be especially useful in emergencies. Disadvantages of using a single-lumen tube include loss of ability to selectively ventilate or suction the contralateral lung and increased difficulty in placing or ascertaining correct placement of the tube. Endobronchial intubation is especially useful for patients who require emergent tracheal intubation for massive hemoptysis. For adults, endobronchial intubation requires a tube of adequate length, often >31 cm, to ensure that the entire cuff is placed below the carina. Occasionally it is necessary to extend the tube using a length of tubing and a connector. Although endobronchial intubation of the right side is easier, preserving ventilation to the right upper lobe is inherently difficult. Mainstem intubation is facilitated using a fiberoptic bronchoscope as a directing stylet. Blind left mainstem placement can be achieved with a 92% success rate by turning the head to the right after the tube has passed through the vocal cords and then rotating the tube 180° so that the convex curve faces posteriorly before advancing it.[78]

The Univent tube is a single-lumen endotracheal tube that contains a bronchial blocker that passes through a small channel within the wall of an endotracheal tube. The bronchial blocker carries a low-pressure, high-volume cuff and has an internal lumen that can be used for suctioning the collapsed lung or for providing CPAP or high-frequency jet ventilation (Fig. 53–17).[79] Initial tube placement in the trachea is accomplished as for any single-lumen tube; then it is rotated 90° toward the lung into which the blocker will be passed and advanced (Fig. 53–18). The blocker is advanced into the targeted mainstem bronchus, after which the tracheal cuff is inflated and the tube secured. The depth of the blocker is adjusted and confirmed using a flexible bronchoscope passed through the main lumen of the tube. Additional techniques to assist in placing the blocker include rotation of the head and placing the fiberoptic scope in the opposite lung to divert the blocker into the contralateral side. The tube offers the advantage of allowing easy conversion from one- to two-lung ventilation (and vice versa), and it is suitable for long-term use in an intensive care unit (ICU) setting. The mobility of the blocker and the large volume of its cuff increase the likelihood of proximal migration, with herniation of the cuff into the trachea.

HYPOXIC PULMONARY VASOCONSTRICTION

Humans encounter hypoxia throughout their lives. Hypoxia occurs in utero, through disease, and by desire, in our quest for higher altitude. HPV is a widely conserved, homeostatic, vasomotor response of precapillary smooth muscle in the PAs to alveolar hypoxia.[80–82] HPV mediates $\dot{V}/\dot{Q}$ matching and, by reducing shunt fraction, optimizes systemic pO_2.

Although total pulmonary blood flow is directly proportional to right ventricular cardiac output, its distribution within the pulmonary vasculature can be altered dynamically. Hypoxia, caused by either atelectasis or ventilation with a hypoxic gas mixture, diverts blood flow to better ventilated, nonhypoxic lung segments. This phenomenon of HPV, first noted by Von Euler and Liljestrand in 1946, is of importance to the anesthesiologist, particularly during thoracic anesthesia. In the absence of inhibiting factors, HPV can divert blood flow away from nonventilated regions.[80] When a patient is in the lateral decubitus position, the dependent lung receives 60% of the cardiac output, whereas the nondependent lung receives 40%. If

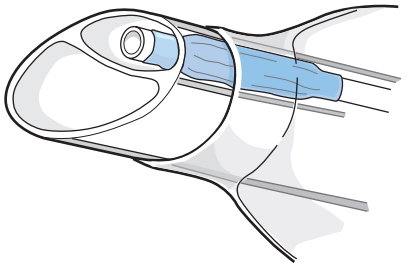

FIGURE 53–17. Close-up of the Univent tube shows two lumens. The small tube is retracted into the small lumen before intubation. (Modified from Kamaya H, Krishna PR. New endotracheal tube [Univent tube] for selective blockade of one lung, Anesthesiology 1985;63:342, with permission.)

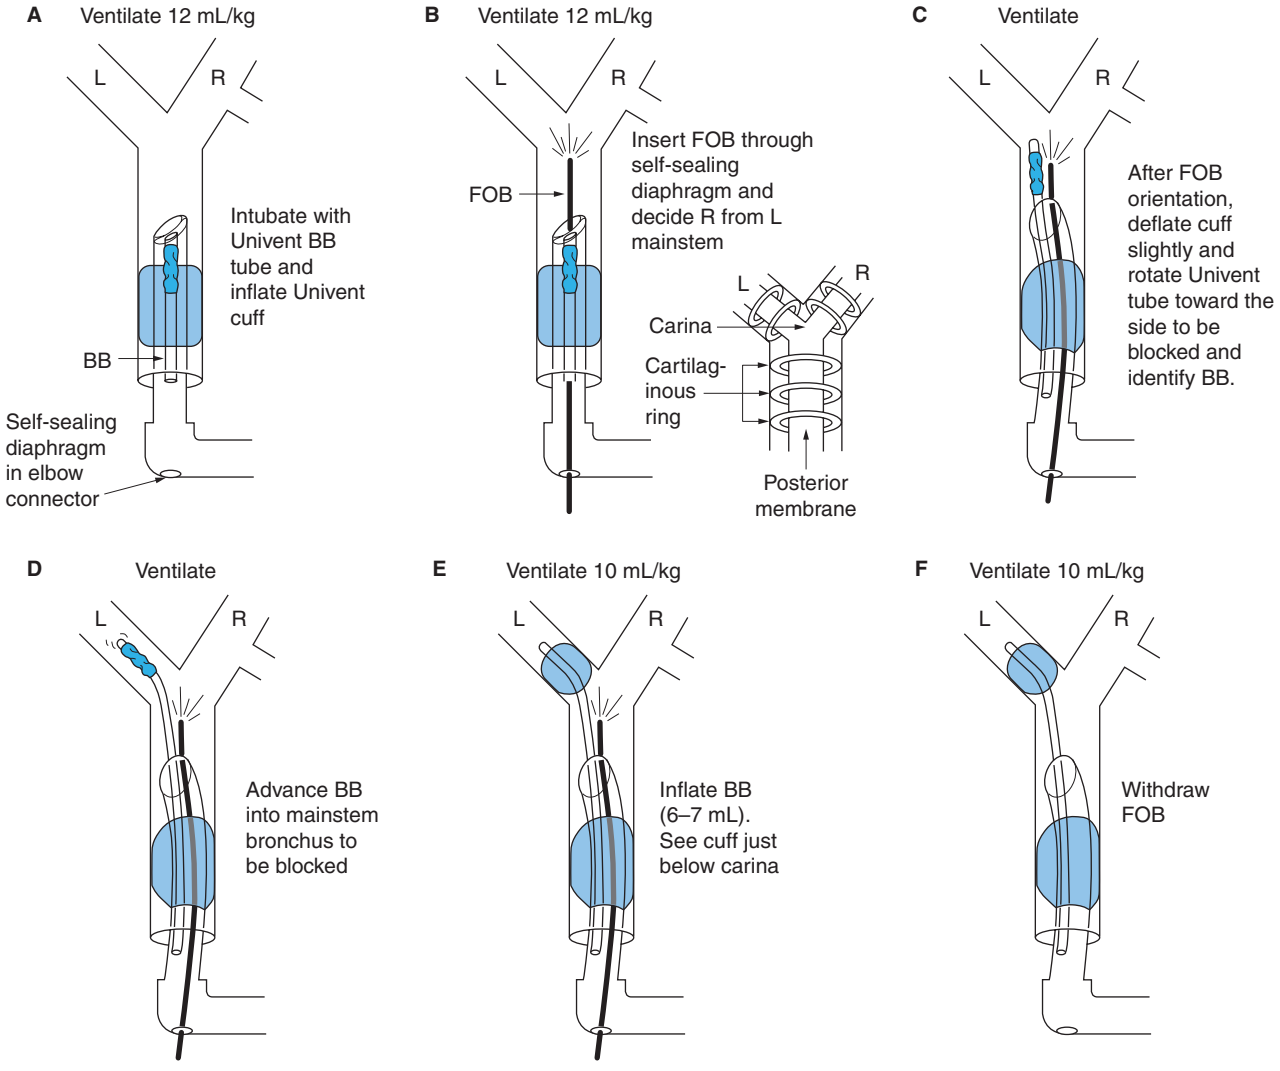

FIGURE 53–18. Sequential steps of the fiberoptic-aided method for inserting and positioning the Univent bronchial blocker in the left mainstem bronchus. One- and two-lung ventilation are achieved by simply inflating and deflating, respectively, the bronchial blocker balloon. FOB, fiberoptic bronchoscope.

the nondependent lung is not ventilated and is atelectatic, a maximal HPV response can reduce its blood supply by 50%. As a result, the dependent lung receives 80% of the cardiac output, and the atelectatic nondependent lung receives only 20% of the cardiac output (Fig. 53–19). Therefore, the arterial oxygen tension (Pao_2) observed during regional lung hypoxia is much greater than would be expected if the HPV response were not present (Fig. 53–20).

Mechanisms

HPV is mediated by the smooth muscle cells throughout the lung. Although modulated by the endothelium, the core mechanism is in the smooth muscle cell. The Redox Theory for the mechanism of HPV proposes the coordinated action of a redox sensor (proximal mitochondrial electron transport chain) that generates a diffusible mediator (reactive O_2 species) that regulates an effector protein [voltage-gated potassium (Kv) and calcium channels]. The subsequent inhibition of O_2-sensitive Kv channels, particularly Kv1.5 and Kv2.1, depolarizes PA smooth muscle,

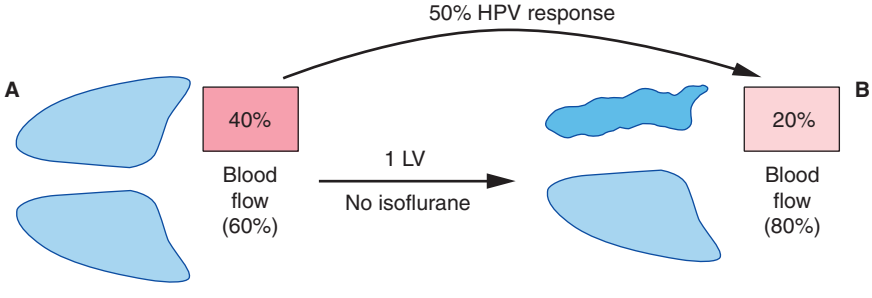

FIGURE 53–19. A. Schematic diagram showing that the two-lung ventilation nondependent-to-dependent lung blood flow ratio is 40%/60%. **B.** When two-lung ventilation is converted to one-lung ventilation (as indicated by atelectasis of the nondependent lung), the hypoxic pulmonary vasoconstriction response decreases the blood flow to the nondependent lung by 50% so that the nondependent-to-dependent lung blood flow ratio is now 20%/80%.

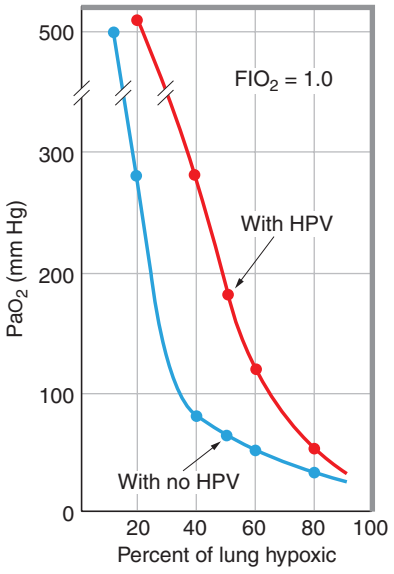

FIGURE 53–20. Effect of hypoxic pulmonary vasoconstriction (HPV) on arterial PO_2 (Pao_2). As the percent of lung that is hypoxic increases (X-axis), Pao_2 decreases (Y-axis). When the amount of lung that is 30% to 70% hypoxic, which is in the one-lung ventilation/anesthesia range, the decrease in Pao_2 is much greater if there is no HPV compared with the normal expected amount of HPV. (From Benumof JL. One-lung ventilation and hypoxic pulmonary vasoconstriction: implications for anesthetic management. Anesth Analg 1985;64:821, with permission.)

activating voltage-gated Ca^{2+} channels and causing Ca^{2+} influx and vasoconstriction.[81] A similar mechanism for regulating O_2 uptake/distribution exists in simpler organisms and in other specialized mammalian O_2-sensitive tissues, including the carotid body and ductus arteriosus.[82]

Hemodynamic variables can influence the magnitude of HPV. The pulmonary vasoconstrictor response to hypoxia is decreased with increases in PA pressure, cardiac output, left atrial pressure, and central blood volume.[83] Increases in pulmonary vascular pressures can mechanically open and recruit closed vessels in hypoxic lung regions, overcoming part of the active pulmonary vasoconstriction.[84] An increase in cardiac output can mask the HPV response by recruiting pulmonary vessels or increasing PvO_2. Alternatively, HPV may increase PVR and PA pressures as flow is diverted from a proportionately large section of hypoxic lung to a smaller section of normoxic lung.[84] When flow is diverted from small hypoxic segments, the high compliance of the pulmonary circulation prevents clinically significant changes in PVR or PA pressure.

Drugs and anesthetics may modulate HPV and interfere with $\dot{V}/\dot{Q}$ matching. Calcium channel blockers and vasodilators, such as sodium nitroprusside, attenuate the HPV response (Table 53–6). These drugs increase the A–a gradient, often leading to hypoxemia perioperatively. Other perioperative conditions, such as hypocapnia and hypothermia, also decrease the normal HPV response.[83,85]

Effects of Anesthetics

Extensive studies have been performed to examine the effect of inhalation and intravenous (IV) anesthetics on HPV. The results and implications of these studies differ according to the type of experimental preparation used. In human studies and in more physiologic in vivo investigations with an intact systemic circulation, inhalation anesthetics produced either no effect or only a mild decrease in HPV.[97,98] In part, the discrepancy between the more complex in vivo studies and simpler in vitro models occur because the additional factors that can modulate the HPV response, such as pulmonary vascular pressure, cardiac output, PCO_2, and temperature, are absent. In the more biologically complex in vivo models, these factors seem to diminish the inhibitory effect of inhaled anesthetics on HPV.[99,100]

IV agents such as ketamine and propofol do not significantly affect HPV.[99,101] HPV is not directly affected by thoracic epidural analgesia. Any changes that have been observed during epidural may be attributable to alterations in cardiac function and loading conditions.[102]

Nitric Oxide

Nitric oxide (NO) is a unique endogenous compound that is found in endothelium and smooth muscle cells. NO induces vasodilatation by activating protein kinases and guanylate cyclase and reducing or resequestering intracellular Ca^{2+}. A class of IV vasodilators, including nitroglycerine and nitroprusside, produces muscle relaxation in a similar manner.

The most common clinical uses of NO are for management of pulmonary hypertension and $\dot{V}/\dot{Q}$ mismatching. IV therapy nonselectively produces pulmonary and systemic vasodilatation. In contrast, NO administered as an inspired gas selectively dilates the vascular supply to those areas, thereby improving $\dot{V}/\dot{Q}$ matching. NO has been used clinically in cases of primary pulmonary hypertension, lung transplantation, cardiac transplantation, cardiac disease, adult respiratory distress syndrome (ARDS), acute pulmonary hypertension, congenital heart disease, and idiopathic pulmonary hypertension. Its clinical potential has been hampered by the complexity and cost of the gas and its delivery system.

Delivery systems require an adequate scavenging system to reduce the risk of occupational exposure and continuous gas concentration monitoring. The potential toxicity of NO focuses on its conversion from the free radical form to NO_2, which is associated with lung toxicity, and the formation of nitrosylhemoglobin, which is rapidly converted to methemoglobin.[103–106] Clinical reports of NO-associated toxicity include methemoglobin toxicity, paradoxical deterioration in oxygenation related to edema or worsening of right-to-left shunting,[79,103,105,107–109] and rebound pulmonary hypertension.[103,110,111] Because of these latter responses, the dose of NO should be gradually decreased to avoid prevent in oxygenation or rebound pulmonary hypertension.

Prostacyclin

Prostacyclin (PGI_2, Epoprostenol, Flolan) is a member of the prostaglandin fam-

ily of lipid mediators derived from arachidonic acid. It is synthesized predominantly by endothelial cells, including the pulmonary vascular endothelium.[112] PGI_2 produces vasodilatation in low-resistance vascular beds such as the pulmonary circulation.[113] Not only has PGI_2 been shown to stimulate endothelial release of NO,[114] but NO has been shown in turn to enhance the production of PGI_2 in human PA smooth muscle cells. It has a good safety profile; PGI_2 is spontaneously hydrolyzed in plasma to its inactive metabolite, 6-keto-prostaglandin F. The in vitro half-life of prostacyclin in human blood at 37°C and pH 7.4 is approximately 6 minutes.[115] Animal studies demonstrate that IV PGI_2 has a high clearance (93 mL/min/kg), small volume of distribution (357 mL/kg), and short half-life (2.7 minutes).[115]

Prostacyclin that can be delivered as an aerosol has replaced NO as the preferred inhaled selective pulmonary vasodilators because of its lower cost and absence of toxic metabolites.[112] It has minimal effects of systemic arterial pressure but results in dramatic improvements in arterial oxygenation and lowering of pulmonary arterial pressures. Its use during one-lung anesthesia can improve $\dot{V}/\dot{Q}$ matching, but it is not as effective as CPAP in the nonventilated (nondependent, operative) lung (see Strategies for Improving Oxygenation during One-Lung Ventilation).

STRATEGIES FOR IMPROVING OXYGENATION DURING ONE-LUNG VENTILATION

Arterial hypoxemia during one-lung ventilation is difficult to predict clinically. Previous studies have attempted to identify predictive preoperative and intraoperative factors of Pao_2 during single-lung ventilation. Some variables (relative perfusion to the operative lung, intraoperative Pao_2 during two-lung ventilation) were strongly identified as predictors of low Pao_2 during one-lung ventilation, whereas other factors (side of operation, preoperative pulmonary function tests) have been controversial.[117,118] Interestingly, patients with a hematocrit value >45% are reported to have lower Pao_2 values during one-lung ventilation.[119] The occurrence of hypoxia mainly depends on factors such as residual shunt to the nonventilated lung, cardiac output, and degree of pulmonary vasoconstriction. However, strategies for managing hypoxemia during one-lung ventilation are available.

The basic principles for management of one-lung ventilation include (1) delaying initiation until after the patient to turned to the lateral decubitus position while still allowing sufficient time for the nondependent lung collapse, (2) confirming correct positioning of the double-lumen tube by fiberoptic bronchoscopy, (3) using high-inspired O_2 concentrations to decrease the risk of systemic hypoxemia, (4) using a large tidal volume of approximately 10 mL/kg and adjusting respiratory rate to keep $Paco_2$ at approximately 40 mm Hg, (5) continuously monitoring oxygenation using pulse oximetry, and (6) continuously monitoring ventilation by noting changes in end-tidal CO_2 concentrations and peak inspiratory pressures.

Measures for improving oxygenation during one-lung ventilation include one or more of the following strategies: (1) improving $\dot{V}/\dot{Q}$ distribution in the dependent lung (i.e., lung recruitment maneuver, PEEP), (2) increasing alveolar partial pressure of oxygen (Pao_2) in the nondependent lung (i.e., CPAP), (3) decreasing blood flow to the nondependent lung (i.e., placement of a ligature on the PA), and (4) increasing blood flow and perfusion to the dependent lung (i.e., prostacyclin or NO).

Prevention of Absorption Atelectasis

Absorption atelectasis, caused by increased FiO_2, can be decreased or prevented by ventilation using large tidal volumes, application of PEEP to the dependent lung, and ventilation with FiO_2 <100%.[81] Use of 10–20% nitrogen with 80–90% O_2 has been suggested to decrease the possibility of absorption atelectasis because nitrogen keeps open the alveoli in areas of low $\dot{V}/\dot{Q}$. The small reduction in FiO_2 causes only a small decrease in Pao_2.

Verification of Lung Isolation

The most important factor in assuring adequate oxygenation and ventilation is proper positioning of the double-lumen endotracheal tube or bronchial blocker. Tube position should be reconfirmed after the patient is turned. Secretions that interfere with ventilation and increase inflation pressure should be suctioned from the airway.

Recruitment Maneuver

Progressive atelectasis associated with decreasing Pao_2 is a common problem in patients undergoing single-lung ventilation during thoracic surgery. These patients are at increased risk for atelectasis as a result of single-lung ventilation, lateral decubitus positioning, inhibition of HPV, and periodic disconnection from the ventilator. Recruitment maneuvers are used to reinflate collapsed alveoli, resulting in improved oxygenation and ventilation. A sustained pressure of approximately 35 cm H_2O, which is above the tidal ventilation range, is applied for a period of 30–60 seconds in order to inflate lung units. After this maneuver, increasing the tidal volume or PEEP is not necessary because the subsequent lung volumes should be maintained. A successful procedure will result in improved oxygenation, reduced end-tidal CO_2, and improved compliance.

Ventilation Using Large Tidal Volumes

Small tidal volume ventilation to the dependent lung decreases FRC and promotes airway closure and atelectasis. The development of hypoxic areas in the dependent lung interferes with the overall effectiveness of HPV in the nondependent lung, optimizing oxygenation of the dependent lung. The tidal volume at initiation of one-lung ventilation should be approximately 10 mL/kg, which is relatively large compared with the usual tidal volume during two-lung ventilation of 12 mL/kg. The tidal volume is adjusted upward or downward according to the airway pressures and arterial blood gas values. Delivering an excessively large tidal volume to the dependent lung paradoxically can worsen oxygenation and ventilation of the dependent lung. Increased airway pressures with the associated the risks of pneumothorax or barotrauma and increased PVR can divert blood, that is, perfusion, to the nonventilated nondependent lung.[120–123]

Maintenance of Normocapnia

Respiratory rates should be adjusted to maintain normocapnia. Because tidal volume decreases with initiation of one-lung ventilation, the respiratory rate should be increased to maintain the same minute ventilation and $Paco_2$. The change from two-lung ventilation to one-lung ventilation usually causes no problem with CO_2 elimina-

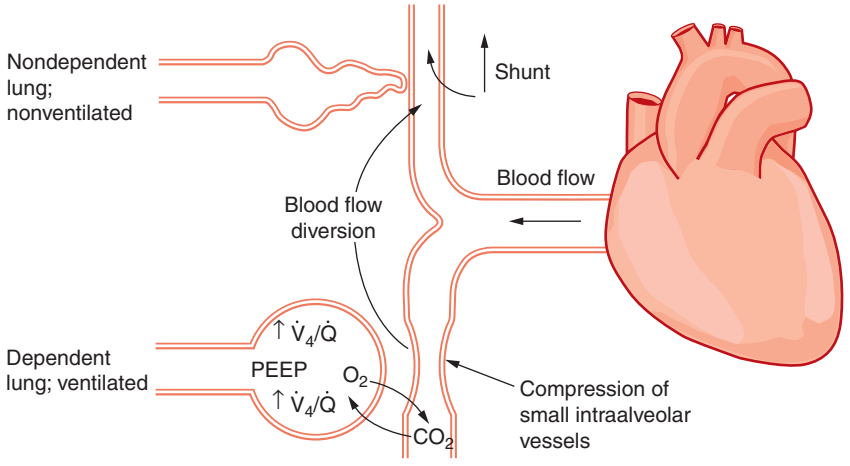

FIGURE 53–21. Selective positive end-expiratory pressure (PEEP) to the ventilated-dependent lung can increase dependent lung ventilation-to-perfusion ratios ($\uparrow \dot{V}_A/\dot{Q}$). Dependent lung PEEP also can cause compression of the small intraalveolar vessels in the dependent lung, causing blood flow diversion to the nonventilated nondependent lung, thereby increasing the shunt through the nonventilated nondependent lung. Therefore, the overall arterial oxygenation effect of dependent lung PEEP will be a tradeoff between the good effect of an increase in dependent lung $\dot{V}_A/\dot{Q}$ and the bad effect of increased nonventilated lung blood flow.

tion because of the high diffusibility of CO_2 across the alveolar membrane.[123–125] Theoretically, hypocapnia should be avoided because it can directly dilate the pulmonary vessels, interfering with HPV in the nondependent lung. Alternatively, hypercapnia will increase PVR and can increase right-heart strain.

Dependent-Lung PEEP

Because the dependent lung often has decreased volume during one-lung ventilation, attempts have been made to improve oxygenation by managing the ventilated lung with PEEP. The application of PEEP to the dependent lung maintains recently recruited atelectatic alveoli to increase FRC and lung compliance. The disadvantage of applying PEEP to the dependent lung is that the associated increased mean airway pressure and PVR may divert some blood flow to the nondependent, atelectatic, nonventilated lung. Therefore, the effect of using PEEP is a balance between its potential beneficial effects and the possible deleterious effects of decreasing HPV, causing the redistribution of blood flow to the nondependent nonventilated lung. In a patient with a diseased dependent lung, the positive effect of selective dependent lung PEEP may outweigh its negative effects. In contrast, patients who have a relatively normal dependent lung may have decreased oxygenation if PEEP is selectively applied to that lung (Fig. 53–21).

Selective Nondependent-Lung CPAP

Application of CPAP to the nonventilated nondependent lung improves oxygenation during one-lung ventilation (Fig. 53–22). Even with a maximal HPV response, 20% of the cardiac output still flows through the nondependent lung. Use of an inhalational agent, such as isoflurane, may increase the nondependent lung blood flow. Application of CPAP during one-lung ventilation leads to oxygenation of blood that perfuses the nondependent lung, thereby increasing Pao_2. CPAP is initiated during the deflation phase of a large tidal volume breath to maintain uniform expansion and prevent the need to overcome critical opening pressures of collapsed alveoli. Application of 5–10 cm H_2O CPAP may not interfere with surgical exposure during open thoracotomies but will significantly impede visualization during thoracoscopy. In addition, CPAP < 10 cm H_2O does not compress small intraalveolar vessels or produce significant hemodynamic effects, but 15 cm H_2O CPAP decreases blood flow through the nondependent lung, diverting flow to the dependent lung.[126]

During one-lung ventilation, the nondependent lung does not remain totally unventilated. Each time the dependent lung is inflated, the mediastinum is displaced upward into the nondependent thorax. During the exhalation phase, the mediastinum falls away from the nondependent side. The effect of mediastinal movement created by ventilation is asynchronous, "pendelluft" ventilation of the nondependent lung. This phenomenon can be observed as a small puff of air emanating from the lumen of nondependent endotracheal

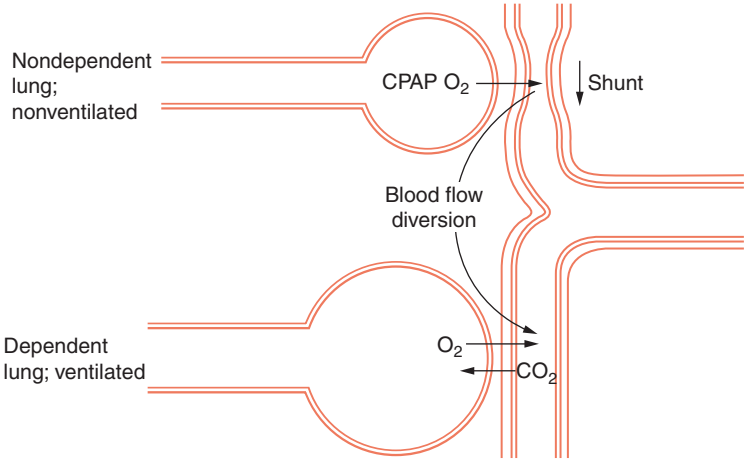

FIGURE 53–22. Selective continuous positive airway pressure (CPAP) to the nonventilated nondependent lung (static distension without tidal movement) allows this lung to participate in oxygen uptake and markedly decreases the shunt through the nonventilated nondependent lung. Even if the nonventilated nondependent lung CPAP causes blood flow diversion to the ventilated dependent lung, the diverted flow can still participate in oxygen uptake and CO_2 elimination in the ventilated dependent lung. Usually 5–10 cm H_2O of nondependent lung CPAP is all that is clinically needed, and this amount of CPAP does not cause any serious surgical interference. (From Benumof JL, ed. Anesthesia for Thoracic Surgery. Philadelphia: WB Saunders, 1995, pg. 416, with permission.)

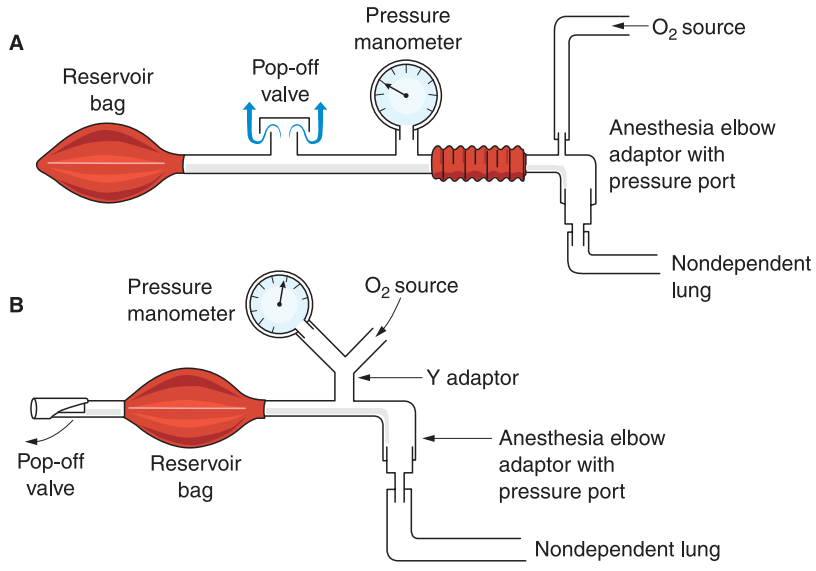

FIGURE 53–23. A, B. Schematic diagram showing two nondependent lung continuous positive airway pressure (CPAP) systems without reservoir bags. Both contain an oxygen source and a pressure relief valve, but A has a pressure manometer to measure CPAP, whereas B does not.

tube, which may be misinterpreted as a failed seal of the bronchial cuff. Because the nondependent lung is ordinarily open to the atmosphere, the pendelluft ventilation introduces room air into the tracheobronchial tree. Thus, even in the absence of CPAP, delivering 100% oxygen via a T-piece may improve oxygenation of blood flowing through the nondependent lung.

The conventional method for instituting CPAP during one-lung ventilation uses an O_2 source and a manometer or PEEP valve (Fig. 53–23).[127] Alternatively, delivery of oxygen at high flows via a catheter placed in the mainstem bronchus of the nondependent lung produces CPAP without need for a PEEP valve. In most situations, an O_2 flow rate of 5–10 L/min creates CPAP of 5–10 cm H_2O, which is sufficient for improving oxygenation. One advantage of this system is that elimination of CO_2 is proportional to the flow rate of the gas in the CPAP system. A very high O_2 flow rate delivered at or below the carina may improve gas exchange without any tidal exchange, which is known as "continuous high-flow apneic ventilation."

Strategies for Improving Oxygenation during Single-Lung Ventilation

The strategies for maintaining oxygenation are individualized to account for patient factors and surgical considerations. Although application of CPAP during video thoracoscopy is contraindicated, its use for open thoracotomy would be better tolerated. The first step to improve arterial oxygenation is confirming proper tube placement. If oxygenation is still inadequate, the strategies of applying CPAP to the dependent lung and PEEP to the dependent lung can be sequentially and additively applied. If arterial oxygenation remains poor, the patient's hemodynamic status should be assessed. A decrease in cardiac output, leading to a decrease in mixed venous oxygen saturation (SvO_2), can magnify the effect of shunt on arterial oxygenation.

If hypoxemia still persists after differential CPAP/PEEP, the nondependent lung may be intermittently ventilated with positive pressure and 100% O_2. Intermittent reinflation of the collapsed lung with O_2 is beneficial, but its beneficial value was found to decline with repeated inflations.[128] Finally, most of the $\dot{V}/\dot{Q}$ mismatch and arterial hypoxemia can be eliminated by decreasing blood flow to the nondependent lung by temporarily ligating its PA (Fig. 53–24).

Selective Nondependent Lung High-Frequency Ventilation

Any method that results in splinting the alveoli and air spaces of the nondependent lung will lead to an improvement in arterial oxygenation and a decrease in the transpulmonary shunt.

Reconfirm proper tube placement after turning to the lateral decubitus position.

↓

Initial one-lung ventilation setting
- TV 10 mL/kg
- FIO_2 80%–100% ± nitrogen 0%–20%
- adjust respiratory rate to maintain $PaCO_2 \approx 40$ mm Hg
- PEEP 0–5 mm Hg

↓

↑FIO_2
↑TV if too small or ↓TV if too large
Consider malposition of double-lumen tube or balloon
reconfirm position of ETT with bronchoscope

↓

Optimize volume status, cardiac output, and hemoglobin content to improve O_2 delivery and prevent mixed venous O_2 desaturation; the latter will magnify the effect of any given degree of shunt on PaO_2

↓

Start nondependent lung CPAP with 5 cm H_2O; increase as needed

↓

Start dependent lung PEEP to follow, then match CPAP of nondependent lung

↓

Intermittent reinflation of the nondependent lung with positive pressure breaths with 100% FIO_2 every 5 minutes, as needed

↓

Reinstitute two-lung ventilation

↓

Clamping/ligation of the pulmonary artery of the nondependent lung

FIGURE 53–24. Algorithm for managing one-lung ventilation and improving oxygenation.

High-frequency ventilation of the nondependent lung has been studied in combination with conventional positive-pressure ventilation of the dependent lung. Using this combination, Pao_2 was much better than with intermittent positive-pressure ventilation of the dependent lung with total collapse of the nondependent lung.[129] In most patients, the same increase in arterial oxygenation can be achieved using selective nondependent lung CPAP, which requires much simpler equipment compared with high-frequency ventilation apparatus. In some situations, high-frequency ventilation may be more advantageous.

If the nondependent lung has a major bronchopleural fistula, high-frequency ventilation to the nondependent lung using low airway pressures helps to decrease the air leak and improve oxygenation and ventilation.[130]

During operation on the major conducting airways, high-frequency ventilation permits the use of small ventilation catheters that pass through the operating field.[130–133]

Unilateral high-frequency jet ventilation with contralateral intermittent positive-pressure ventilation has been used in the anesthetic treatment of patients with severely compromised respiratory reserve. The technique provided satisfactory anesthesia, good operating conditions, and adequate gas exchange.[134]

ANESTHETIC TECHNIQUES

Although thoracic surgery can be performed solely using a regional block, most thoracotomies are performed using general anesthesia with controlled ventilation. Epidural or other regional anesthetic techniques often are used to decrease the intraoperative anesthetic requirement, to facilitate emergence and extubation, and to control postoperative pain.[135,136]

General Anesthesia

The choice of induction agent and dosage is influenced by the patient's medical condition. In patients in whom extensive airway instrumentation or manipulation precedes thoracotomy, the antisialagogue glycopyrrolate can reduce secretions. Opioids supplement the inhalational anesthetic, although the dosage of systemic narcotic should be reduced in patients who will receive epidural opioids. The incidence of postoperative respiratory depression is related to the total dosage of opioids administered systematically and epidurally.

After induction of anesthesia, the trachea is intubated with a single-lumen or double-lumen tube as indicated by the surgical procedure. Position of the endotracheal tube is confirmed by careful auscultation, capnography, and, if indicated, fiberoptic bronchoscopy.

Volatile, halogenated anesthetic drugs have several desirable properties for use during thoracic procedures. They decrease airway irritability and obtund airway reflexes in patients who usually have reactive airways, and they maintain adequate anesthesia while allowing increased inspired oxygen concentrations. They can be eliminated rapidly, allowing tracheal extubation in the operating room with less concern for postoperative respiratory depression. Although volatile anesthetics allow high inspired O_2 concentrations, they may reduce Pao_2 by increasing the shunt related to partial inhibition of HPV.[97,98,137] Inhibition of HPV by inhaled anesthetics may exhibit substantial variability.

Patients with mediastinal and airway tumors may be at risk for airway obstruction during induction of anesthesia. In such patients, the anesthetic plan and emergency treatment strategies should be discussed with the surgeon preoperatively. If emergent tracheostomy, rigid bronchoscopy, or extracorporeal oxygenation is anticipated, the entire operating team should be prepared to act smoothly and efficiently. Patients at increased risk for airway obstruction may require awake fiberoptic intubation or spontaneous ventilation to avoid airway obstruction.

Regional Anesthesia

Epidural anesthesia, paravertebral block, intercostal nerve blocks, or field blocks have been used occasionally as the sole anesthetic for various thoracic procedures, including thoracotomy. Thoracic epidural blockade in awake sedated patients has been used successfully for open thoracotomies and thoracoscopies.[138,139] Crawford et al.[140] described 677 patients with tuberculosis in whom epidural anesthesia was used for thoracotomy. The most surprising results were the absence of paradoxical respiration and dyspnea. The breathing pattern and speech appeared normal even when an upper lobe bronchus was transected and held open. Several factors may have contributed to the success of this unorthodox technique: (1) the patients were extremely cooperative and had a good rapport with the anesthesiologist; (2) analgesia was complete, and patients were comfortable; (3) use of premedication and sedation avoided the pitfalls of over sedation and excitability; (4) supplemental O_2 was administered by positive-pressure mask if the patient reported any shortness of breath; and (5) operation was remarkably gentle and swift. It is doubtful that all of these conditions could be fulfilled during an anatomic resection in the routine patient by the average surgeon.

Combined Epidural Blockade and General Anesthesia

The techniques of general and epidural anesthesia often are combined to achieve the benefits of each. Epidural block may be used either for postoperative analgesia or as the major anesthetic, with light general anesthesia used for amnesia and sedation. Epidural anesthesia has the advantages of reduction in afterload,[141] improved pulmonary function, decreased incidence of venous thromboembolism,[142,143] and suppression of the stress response.[97,144–145] Potential disadvantages include the time required to establish the block, increased fluid requirements and relative decrease in blood pressure associated with sympathectomy, and potential for technical complications such as epidural hematoma.

Vital capacity and lung compliance decrease after general anesthesia and neuromuscular blockade in patients undergoing thoracotomy. Epidural analgesia with light general anesthesia results in less decrease in static compliance and fewer alterations in postoperative pulmonary function.[146] Perioperative use of epidural anesthesia is associated with fewer major postoperative infections. This may result from (1) decreased duration of endotracheal intubation and mechanical ventilation, which diminishes many of the defense mechanisms against infection[147,148]; (2) decreased duration of ICU stay postoperatively and reduced risks of nosocomial infection; and (3) suppression of the endocrine stress response to operation, which has an inhibitory effect on the im-

mune system.[149] Immune competence is less disturbed postoperatively when epidural anesthesia is used compared with other anesthetic and analgesic techniques.[150–154]

An epidural catheter can be inserted in the midthoracic (T4–T9) or low thoracic–lumbar (T9–L2) regions. To date, no studies have demonstrated superiority of one approach. In the experience of the authors, the midthoracic level, approximately T7, provides excellent conditions for thoracic and thoracoabdominal procedures. The higher thoracic approach generally is avoided because of the risk of blocking the phrenic nerve (C3, C4, C5) through cephalad extension of epidural local anesthetics. The low thoracic region is suitable for thoracoabdominal procedures, such as gastrectomy. Use of a lumbar epidural blockade in patients undergoing thoracic surgery requires a larger dosage of local anesthetics or narcotics to provide analgesia in the thoracic regions and is not routinely recommended. Because of the multiple advantages conferred by thoracic epidural analgesia, the anesthetic plan for open thoracotomy should always include placement of a thoracic epidural catheter unless an absolute contraindication is present.

THORACOSCOPY VERSUS THORACOTOMY

Evolution of surgical technique and technical advances in electronics and instrumentation have led to renewed interest in thoracoscopy. In a healthcare environment that values cost and patient outcome, VATS has advantages beyond open thoracotomy, including decreased postoperative pain, pulmonary impairment, and hospital stay. Thoracoscopy permits visualization of the pulmonary cavity through several small portals. These portals provide access for the video camera and allow manipulation of thoracic structures and use of surgical instruments such as staplers, dissectors, coagulators, and lasers. Although initially used for only minor surgical procedures, the application of VATS has expanded considerably for both diagnostic and therapeutic procedures (Box 53–6). If access is inadequate or if bleeding complications occur, VATS is easily converted to a limited open thoracotomy.

Anesthetic treatment for patients undergoing thoracoscopy is similar to that for open thoracotomy (Table 53–7). Although limited thoracoscopy has been performed in spontaneously breathing, sedated patients, this procedure usually is performed during general anesthesia with placement of a double-lumen endotracheal tube for lung separation. Because the ability to visualize the contents of the thoracic cavity is predicated on adequate lung isolation and deflation of the operative lung, use of bronchial blockers is generally deemed inadequate, especially for right-sided procedures. Many patients have obstructive lung disease that impedes passive deflation of the nonventilated lung. To foster deflation, the nondependent lung should be carefully suctioned of secretions that may cause air trapping, then denitrogenated by ventilating with 100% oxygen, with single-lung ventilation initiated before skin incision. The tidal volume delivered to the ventilated dependent lung should be decreased to prevent upward shift of the mediastinum during single-lung ventilation. If deflation is inadequate, CO_2 can be insufflated into the nondependent thoracic cavity. Hypercarbia and hypotension may develop if excessive gas inflation causes mediastinal shift and reduction in venous return to the heart. Use of VATS over open thoracotomy has several advantages. Analgesic requirements and length of hospital stay are less than those for open thoracotomy.[155–159] Adequate postoperative analgesia can be obtained with a combination of parenteral opioids, nonsteroidal antiinflammatory drugs (NSAIDs), or intercostal nerve blocks. It is not our practice to place an epidural catheter for VATS except in patients with severe pulmonary or cardiac disease.

ANESTHESIA FOR PATIENTS UNDERGOING BRONCHOSCOPY

Background

Although introduced in the 1890s, it remained for Chevalier Jackson to perfect the therapeutic application of rigid bronchoscopy for retrieval of foreign bodies and diagnostic use in patients with neoplastic and inflammatory disease. The rigid bronchoscope is a hollow, metal tube with a blunted and beveled distal tip that allows insertion into the airway with minimal trauma. The proximal end is adapted for observation of the airway, maintenance of gas exchange, and introduction of surgical instruments. The proximal side arm is adapted for administration of oxygen or other gases and enables mechanical ventilation during bronchoscopy. Within the wall of the bronchoscope are a series of channels for illumination of the distal field and for suctioning of secretions and blood. The large size of the rigid bronchoscope permits insertion of sponges, snares, knives, scissors, electrodes, and other special devices. The most common uses of a rigid bronchoscope are retrieval of large foreign bodies, evaluation and debulking of bronchial tumors, access to bleeding sites, and overall evaluation of the airways.

The introduction of the fiberoptic bronchoscope has had a dramatic impact by supplanting the use of the rigid instrument in many patients. Several hollow ports or channels are incorporated for suctioning, instillation of medications or lavage fluid, and introduction of accessory instruments. Flexion

of the distal tip by cables allows the instrument to be directed to all segments of the tracheobronchial tree. Indications for fiberoptic bronchoscopy are listed in Box 53–7. Bronchoscopy often is only the first of several diagnostic or therapeutic procedures. After bronchoscopy, mediastinoscopy or thoracoscopy may be performed to further evaluate the presence of disease or for its management.

Flexible Fiberoptic Bronchoscopy

Anesthetic Management

Flexible fiberoptic bronchoscopy can be performed during local anesthesia in sedated spontaneously breathing patients or during general anesthesia with or without placement of an endotracheal tube (Table 53–8).

BOX 53–7.

Indications for Fiberoptic Bronchoscopy

- Diagnostic Indications
  - Staging and characterization of pulmonary disease
  - Evaluation of the site and etiology of pulmonary symptoms
- Therapeutic Indications
  - Tracheal intubation
  - Positioning of double-lumen endotracheal tube
  - Removal of secretions and bronchial toilet
  - Laser of tumors

Awake fiberoptic bronchoscopy is performed after administration of sedation, an antisialagogue, and adequate local anesthesia. If the correct balance of these components is not achieved, trauma can result from coughing and movement of the uncomfortable patient.

Ventilation Management

When performed during general anesthesia, fiberoptic bronchoscopy usually is accomplished through an endotracheal tube. The resulting marked reduction in the effective functional internal diameter of the endotracheal tube available for ventilation is associated with increased airway resistance and can result in distal air trapping. To reduce complications, the anesthesiologist should avoid spontaneous ventilation, eliminate PEEP from the circuit, ventilate with a prolonged expiratory phase (inspiratory:expiratory [I/E] ratio of 1:3), and use the largest endotracheal tube possible.

Rigid Bronchoscopy

Anesthetic Management

Maintenance of anesthesia can be achieved with mixtures of IV sedatives and narcotics or in combination with potent inhalational anesthetics. Use of inhaled anesthetics has the obvious disadvantage of exposing personnel to the escaping anesthetic vapors. In our experience, an infusion of remifentanil and propofol provides very acceptable anesthetic conditions characterized by quick emergence and negligible residual sedation. Topical anesthesia with lidocaine can be used to suppress

[a]Same as fiberoptic bronchoscopy.

cough reflexes and prevent bronchospasm. Patients undergoing rigid bronchoscopy can be paralyzed to prevent sudden movement or cough, which can result in major morbidity.

Ventilation Management

Intermittent positive-pressure ventilation can be delivered during rigid bronchoscopy by connecting the standard anesthesia circuit to the ventilating side port of the rigid bronchoscope (Fig. 53–25). This ventilating technique requires no special equipment, allows for accurate measurement of FiO_2 and inhaled anesthetic concentration, and provides adequate oxygenation in most patients. The ventilating gases may leak through the space between the bronchoscope and the tracheal wall. To compensate for the leak, gas flows should be increased, and the posterior pharynx and larynx can be packed with gauze.

Jet Ventilation

Use of jet ventilation has been advocated for prolonged rigid bronchoscopy. The Venturi jet ventilation technique allows the surgeon an unhurried, undisturbed period of viewing without the need for an eyepiece. A potential disadvantage is that jet ventilation can result in spillage of blood and other debris into the tracheobronchial tree.

An intermittent high-velocity jet of oxygen entrains air into the bronchoscope, resulting in expansion of the lungs. If the lungs are noncompliant or if the bronchoscope is small in relation to the trachea, large amounts of tidal volume will escape between the bronchoscope and tracheal wall, resulting in poor alveolar ventilation. Careful observation of the patient's chest movement is necessary to ensure adequate tidal volumes. The adequacy of ventilation, a function of total thoracic compliance, can be monitored by obtaining an arterial blood sample, by transcutaneous CO_2 monitoring, or by intermittent capnography. Determining the inspired concentration of oxygen can be difficult because of the variable entrainment of room air, but the adequacy of oxygenation can be monitored by pulse oximetry or arterial blood gas sampling.

Intraluminal pressure is a function of the driving pressure from the inline reducing valve, size and length of the needle jet, and design of the bronchoscope. In addition, a decrease in the effective intraluminal diameter by the introduction of suction catheters or biopsy forceps can prevent escape of gas introduced by the jet and results in a dramatic increase in intratracheal pressure. If the instruments are tight fitting, the driving pressure should be decreased to minimize barotrauma.

The apparatus described by Sanders uses a high-pressure oxygen source of

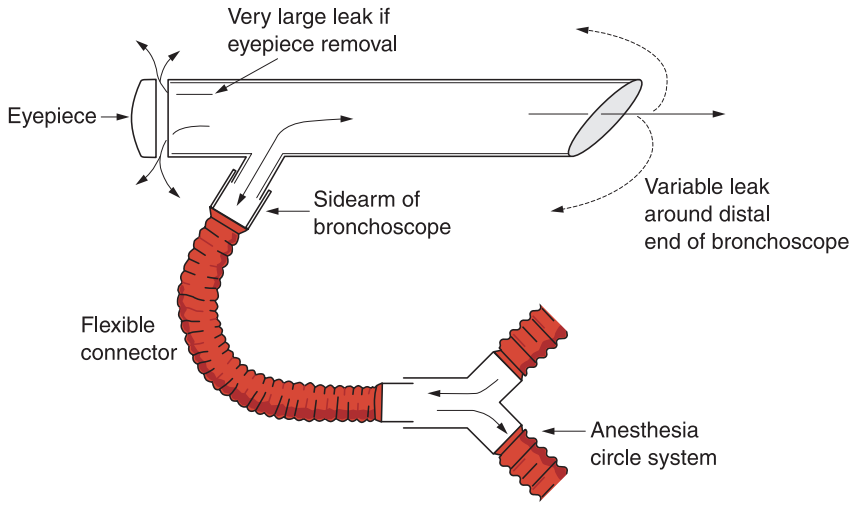

FIGURE 53–25. Schematic diagram showing a rigid ventilating bronchoscope system, which consists of the anesthesia circle system attached to a flexible connector that is attached to the sidearm of the bronchoscope. With the proximal eyepiece in place, most of the inspired gas goes into the patient. Because the bronchoscope cannot fully fill the area of the trachea, there is a variable leak around the distal end of the bronchoscope. Exhaled gases are exhaled either through the leak around the bronchoscope or through the anesthesia circle system. When the eyepiece is removed, there is a very large leak out the proximal end of the bronchoscope.

50 psi, which is delivered through a 16- or 18-gauge needle located within the rigid bronchoscope (Fig. 53–26). The original jet ventilation system has been improved by connecting the side arm to the anesthesia circuit, thereby entraining an oxygen anesthetic gas mixture. Increasing the size of the jet port (the Carden side arm) results in increased inflation pressure and increased FiO_2 at the distal tip of the bronchoscope.[160] Jet ventilation at low frequencies can provide for adequate oxygenation and ventilation. Commercial high-frequency jet ventilators (HFJVs) have been used with the rigid bronchoscope. Rates of 150–300 breaths/min result in ventilation and oxygenation comparable with intermittent low-frequency jet ventilation,[161] but rates >300 breaths/min result in a decrease in oxygenation and an increase in $Paco_2$. The major advantage of HFJV over low-frequency jet ventilation is less movement of the tracheobronchial tree, providing better surgical conditions for procedures such as laser therapy.

Apneic Oxygenation

In the absence of ventilation, adequate oxygenation can be maintained for a prolonged period at the expense of increasing $Paco_2$. Initially, the patient is hyperventilated ventilated with 100% inspired oxygen until relative hypocapnia and denitrogenation is achieved. A period of hyperventilation, to $Paco_2$ of approximately 30 mm Hg, will increase the period of apnea that can be tolerated before respiratory acidosis ensues. A small catheter is placed above the carina and insufflated with O_2 at 10–15 L/min. The adequacy of oxygen reserve and generation of CO_2 are functions of pulmonary mechanics and body size.

Complications

Aside from the inherit risks of local and general anesthetics, bronchoscopy of the airway may exhibit decreases in FEV_1, FVC, peak expiratory flow rate, and peak inspiratory flow rate. Additional factors that may contribute to decreased lung function or bronchospasm are airway mucosal edema and mechanical activation of irritated airway reflexes.[162] These responses may be mediated in part by the vagus nerve because preoperative administration of an anticholinergic agent, such as glycopyrrolate or atropine, has been shown to prevent or attenuate these response.

Rigid bronchoscopy is associated with more trauma than is flexible fiberoptic bronchoscopy. Positioning of the patient and placement of the rigid bronchoscope can result in dental trauma or laceration of the mucosa of the larynx, trachea, or bronchi. The trauma has been associated with pneumomediastinum, pneumothorax, and perforation of the esophagus. The cervical hyperextension required for placement of the rigid bronchoscope can cause injury to the cervical spine, vasovagal reaction, and cerebral ischemia by occlusion of vertebral arteries.

Hypoxemia and hypercarbia are common complications during rigid bronchoscopy.[121,163–165] At the end of a procedure during general anesthesia, a single-lumen endotracheal tube should be placed, and the lung should be suctioned and ventilated with large tidal volumes to restore atelectatic alveoli.

Transient cardiac dysrhythmias are common in patients undergoing bronchoscopy.[166–169] They are caused by hypoxia, intense stimulation, hypoventilation with hypercapnia, inadequate depth of anesthesia, vasovagal reaction, β_2-adrenergic agonists, and bronchodilators.

ANESTHESIA FOR PATIENTS UNDERGOING BRONCHOALVEOLAR LAVAGE

Bronchopulmonary lavage is indicated for management of alveolar proteinosis.[170–176] The long-term improvements in arterial oxygenation, exercise tolerance, and level of activity vary among patients. Some patients require annual or semiannual lavage, whereas others remain in remission for years.[177] The pathophysiology of the disease is characterized by abnormal bilateral accumulation of alveolar surfactant.[177,178] Its accumulation is attributed to a failure of clearance mechanisms rather than increased formation. Most patients are diagnosed between the ages of 20 and 50 years and have symptoms of cough, fever, and chest pain. Pulmonary function tests and chest radiographs are abnormal, but definitive diagnosis requires lung biopsy.

Intraoperative Management

Unilateral lung lavage is performed by irrigation of the tracheobronchial tree during general anesthesia (Table 53–9). Preoperative assessment should include $\dot{V}/\dot{Q}$ scans to characterize the distribution of impairment. Unilateral lung lavage requires placement of a double-lumen endotracheal tube to prevent spillage to the contralateral lung. After induction of general anesthesia, the trachea is intubated with the largest left-sided double-lumen endotracheal tube that can be positioned properly. Correct tube position is essential and should be confirmed with a fiberoptic bronchoscope. To prevent leakage of lavage fluid into the contralateral lung, it has been suggested that the bronchial cuff be inflated to 50 cm H_2O. The patient should be ventilated with 100% oxygen to minimize the risk of hypoxemia and eliminate nitrogen from the lung. Failure to adequately denitrogenate before lavage may leave residual pockets of intraalveolar nitrogen, thus limiting the effectiveness of the procedure.

The positioning of the patient is controversial. Lavage of the nondependent lung in the lateral decubitus position has the advantage of improving oxygenation by decreasing blood flow to the nonventilated lung. However, this arrangement increases the risk of displacement of the bronchial cuff and spillage from the nondependent to the dependent lung. Lavage of the dependent lung decreases the possibility of spillage, but it may be associated with hypoxia resulting from shunt flow. The supine position balances the risk of aspiration against the risk of hypoxia.

The choice of which lung to lavage first is based on the ventilation and perfusion studies; the lung with the least perfusion is chosen to be lavaged first. The procedure is performed by instilling warm isotonic saline by gravity from a height of 30 cm. The lung will accept 700–1000 mL of lavage fluid in the adult. Vigorous manual chest percussion is applied to the hemithorax throughout the lavage. Then, the lavage fluid is drained passively into a collecting system. The lavage procedure is repeated until the drainage decreases in turbidity to near clarity so that fine print can be read through a 0.25-inch diameter column of fluid. Typically, 12–30 L of saline is required. Accurate records of fluid administration and drainage are kept. After the effluent lavage fluid clears, the procedure is terminated, the lavaged lung thoroughly suctioned, and ventilation reestablished. Because the lavaged lung has decreased compliance, it is ventilated with a large tidal volume (15–20 mL/kg) to reexpand the alveoli. To improve compliance during the immediate postprocedure period, the patient should be positioned to enhance drainage, and secretions should be suctioned from the airway.

During the lavage procedure, most patients remain hemodynamically stable, although this procedure may increase right-heart strain and decrease left ventricular filling and systemic blood pressure.[179] Arterial oxygen saturation increases during lung filling and decreases with drainage. The increase in intraalveolar pressure, resulting from fluid administration, causes an increase in PVR, thereby diverting blood flow to the ventilated side and decreasing the venous admixture. When the lavage fluid is drained, PVR decreases, and the venous admixture increases.

Spillage of lavage fluid into the untreated lung is a serious complication. Leakage is detected by the appearance of bubbles in the lavage fluid, rales or rhonchi in the ventilated lung, discrepancy between the drained lavage fluid

TABLE 53–9.

Anesthetic Guidelines for Bronchial Alveolar Lavage

Indication	Diagnostic
	Therapeutic (alveolar proteinosis, cystic fibrosis)
Monitors	Standard monitoring, optional (arterial catheter)
Anesthesia	General anesthesia (allows for sequential lavages on both sides)
	Awake, sedated (lavage by bronchoscopy limited to lobe)
Ventilation	Left double-lumen endotracheal tube
Position	Lateral decubitus
	Supine
Unique considerations	Single-lung ventilation
	To prevent spillage to the opposite lung, endobronchial balloon should be inflated to functionally separate lungs (~50 cm H_2O)
	(1) Drain 700–1000 mL warm saline into lung
	(2) Manual chest percussion
	(3) Drainage of fluid in Trendelenburg position
	(4) Repeat until turbidity clears
	(5) Repeat for contralateral lung
	(6) Maintain accurate account of infusion and drainage volumes
	(7) After lavage is completed, suction both lungs thoroughly ventilate and positive end-expiratory pressure
Intraoperative complications	Spillage of lavage fluid to contralateral lung
	Hypoxia
	Decrease pulmonary compliance
	Pneumothorax, hydropneumothorax
	Pulmonary edema
Analgesia	None required
Postoperative care	Supplemental O_2
	Chest radiography

volumes, and arterial desaturation. If spillage is suspected, lavage should be stopped, the lung drained, and position of the double-lumen endotracheal tube confirmed. Massive spillage produces acute decreases in lung compliance and severe arterial desaturation. An unusual but serious complication of lung lavage is hydropneumothorax, which is characterized by increased peak airway pressures, decreased oxygen saturation 20 minutes after an uneventful lung lavage, and a chest radiograph revealing mediastinal shift and a left pneumothorax. It was hypothesized that lung lavage decreased lung compliance by washing out surfactants, making it more susceptible to barotrauma. A chest radiograph should be obtained routinely within the first hour after lavage and compared with prelavage examination.[180]

ANESTHESIA FOR PATIENTS WITH BRONCHOPLEURAL FISTULA

Etiology

The possibility of a bronchopleural fistula should be considered after pneumonectomy, lobectomy, bullectomy, or volume reduction surgery. The symptoms and findings of a clinically significant bronchopleural fistula include dyspnea, subcutaneous emphysema, contralateral deviation of the trachea, expectoration of purulent material, persistent air leak, and purulent drainage from the chest tube. Diagnosis is confirmed by bronchoscopy. Factors that predispose patients to developing air leaks after lung resection include cancer, malnourishment, debilitation, trauma, barotrauma, lung abscesses, immunosuppression, steroid therapy, diabetes, preoperative or postoperative radiation therapy, and pulmonary resection for tuberculosis. A continued air leak can lead to infection in the pleural space and dehiscence of the bronchial stump.[181]

Therapeutic Management

When bronchopleural fistula occurs early after resection, prompt resuturing of the bronchial stump may correct it. If the fistula develops later after operation, adequate drainage and reduction of the pleural space constitute initial therapy. Many small fistulas close spontaneously using conservative therapy of nutritional support, antibiotics for infection, and spontaneous ventilation. If the lung expands to fill the thoracic cavity, the leak usually can be controlled with passive chest tube drainage. A persistent space indicates a leak from a larger bronchus, usually requiring surgical treatment.[181] Sepsis should be controlled with antibiotics and adequate chest drainage.

Surgical options include (1) decortication if the lung is entrapped by a thick purulent layer; (2) revision of a long bronchial stump; (3) closure of the bronchopleural fistula with a pedicled muscle flap, usually in the form of an intercostal flap[182,183]; (4) thoracoplasty to obliterate the pleural space, usually combined with a pedicled muscle flap to cover the bronchial stump; (5) bronchoscopic application of fibrin glue to seal the communication; and (6) temporary deployment of a Silastic stent.

Ventilation

Goals include maintenance of adequate ventilation and oxygenation and protection of the contralateral lung from spillage of purulent material. Application of positive pressure by a mask or a mechanical ventilator may lead to apparently inadequate ventilation because the tidal volume is lost through the fistula. Several methods have been developed to improve the ventilation of patients with bronchopleural fistula and decrease the risk of pneumothorax. Chest tubes with unidirectional valves have been used to prevent air leak during spontaneous inspiration. During positive-pressure ventilation, low inflation pressures should be used, and spontaneous ventilation with pressure support should be encouraged to decrease the air leak and to promote closure of the bronchopleural fistula. High-frequency ventilation has been used to manage bronchopleural fistula but with varying results.[184–186]

The proposed advantage of high-frequency ventilation is that lower inspiratory pressures and smaller tidal volumes may result in less gas leak through the fistula. It appears to be less effective when patients have bilaterally diseased, noncompliant lungs. Improvement in the air leak depends on a decrease in peak and mean airway pressures; it is recommended that tracheal pressures and air flow through the leak be measured during HFJV and compared with values obtained during conventional mechanical ventilation.

Anesthetic Management

Intraoperative treatment of patients with bronchopleural fistula presents unique challenges. Management strategies for induction and intubation depend on the severity of the bronchopleural fistula and the presence of infection. If a chest tube is not in place or is malfunctioning, accumulation of escaping air into the enclosed pleural space will result in a tension pneumothorax. Because positive-pressure ventilation increases the air leak and risks contaminating the noninfected lung, patients often are induced using rapid sequence induction to minimize the time before tracheal intubation and lung isolation. An alternative approach is to intubate a spontaneously ventilating patient with a double-lumen tube. Awake sedated intubation can be considered for patients at increased risk for aspiration of gastric contents caused by full stomach or bronchopleuroenteric fistula.[187] Once the tube has been positioned, the healthy lung should be isolated immediately and the head raised slightly to decrease the likelihood of contamination of the healthy lung.

In patients with a small chronic bronchopleural fistula with minimal air leak and no associated infection or empyema, a standard endotracheal tube is often used safely. If intermittent positive-pressure ventilation is then found to be inadequate, the tube can be advanced into the bronchus of the normal lung or replaced with a double-lumen tube. An empyema, if present, should be drained before induction of anesthesia. Decreasing the amount of pus in the pleural cavity reduces the chance of contaminating the contralateral lung and developing a tension pneumothorax. If intermittent positive-pressure ventilation using a double-lumen tube provides inadequate oxygenation or ventilation, HFJV to the affected lung through the double-lumen tube is another option.[130] When a double-lumen tube cannot be used, as in small pediatric patients or in those with difficult airway anatomy, lung separation can be achieved by endobronchial placement of a single-lumen endotracheal tube.

ANESTHETIC IMPLICATIONS OF SPONTANEOUS PNEUMOTHORAX

Patients who develop spontaneous pneumothorax usually are young, healthy, and sometimes athletic, with

no preexisting lung disease and no previous lung resections. Surgical treatment of spontaneous pneumothorax includes pleurectomy and chemical pleurodesis.[188]

Surgical treatment is indicated in the following situations: (1) failure of the pneumothorax to resolve with chest tube drainage and suction, which indicates that bronchopleural fistula has formed; (2) when a second ipsilateral or first contralateral spontaneous pneumothorax occurs; and (3) if the patient's lifestyle is such that a recurrence may be life threatening or highly inconvenient (recurrence rate for spontaneous pneumothorax is 10–25%).

When patients with pneumothorax come to the operating room, they typically have a chest tube in place, so tension pneumothorax usually is not a major concern. Patients usually are treated with a double-lumen endotracheal tube to facilitate surgical exposure for either thoracoscopy or thoracotomy. If a single-lumen tube is placed and the air leak is too large, a single-lumen tube can be advanced into the bronchus of the unaffected side with the guidance of a fiberoptic bronchoscope, or it can be replaced with a double-lumen tube.

ANESTHESIA FOR PATIENTS UNDERGOING BULLECTOMY AND VOLUME REDUCTION PNEUMOPLASTY

There has been resurgence in the surgical management of bullous disease and emphysema. Studies have documented the efficacy of this procedure for patients with isolated large bullae, although the benefits of resection of diseased peripheral lung tissue in the presence of bullous emphysema is less certain. Large multicenter trials assessing the efficacy of this therapeutic modality are under way.

Bullae are air-filled spaces within the lung parenchyma. As bullae expand, the volume of the remaining lung is reduced (Fig. 53–27). The rationale for surgical resection of the diseased lung is removal of areas of nonfunctional lung to permit reexpansion of compressed functional alveoli and to improve diaphragmatic function.[33,189] Patients most likely to benefit from the plication of large bullae are those in whom the bullae occupies >30% of the hemithorax,[190–192] those with progressively enlarging nonfunctional pulmonary units and recurrent pneumothoraces, and those with moderate-to-severe dyspnea that is refractory to conventional medical therapy.[191] A prospective trial with 20 patients reported an increase in FEV_1 (from 0.77 to 1.4 l), FVC (from 2.2 to 2.8 L), and arterial oxygenation on inspired room air (from 64 to 70 mm Hg). Patients experienced less dyspnea and improved quality of life during the next 6 months. The beneficial effects were attributed to expansion of the remaining lung and improved diaphragmatic function, resulting in improved respiratory mechanics and decreased $\dot{V}/\dot{Q}$ mismatching. Another study reported more modest improvements in symptoms and pulmonary function analysis (FEV_1, from 1.74 to 1.85 l; FVC, from 1.82 to 2.21 l) and was associated with a mortality rate of 5.5%.[192] Whether the difference between these two studies reflects patient selection or a difference in surgical technique is not known.

Lung Volume Reduction Surgery

In 1995, Cooper et al.[193] initiated a renewed interest in lung volume reduction surgery, the technique of removing hyperinflated emphysematous lung to allow normal lung more space to function properly.[193–196] From this case series, many institutions started offering this invasive procedure to this high-risk patient population. Although many centers reported good results, increased rates of morbidity and mortality raised the need for a comprehensive multicenter trial.

Surgery

These procedures can be performed as single unilateral, sequential unilateral, or bilateral operations. Single unilateral bullectomy and volume reduction procedures are performed using the lateral decubitus position and video thoracoscopy or open thoracotomy. Sequential unilateral procedures can be performed by repositioning the patient to the contralateral decubitus position after the first side is completed. Bilateral procedures can be performed through a median sternotomy. Median sternotomy does not require repositioning and provides access to the contralateral pleural space in patients with pneumothorax. Plication of bullae and resection of peripheral lung tissue are accomplished with the use of a stapler. A major complicating factor in postoperative recovery is persistent air leaks at the suture line. This problem is decreased by using a stapler with a pericardial buttress.[190]

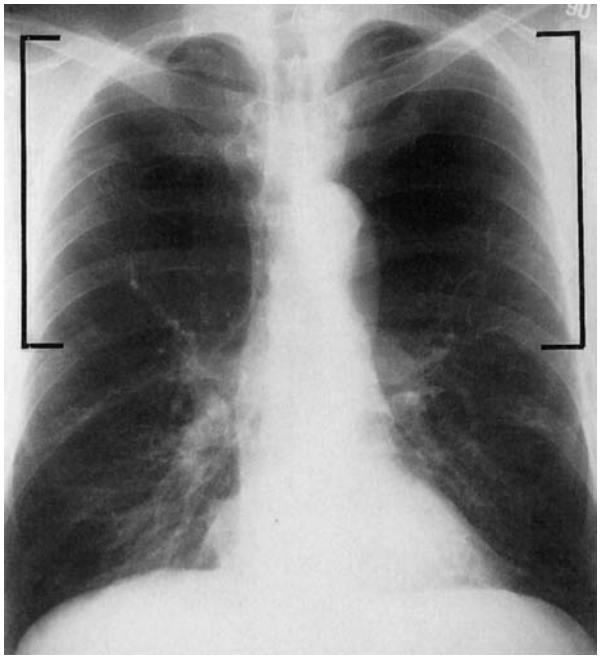

FIGURE 53–27. Characteristic radiographic findings of patients with bullous disease. Typical findings in patients with chronic obstructive pulmonary disease include an increased size of lung fields and flattened hemidiaphragms. The appearance of hyperaeration of both apical lung fields (bracketed area), decreased vascular marking in upper lung fields, and compressive atelectasis of the lower lung fields are consistent with severe bullous lung disease.

TABLE 53–10.

Anesthetic Guidelines for Bullectomy and Volume Reduction Pneumoplasty

	Bullectomy/Volume Reduction Pneumoplasty	Volume Reduction Pneumoplasty
Indication	Bullectomy—large bullae >30% of hemithorax	Severe bullous emphysema
	Volume reduction—severe bullous emphysema	
Preoperative concerns	Review preoperative pulmonary function tests and check arterial blood gases	Same[a]
	Pulmonary symptoms may mask presence of coronary artery disease	
Monitors	Standard monitors and A-line	Same[a]
Anesthesia	General anesthesia	Same[a]
	Combined regional/general anesthesia	
Additional equipment	Optional (jet ventilator)	Same[a]
Ventilation	Double-lumen endotracheal tube	Same[a]
Position	Bullectomy (lateral decubitus)	Lateral decubitus
	Volume reduction pneumoplasty (lateral, supine)	Supine (median sternotomy)
Incision	Bullectomy (thoracotomy, VATS)	Thoracotomy
	Volume reduction pneumoplasty (thoracotomy, VATS, median sternotomy)	VATS Median sternotomy
Unique considerations	Single-lung ventilation	Same[a]
	Avoid positive end-expiratory pressure	Same[a]
	Minimize use of long-lasting respiratory depressants	
	Restrict administration of intravenous fluids	
Intraoperative complications	Tension pneumothorax	Same[a]
	Pneumothorax	
	Hypoxia	
	Hypercarbia	
Blood loss	Minimal <500 mL	Same[a]
Postoperative analgesia	Epidural	Same[a]
	Parenteral opiates/NSAIDs	
Postoperative morbidity	Persistant air leak	
	Respiratory dysfunction	
	Hypoxia	
	Hypercarbia	
	Pneumothorax	
	Difficulty weaning from ventilator	
Postoperative care	Monitor respiratory status overnight for signs of decompensation	
	Supplemental O_2	
	Chest radiography	
	Adequate analgesia	
	Minimize air leak by placing chest tubes to water seal or minimizing suction	

[a]Same as bullectomy/volume reduction pneumoplasty.
VATS, Video-assisted thoracoscopic surgery.

Anesthetic Considerations

Patients presenting for bullectomy or lung volume reduction surgery have poor respiratory reserve and challenge the anesthesiologist during induction, single-lung ventilation, and extubation.[197,198] Many patients may have been considered for lung transplantation but were excluded because of their age or the presence of coexisting diseases. Their cardiopulmonary status requires judicious use of any benzodiazepines or narcotics. In addition to the standard monitors, an arterial catheter should be placed to assess adequacy of oxygen and ventilation perioperatively.

Either thoracotomy or thoracoscopy requires general anesthesia and single-lung ventilation (Table 53–10). The combination of general anesthesia and epidural analgesia decreases the anesthetic requirement intraoperatively, thereby minimizing postoperative residual sedation. Patients with end-stage emphysema tend to have increased endogenous catecholamines caused by hypoxemia and hypercapnia, often are hypovolemic, and are at risk for hypotension after induction of general anesthesia. General anesthesia can be maintained with either inhalational of IV agents or with a combination of techniques. Nitrous oxide should be avoided because of the risk for increasing the size of bullae, further compressing the adjacent lung or causing rupture. Communications between bullae and the airway may function as one-way valves, resulting in air trapping with rapid enlargement and compression of the surrounding lung. Initiation of controlled ventilation may be associated with hypoxemia and hypercapnia. Acute rupture of bullae with resulting pneumothorax is a constant threat. An acute decrease in blood pressure associated with increased inspiratory pressures and loss of breath sounds should be considered a pneumothorax unless proven otherwise. Prompt placement of a chest tube is indicated. Low inflation pressures, that is, inspiratory pressures < 25 cm H_2O, will decrease the risk of pneumothorax.

One-lung ventilation with a double-lumen tube facilitates bilateral volume reduction by providing selective ventilation yet retaining the capacity for intermittent ventilation of the operative lung to manage hypoxia or hypercapnia or to assist the surgeon in identifying the location of bullae. Initiation of single-lung ventilation is associated with an increase in airway pressure and the concomitant risk of pneumothorax. Jet ventilation has been used to decrease airway pressures. The nonoperated, ventilated lung should be prepped and draped to allow access in case of a pneumothorax. Increased concentrations of halogenated anesthetics may worsen the venous admixture by inhibition of HPV.

Postoperative Ventilation

Extubation of the trachea at the end of operation can be accomplished in most

patients. The need for continued mechanical ventilation is greater after volume reduction pneumoplasty compared with plication of bullae. The beneficial effects of operation are not realized immediately after operation. Patients undergoing volume reduction may decompensate in response to the usual decrement in postoperative pulmonary function associated with thoracic surgery and pain. They also seem to be more sensitive to residual sedation, respiratory depression from analgesics, residual muscle relaxants, and hypercapnia. The presence of a major air leak can interfere with respiratory function. Criteria for extubation include the presence of a regular respiratory pattern, adequate patient strength, alertness, ability to respond to command, and measurement of arterial blood gas. If mechanical ventilation is required postoperatively, positive airway pressure should be minimized to decrease the chance of producing pneumothorax from rupture of residual bullae or suture lines. If air leak remains an important factor, airway peak pressure can be minimized by changing the mode of ventilation to pressure control. In addition, the chest tube suction should be put to water seal, or at least the suction pressure should be minimal.

ANESTHESIA FOR PATIENTS UNDERGOING DECORTICATION AND PLEURODESIS PROCEDURES

Clinical Features

Pleural inflammation, either infectious or noninfectious, increases permeability and results in the collection of high-protein pleural fluid. Lymphatic obstruction, altered central venous pressures, and low oncotic pressure contribute to pleural fluid accumulation. Large effusions may dramatically decrease pulmonary function. The collection of blood or empyema precipitates deposition of a fibrin layer on the pleura. As the fibrin layer (or peel) matures, the underlying lung is entrapped, and lung expansion is decreased, necessitating surgical intervention to release and expand collapsed lung and to manage infection.

Patients with a simple nonloculated empyema may be treated conservatively with antibiotic therapy and chest tube drainage. Once the empyema becomes loculated or develops into a fibrous peel, surgical intervention by thoracotomy or thoracoscopy is performed during general anesthesia. The access provided by VATS may be limited, and open thoracotomy may be required for more definitive procedure. Failure to adequately manage a chronic draining empyema may require the placement of an open window thoracostomy for long-term care. This procedure consists of suturing a flap of skin to the pleura, creating an epithelial-lined sinus into the empyema cavity.

Occasionally, additional intervention, pleurodesis, is required because reaccumulation of the effusion either causes respiratory compromise or is refractory to medical therapy, as in the case of malignancies. A number of agents have been used intrapleurally to produce a chemical pleurodesis that leads to formation of adhesions and obliteration of the pleural space. Common sclerosing agents include tetracycline, talc, and bleomycin. Fever and chest pain are the most common complications of pleurodesis.

Anesthesia Management

Surgical decortication requires the differential ventilation of healthy from diseased lung in order to facilitate surgical exposure and permit complete reexpansion after surgical intervention.[199] After induction and tracheal intubation, patients usually are placed in a lateral decubitus position with the affected lung in the nondependent position. In patients with a lung abscess, placement of an infected lung in the nondependent position increases the risk of contamination to the dependent lung. Most common management issues involve hypovolemia related to bleeding or sepsis and pain associated with decortication and pleurodesis. Inability to remove the fibrous peel may result in failure to reexpand the entrapped lung. After the decortication procedure is completed, positive pressure can be applied to the diseased lung to help break residual fibrous deposition, thus enabling lung reexpansion. Options for postoperative analgesia include patient-controlled analgesia or placement of an epidural catheter.

ANESTHESIA FOR PATIENTS UNDERGOING ESOPHAGEAL SURGERY

Dysphagia is the most common symptom of esophageal disease. When present for any major length of time, dysphagia can result in dramatic weight loss, dehydration, hypoalbuminemia, anemia, and depressed immune status. Postprandial heartburn, another common symptom of esophageal disease, is related to reflux of gastric contents into the esophagus. Symptoms may manifest with change in position, exercise, or belching. Patients who experience such symptoms usually are evaluated by barium swallow under fluoroscopy, followed by esophagoscopy and tissue biopsy. Common esophageal lesions are summarized in Box 53–8.

BOX 53–8.

Common Lesions of the Esophagus

- Tumors
  - Squamous cell
  - Adenocarcinoma
  - Hiatal hernia
- Benign strictures
  - Reflux esophagitis in the lower third of the esophagus
  - Caustic fluid ingestion in the upper third of the esophagus
- Motility disorders
  - Achalasia
  - Schatzki ring
- Collagen diseases (e.g., scleroderma)
- Diverticula
- Tracheoesophageal fistula (congenital or malignant)
- Traumatic perforation or rupture
- Foreign bodies

Esophagoscopy

Esophagoscopy is used for tissue biopsy or clarification of esophageal lesions detected after barium contrast studies. In addition, esophagoscopy is used for removal of foreign bodies, dilation of esophageal strictures, sclerotherapy of esophageal varices, diagnosis and management of bleeding lesions, and placement of prosthetic stents across malignant strictures.

Esophagoscopy can be performed using either a rigid or a flexible fiberoptic esophagoscope. Flexible esophagoscopy allows for greater comfort while examining the upper gastrointestinal tract and usually is performed on awake, slightly sedated patients. Although rigid esophagoscopy can be performed on awake, sedated patients, it is more readily accomplished during general endotracheal anesthesia. Rigid

TABLE 53–11.

Anesthetic Guidelines for Esophagoscopy

Indication	Diagnostic (biopsy mass, evaluate esophagus)
	Therapeutic (removal foreign body, arrest bleeding, sclerosis)
Monitors	Standard monitors
Anesthesia	Awake sedated (flexible fiberoptic)
	General anesthesia (flexible fiberoptic and rigid)
Additional equipment	None
Ventilation	Awake spontaneous respiration
	Single-lumen endotracheal tube (may require small size or cuff deflation to pass scope)
Position	Supine
Incision	None
Unique considerations	Antisialagogue
	Aspiration precautions
Intraoperative complications	Dysrhythmia
	Aspiration
	Hematemesis
	Pneumomediastinum
	Pneumoperitoneum
	Pneumothorax
	Dental trauma
	Respiratory compromise
	Perforation esophagus
Postoperative analgesia	Minimal pain (parenteral opiates, nonsteroidal anti-inflammatory drugs)
Postoperative morbidity	Hematemesis
	Respiratory distress (vocal cord paralysis)
Postoperative care	Chest radiography
	No eating or drinking until protective airway reflexes have returned

esophagoscopy is particularly valuable for removal of foreign bodies and for the examination and management of massive esophageal bleeding.

Anesthetic Management

Fiberoptic esophagoscopy can easily be performed during topical anesthesia of the mouth and pharynx combined with mild sedation and an antisialagogue (Table 53–11). Patients should not be allowed to eat or drink until several hours after the procedure when the effect of topical anesthesia has dissipated and protective airway reflexes have returned.

Rigid esophagoscopy usually is performed on patients during general anesthesia with endotracheal intubation and muscle relaxation. An anticholinergic agent is administered to decrease airway secretions and vagal responses to airway manipulation and gastric distension. Cricoid pressure should be used during induction because many patients are at risk for regurgitation from esophageal diverticula, stenosis, or obstruction. Awake, sedated endotracheal intubation is an option. To avoid injury to the esophagus during passage of the esophagoscope, a smaller than typical endotracheal tube is used, and the patient is paralyzed before introduction of the esophagoscope. Temporary deflation of the endotracheal tube cuff to facilitate passage of the esophagoscope may be necessary. Complications during esophagoscopy include hemorrhage, cardiac dysrhythmias, aspiration pneumonia, and perforation of the esophagus. Perforation can result in pneumothorax, pneumomediastinum, pneumoperitoneum, or subcutaneous emphysema. At the conclusion of the procedure, the trachea should remain intubated until protective reflexes have returned.

Esophageal Cancer

Patients with esophageal malignancy often are malnourished and have poor nutritional status predictive of poor outcome. Preoperative improvement in nutritional status has been shown to decrease the incidence of wound sepsis and perioperative morbidity and mortality.[169,200] Indications for total parenteral nutrition include inability to swallow food, at least 10% decrease in body weight, serum albumin <3 g/dL, cachexia and anergy, leukopenia, and low transferrin value.

Patients with esophageal cancer often are treated with chemotherapeutic agents before surgery. Perioperative implications of previous use of antineoplastic agents for management of esophageal cancer include anemia, leukopenia, and thrombocytopenia. Drugs such as doxorubicin (Adriamycin), bleomycin, and mitomycin C have additional side effects that are important considerations for the anesthesiologist.

Doxorubicin can result in acute and chronic toxic cardiac effects. Acute cardiac toxicity from doxorubicin is characterized by supraventricular and ventricular dysrhythmias, abnormal conduction patterns, and ST-T wave changes. These acute changes usually resolve 1–2 months after cessation of therapy,[201] although doxorubicin administration also may result in irreversible cardiomyopathy and congestive heart failure. To avoid this complication, the total cumulative dose of doxorubicin usually is limited to a maximum of 300 mg/m^2. Doxorubicin-induced cardiomyopathy is diagnosed by obtaining an endomyocardial biopsy and determining the ejection fraction using a multigated acquisition (MUGA) nuclear scan. If the usual maximal dose is exceeded or if patients demonstrate evidence of cardiomyopathy, then dexrazoxane (Zinecard) is given before future doxorubicin therapy.

Bleomycin and mitomycin C395 can result in pulmonary toxicity. Early symptoms include cough, dyspnea, and rales. The toxic signs may progress to severe hypoxemia at rest and a radiologic picture similar to that of ARDS, followed by pulmonary fibrosis. Predisposing factors include age older than 20 years, dosage >400 U, underlying pulmonary disease, and previous radiation therapy. O_2 in high concentration can predispose the patient to pulmonary toxicity from bleomycin. Because the duration of O_2 sensitivity after the conclusion of bleomycin therapy is unknown, the lowest FiO_2 necessary to maintain adequate arterial saturation should be used perioperatively.

Esophageal Surgery: Esophageal Cancer

Management Strategies

Tumors of the lower third of the esophagus are managed by esophagogastrectomy through a left-sided thoracotomy or transhiatal esophagogastrectomy and gastric pull-through technique (Fig. 53–28).[202] Lesions of the middle third of the esophagus are managed by a combined laparotomy and right-sided thoracotomy.[203] Lesions of the upper third of the esophagus can be managed by combined laparotomy and cervical incision (Fig. 53–29).[202] Esophagogastrectomy with colon interposition is a two-stage procedure used for lesions in the upper third of the esophagus when insufficient stomach length or gastric disease prevents performing an esophagogastrostomy. During the first stage, the esophagogastrectomy is performed through a midline laparotomy and right thoracotomy. The patient is then turned supine, and a cervical esophagostomy is performed. During the second stage, an antiperistaltic segment of the colon is passed into the retrosternal space and anastomosed to the cervical esophagus above and to the stomach remnant below (Fig. 53–29).

The approach to surgical management of esophageal cancer is controversial. Major issues involve whether the goal is cure or merely is palliation. The transthoracic approach, which involves complete resection of lymph nodes, is potentially curative, whereas the transhiatal approach is considered palliative. Other controversies include whether the patient should undergo immediate reconstruction with colon or stomach to restore continuity or delayed repair. Long-term survival appears to be a function of the stage and aggressiveness of the tumor at the time of operation rather than the type of operation. Surgical resection is associated with a local recurrence rate of 30–60% and 5-year survival rate of 20–25%. The addition of induction therapy of any kind does not significantly alter these survival rates.[204]

Anesthetic Management

Preoperative evaluation should concentrate on the hematologic, nutritional, and cardiopulmonary systems. Preoperative improvement of nutritional status improves outcome. Hypoalbuminemia, an indicator of poor nutritional status, is associated with increased tissue edema, and anemia may increase the risk of ischemia. Because the operation may be associated with episodes of hemodynamic instability and cardiac arrhythmias, the patient should undergo a thorough cardiac evaluation preoperatively. Accompanying respiratory disease should be

FIGURE 53–29. TABLE 53–12.

Anesthetic Guidelines for Esophagogastrectomy and Esophagectomy

Indication	Therapeutic (palliative and curative procedures for esophageal cancer)
Preoperative considerations	Assessment of nutritional status Presence of coexisting cardiopulmonary disease Implications of preoperative chemotherapy
Monitors	Standard monitors, optional (arterial catheter, central venous, or pulmonary artery catheters)
Anesthesia	General anesthesia, optional (combined regional and general anesthesia)
Additional equipment	Shoulder roll
Ventilation	Double-lumen ETT or bronchial blocker Single-lumen ETT
Position	Supine Lateral decubitus
Incision	Left thoracotomy—mobilize distal esophagus and stomach without changing positions Right thoracotomy—good exposure of upper and midesophagus, easy access to the azygous vein Abdominal transhiatal, abdominal and neck incisions, esophagus mobilized by blunt dissection
Unique considerations	Single-lung ventilation Anticholinergic drug to block carotid sinus reflex (vagal-mediated response) Avoid N_2O with abdominal surgery Increased risk for aspiration
Intraoperative complications	Aspiration Hypotension Bradycardia Dysrhythmia Hemorrhage Tracheal tears Recurrent laryngeal nerve injury Hypoxia and hypercapnia during one-lung ventilation
Blood loss	1000 mL, but potential for large acute blood loss
Postoperative analgesia	Epidural › parenteral opiates
Postoperative morbidity	Aspiration Pneumothorax Respiratory compromise Hemoptysis Infection Anastomotic leaks
Postoperative care	Chest radiography Elevate head to bed to decrease edema and improve respiratory function Increased fluid requirements during early postoperative procedures

ETT, Endotracheal tube.

managed if possible, and strong consideration should be given to placement of an epidural catheter for postoperative analgesia.

Preoperative medication is given to allay anxiety in accordance with the patient's general condition. Use of an anticholinergic drug may be helpful if awake intubation is planned. Guidelines for anesthetic management are given in Table 53–12. Use of central venous catheterization is encouraged for monitoring of central venous pressure, administration of antiarrhythmics or vasopressors, and fluid resuscitation. A PA catheter should be placed if indicated, based on the patient's cardiopulmonary status; it may prove beneficial postoperatively for optimizing fluid therapy. Arterial lines are strongly recommended, particularly for transhiatal esophagogastrectomy where surgeons are bluntly dissecting behind the heart and induce profound hypotension.

Before induction of anesthesia, a large-bore nasogastric tube should be passed, and the proximal esophageal pouch should be emptied. The patient should be considered to have a full stomach because the esophagus cannot be completely emptied through an nasogastric tube. Awake intubation during topical anesthesia or induction with cricoid pressure is indicated. If airway compression by large mediastinal lymph nodes is noted, the patient should be treated as described in the section entitled Anesthesia for Patients with Mediastinal Masses (Fig. 53–1). Anesthesia is maintained using inhalation anesthetics in O_2, supplemented with intermittent or continuous infusion of narcotics and nondepolarizing muscle relaxants. The combination of epidural and general anesthesia can dramatically decrease inhalation anesthetic and muscle relaxant requirements.

If thoracotomy is planned for esophageal surgery, a double-lumen endobronchial tube or bronchial blocker to permit single-lung ventilation facilitates surgical exposure. Whether a right-sided or left-sided thoracotomy is performed, a left-sided double-lumen endobronchial tube is recommended because it is easier to position and offers less risk of obstruction of the upper lobe bronchial orifice. In patients undergoing nonpulmonary surgery, the nondependent lung usually is not severely diseased and thus contributes greatly to normal respiratory function. Paradoxically, this increases the incidence of hypoxemia during single-lung ventilation compared with that during pulmonary surgery, and the hypoxemia persists as long as the lung is collapsed.[125]

Fluctuating cardiovascular responses are observed frequently during transhiatal esophagectomy. Bradycardia and hypotension may result from stimulation of carotid sinus reflexes during neck dissection and mobilization of the esophagus. They are easily managed with an anticholinergic drug such as atropine. Blunt manual dissection of

the esophagus through the diaphragmatic hiatus is associated with hemodynamic lability. Arterial hypertension often occurs during manual dissection of the esophagus and when the stomach is brought up through the posterior mediastinum, whereas hypotension may result from impaired venous return and cardiac function during manual dissection. Patients with advanced cardiac dysfunction may not tolerate these manipulations and therefore are not good candidates for transhiatal esophagectomy. Sudden severe intraoperative hemorrhage can occur, so large-bore venous access is essential. Other complications include tracheal damage and recurrent laryngeal nerve palsy. Tracheal damage has been reported during transhiatal esophagectomy without thoracotomy and during dissection of the middle third of the esophagus during thoracotomy.

Postoperative Concerns

Because esophagogastrectomy is associated with extensive visceral manipulations, difficulty in clearing secretions, advanced patient age with concomitant debilitation, and cardiorespiratory impairment, patients may remain intubated overnight in the ICU. They often have increased fluid requirements during the initial postoperative period, and central venous monitoring is useful in guiding fluid management. Postoperative complications include pleural effusions, wound infection, pneumonia, and leak from the anastomotic site, resulting in mediastinitis, sepsis, hydrothorax, or pyrothorax.[205] Impaired pulmonary function, airway closure, atelectasis, and hypoxemia typically occur postoperatively because of lung manipulation, residual anesthesia, and postoperative incisional pain. Effective postoperative pain control is essential to facilitate deep breathing, cough, mobilization of secretions, participation in chest physiotherapy, and early ambulation. Postoperative analgesia is most effectively achieved using a thoracic epidural catheter for infusion of narcotics, with or without local anesthetics.

ANESTHESIA FOR PATIENTS UNDERGOING LASER SURGERY OF THE AIRWAY

Laser technology has been applied extensively for procedures on the upper and lower airways. It has been used successfully in the management of laryngeal tumors, subglottic stenosis, recurrent laryngeal papillomatosis in children, and for removal and debulking of obstructing airway tumors.[206–213]

Laser Surgery of the Airway

Malignant tumors of the tracheobronchial tree lead to progressive obstruction of major airways that manifest as progressive stridor. Laser resection has been used in the treatment of partially or totally occluding airway lesions with partial or complete relief of symptoms.[214–216] In patients with a totally obstructing airway lesion, lasers can be used to bore through the tumor to reestablish an airway. A serious risk of bronchial perforation and hemorrhage exists. On the other hand, a partially obstructing tumor can be approached tangentially and gradually resected, resulting in widening of the available airway lumen. For partially obstructing lesions, laser resection often provides immediate and dramatic relief of symptoms with a low incidence of bleeding complications. The neodymium:yttrium aluminum-garnet (Nd:YAG) laser is the most frequently used laser to resect obstructing tracheobronchial tree tumors.[214–216] If a CO_2 laser is to be used for a subglottic lesion, a rigid bronchoscope or laryngoscope is required because the CO_2 laser beam cannot be transmitted along fiberoptic bundles. For supraglottic lesions being managed with a CO_2 laser, a small endotracheal tube can be used for patient ventilation, but the tube should be protected from the laser beam to prevent ignition.

Intraoperative Considerations

Safety Issues

Use of a laser in the operating rooms poses safety hazards for patients and operating room personnel. Warning signs on the operating room door should be clearly visible. The most common major complication of CO_2 laser surgery is the risk of explosion or fire.[217,218] The anesthesiologist should limit the O_2 concentration to the minimum needed to maintain adequate oxygenation, even if the endotracheal tube is adequately wrapped and protected.

Use of Helium

Use of helium and O_2 mixtures (60%/40%) during CO_2 laser application has been reported to prevent ignition and fires with unwrapped polyvinyl chloride (PVC) tubes.[209,219] Helium has greater thermal conductivity, thermal capacity, and thermal diffusivity than does nitrogen. These properties of helium inhibit the increase in temperature around the site of laser exposure and thus prevent spontaneous ignition. Besides protecting against airway fire, helium may improve ventilation across an obstructing airway lesion because of its lower density compared with nitrogen, thereby decreasing turbulent gas flow across the stenotic area. The problem of delivering a hypoxic gas mixture of helium in certain anesthesia machines can be circumvented by using heliox, a commercially available O_2–helium mixture.

Anesthetic Management

Because of the risk of life-threatening airway obstruction during induction of anesthesia or manipulation of the airway, the anesthesiologist should carefully examine the radiologic and other studies to define precisely the site and extent of airway compromise. Good communication with the surgeon or pulmonologist is necessary to plan anesthetic (e.g., choice of endotracheal tube will depend on the size of bronchoscope and type of laser) and management strategies in case of emergencies.

Patients at risk for developing airway obstruction or those with severe pulmonary disease should be premedicated with an antisialagogue and minimal sedation only. If the patient is not at risk for airway obstruction, sedative premedications can be administered more liberally. Some ventilation techniques described in the section entitled Use of Rigid Bronchoscopy during Resection of Airway Tumors do not allow the use of capnography. In these patients, monitoring of ventilation is done by careful auscultation of breath sounds, observation of chest movements, or monitoring of arterial blood gases.

Patients with minimal or no airway obstruction can receive a routine induction of anesthesia, followed by muscle relaxation and endotracheal intubation or placement of a laryngeal mask airway. The choice of anesthetic induction technique depends on the extent of airway compromise. Patients who have major airway obstruction should maintain spontaneous ventilation during induction. Therefore, induction can be achieved with inhalational agents or by administer-

ing incremental doses of IV hypnotics and narcotics followed by the gradual introduction of inhalational anesthetics by mask. Alternatively, fiberoptic bronchoscopy can be performed in an awake sedated patient whose airway has been topically anesthetized (Table 53–13).

Local anesthesia can be used for laser resection of an airway tumor via flexible fiberoptic bronchoscopy. Adequate anesthesia can be achieved by topicalization of the mouth and oropharynx, spraying of the larynx and vocal cords with local anesthetics, superior laryngeal nerve block, or transtracheal injection of a local anesthetic. To avoid serious potential complications, adequate sedation is imperative when awake sedated anesthesia is used. This technique is not recommended for patients undergoing laser airway surgery performed with a rigid bronchoscope. The degree of discomfort is greater than that with fiberoptic bronchoscopy, and patient movement resulting in trauma and misdirection of the laser beam is more likely to occur.

Use of Fiberoptic Bronchoscopy during Laser Therapy

Fiberoptic bronchoscopy for laser resection of airway tumors can be performed during local anesthesia and sedation or during general anesthesia with the fiberoptic bronchoscope introduced through the lumen of the endotracheal tube or laryngeal mask airway. The device with largest luminal diameter should be used to allow for sufficient ventilation after the fiberoptic bronchoscope is introduced. Because resistance to airflow occurs with introduction of the bronchoscope into an endotracheal tube, patients should receive either total mechanical or pressure support ventilation to overcome the resistance created by the bronchoscope. The administration of muscle relaxants is relatively contraindicated in patients with partial airway obstruction.

Hypercapnia is a common complication of transfiberoptic laser tumor resection, with $Paco_2$ ranging from 45–60 mm Hg.[212] Long-acting opioids and benzodiazepines should be avoided because of prolonged postoperative somnolence and respiratory depression. Short-action inhalation anesthetics and sedatives allow for rapid emergence without postoperative respiratory depression or sedation.

TABLE 53–13.

Anesthetic Guidelines for Laser Ablation

Indication	Therapeutic (palliative of airway obstruction related to tumor)
Monitors	Standard monitors
	Optional (arterial)
Anesthesia	General anesthesia
Additional equipment	Anesthetic ventilator capable of blending an O_2 and air mixture
Ventilation	Rigid bronchoscope
	Single-lumen ETT (special laser tube, but may be less important when using laser way distal to the ETT)
Position	Supine
Unique considerations	Maintain FiO_2 <40%
	Avoid nitrous oxide (N_2O; also supports combustion)
Intraoperative complications	Hemoptysis
	Hemorrhage
	Airway fire
	Airway obstruction
	Bronchospasm
	Hypoxia
	Perforation of the tracheobronchial tree
Analgesia	Opiates
Postoperative morbidity	Hemoptysis
	Bronchospasm
	Airway edema
Postoperative care	Humidified O_2

ETT, Endotracheal tube.

Use of Rigid Bronchoscopy during Resection of Airway Tumors

Many laser resections are performed using a rigid, open-tube bronchoscope.[216] It allows easy manipulation of the laser beam and provides a greater field of vision and greater access for suction catheters, removal of tumor fragments, and restoration of homeostasis. The rigid bronchoscope can be used to establish an airway. If airway obstruction occurs, the bronchoscope is advanced distally to the site of obstruction, thereby reestablishing airway patency. The absence of a combustible endotracheal tube decreases the chance of an airway fire. Although the metal bronchoscope will not burn, carbonized tissue may flare.[220] It is important to use the lowest O_2 concentration needed to maintain adequate arterial saturation. The rigid bronchoscope facilitates homeostasis because the bronchoscope can be gradually withdrawn while the endoscopist coagulates bleeding sites as they appear.

Maintenance of ventilation can be achieved using one of several techniques. Conventional intermittent positive-pressure ventilation can be maintained by connecting the anesthesia circuit to the ventilating side arm of the rigid bronchoscope, which allows the administration of O_2 and inhalation anesthetics from the anesthesia machine. If a major leak occurs around the rigid bronchoscope interfering with the adequacy of ventilation, packing the nose, mouth, and pharynx with gauze is helpful. Alternatively, anesthesia can be provided by use of IV agents to avoid exposing the surgical staff to any inhalational agents. Often, the patients are paralyzed to eliminate the risk of sudden unexpected movement. Ventilation and oxygenation may be further compromised if the rigid bronchoscope is advanced into the mainstem bronchus. Inadequate ventilation to the contralateral lung will result unless the bronchoscope has side holes that allow ventilation of the opposite lung.

ANESTHESIA FOR PATIENTS UNDERGOING MEDIASTINOSCOPY

Mediastinoscopy and mediastinotomy are performed to diagnose and stage

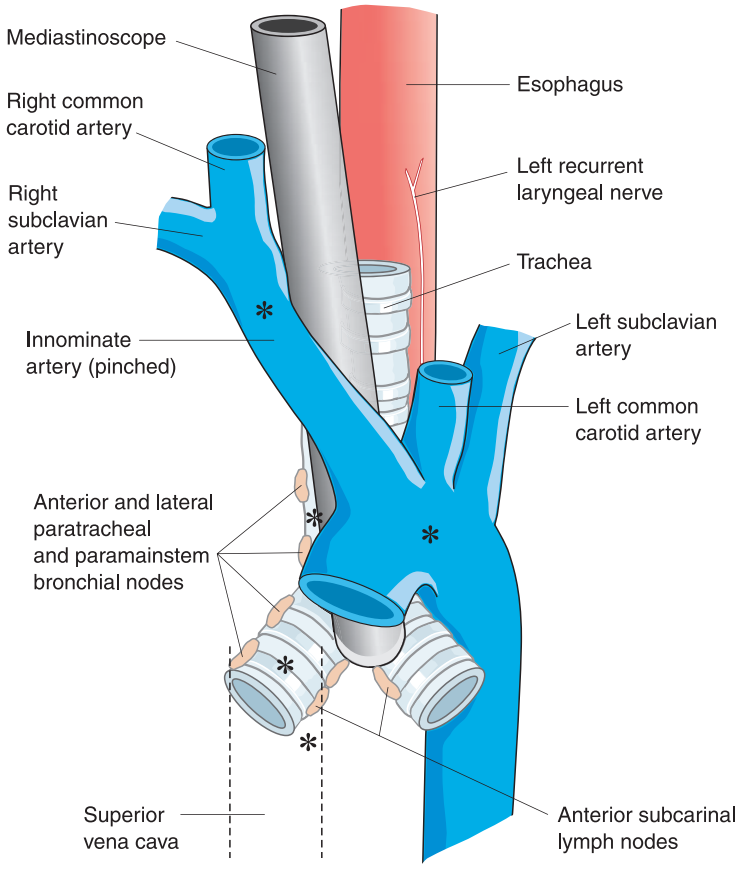

FIGURE 53–30. Mediastinoscope within the mediastinum. Note the pinched innominate artery.

lung cancer to determine resectability. These procedures provide access to paratracheal, subaortic, and bronchial lymph nodes to detect metastatic spread of lung carcinomas. Lymphatics of the lung initially drain into the subaortic and paratracheal areas and then to the sides of the trachea, supraclavicular areas, and thoracic ducts. The surgical site is chosen based on likely path for regional spread of metastatic disease. Cervical mediastinal exploration (mediastinoscopy) yields a greater percentage of positive results for tumors affecting the right upper and middle lobes and, to a lesser extent, left lower lobes. Anterior mediastinotomy is recommended for patients suspected of having tumor in the left upper lobe.

Mediastinoscopy is performed in patients in the supine position with the neck extended. Access is gained through an incision in the suprasternal notch, and a tunnel is created by blunt dissection anterior and slightly lateral to the trachea into the mediastinum. The rigid mediastinoscope passes posterior to the innominate and aortic arteries down to the subcarinal area. The mediastinoscope can injure adjacent structures (Fig. 53–30). Increased risk of complications during mediastinoscopy has been noted in patients with major collateral vascular flow and in those with abnormal or altered anatomy (Table 53–14).[221]

Anesthetic Management

Preoperative assessment should include inspection for the presence of occult airway obstruction or distortion, superior vena cava outlet obstruction, evidence of paraneoplastic syndromes, and cerebral vascular disease. The standard anesthetic plan is designed to permit rapid emergence and extubation after surgical pathology confirms adequacy of the specimen. General anesthesia with mechanical ventilation is the most commonly used technique (Table 53–15). However, mediastinoscopy can be performed using local anesthesia with sedation in rare cases, that is, mediastinal masses with airway compromise. Muscle relaxants are advantageous for facilitating intubation, controlling ventilation, and preventing sudden movement or coughing that would increase the risk of surgical complications.[222] The negative intrathoracic pressure associated with spontaneous ventilation may increase the risk of air embolism through open venous structures. Manipulation of the mediastinoscope can compress the innominate artery, thereby decreasing arterial blood flow to the right upper extremity and the right common carotid arteries and obliterating the pulse and pressure in the right arm.[223] It is recommended that a noninvasive blood pressure cuff be placed on the patient's left arm and either pulse oximetry probe or an arterial catheter (if indicated) be placed in the right upper extremity. Waveform analysis of the arterial pressure or pulse oximeter plethysmograph trace can detect compression of the innominate artery.[224]

Foster ED, Munro DD, Dobell AR. Mediastinoscopy. A review of anatomical relationships and complications. Ann Thorac Surg 1972;13:273–286. This article was published in The Annals of Thoracic Surgery.

Complications

The overall complication rate for mediastinoscopies ranges from 1.5–3%.[221,225–227] Appreciation for the surgical risks associated with mediastinoscopy comes from an understanding of the anatomy relevant to the procedure. The most common and potentially serious complications are bleeding, cardiac tamponade, and air embolism. Compromise of other structures, such as the trachea, bronchi, esophagus, laryngeal nerve, and innominate artery, can lead to temporary or permanent complications. Hemorrhage can result from laceration of a PA or a thoracic aortic artery.[227] Therefore, a large-bore IV access catheter should be placed before induction of anesthesia. Clinical situations that increase collateral vascular flow, such as superior vena cava syndrome or aortic coarctation, predispose to bleeding and are relative contraindications to the procedure. Hemorrhage may be temporarily controlled by packing the surgical wound. Immediate thoracotomy may be required to control bleeding. In patients with superior vena cava obstruction, IV access should be secured in the lower extremity to avoid distending the thoracic venous vasculature and increasing the risk of bleeding.

Laceration of venous structures in the mediastinum increases the risk of air embolism.[228] Air embolism is associated with a sudden decrease in end-tidal CO_2, relative hypotension, tachycardia, and a change in heart sounds heard through an esophageal stethoscope or by precordial Doppler monitor.

Compression of the vertebral arteries from hyperextension of the cervical spine or compression of the innominate artery that feeds the right common carotid artery can cause central nervous system (CNS) complications.[224,229,230] One study documented transient decreases in blood flow for periods ranging from 15–35 seconds in four of seven patients.[229] However, the clinical significance of such transient effects is unknown.

Tracheal laceration can lead to mediastinal emphysema and loss of effective ventilation. If tracheal laceration is suspected, fiberoptic bronchoscopy should be used to define the site and to guide advancement of the endotracheal tube beyond the laceration. Tracheomalacia resulting from long-standing compression of the trachea by mediastinal tumor can predispose to acute tracheal injury or collapse.

TABLE 53–15.

Anesthetic Guidelines for Mediastinoscopy and Mediastinotomy

Indication	Diagnostic (biopsy mass, lymph nodes)
Monitors	Standard monitors, optional (arterial catheter)
Anesthesia	General anesthesia
Additional equipment	Shoulder roll
Ventilation	Single-lumen endotracheal tube
Position	Supine with cervical extension
Incision	Mediastinoscopy (suprasternal) Mediastinotomy
Unique considerations	To avoid artifact induced by innominate artery compression, place noninvasive blood pressure cuff on left To detect innominate artery compression, place pulse oximeter on right hand
Intraoperative complications	Dysrhythmia Asthma Hemorrhage Pneumothorax Recurrent laryngeal nerve injury Respiratory compromise Air embolism Perforation esophagus or bronchus Neurologic event (compression innominate artery or hyperextension of the neck)
Blood loss	Usually minimal
Postoperative analgesia	Parenteral opiates
Postoperative morbidity	Pneumothorax Hemoptysis Respiratory distress (vocal cord paralysis)
Postoperative care	Chest radiography Elevate head of bed to decrease edema and improve respiratory function

Pneumothorax is the second most common complication of mediastinoscopy. It may be unilateral or bilateral. Use of positive-pressure ventilation can rapidly increase pneumothorax size, causing hemodynamic compromise. It should be suspected if the patient exhibits an increase in peak airway pressures, hypotension, dysrhythmias, deviation of the trachea, or unilateral absence of breath sounds. If time permits, a chest radiograph can be obtained to confirm the diagnosis. If the patient exhibits hemodynamic instability, rapid placement of a chest tube is indicated.

Postoperative Concerns

Dyspnea and respiratory difficulty may occur in the initial postoperative period. Intraoperative bleeding or edema can cause compression of the airway, especially in patients with tracheomalacia.[226] Raising the head of the bed improves ventilatory mechanics, facilitates venous return, and decreases edema. Damage to the recurrent laryngeal nerve during mediastinoscopy does not become evident until after extubation. If injury to the recurrent laryngeal is suspected, the vocal cords should be visualized during extubation with the patient breathing spontaneously. Unilateral nerve damage without airway obstruction is managed conservatively.[228,231] Bilateral nerve injury requires reintubation to prevent airway obstruction. Laryngeal nerve injury during these conditions is permanent in 50% of patients.[232]

ANESTHESIA FOR PATIENTS WITH MEDIASTINAL MASSES

Patients with mediastinal masses may experience significant complications during general anesthesia.

The mediastinum is divided into the superior, anterior, middle, and posterior mediastina. The most common tumors in the anterior mediastinum are thymomas, mesenchymal tumors, dermoid cysts, thyroid and parathyroid

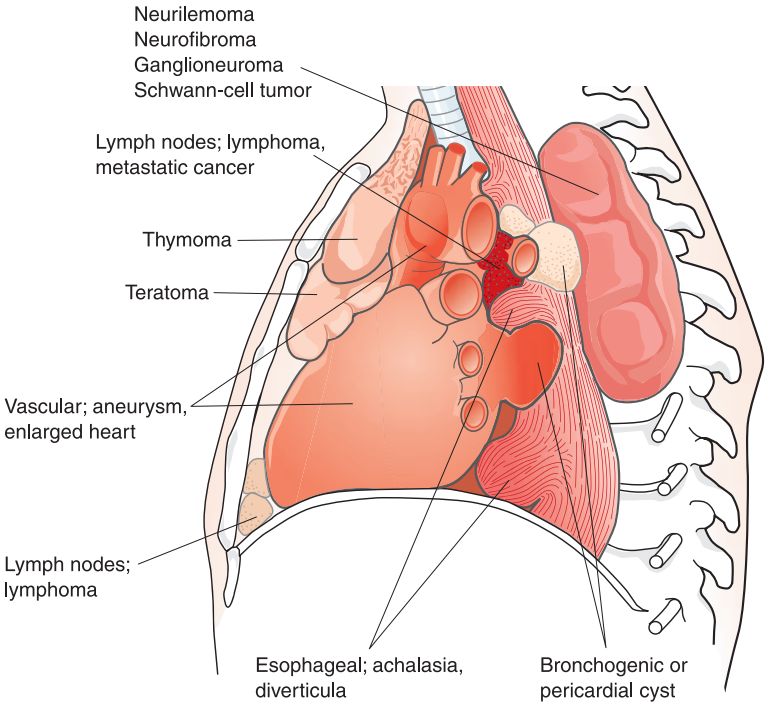

FIGURE 53–31. Anatomic location of commonly encountered mediastinal masses. (Modified from Netter FH. The CIBA Collection of Medical Illustrations, vol 7. Summit, NJ: CIBA, 1979, pg. 23, with permission.)

tumors, and lymphomas (Fig. 53–31 and Table 53–16). In the middle and posterior mediastinum, tumor pathologies include pericardial cysts, bronchogenic cysts, lymphomas, neurogenic tumors, and aortic aneurysms.

Signs and Symptoms

The mechanisms postulated for the clinical symptoms of respiratory and cardiovascular compromise in awake patients (Table 53–17) include (1) progressive airway obstruction caused by compression of the distal trachea or bronchi, (2) loss of lung volume, (3) compression of the PA or the heart, (4) superior vena caval obstruction, (5) involvement of the important nervous system elements in the mediastinum (e.g., recurrent laryngeal nerves, sympathetic chain), and (6) spinal cord compression from intraspinal extension of neurogenic tumors of the posterior mediastinum.

The incidence of perioperative complications generally is related to the size of the mediastinal mass and to the extent of disease within the thoracic cavity.[233] In one large series, clinical manifestations included (1) cough and pain, 40% each; (2) weight loss and fever, 24% each; (3) dyspnea and dysphagia, 20% each; (4) superior vena caval obstructions, 16%; (5) tracheal deviation, 12%; (6) Horner syndrome, 7%; (7) spinal cord compression, 5%; and (8) cyanosis, mediastinal widening, and hoarseness, 3% each. Twenty percent of patients were asymptomatic. Not all patients with mediastinal masses who have acute life-threatening airway complications during anesthesia are symptomatic preoperatively. Some are asymptomatic and show no airway compression on chest radiographs. Therefore, the severity of the patient's preoperative respiratory symptoms may be unrelated to the extent of respiratory or cardiovascular compromise encountered during anesthesia.[233–235]

Diagnostic Evaluation

Careful preoperative diagnostic evaluation should be performed, even in the asymptomatic patient, to determine the extent of mediastinal pathology. A flow chart showing the preoperative evaluation of patients with mediastinal masses is shown in Fig. 53–32. Most patients with mediastinal masses require scans to delineate tumor size and location. The anesthesiologist should evaluate the extent of compression of the airway, heart, and vascular

TABLE 53–16.

Mediastinal Mass Location

Superior	Anterior	Middle	Posterior
Children			
Lymphoma	Lymphoma	Lymphoma	Neurogenic tumors

TABLE 53–17.

Clinical Findings in Patients with Mediastinal Masses

History	Physical Examination	Laboratory
Airway		
Cough	Decreased breath sounds	Chest radiograph (posteroanterior and lateral to look for tracheal deviation or compression)
Cyanosis	Wheezing	Flow–volume loops, supine and sitting
Dyspnea	Stridor	
Orthopnea	Cyanosis	
Cardiovascular		
Fatigue	Neck or facial edema	Chest radiographic changes in cardiac silhouette
Faintness	Jugular distension	Echocardiogram, supine and sitting
Headache	Papilledema	
Shortness of breath, orthopnea	Blood pressure changes or pallor with postural changes	
Cough	Pulsus paradoxus	

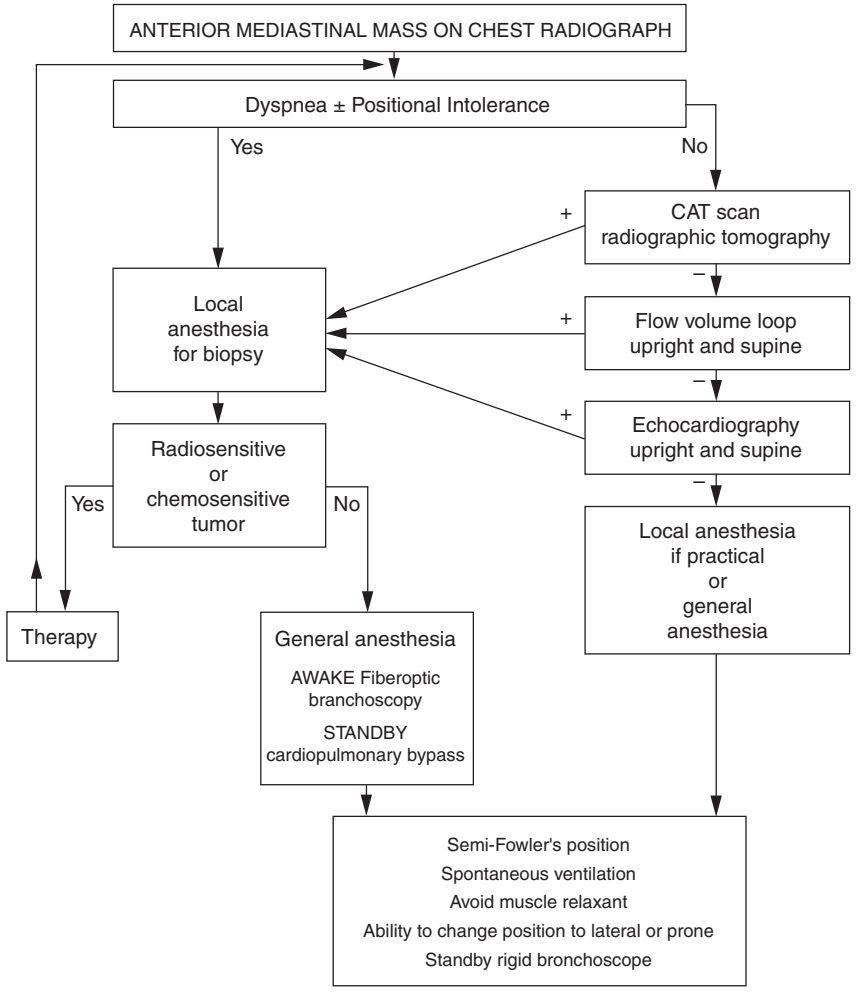

FIGURE 53–32. Flowchart showing the preoperative evaluation of the patient with an anterior mediastinal mass. +, Positive finding; –, negative workup. (From Neuman GG, Weingarten AE, Abramowitz RM, et al. The anesthetic management of the patient with an anterior mediastinal mass. Anesthesiology 1984;60:144, with permission.)

structures preoperatively.[236,237] The extent of tracheal compression is a reliable predictor of whether difficulty with the airway may be expected. In one series, all patients who developed total or near-total airway obstruction during induction or emergence from anesthesia had a >50% decrease in tracheal cross-sectional area as measured by CT scan.[238]

In addition to the chest radiograph and CT scan, a series of noninvasive studies can be performed to evaluate the risk of occult airway or cardiac involvement. Upright and supine flow–volume loops are simple, noninvasive, sensitive studies for the diagnosis of occult airway obstruction. The dynamic nature of this study makes it an extremely sensitive tool for evaluating obstructive lesions of major airways. The inspiratory limb of the flow–volume loop is useful in diagnosing extrathoracic airway obstruction, whereas the expiratory limb is sensitive to intrathoracic airway obstruction. Maximal inspiratory and expiratory flow–volume loops obtained with the patient in the upright and supine positions enable quantitation of the extent of functional impairment and help distinguish fixed from variable intrathoracic airway obstruction.[239] A disproportionate reduction in maximal expiratory flow should alert the physician to the presence of tracheomalacia and the inherent risk of airway collapse after extubation of the trachea. In addition, echocardiography in the upright and supine positions can reveal encroachment of tumor on the heart and intrathoracic vessels. Flexible fiberoptic bronchoscopy is another method for evaluating dynamic airway obstruction (Fig. 53–33). It allows assessment of the functional anatomy of the entire airway and the response of the airway to variations in intrathoracic pressure and position.

Pretreatment with radiotherapy or chemotherapy to reduce the tumor size decreases the risk of perioperative complications. Several investigators have suggested that patients receive empiric treatment of mediastinal pathology for the presumed diagnosis.[240] Dramatic decrease in postoperative respiratory complications and improvement in risk category were achieved by preoperative radiation therapy for patients with severe clinical or radiologic findings.[241] Such views are controversial, and most clinicians advocate obtaining a biopsy

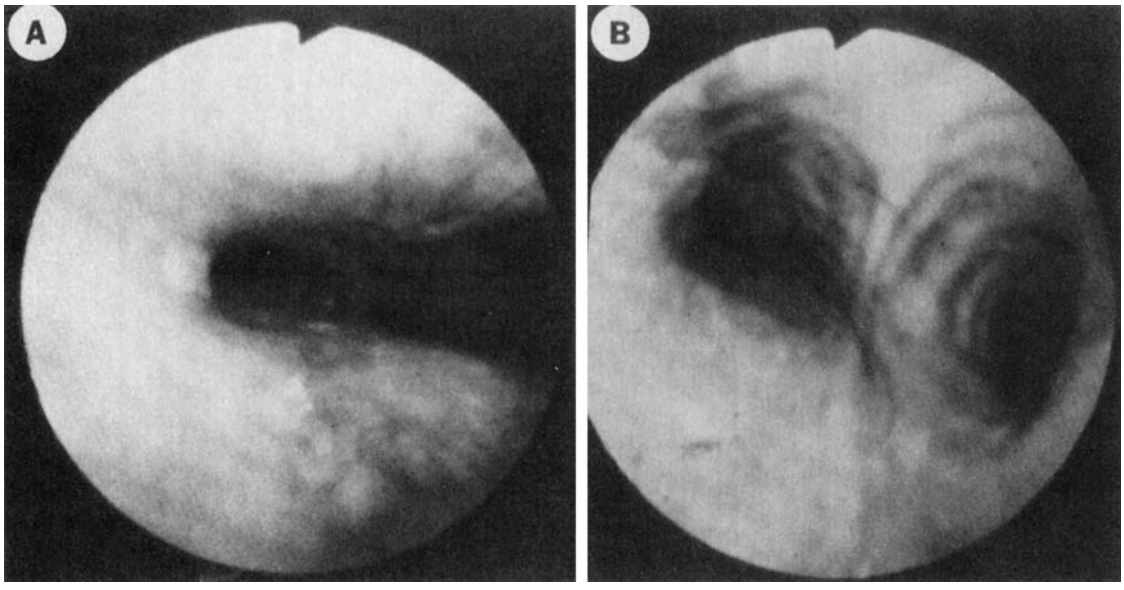

FIGURE 53–33. Fiberoptic bronchoscopic appearance of lower trachea with patient in supine position (**A**), exhibiting almost total obstruction of trachea in anteroposterior plane. With patient in sitting position (**B**), the lumen appears normal. (From Prakash UBS, Abel MD, Hubmayr RD. Mediastinal mass and tracheal obstruction during general anesthesia. Mayo Clin Proc 1988;63:1004, with permission.)

before initiating therapy, even if this procedure requires administration of general anesthesia with its inherent risks. An accurate pathologic diagnosis may be compromised if patients are empirically pretreated. In addition, the option of administering radiotherapy or chemotherapy to reduce the size of the mediastinal mass is not applicable to all patients. Some patients have large, benign mediastinal masses, such as large dermoid cysts that cannot be managed except by surgical excision. Transcarinal aspiration of a large cystic subcarinal mass can be performed through a fiberoptic bronchoscope. This technique can be used preoperatively in patients who have cystic subcarinal masses to decrease the size of the mass before anesthetic induction. This technique has been reported to facilitate anesthetic management intraoperatively when a patient developed airway obstruction after induction of anesthesia.[242]

Anesthetic Implications and Management

Symptomatic and asymptomatic patients are at risk for developing severe, life-threatening complications after induction of general anesthesia (Table 53–18). Infants and small children may have obstructive symptoms earlier than adults do because their small airway size increases the magnitude of airway resistance produced by decreases in airway dimensions. To avoid the risk of complications inherent with

TABLE 53–18.

Anesthetic Guidelines for Mediastinal Mass

Indication	Biopsy or resection of mediastinal mass
Monitors	Standard monitors, arterial catheter
Anesthesia	Preferably awake, sedated using local anesthesia
	If general anesthesia is necessary, spontaneous ventilations should be maintained[a]
Additional equipment	Fiberoptic and rigid bronchoscope
	Multiple-sized endotracheal tube
	Standby of cardiopulmonary bypass or extracorporeal membrane oxygenation
Ventilation	Spontaneous ventilation preferred
	Intubation does not guarantee a secure patent airway
	Use of flexible bronchoscope to evaluate and intubate airway
Position	As tolerated by patient (sitting, semirecumbent, or supine)
Incision	Depends on location and size of tumor
	Surgical options include biopsy during local anesthesia, mediastinoscopy, mediastinotomy, median sternotomy
Unique considerations	Inability to ventilate
	Risk of cardiovascular collapse
	Superior vena cava syndrome (increased risk of airway edema, bleeding, placement of IV access in lower extremity)
	Avoid use of muscle relaxants
	Maintenance of spontaneous ventilation
Intraoperative complications	Hypoxia
	Bleeding
	Hypotension
	Obstruction of airway
Postoperative morbidity	Airway edema, inability to extubate
Postoperative care	Monitor in intensive care environment

[a]Until one can demonstrate that controlled ventilation does not cause airway obstruction or cardiovascular instability.

general anesthesia, alternate diagnostic techniques can be used. Alternative methods that can be performed in awake, sedated patients include percutaneous needle aspiration of the hilum and mediastinum, mediastinotomy, and thoracoscopy.[243]

When the surgical procedure requires general anesthesia, the anesthesiologist and surgeon should discuss the plan and confirm availability of equipment for emergency airway management (e.g., fiberoptic and rigid bronchoscopes). Difficulties may occur during induction when the patient position is changed, when positive pressure is applied, after administration of muscle relaxants, after intubation, during emergence, or after extubation. The patient should undergo a slow controlled inhalational induction, with a staged approach that confirms an adequate airway before progressing. Induction may begin in a semirecumbent or seated position and progress to the supine position. After a deep anesthetic plane has been achieved, the anesthesiologist should attempt to gradually control ventilation. If wheezing or stridor ensues, the patient should be returned to spontaneous ventilation. If muscle relaxation is required to facilitate tracheal intubation, an ultrashort-acting relaxant such as succinylcholine should be used. The anesthetic technique should include the use of short-acting agents and avoidance of bolus administration of large doses of drugs. Intubation does not eliminate the risk of complications. Obstruction may even occur distal to a properly placed endotracheal tube and interfere with the normal protective glottic mechanism of physiologic PEEP that increases the tracheal distending pressure and reduces the possibility of dynamic collapse. Dynamic collapse of a tracheal segment also may occur with rapid respirations or cough during awakening from anesthesia.

Compression of the Tracheobronchial Tree

Neither the presence nor the severity of the patient's preoperative respiratory symptoms reliably predicts the extent of respiratory compromise that could be encountered during anesthesia, although most patients with severe respiratory symptoms have significant decreases in tracheal cross-sectional area.[238] The supine position, anesthesia, and muscle paralysis are associated with decreased dimensions of the rib cage, cephalad displacement of the dome of the diaphragm, and a reduction in thoracic volume limiting the space available for the trachea.[244–247] At low lung volumes, the decreased tracheal distending pressure can lead to tracheal collapse, particularly with tracheomalacia. Spontaneous ventilation is preferred to positive-pressure ventilation because the negative intrapleural pressure of spontaneous ventilation exerts a distending force that opposes bronchial and tracheal collapse. The supine position increases the central blood volume, which can further increase tumor volume and size. Edema, bleeding, and hematoma formation in the tumor as a result of surgical biopsy can contribute to airway compromise.

Compression of PA and Heart

Compression of the main PA is relatively rare, partly because of the protective effect of the aorta. Compression of the pulmonary trunk or one of the main pulmonary arteries can result in sudden hypoxemia, hypotension, and cardiac arrest. Syncope during forced Valsalva maneuvers, such as occurs with a bowel movement, should alert the physician to the possibility of cardiovascular compression. Important factors contributing to a reduction in right ventricular output, hypotension, and severe hypoxemia include patient position, induction of anesthesia, and gravitational effects of the tumor on the heart and PA.

Superior Vena Cava Syndrome

Pathophysiology

Superior vena cava syndrome occurs in approximately 6–7% of patients with lung carcinoma. Other causes are bronchial carcinoma, malignant lymphoma, and benign conditions, including multinodular goiter, mediastinal granulomas, idiopathic mediastinal fibrosis, and catheter-induced thrombosis of the superior vena cava.[24] Obstruction of the superior vena cava impedes venous flow from the head and upper extremities. Clinical features are listed in Box 53–9. The symptoms of dyspnea, dysphasia, and stridor may be associated with ruddy complexion and dilated veins across the upper chest and neck (Fig. 53–34). The severity of clinical manifestations depends on the rate at which the superior vena cava is occluded. Slow gradual obstruction is associated with mild signs and symptoms, whereas more severe symptoms occur with rapid onset of obstruction. The severity also depends on the extent of obstruction, site of obstruction (above or below the azygos vein), and integrity of the azygos venous system. Occlusion of the azygos venous system often is symptomatic and may require surgery to bypass the spinal vein and to resect the obstructing lesion.

Choice of therapy depends on etiology. Therapeutic options include radiation, chemotherapy, and thrombectomy. Once obstruction has produced complete thrombosis, thrombectomy is of little benefit. Patients having total or near-total obstruction are at risk for cerebral vascular and airway compromise, both predictors of poor outcome. A tissue diagnosis should be obtained before institution of therapy, if possi-

BOX 53–9.

Clinical Features of Superior Vena Cava Syndrome

Neurologic
- Headache, dizziness, decreased mentation, visual changes, restlessness, agitation, Horner syndrome, stupor, convulsions

Pathophysiology
- Low cardiac output, decreased cerebral perfusion, increased cerebral venous pressure, cerebral edema

Respiratory
- Shortness of breath, cough, hoarseness, hypoxemia, tachypnea, stridor

Pathophysiology
- Upper airway edema, tracheal obstruction, vocal cord paralysis

Cardiac
- Tachycardia; thoracic and cervical venous distension; plethoric face; edema of the face, neck, upper extremities, and trunk; cyanosis; distended veins over chest wall

Pathophysiology
- Decreased venous return, development of collateral venous circulation, increased peripheral venous circulation, increased peripheral venous pressure, as high as 40 mm Hg

Gastrointestinal
- Nausea, vomiting, dysphagia

Pathophysiology
- Fluid imbalance, upper airway edema

Renal
- Decreased urine output

Pathophysiology
- Low cardiac output

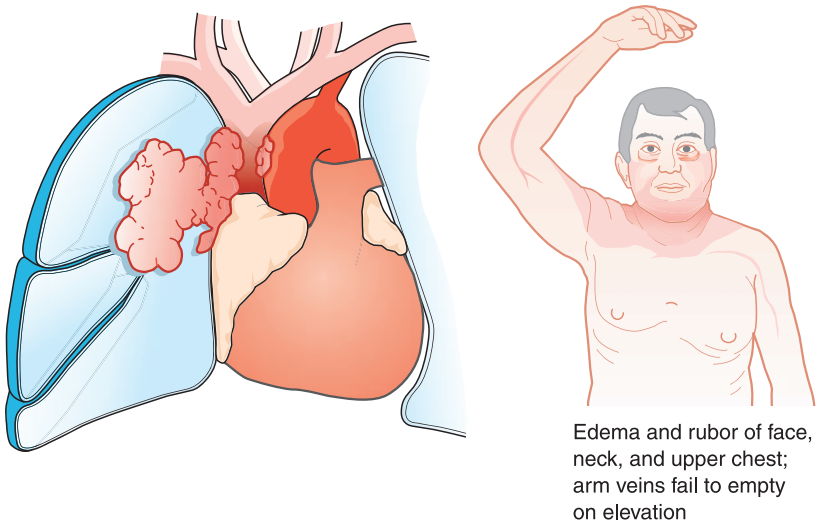

FIGURE 53–34. Bronchogenic carcinoma producing superior vena cava obstruction. Superior vena cava syndrome is characterized by edema and rubor of the face, neck, and upper chest. Arm veins fail to empty on elevation. (Modified from Netter FH. The CIBA Collection of Medical Illustrations, vol 7. Summit, NJ: CIBA, 1979, pg. 28, with permission.)

ble. In most patients this can be achieved noninvasively by bronchoscopy or lymph node biopsy. Occasionally, an open procedure requiring general anesthesia is necessary. MRI and contrast venography are used to define the type and location of obstruction. If biopsy of the mediastinal mass is required, an open mediastinotomy should be performed instead of mediastinoscopy because the increased venous pressure increases the risk of bleeding during cervical exploration.

Anesthetic Management

Patients with superior vena cava syndrome are at increased risk for airway compromise resulting from acute laryngospasm, bronchospasm, and airway edema caused by tumor edema or surgical manipulation.[248] Venous distension and symptoms are exacerbated by changes in positioning (supine or Trendelenburg) and by administration of IV fluids, especially through a catheter placed in the upper extremity. All venous access should be placed in the lower extremity, and an arterial catheter should be placed to monitor blood gases and blood pressure. Venous congestion increases the risk of airway compromise, bleeding, and hypotensive episodes. Preoperative evaluation should include careful assessment of the airway. Edema of the oral pharynx, larynx, and trachea may be more severe than the external edema and swelling of the face and neck. Venous engorgement and tumor may involve the recurrent laryngeal nerve and cause external compression of the airway. These patients should be regarded in a manner similar to those with mediastinal masses. Premedication should be limited to administration of an antisialagogue, and patients should be transported in a semiseated position to decrease airway edema and facilitate venous drainage. If major airway edema is present, general anesthesia should be induced in a sitting position, and fiberoptic bronchoscopy may be required for airway access. Intraoperative management may be complicated by an abnormal response to muscle relaxants related to a paraneoplastic myasthenic syndrome.[249] Many of these patients remain intubated postoperatively until edema of the airways and laryngeal structures decreases.

ANESTHESIA FOR PATIENTS WITH THORACIC OUTLET SYNDROME

Thoracic outlet syndrome refers to neurologic and vascular symptoms affecting the upper extremity resulting from compression of the neurovascular bundle at the thoracic outlet between the first rib and the clavicle or between the anterior scalene muscle and the medial scalene muscle.[78,250–253] The etiology is classified as either noncancerous or cancerous.

The majority of noncancerous causes are related to either trauma or the presence of a cervical rib. A less frequent etiology is hypertrophy of the scalene and subclavian muscles. Clinical manifestations usually are vague and obscure and may be misinterpreted as angina. Pain may be localized to the shoulder or extend along the medial aspect of the arm and forearm, along the proximal shoulder girdle, or to the neck and face. Symptoms may include weakness, numbness, and paresthesias. Conservative management includes rehabilitation exercises, antiinflammatory drugs, and analgesics. In those with vascular insufficiency or with symptoms refractory to medical therapy, operation may be indicated. Surgical approaches include resection of the first rib, partial resection of the scalene muscles, and removal of anomalous fibromuscular bands.

The presentation of lung cancer with symptoms of thoracic outlet syndrome is known as *Pancoast syndrome.* The most common etiology is a bronchogenic carcinoma originating in or near the superior pulmonary sulcus. These tumors invade the lymphatic system and spread by direct extension to entwine the brachial plexus intercostal arteries, stellate ganglia, and sympathetic chain, thereby producing Horner syndrome. If the tumor is considered resectable, the pulmonary tumor and extension into the chest wall and brachial plexus should be excised.

Anesthetic management includes the use of routine monitoring and may require one-lung isolation (Table 53–19). The patient is placed in the lateral decubitus position, and an incision is made in the lower margin of the anterior axilla. Intraoperative complications include hemorrhage, pneumothorax, brachial nerve injury with resulting nerve dysfunction, temporary phrenic nerve palsy, injury to the subclavian artery, and cervical sympathectomy on the ipsilateral side. Because of the position of the nondependent arm and the site of surgery, stretch and surgical trauma to the brachial plexus are major risks.

ANESTHESIA FOR PATIENTS UNDERGOING THYMECTOMY: MYASTHENIA GRAVIS

Clinical Features

The thymus is a central lymphoid gland that functions in the development and maintenance of immunologic competence. Surgical resection of the thymus most often is performed for myasthenia gravis and less often

TABLE 53–19.

Anesthetic Guidelines for Thoracic Outlet Syndrome

Indication	Therapeutic (syndrome characterized by lateral upper extremity weakness, numbness, paresthesias, pain)
Monitors	Standard monitors Noninvasive cuff on opposite side Ipsilateral pulse oximetry
Anesthesia	General anesthesia
Ventilation	Single-lumen or double-lumen endotracheal tube
Position	Supine or lateral decubitus position, determined by surgical approach
Incision	Cervical region (partial resection of first rib) Scalene muscles
Unique considerations	Intravenous access on opposite side
Intraoperative complications	Pneumothorax Pleural effusion Vascular injury Neural injury Cervical sympathectomy
Blood loss	Minimal <500 mL
Postoperative analgesia	Parenteral opiates
Postoperative morbidity	Temporary phrenic nerve palsy Pneumothorax Brachial plexus neuralgia or palsy Injury to long thoracic nerve and T1 roots
Postoperative care	Chest radiography

for primary neoplasm, carcinoid tumor, and multiple endocrine neoplasm syndrome. Seventy-five percent of the patients with myasthenia gravis have associated thymic hyperplasia or thymomas (Table 53–20).

Therapy for myasthenia gravis includes anticholinesterase drugs, corticosteroids, other immunosuppressants, plasmapheresis, and thymectomy. These therapies can be used individually or in combination. Anticholinesterase drugs, such as neostigmine or pyridostigmine, most often are selected because they provide immediate symptomatic relief. These drugs inhibit the enzyme responsible for hydrolysis of acetylcholine and thereby increase the concentration of neurotransmitter at the neuromuscular junction. Surgical resection of the thymus gland may result in complete remission or dramatic improvement in symptoms.[254]

Anesthetic Considerations

Management of anesthesia for patients with myasthenia gravis should consider the severity of symptoms, presence of other associated disorders (Box 53–10), and preoperative drug therapy. Considerations for the perioperative period are given in Table 53–21. An assessment of preoperative pulmonary function should be obtained as a baseline for comparison. The patient's preoperative medications should be reviewed for drugs that could interfere with neuromuscular function (Box 53–11). Drugs that have the potential to exacerbate muscle weakness in these patients include calcium channel blockers, aminoglycosides, and antiarrhythmic agents.[255–257] Most authors recommend that patients continue their usual dose of anticholinesterase therapy the night before surgery. On the day of operation, patients who are severely symptomatic should receive a full morning dose. Patients who are only mildly affected should receive half a dose or none at all. The rationale for withholding the morning dose is to prevent antagonism of muscle relaxants that may be used to facilitate tracheal intubation. Patients receiving systemic steroids should continue steroid supplementation on the day of surgery.

Special attention should be given to the psychological preparation of these patients. They should be told about the increased risk for prolonged muscle weakness and respiratory depression that uncommonly require temporary postoperative ventilation.

We believe all patients undergoing thymectomy require general anesthesia regardless of the surgical approach. In patients undergoing a transmediastinal approach, use of an epidural block

TABLE 53–20.

Clinical Classification of Myasthenia Gravis

Stage	Term	Description
I	Ocular myasthenia	Involvement of ocular muscles only; mild symptoms of ptosis and diplopia
II	Mild-to-moderate generalized myasthenia	Slow onset; usually ocular, spreading to skeletal and bulbar muscles; no respiratory involvement; good response to drug
III	Acute fulminating myasthenia	Rapid onset of severe bulbar and skeletal weakness with involvement of respiratory muscles; poor response to therapy
IV	Late severe myasthenia	Severe disease developing 2 years after onset of stage I or II symptoms; poor response to therapy and poor prognosis

BOX 53–10.

Disorders Associated with Myasthenia Gravis

- Thyroid disease
  - Hyperthyroidism
  - Hypothyroidism
  - Thyroiditis
- Thymoma
- Pernicious anemia
- Multiple sclerosis
- Ulcerative colitis
- Leukemia
- Lymphoma
- Autoimmune disorders
- Systemic lupus erythematosus
  - Idiopathic thrombocytopenic purpura
  - Rheumatoid arthritis
  - Scleroderma
  - Polymyositis
  - Sjögren syndrome

TABLE 53–21.

Anesthetic Guidelines for Thymectomy: Myasthenia Gravis

Indication	Therapeutic (myasthenia gravis, thymoma, multiple endocrine neoplasm syndrome)
Monitors	Standard monitors
Anesthesia	General anesthesia
Preoperative considerations	Review use of anticholinesterase medications
	Evaluate strength
	Assess respiratory function
Ventilation	Usually single-lumen ETT
	Double-lumen ETT if by video-assisted thoracoscopic surgery
Position	Supine with shoulder roll
	Occasionally by left lateral decubitus (thoracoscopy)
Incision	Sternotomy, transcervical
	Portals for video-assisted thoracoscopic surgery
Unique considerations	Myasthenia gravis (increased sensitivity to muscle relaxants, risk of remaining intubated postoperatively, avoid neuromuscular blocking effects of antiarrhythmics, diuretics, and aminoglycosides)
Intraoperative complications	Myasthenia gravis (residual weakness or sedation leading to inability to extubate)
Blood loss	Minimal
Postoperative analgesia	Parenteral opiates, epidural
Postoperative morbidity	Respiratory insufficiency (inadequate reversal of muscle relaxants, excessive sedation, not received daily dose of anticholinesterase)
Postoperative care	Chest radiography
	Optimize respiratory function (analgesics, raise head of bed)
	Observe in monitored environment

ETT, Endotracheal tube.

as an adjunct to general anesthesia has been found to decrease the intraoperative minimum alveolar concentration (MAC), lessen postoperative analgesic requirements, improve respiratory mechanics, and dramatically decrease the frequency of prolonged intubation.[258] Use of a muscle relaxant is not required but may facilitate tracheal intubation. Patients with myasthenia gravis have a marked sensitivity to nondepolarizing muscle relaxants, increasing their sensitivity and duration of action. If muscle relaxation is required, a small dose of a short-acting nondepolarizing drug, such as cisatracurium, should be used. Although muscle relaxation usually is less sensitive to succinylcholine in patients receiving anticholinergic therapy, the duration of action of the drug may be extended. If succinylcholine is to be used, the dose should be reduced to avoid prolongation of the response and associated phase II block.[258–261] Halogenated inhaled anesthetics have muscle-relaxing properties. One study found that patients with myasthenia gravis were more sensitive to the neuromuscular depressant effects of isoflurane.[262] Recovery of the electromyographic response still was incomplete 1 hour after terminating isoflurane, despite satisfactory clinical recovery.

The most common surgical approaches are the transcervical and transsternal approaches; a minority of cases are performed by thoracotomy or VATS. The transcervical approach has the advantage of avoiding the immediate postoperative alterations in pulmonary mechanics.[263–265] Mediastinotomy may be necessary when resecting a hypertrophied thymus that extends substernally. If mediastinotomy or the cervical approach is to be used, a single-lumen tube is appropriate. Alternatively, a double-lumen endotracheal tube or bronchial blocker is indicated if lateral thoracotomy is planned.

Postoperative Concerns

Improvement in myasthenic symptoms after thymectomy may take weeks to months. Therefore, the patient should receive any missed dose of anticholinesterase from the morning of operation. At the end of the operation, neuromuscular transmission is assessed using a nerve stimulator; nondepolarizing muscle relaxants are reversed. Residual weakness from an inhaled anesthetic can cause fade in the response to tetanic stimulation. Suitability for extubation is judged by measuring the patient's pulmonary function and comparing the results with preoperative values. Negative inspiratory force, tidal volume, and vital capacity should be measured immediately before induction and used as the basis for comparison. To improve respiratory mechanics, the patient is placed in a semirecumbent position with the head of the bed raised approximately 30°, is suctioned for secretions, and receives adequate analgesia without inducing respiratory depression. The patient should be monitored closely for 18–24 hours after operation. A chest radiograph is obtained immediately postoperatively to rule out the presence of a pneumothorax.

BOX 53–11.

Drugs That Can Exacerbate Myasthenia Gravis

- Acetylcholinesterase in high doses
- Aminoglycosides
- Other antibiotics (e.g., clindamycin, colistin, polymyxin B, tetracycline, trimethaphan)
- Antidysrhythmics (e.g., procainamide, quinidine, propranolol, lidocaine)
- Thyroid hormones
- Quinine (tonic water)
- Lithium
- Phenytoin (Dilantin)
- Oxytocin
- Chlorpromazine
- Chloroquine

ANESTHESIA FOR PATIENTS UNDERGOING TRACHEAL RESECTION AND TRACHEOBRONCHIAL RECONSTRUCTION

Indications for tracheal resection include the following:

- Tracheal tumors, most of which are malignant
- Carinal tumors or carinal involvement with a bronchogenic carcinoma

- Tracheal involvement with a thyroid carcinoma
- Traumatic disruption of the trachea and bronchi, which may occur as a result of blunt trauma, penetrating injuries, iatrogenic manipulations, and aspirated sharp foreign bodies
- Tracheal stenosis after prolonged intubation or trauma

Patients undergoing surgical resection of the trachea, main bronchi, or both impose special anesthetic management problems. The surgical procedure often is prolonged, and episodes of ventilatory insufficiency may be unavoidable. Communication between the anesthesia and surgical teams, with emphasis on the ventilatory treatment of the patient during each phase of the procedure, is imperative. The most challenging aspect of these procedures is designing an effective method for ventilating the lungs during the resection and reconstruction of the airway that does not interfere with surgical exposure and that provides adequate ventilation and oxygenation. Patients with large intratracheal or carinal masses may develop total airway obstruction upon induction of anesthesia. Fortunately, many of these patients undergo laser debulking procedures before surgical resection. Because an inflated cuff and positive-pressure ventilation adjacent to the suture line may interfere with healing or cause disruption of the anastomosis, after the procedure the patient should breath spontaneously and be extubated in the operating room or shortly thereafter.

Surgical techniques include resection and primary anastomosis, resection, and reconstruction with prosthetic material or with insertion of a T-tube stent.

Therapeutic adjuncts include radiotherapy (preoperatively or postoperatively), radioactive seed implantation, and preoperative laser debulking.

Surgical Considerations

Surgery on the trachea and bronchi usually is performed through a right thoracotomy to avoid the aortic arch, although if the left bronchus is involved or a left pulmonary resection may be done, a left thoracotomy may be performed. The surgical procedure requires extensive hilar dissection, mobilization of the lungs, and possibly opening of the pericardium. Use of the omentum, serratus muscle, or intercostal muscle to wrap the anastomosis or to cover defects in the tracheobronchial tree may be necessary. Mobilization of the omentum requires an additional abdominal incision. Thoracoabdominal exposure substantially increases fluid requirements. On occasion, pericardium can be used to patch sections of the PA involved with tumor. Every effort should be made to maintain normothermia and minimize heat loss. After the procedure, maintaining the patient's neck in a flexed position by suturing the skin and soft tissues of the chin to the anterior chest wall may be necessary to decrease tension on the anastomosis. Even in this situation, it is advantageous to extubate the trachea as soon as possible after surgery to minimize airway pressures. Therefore, the anesthetic should be planned with the goal of rapid emergence and recovery from muscle relaxants. Thorough suctioning of the tracheobronchial tree, via a fiberoptic bronchoscope if indicated, should be performed immediately before emergence from anesthesia.

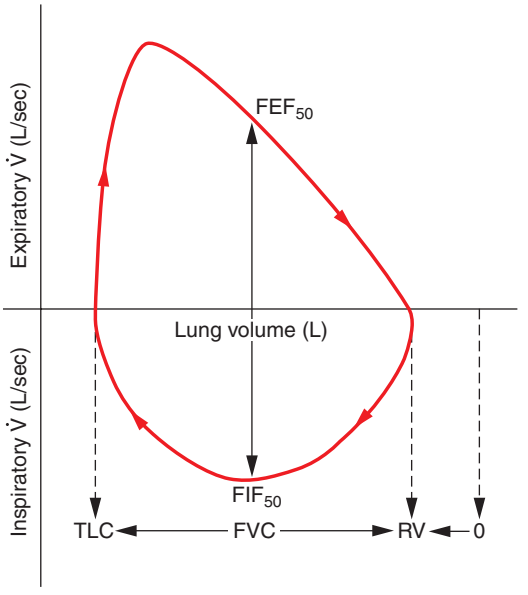

FIGURE 53–35. Idealized flow–volume (V-V) loop. During forced expiration, the rate of airflow increases rapidly at volume close to total lung capacity. As lung volume decreases, flow progressively falls in a near-linear fashion caused by increasing airway resistance. With maximum inspiratory effort, flow normally peaks at a lung volume near the midportion of the forced vital capacity. At midpoint lung volume, the forced inspiratory flow (FIF_{50}) and forced expiratory flow (FEF_{50}) should normally be equal. FIF_{50}/FEF_{50} < unity suggests an extrathoracic obstruction, compromising inspiratory flow. FIF_{50}/FEF_{50} >1 supports a diagnosis of intrathoracic airway obstruction.

Perioperative Management Issues

Preoperative Assessment and Preparation

Patients should be evaluated for airway patency and cardiopulmonary reserve. Unless airway obstruction is imminent, requiring emergency surgery, pulmonary function studies should be obtained (Figs. 53–35 and 53–36). Flow–volume loops are helpful in detecting fixed or variable intrathoracic or extrathoracic obstructions. Most of these patients have serious underlying pulmonary disease that may further compromise gas exchange intraoperatively and postoperatively. Reversible conditions that alter pulmonary function should be managed with antibiotics and bronchodilators preoperatively. All considerations that apply to patients with airway obstruction resulting from extrinsic compression by mediastinal masses also apply to patients with intrinsic obstruction of the airways. Preoperative arterial blood gas values should be obtained. Mucosal edema frequently contributes to airway obstruction in these patients, and preoperative steroids and diuretics may be beneficial.

Monitoring

An intraarterial catheter is indicated for continuous monitoring of blood pressure and for frequent sampling of arterial blood gases. Noninvasive monitoring should include pulse oximetry and capnography. Placement of the pulse oximetry probe on the hand opposite

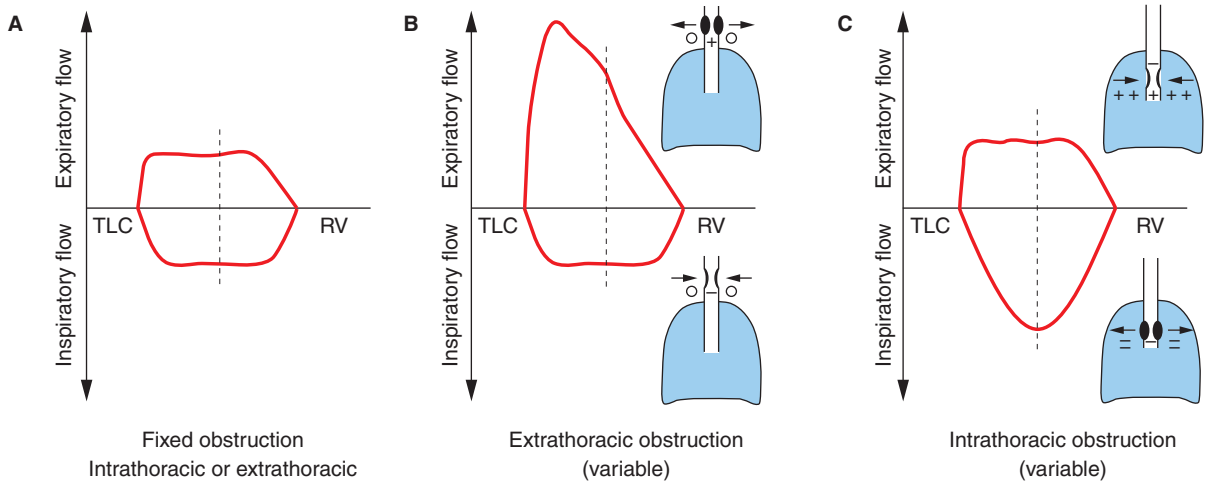

FIGURE 53–36. Maximal inspiratory and expiratory flow–volume curves in fixed obstruction (intrathoracic or extrathoracic), in which airway diameter does not change with either inspiration or expiration, extrathoracic variable obstruction, or intrathoracic variable obstruction. The dotted line indicates 50% of the vital capacity (VC). The ratio of expired-to-inspired flow at this point is the mid-VC ratio and is normally 0.9–1.0. **A.** With a fixed obstruction, expiratory and inspiratory flows are equally altered, and the mid-VC ratio remains normal. **B.** With a variable extrathoracic obstruction, forced expiration results in a slightly positive (+) intratracheal pressure that is greater than the pressure around the airway (atmospheric or 0), resulting in a decrease of the obstruction (airway dilates). During forced inspiration, when pressure around the airway (0) exceeds the intratracheal pressure (–), the obstruction is increased (airway narrows). Because the expiratory curve is normal and the inspiratory curve is altered, the mid-VC ratio is much greater than normal. **C.** With a variable intrathoracic obstruction, forced expiration results in a very positive (++) pleural pressure that is greater than the slightly positive (+) intratracheal pressure, resulting in an increase of the obstruction (airway narrows). During forced inspiration, the intratracheal pressure (–) is greater than the pleural pressure (––), thus decreasing the obstruction (airway dilates). Because the inspiratory curve is normal and the expiratory curve is attenuated, the mid-VC ratio is much less than normal. A normal flow–volume curve is a composite of the inspiratory curve in B and the expiratory curve in C. RV, Residual volume; TLC, total lung capacity.

the intraarterial catheter facilitates continuous verification of adequate blood delivery to both upper extremities and can signal the need for adjustment of patient position or surgical retraction.

Induction of Anesthesia

Induction of anesthesia follows the same guidelines as discussed in the Section on Anesthesia for Patients with Mediastinal Masses.

Modes of Ventilation

The major challenge during operation for tracheobronchial resection and reconstruction is maintenance of ventilation. The options include (1) a single-lumen endotracheal tube, (2) a single endobronchial tube or two endobronchial tubes, one into each mainstem bronchus distal to the area of resection, (3) low-frequency jet ventilation, (4) high-frequency ventilation to one or both lungs, above the site of the lesion, and (5) cardiopulmonary bypass through the femoral approach during resection of the carina. [266,267] Because of the risk of intrapulmonary hemorrhage with heparinization, cardiopulmonary bypass should be used only in selected patients when absolutely necessary.

Use of Conventional Ventilation for Tracheobronchial Reconstruction

When planning to use conventional ventilation during tracheobronchial reconstructive surgery, the anesthesiologist should have several different sizes of armored endotracheal tubes available, some of them still sterile. A long sterile anesthesia circuit is required because often the surgeon must intubate the trachea or bronchus within the sterile field. Airway management depends on the location of the lesion and its distance from the carina.

Resection of a High Tracheal Lesion

A single-lumen, uncut endotracheal tube is placed above the tracheal lesion after induction of general anesthesia. If the obstruction is mild or if the area of obstruction can be bypassed, mechanical positive-pressure ventilation is safe. The surgeon may help guide the endotracheal tube past the area of stenosis when the trachea is open. Alternatively, a sterile tube can be passed through the field into the distal trachea after the trachea has been transected below the lesion. That tube is then connected, via sterile anesthesia hoses and Y-piece, to the anesthesia machine. Armored endotracheal tubes should be used to decrease the possibility of kinking and obstruction. If the distal segment of the trachea is short, the tip of the endotracheal tube can be cut distal to the cuff so that the tube can remain above the carina (Fig. 53–37).

Repair of a high tracheal lesion usually is done through a cervical incision, possibly combined with a median sternotomy. After excision of the tracheal lesion and placement of the posterior tracheal suture line, the distal endotracheal or endobronchial tube is removed from the trachea. The proximal endotracheal tube is advanced past the anastomotic lines, reconnected to the anesthesia circuit, and the anastomosis completed.

Resection of a Low Tracheal Lesion

This usually is performed through a right thoracotomy incision. A single-lumen endotracheal tube is placed with its tip above the lesion. If sufficient length of trachea distal to the area of resection is available, a Foley catheter with its tip removed just distal to the balloon can be used as a single-

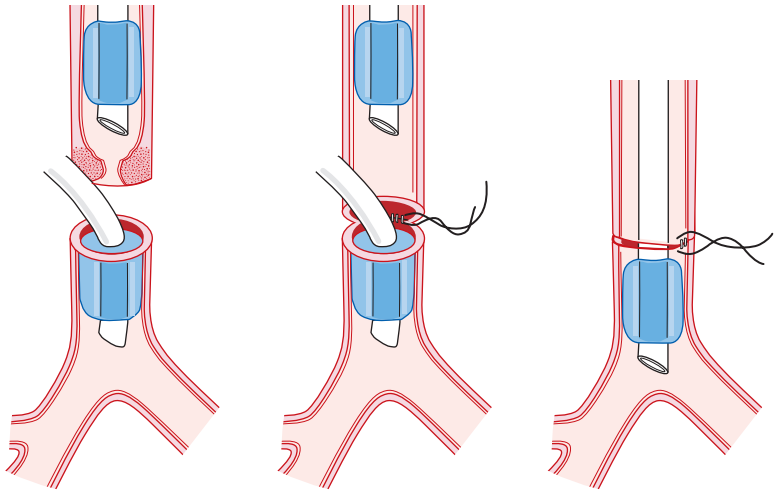

FIGURE 53–37. Procedure for resection of high tracheal lesion. (Modified from Geffin B, Bland J, Grillo HC, et al. Anesthetic management of tracheal resection and reconstruction. Anesth Analg 1969;48:884, with permission.)

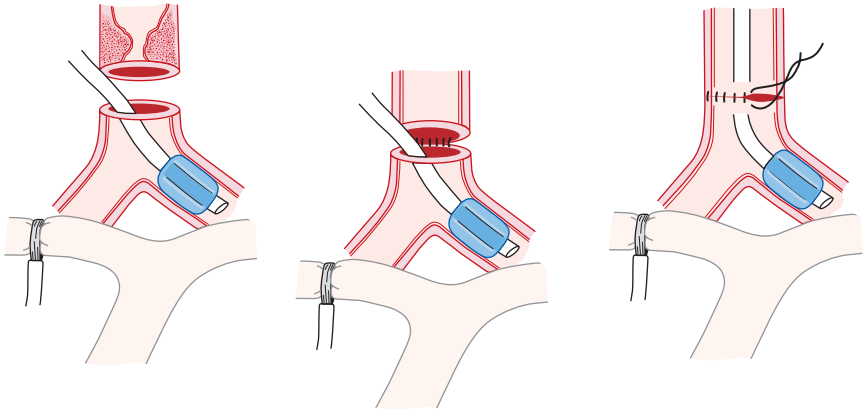

FIGURE 53–38. Procedure for resection of lower tracheal lesions. (Modified from Geffin B, Bland J, Grillo HC, et al. Anesthetic management of tracheal resection and reconstruction. Anesth Analg 1969; 48:884, with permission.)

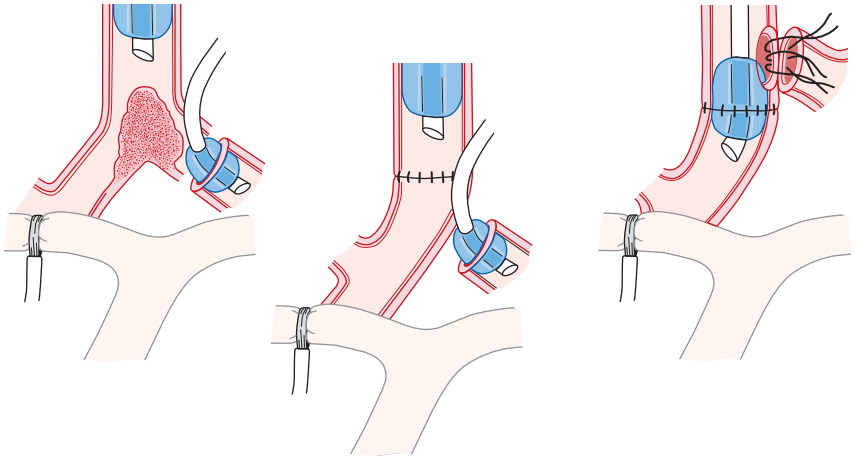

FIGURE 53–39. Procedure for resection of carinal lesions. (Modified from Geffin B, Bland J, Grillo HC, et al. Anesthetic management of tracheal resection and reconstruction. Anesth Analg 1969;48: 884, with permission.)

lumen endotracheal tube. It is inserted by the surgeon and maintained in place above the carina, thereby avoiding endobronchial intubation and the need for one-lung ventilation. If the distal tracheal stump is very short, the tube should be advanced into the bronchus of the dependent (usually the left) lung. If oxygenation is inadequate, the shunt can be decreased by temporarily clamping the PA of the nondependent side (Fig. 53–38).[268,269] When the posterior tracheal suture line has been completed, the distal endobronchial tube or Foley catheter is removed, and the original orotracheal tube is advanced across the suture line into the bronchus of the dependent lung. The anterior suture line then is completed. The endotracheal tube is pulled proximally so that its tip lies above the suture line.

For carinal resection, a single-lumen endotracheal tube is inserted through the larynx (Fig. 53–39). After the carina is resected, the surgeon places a second endotracheal tube into the bronchus of the dependent lung, usually the left. The tube is connected by a set of sterile anesthesia hoses and Y-piece to the anesthesia machine. The left lung is ventilated through the endobronchial tube, whereas the right lung is collapsed as the right bronchus is attached to the trachea. After the right mainstem bronchus has been reattached to the trachea, the original translaryngeal endotracheal tube is advanced past the suture line into the right mainstem bronchus. Cutting the tip of this endotracheal tube helps prevent obstruction of the right upper lobe bronchus. The left endobronchial tube is removed, and the left mainstem bronchus is attached to the trachea by an end-to-side anastomosis. The endotracheal tube is pulled proximally so that its tip is above both anastomotic lines.

Alternatively, after the carina is resected, the anesthesiologist can independently ventilate each lung through the distal bronchial stumps. The surgeon places a single-lumen endotracheal tube into each bronchial stump. A plastic Y-connector is used to deliver the tidal volume to both endotracheal tubes. A good air seal can be achieved by using stay sutures to pull the bronchial stump against the distal end of the inflated cuff. As the posterior layer of the anastomosis is performed, ventilation is maintained through the accessible distal bronchi. To attach the lateral

wall of a bronchus to the trachea, the corresponding endobronchial tube is removed, and one-lung ventilation is used for a limited period. As the anastomosis of the anterior wall nears completion, ventilation from above is restored. The remaining air leak will progressively diminish as the incision is closed. If the air leak is too large, the proximal translaryngeal endotracheal tube can be passed across the anastomotic line into the distal bronchus for short periods. When the anastomosis of one side is complete, that side then is ventilated, and the other endobronchial tube is removed to allow surgical access. Once the second anastomosis is complete, ventilation through the trachea is reestablished. Airway stents can be left in the trachea postoperatively to maintain airway patency.

Low Frequency Jet Ventilation/ Low-Frequency Interrupted High-Flow Ventilation

Low-frequency jet ventilation has been used to maintain ventilation during tracheal resection.[270,271] Intermittent O_2 jets at a rate of 10–20 breaths/min and a pressure of 40–60 psi are delivered into the lungs via a small-bore catheter inserted through the endotracheal tube.[270] The pressure is regulated to produce adequate chest expansion and oxygenation. After the tracheal anastomosis is complete, the catheter is removed, and the endotracheal tube above the suture line is used conventionally.

High-Frequency Ventilation

High-frequency positive-pressure ventilation (HFPPV) usually uses a respiratory rate of 60–100 breaths/min administered with a volume-cycled ventilator. It does not depend on gas entrainment. Inspiration is active, and expiration is passive. HFJV uses jet pulsations at a rate of 100–400 breaths/min. It depends on gas entrainment. Again, inspiration is active, and expiration is passive. Several reports have described the successful use of HFPPV or HFJV in the treatment of patients undergoing tracheobronchial reconstructions.[272–275]

HFJV depends on gas entrainment for adequate ventilation and can result in distal aspiration of blood and tumor debris. With HFPPV, a continuous flow of gas occurs to the outside, which protects against distal aspiration of blood and debris. HFPPV provides adequate oxygenation and ventilation by the generation of eddy flows in the airway. It may lead to improved distribution of gas flow compared with conventional mechanical ventilation. Airway pressure during HFPPV is continuously positive. Intrapleural pressure is continuously subatmospheric, with minimal effect on pulmonary and systemic hemodynamics. The principal advantage of HFPPV in tracheobronchial resection is the ability to deliver ventilation through small catheters either located free in the airway or passed through standard endotracheal tubes. These catheters provide less interference with the surgical technique than do standard single-lumen or double-lumen endotracheal tubes. In addition, as soon as the lesion is resected, jet ventilation catheters can be passed into one or both bronchi, providing independent ventilation to both lungs.

HFPPV is likely to be beneficial in patients undergoing (1) carinal resections, (2) sleeve pneumonectomies or sleeve upper lobe resections, (3) tracheal reconstruction supported by Montgomery T-tubes, and (4) tracheal resections (Fig. 53–40). For left-sided sleeve pneumonectomy, endobronchial intubation, with a small catheter passed through an endotracheal tube, provides the surgeon with an unobstructed field of vision. The catheter is passed through the operative field and

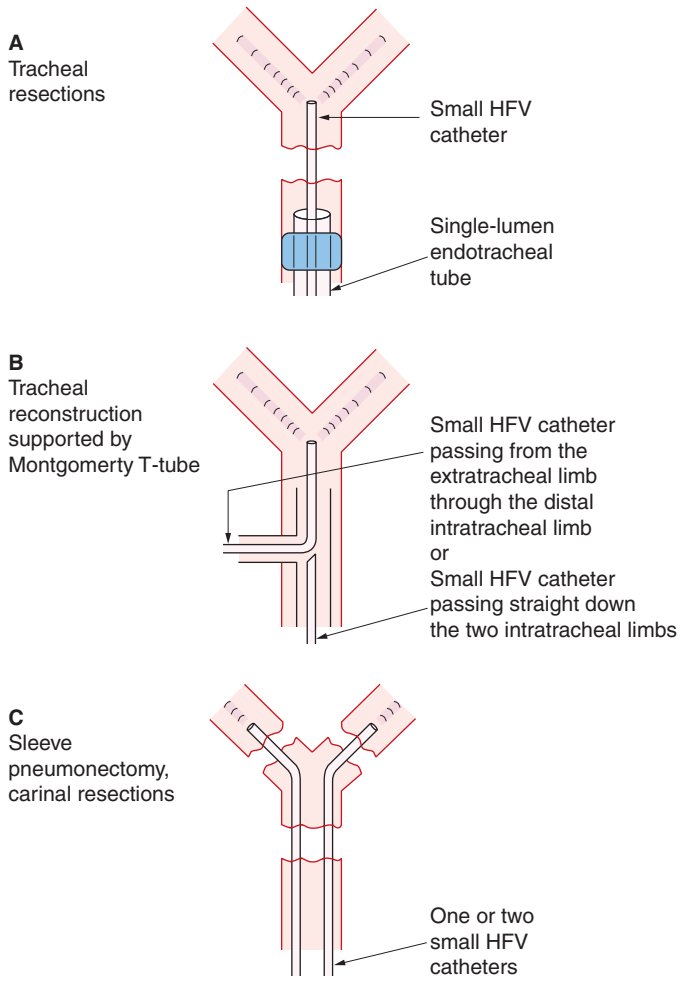

FIGURE 53–40. Three types of airway surgery aided by small high-frequency ventilation (HFV) are tracheal resections, tracheal reconstructions that require support by a Montgomery T-tube, and carinal procedures (sleeve pneumonectomy, carinal resections). **A.** With tracheal resections, a simple HFV catheter can be passed beyond the point of airway interruption, but above the tracheal carina, and used to ventilate both lungs with HFV. **B.** With tracheal reconstructions supported by a Montgomery T-tube, the small HFV catheter can be passed from either the extraluminal limb or the proximal intraluminal trachea limb to the distal intraluminal tracheal limb and can be used to ventilate both lungs with HFV. **C.** With carinal procedures, one or two HFV catheters can be passed into one or both of the mainstem bronchi and can be used to ventilate one or both of the lungs with HFV.

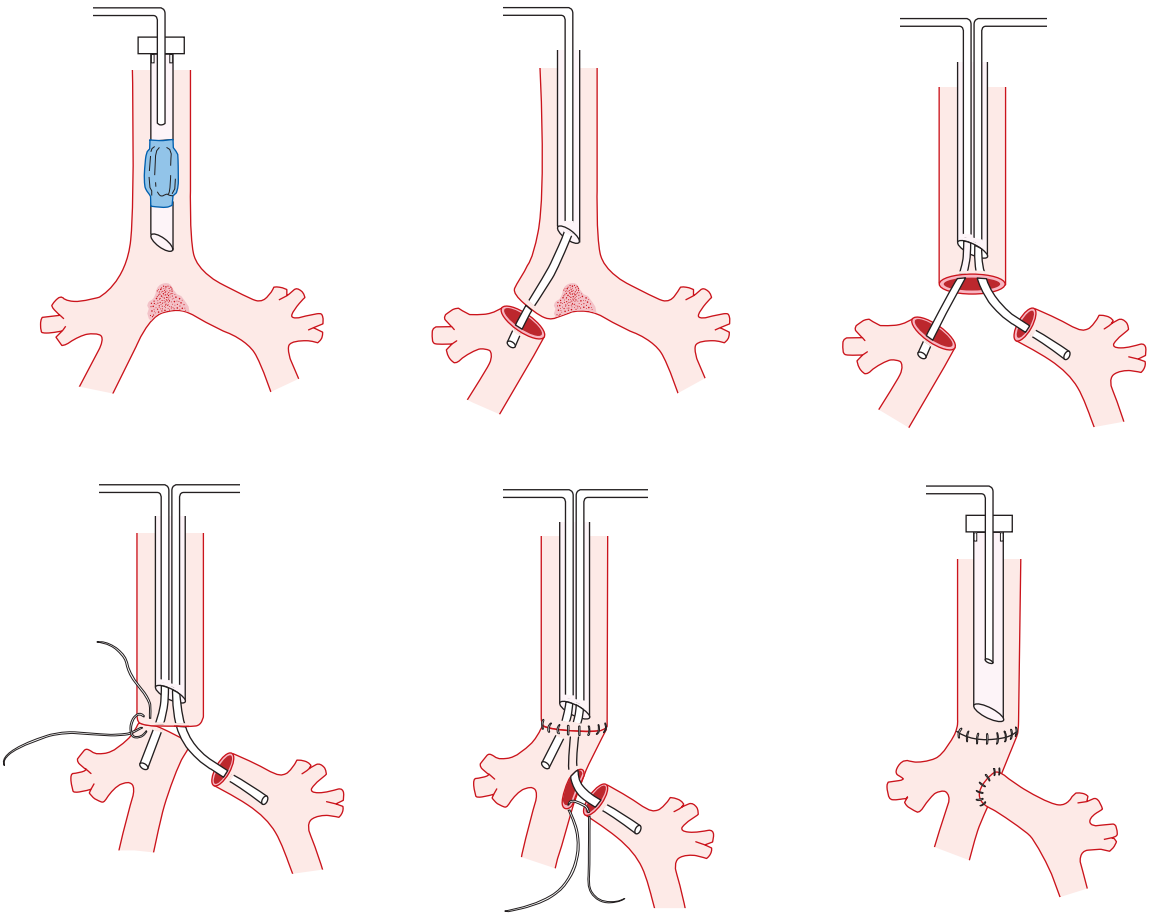

FIGURE 53–41. Arrangement of high-frequency jet ventilation (HFJV) catheters during the different phases of the operation. At the end of the right tracheobronchial anastomosis, the left catheter passes between two membranous sutures. It is then withdrawn and introduced into the left main bronchus via the bronchotomy of the right middle bronchus. (Modified from Crinquette et al.[272] with permission.)

guided by the surgeon into the left mainstem bronchus. The continuous outflow of gas through the open bronchus during HFPPV minimizes soiling with blood. Ventilation of the right lung with HFPPV via a thin catheter inside the right main bronchus eliminates the problem of right upper lobe collapse associated with the use of right-sided endobronchial tubes.

Carinal resection has been performed using two HFJVs and two catheters, one into each bronchus, to provide independent ventilation to both lungs (Fig. 53–41).[272] This is particularly advantageous when a large carinal tumor obstructs one or both bronchi, preventing delivery of adequate tidal volume to either lung. In this situation, a catheter is passed into one or both bronchi under fiberoptic bronchoscope guidance. The presence of even two HFJV catheters through the surgical field does not interfere with surgical exposure.

Patients with major tracheal stenosis may not accommodate an endotracheal tube large enough to permit adequate ventilation. Several solutions exist for this problem. First, a special long endotracheal tube that has a small internal diameter can be used; for example, a long 5-mm oral endotracheal tube may pass through the tracheal lesion. Ventilation of an adult through such a small endotracheal tube requires high proximal airway pressures and may not be effective. Second, HFPPV with a small catheter passed through the stenotic area can be used. The anesthesiologist should ensure enough space between the stenotic lesion and the catheter to allow for the adequate outflow of gas; otherwise, barotrauma will occur. Third, the surgeon first can perform laser resection of the stenotic lesion to increase airway diameter.

HFPPV facilitates tracheal reconstruction supported by a Montgomery tracheal T-tube.[276] The Montgomery tracheal T-tube is used as a stent to maintain the patency of the upper airway in patients with subglottic and upper tracheal stenosis. The intraluminal limb also maintains the circumference of the airway and supports the tissue graft applied during reconstruction of the larynx and cervical trachea. Because of the design and shape of the Montgomery endotracheal tube, establishing an adequate airway for administration of conventional mechanical ventilation is difficult. Use of the extraluminal limb as an airway for delivery of large tidal volumes is associated with a large gas leak through the open, upper intraluminal limb and around the uncuffed tracheal limb. This can be circumvented by two methods. Occlusion of the superior part of the intraluminal limb can decrease the air leak. The occlusion can be accomplished with a Fogarty embolectomy catheter or with a tight pharyngeal pack. Alternatively, the anesthesiologist can perform translaryngeal intubation of the upper intraluminal limb with a small cuffed endotracheal tube. Occlusion of the extraluminal limb then allows use of positive-pressure ventilation.[277]

HFPPV through a catheter with a 2-mm internal diameter can provide adequate alveolar ventilation and oxygenation during tracheal reconstruction with a tracheal T-tube. The T-tube and open trachea around it function as expiratory ports for the continuous outflow of gas. If the patient already has a tracheal T-tube in place before operation, translaryngeal intubation of the intraluminal limb and trachea can be easily accomplished with the small HFPPV catheter. Alternatively, the catheter can be introduced through the extraluminal limb and gently flexed to direct the catheter to lie above the carina.[274]

Differential lung ventilation with HFJV has been used in patients undergoing tracheobronchial reconstructive surgery, such as pneumonectomy, sleeve lobectomies, and tracheal reconstruction, who have compromised pulmonary reserve. For example, a patient undergoing a right upper sleeve lobectomy is ventilated through an endotracheal tube until resection of the right bronchus and the right upper lobe begins. The endotracheal tube then is advanced into the left mainstem bronchus, and unilateral intermittent positive-pressure ventilation is continued to the left lung. At the same time, HFJV is delivered to the right intermediate bronchus to ventilate the residual right, middle, and lower lobes and thereby maintain better oxygenation.

ANESTHESIA FOR PATIENTS UNDERGOING URGENT SURGERY

Anesthesia for Patients with Massive Hemoptysis

Therapeutic Approaches

Massive hemoptysis is an uncommon but life-threatening event that requires rapid management. Massive hemoptysis refers to bleeding that ranges from >200 mL during one episode to 1000 mL within 24 hours.[278–280] The most common associated diseases are tuberculosis, bronchiectasis, lung abscesses, and lung cancer (Box 53–12). The cause of hemoptysis is either direct invasion by infection or tumor into blood vessels or trauma (e.g., bleeding after use of a PA catheter). Patients at increased risk for perforation of the PA by a PA catheter include those with pulmonary hypertension, hypothermia, or coagulopathy.[281]

Death from hemoptysis usually results from asphyxia and rarely from exsanguination. The most effective way to stop bleeding from pulmonary sources is definitive pulmonary resection. The site of bleeding can be identified with either a rigid or a flexible bronchoscope. Rigid bronchoscopy is preferred because it provides more access for suctioning of blood and removal of clots. The endoscopist can perform therapeutic interventions by the administration of topical saline or vasoconstrictors, laser therapy, or placement of a balloon-tipped Fogarty catheter. Alternative management includes transcatheter embolization of the bronchial and intercostal arteries, but this risks embolization of the spinal cord via collateral circulation. Placement of a PA catheter under fluoroscopic guidance can be used in conjunction with other therapies to decrease bleeding by occluding the branch of the PA feeding the bleeding site.

Anesthetic Management

Management strategies are listed in Table 53–22. Patients with massive hemoptysis often are hemodynamically unstable as a result of hypovolemia and hypoxemia. They require resuscitation with a large-bore IV catheter for rapid infusion of fluids to restore cardiac preload, blood products to correct any coagulopathies, and vasoactive drugs. Time permitting, an arterial catheter should be placed for monitoring of blood pressure and arterial blood gases. One of the major goals is isolating the source of bleeding to prevent contamination of the healthy lung and prevent further hypoxia.

Patients with massive hemoptysis are at significant risk for aspiration. These patients should undergo either awake intubation or rapid sequence induction followed by tracheal intubation during cricoid pressure. Use of ketamine or etomidate for induction of anesthesia may be indicated because the patients are hypovolemic. Intubation may be complicated by blood in the airway, obscuring laryngeal structures. Suctioning may not provide adequate visualization. Air bubbles exiting the trachea may serve as the only guide to the site of the glottic orifice. Choice of endotracheal tube depends on the proposed management. Lung separation is best accomplished by placement of a left double-lumen endotracheal tube but may be technically difficult to accomplish in emergency situations. If bleeding originates from the left side, a single-lumen tube can be blindly advanced into the right mainstem bronchus. If bleeding originates from the right side, intubation of the left mainstem bronchus can be guided with the assistance of a fiberoptic bronchoscope.

If definitive surgical intervention is required, the patient is placed in a lateral decubitus position for resection of the bleeding lung segment. Placement of the bleeding lung in a nondependent position mandates complete separation of the lungs to prevent soilage of the dependent nonbleeding lung. Suctioning of the tracheobronchial tree improves ventilation and oxygenation of the dependent nonbleeding lung. At the end of operation, the double-lumen endotracheal tube should be left in place, and the patient should be mechanically ventilated. Patients should be observed for recurrent bleeding and impaired oxygen exchange during the early postoperative period.

BOX 53–12.

Causes of Massive Hemoptysis

- Infection
  - Tuberculosis
  - Bronchiectasis
  - Bronchitis
  - Lung abscess
  - Necrotizing pneumonia
- Neoplasm
  - Bronchogenic carcinoma
  - Metastatic carcinoma
  - Mediastinal tumor
  - Endobronchial polyp
- Cardiovascular disease
  - Mitral stenosis
  - Pulmonary arteriovenous malformation
  - Pulmonary embolus
  - Pulmonary vasculitis
- Miscellaneous causes
  - Pulmonary artery catheterization
  - Exploratory needling
  - Cystic fibrosis
  - Pulmonary contusion, laceration
  - Reperfusion of pulmonary vasculature after pulmonary embolectomy and after cardiopulmonary bypass

TABLE 53–22.

Anesthetic Guidelines for Patients with Massive Hemoptysis

Indication	Hemoptysis
Monitors	Standard monitors, arterial catheter
Anesthesia	General anesthesia
Additional equipment	Shoulder roll or bean bag
Ventilation	Double-lumen endotracheal tube (if possible)
Position	Lateral decubitus, supine
Incision	Thoracotomy, median sternotomy
Unique considerations	Frequently hypoxic; "full stomach" precautions, hypotensive, tachycardic
	Infectious precautions
	Type and cross for blood products
	Check coagulation status
Intraoperative complications	Hypoxia
	Hypotension
	Hemorrhage
	Dysrhythmia
	Syndrome of inappropriate antidiuretic hormone secretion
	Possibility of extensive lung resection
Blood loss	Variable >500 mL
Analgesia	Epidural thoractomy
Postoperative morbidity	Respiratory insufficiency
	Aspiration pneumonia
	Hemoptysis
	Acute respiratory distress syndrome
	Hypoxia
Postoperative care	Chest radiography
	Monitor in intensive care environment

Anesthesia for Patients Undergoing Removal of Foreign Body from the Airways

Aspiration of foreign bodies is a common problem, particularly in children, and is associated with considerable morbidity and mortality.[166] In adults, acute alcoholism, dementia, bulbar muscle dysfunction, and history of aspiration are common predisposing factors.[166,282,283] The location of the aspirated object depends on the patient's posture at the time of aspiration. The right lung most often is involved because the axis of the right mainstem bronchus is more in line with the trachea. If the patient is upright at the time of aspiration, the right lower lobe most frequently is affected. The right upper lobe most often is involved in patients in the supine position.

More than 80% of aspirated foreign bodies are organic material. Organic material, particularly peanuts and other nuts, produce severe mucosal irritation and swelling around the foreign body. The clinical sequelae of foreign body aspiration include acute airway obstruction, atelectasis, inflammation, pneumonia, and abscess formation (Fig. 53–42). The foreign body may act as a one-way valve, resulting in air trapping and regional hyperinflation.

Clinical Features and Diagnosis

Acute signs and symptoms of aspiration include cough, wheezing, dyspnea, stridor, fever, cyanosis, and hemoptysis. Alternatively, the patient may have a history of recurrent or intractable pneumonia, unexplained atelectasis, or emphysema.[166,283] Physical examination may reveal unilateral decreased air entry, unilateral localized wheezing, or aphonia.[166,283,284] Most foreign bodies are radiolucent but are associated with an abnormal chest radiograph. Findings may include atelectasis, localized hyperinflation, pneumonia, and mediastinal shift.[282]

Therapeutic Approach

The urgency of proceeding to bronchoscopy is dictated by the severity of the patient's respiratory distress. Objects located in the larynx or proximal trachea cause considerably more distress and are associated with greater mortality than objects lodged more peripherally.[285] Foreign bodies typically are removed within the first 24 hours to avoid dislodging them into a more critical position and to decrease the incidence of secondary pneumonia. If possible, removal should be delayed long enough to allow for gastric emptying and patient preparation. Use of bronchodilators, postural drainage, and chest physiotherapy to dislodge and expel the foreign body is contraindicated. These procedures occasionally result in total airway obstruction and cardiac arrest and are no longer recommended.[286,287]

Bronchoscopy for removal of the foreign body is successful in approximately 95% of cases but may need to be repeated because the foreign body either was not found initially or was incompletely removed.[286,287] Fluoroscopic guidance during bronchoscopy can aid in the removal of small radiopaque objects.[288] Rarely, thoracotomy is necessary for retrieval of the foreign body.

Anesthetic Management

Anesthetic management depends on the patient's age, presence of a full stomach, severity of respiratory distress, and location of the foreign body. All patients should be premedicated with an anticholinergic to decrease airway secretions, H_2-recepter antagonists to decrease gastric acid secretion, and metoclopramide to promote gastric emptying (Table 53–23). The endoscopist should be prepared for immediate rigid bronchoscopy in case of total airway obstruction.

Adults receive preoxygenation, IV induction, and direct laryngoscopy. A technique of IV anesthesia would address the concerns of providing adequate doses of inhaled agents. A foreign body located in the larynx often can be removed during direct laryngoscopy, and the patient is allowed to emerge from anesthesia. A foreign body in the trachea or the bronchus requires rigid or fiberoptic bronchoscopy for removal. When a rigid bronchoscope is introduced into the airway, its ventilating side arm is attached to the anesthesia circuit to provide O_2 and inhaled anesthesia. Use of a helium–O_2 mixture can be helpful in patients with partial airway obstruction because the decreased density of the inhaled mixture decreases turbulence and improves flow

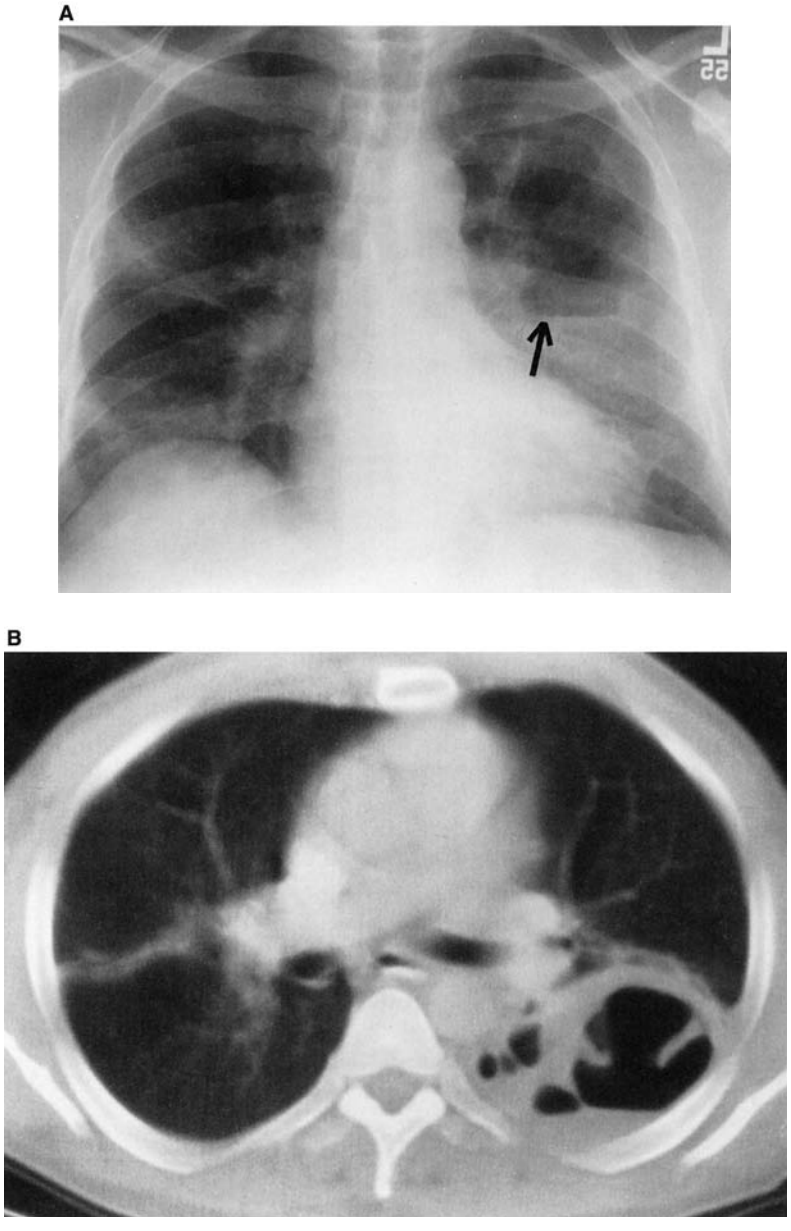

FIGURE 53–42. Aspiration pneumonia in 58-year-old man with a history of alcohol abuse progressed to a suppurative cavitary lesion. The patient presented with progressive shortness of breath, fevers, and foul-smelling sputum. **A.** Chest radiograph shows cavitary lesion with an air–fluid level in the left lung and several pneumonic infiltrates in the right lung. **B.** Chest CT shows a large cavitation in the left lower lobe, consistent with the diagnosis of abscess or tumor. The patient subsequently underwent pulmonary resection that required placement of a double-lumen endotracheal tube to prevent soilage of the contralateral lung.

across the stenotic airway. The maximal effect is obtained with a helium–O_2 mixture of 80% helium and 20% O_2, but helium also is therapeutic when used in lesser concentrations. After the trachea is intubated, a large-bore nasal or oral gastric tube is inserted into the stomach, and the gastric contents are thoroughly suctioned.

Children are more difficult to manage because of their small airway, which makes them more susceptible to major airway obstruction. In children with severe respiratory distress, the risks of total airway obstruction that can occur during rapid sequence induction should be weighed against the risk of aspiration during a slow inhalation induction with spontaneous ventilation. Attempting to place an IV catheter before induction can trigger violent struggling, straining, and crying and can precipitate total airway obstruction. A gentle inhalation induction, using cricoid pressure, can be used even in children with a full stomach. In the absence of IV access, intramuscular ketamine can be used for induction. As soon as the child becomes sleepy, cricoid pressure is applied, and inhalation of anesthetic agents is started while continuing spontaneous ventilation.

If the patient is minimally symptomatic with no serious respiratory distress and if the foreign body is thought to be peripherally located, the anesthesiologist can wait 6–8 hours before bronchoscopy, although some surgeons or endoscopists do not agree with this approach and prefer to proceed immediately to prevent a local inflammatory reaction to the foreign body. In the absence of a full stomach and if symptoms are minimal, the child can be heavily premedicated to facilitate a smooth inhalation induction. Spontaneous ventilation can facilitate detection of airway obstruction and prevents distal migration of the foreign body caused by positive-pressure ventilation. When using a rigid bronchoscope, many anesthesiologists administer muscle relaxants to prevent airway trauma induced by patient movement.

Some objects, such as beads, are hard to grip and may slip during removal, resulting in occlusion more proximally. The object should then be pushed back to its original location to allow adequate ventilation. Multiple instrumentations of the airway may produce mucosal edema and respiratory distress postoperatively. Therapy includes administration of steroids (dexamethasone 0.5–1.5 mg/kg), humidification of inspired gases, nebulized racemic epinephrine, and initiation of broad-spectrum antibiotic therapy.

Anesthesia for Patients Undergoing Endoscopy for Ingested Foreign Bodies

The incidence of ingested foreign bodies in the hypopharynx or esophagus in young children is as common as for aspirations in the airway. Coins and fish bones are the most frequent foreign bodies in the esophagus. Most foreign bodies initially cause laryngeal irritation, coughing, or choking. Subsequent signs and symptoms include refusal to eat, increased salivation, pain or discomfort during swallowing, and vomiting.

The anesthesiologist should determine the nature and location of the foreign body. Lateral neck radiographs should be obtained to determine the

TABLE 53–23.

Anesthetic Guidelines for Retrieval of Foreign Body

Indication	Aspiration of foreign body
Monitors	Standard monitors
Anesthesia	Pediatric (general anesthesia)
	Adult (awake sedated, general anesthesia)
Additional equipment	Fiberoptic bronchoscope
	Rigid bronchoscope
Ventilation	Usually try to maintain spontaneous ventilation
	Controlled ventilation may be appropriate if mass is distal in tracheobronchial tree
Position	Seated or semirecumbent (positioned to optimize respiratory status)
Unique considerations	Respiratory status
	Sedation as tolerated
	Antisialagogue
	Precautions for "full stomach"
	H_2-blocker, metoclopramide, cricoid pressure
	Anesthetize airway for awake, sedated approach
	Availability of additional support personnel
	Place gastric tube to empty stomach after airway is secured
Complications	Loss of airway
	Hypoxia
	Cardiac arrest
	Aspiration
	Hemoptysis
	Soilage from contents distal to obstruction
Postoperative morbidity	Hemoptysis
	Postoperative edema (steroids, raise head of bed)
	Bronchospasm (racemic epinephrine, bronchodilators)
	Pneumonia
	Atelectasis
Postoperative care	Observe in monitored environment
	Aggressive pulmonary toilet, physical therapy
	Supplemental O_2
	Chest radiography

extent of impingement on the airway. In the absence of respiratory distress or airway compression, the anesthesiologist should consider waiting 4–8 hours for gastric emptying.[289] The child then is sedated, and anesthesia is induced with either inhalational or IV anesthetic agents. Emergency endoscopy should be performed in patients with respiratory distress and airway compression. In spontaneously ventilated patients, preoperative sedation is omitted, and general anesthesia is induced. For patients with foreign bodies located in the hypopharynx or upper esophagus, cricoid pressure is contraindicated. The endotracheal tube size chosen should be slightly smaller than usual to facilitate endoscopy and decrease subsequent subglottic swelling.[289] In addition, a prophylactic dose of dexamethasone (0.5–1.0 mg/kg) can be given to decrease laryngeal edema.

A foreign body that is located high in the esophagus may dislodge into the larynx and produce an airway obstruction. Therefore, children with high esophageal foreign bodies should be heavily sedated, IV access obtained, and anesthesia induced. In the absence of major airway compression, an IV induction with muscle relaxants can be used.

ANESTHESIA FOR PATIENTS WITH ZENKER DIVERTICULUM

Clinical Features

Zenker diverticulum is an outpouching of the pharyngeal mucosa between the inferior constrictor muscles of the pharynx, the thyropharyngeus, and the cricopharyngeus muscles. The etiology is believed to be dysfunction or spasm of the cricopharyngeus muscle. Patients complain of food sticking in the throat, difficulty swallowing, noisy swallowing, regurgitation of food, and bouts of coughing when lying supine. Neck radiographs may reveal a collection of air anterior to C5 and C6, but diagnosis is confirmed with a barium swallow. Physical examination may reveal a compressible swelling as the sac enlarges. Patients usually are elderly, malnourished,[290] debilitated with coexisting cardiac and respiratory diseases, and susceptible to recurrent pneumonias and lung abscesses from aspiration. Symptomatic lesions are managed by surgical resection.

Intraoperative Management

Oral premedications are not suitable because tablets may lodge in the pouch or be aspirated into the lungs.[291] The risk of regurgitation and aspiration of diverticular contents into the lungs during the immediate preoperative and intraoperative periods is a major concern for the anesthesiologist. The contents of the pouch usually have an alkaline pH and therefore are unlikely to benefit from H_2-receptor antagonists, antacids, or metoclopramide. Regurgitation and aspiration may occur even after successful tracheal intubation because of seepage of fluid around the endotracheal tube cuff during surgical manipulation. Measures to decrease the risk of aspiration during anesthesia include fasting overnight, preoperative emptying of the pouch by manual external pressure, and tilting the head of the bed upward 10–30°.

Awake intubation is an option, but coughing and straining may result in regurgitation and aspiration. The risk of aspiration may be increased by topical anesthesia and sedation, which blunt airway reflexes. Therefore, some authors advise against awake intubation.[292] Use of topical anesthesia should be limited to either the supraglottic or infraglottic part of the airway, leaving part of the airway responsive as a protection against aspiration.

Use of cricoid pressure may precipitate aspiration. Careful preoperative examination of the barium swallow image may help determine whether cricoid pressure will be beneficial or harmful by defining the size and location of the pouch. If the sac is large, extending

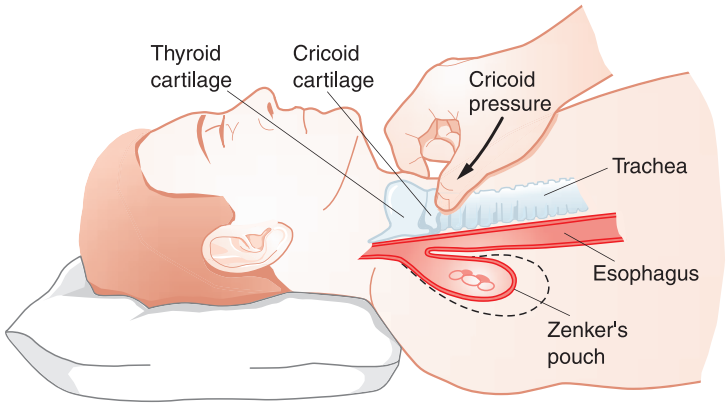

FIGURE 53–43. Zenker pouch in the hypopharynx, with the opening at the level of cricoid cartilage. (From Thiagarajah S, Lear E, Keh M. Anesthetic implications of Zenker's diverticulum. Anesth Analg 1990;70:709, with permission.)

down into the mediastinum with its orifice at the level of the cricoid cartilage, cricoid pressure should obliterate the opening and protect against regurgitation. If the sac is small and the opening is cephalad to the cricoid cartilage, application of cricoid pressure may actually squeeze the sac, resulting in regurgitation of its contents into the hypopharynx (Fig. 53–43).

The preferred approach is a smooth induction with a 30° upward head tilt and avoidance of coughing, bucking, and straining. The combination of IV hypnotics (i.e., thiopental or etomidate) supplemented with opioids and lidocaine and slow, gentle manual mask ventilation should result in a smooth uneventful induction. A nondepolarizing muscle relaxant is administered, and endotracheal intubation is performed after complete relaxation has been achieved. The pharynx around the endotracheal tube can be packed with gauze to prevent seepage of the contents of the diverticulum into the hypopharynx with collection above the endotracheal tube cuff. Surgical access usually is through a cervical incision. A large diverticulum may extend into the mediastinum. Great care and gentleness should be exercised when inserting a nasogastric tube because of the potential for perforation of the diverticulum. Likewise in patients with a difficult airway, blind attempts at intubation of the trachea risk perforating the pouch. Perforation of the diverticulum results in mediastinitis and sepsis. Other complications include air embolism if major vessels are opened during the dissection or bradycardia and hypotension resulting from stimulation of baroreceptors during retraction near the carotid bifurcation.

An alternative is to perform the procedure during regional anesthesia using deep and superficial cervical plexus blocks. Adams[293] describes the use of this approach in 58 patients undergoing repair of a Zenker diverticulum. The risk of aspiration is minimized by preserving protective airway reflexes. Provided the block is limited to one side, the awake, sedated patient is able to cooperate with the surgeon and can swallow on command, allowing the surgeon to view the pathology and assess the adequacy of repair.

COMPLICATIONS OF THORACIC SURGERY AND THEIR MANAGEMENT STRATEGIES

The postoperative complications of thoracic surgery can be characterized as pulmonary, hemodynamic, neurologic, or miscellaneous (Box 53–13). Some of these complications are medical and surgical emergencies that require prompt diagnosis and management. Conditions requiring emergent intervention include pneumothorax, pulmonary edema, torsion of a residual lobe, herniation of the heart, malignant arrhythmias, and major hemorrhage. Early diagnosis and efficient management depend on the cooperative efforts of the anesthesia, surgical, and nursing staff. In the following section, the order of presentation is based on the system involved and the severity of symptoms.

Hemodynamic

Herniation of the Heart

Cardiac herniation is a rare and rapidly fatal injury if not immediately diagnosed and managed. This complication occurs more often after right pneumonectomy in which the pericardium was opened to gain better access to the pulmonary vessels. It may occur after the creation of a pericardial window for management of a pericardial effusion. This complication has been associated with changing of patient position (from lateral decubitus to supine position or placement of the operative lung in the dependent position) or a differential change in intrapleural pressures caused by suctioning of the chest tube after pneumonectomy or vigorous coughing.[294,295]

The clinical features of cardiac herniation include acute cardiovascular collapse, evidence of superior vena cava obstruction (distension of neck veins, facial flushing, edema), altered axis of ECG, bulging of cardiac silhouette, and unusual positioning of PA catheter on chest radiograph. Differential diagnosis includes tension pneumothorax, cardiac tamponade, dysrhythmia, pulmonary emboli, and massive hemorrhage. These patients require immediate operation, but they may be stabilized by placing them in a

  - Paradoxical embolization
  - Spinal cord
- Miscellaneous
  - Alopecia
  - Necrosis ear, nose
  - Infection

lateral position with the operated lung in the nondependent position.[296,297] Even if the heart does not fall back into its normal position, repositioning may relieve aortocaval kinking and increase cardiac output. The tidal volume should be decreased and use of PEEP discontinued to decrease any mediastinal shift. Suctioning of the chest tubes should be discontinued, and injection of air to counter cardiac herniation should be considered.

Definitive management requires that the thorax be reexplored and pericardial defect repaired by primary closure, autograft, or prosthetic material.[298] Anesthesia should be induced with either ketamine or etomidate and a muscle relaxant. To decrease mediastinal shift, the lungs should be ventilated with small tidal volumes.

Cardiac Dysrhythmias

Supraventricular dysrhythmias, primarily sinus tachycardia and atrial fibrillation or flutter, which occur after thoracic surgery are associated with increased postoperative morbidity. Significant risk factors include male sex, advanced age, history of congestive heart failure or arrhythmias, and type of surgery (pneumonectomy > bilobectomy > lobectomy > esophagectomy > resection of mediastinal tumor or thymectomy).[299,300] Manipulation of the pulmonary veins, a major nidus for atrial fibrillation, is thought to be a significant factor.[301] Other potential causes are retraction and trauma of the heart (intrapericardial dissection), increased sympathetic tone related to inadequate postoperative analgesia, and postoperative respiratory or metabolic imbalance (hypoxia, hypercapnia, respiratory acidosis, electrolyte imbalances). Whereas use of digitalis for thoracic surgery is not supported by clinical trials, calcium channel blockers and β-blockers are effective in reducing postoperative atrial tachyarrhythmias.[302] However, the use of such medications should be individualized to account for the possible adverse consequences of β-blocker use in this patient population. Interestingly, the preoperative use of statins has also been associated with a protective effect against postoperative atrial fibrillation, but its mechanism has not been elucidated.[303]

Right Ventricular Failure

The postoperative course after anatomic pulmonary resection may be complicated by right ventricular failure and acute cor pulmonale. Decreases in the vascular cross-sectional area caused by pulmonary resection increase PVR and right ventricular afterload. Preoperative right-heart catheterization or echocardiography may predict patients at risk for this postoperative complication. Operative risk is increased if PVR is >190 dynes/sec/cm^5 or if PA pressure increases by >40 mm Hg in response to balloon occlusion. In addition, hypercapnia, acidosis, and increases in airway pressure may increase the risk for developing right-heart failure. Patients with right-heart failure have distended neck veins, peripheral edema, and new onset of atrial dysrhythmias. Echocardiography can be used to differentiate right-heart failure from cardiac tamponade. Increased right-heart volume and ventricular dysfunction can lead to a shift of the intraventricular septum and impede left ventricular filling and function. A decrease in left ventricular preload caused by increased PVR and abnormal septal wall motion will result in decreased cardiac output and peripheral perfusion pressure. Patients who have chronic right-sided heart failure with right ventricular hypertrophy may be at increased risk for developing myocardial ischemia and dysfunction related to decreased coronary perfusion. Increased oxygen demand related to wall stress and decreased coronary perfusion resulting from decreased cardiac output and hypotension may exacerbate preexisting right ventricular dysfunction.

The treatment strategies for patients having right ventricular failure differ from those used for patients with primary left ventricular dysfunction. Volume expansion in patients with increased PVR will increase wall stress and further exacerbate right ventricular dysfunction. The management goals are to improve right ventricular function by decreasing PVR, increasing myocardial contractility, and maintaining coronary perfusion. Vasodilating agents, such as milrinone, prostacyclin, NO, and nitroglycerin, have been used to decrease PVR. Often agents such as dobutamine or milrinone are chosen for their combined inotropic and vasodilator properties. In patients with decreased systemic blood pressure and inadequate coronary perfusion, vasopressors such as epinephrine, dopamine, phenylephrine, or norepinephrine can be added to enhance coronary perfusion.

Intracardiac Shunting

The incidence of a probe patent foramen ovale is approximately 25% in adults. During normal conditions, right-to-left shunt across the atrial septal defect is negligible because the left atrial pressure exceeds that of the right. If the gradient between the right atrium and left atrium is reversed, oxygenated blood can flow from right to left, resulting in paradoxical embolization and hypoxia. The reversal of atrial pressures can occur during conditions of increased peripheral vascular resistance related to use of PEEP or during the occurrence of pulmonary emboli, pulmonary hypertension, valvular stenosis, ARDS, or even coughing. Reversal of pressures may occur after pneumonectomy or lobectomy.[304–306] The occurrence of intracardiac shunt should be suspected in patients with unexplained postoperative dyspnea and systemic oxygen desaturation. Transesophageal echocardiography can confirm the diagnosis and visualize the atrial septal defect.

Management goals are to decrease shunt flow by decreasing right-sided pressures and PVR. Initial management should involve correction of hypoxia, hypercapnia, acidosis, and increased sympathetic tone related to inadequate postoperative analgesia. Administration of pulmonary vasodilators and preload reduction can be used to decrease right-heart pressures. Use of PEEP should be avoided if possible in patients who are mechanically ventilated. When conservative measures fail, open surgical or percutaneous closure of the atrial septal defect may be necessary. Because the presence of an intracardiac shunt predisposes to paradoxical embolization, all IV solutions should be rigorously free of air bubbles, and blood products should be administered through filters to exclude particulate matter.

Major Hemorrhage

Postoperative bleeding that requires surgical intervention is uncommon. The postoperative findings are those of hypovolemia (tachycardia, hypotension, respiratory variation, absence of jugular venous distension). Most major hemorrhage results from slippage of ligatures around major pulmonary vessels. Bleeding from raw pleural surfac-

es is likely when vascular adhesions between the visceral and parietal pleura have been divided. Other sites of potential bleeding include the bronchial and intercostal arteries. Although chest tube drainage is an indicator of the extent of bleeding, the absence of chest tube drainage does not rule out major hemorrhage. Chest tubes may be malpositioned or occluded by clot, thus hiding the resulting hemothorax. If suspected, repositioning the patient and obtaining a chest radiography will confirm the presence of serious pleural effusion with blood.

Pulmonary

Pneumothorax

Pneumothoraces are common complications occurring intraoperatively and postoperatively. The presence of a large pneumothorax is a medical emergency. Clinical signs and symptoms include respiratory distress, decreased breath sounds unilaterally, increased airway pressure with decreased chest compliance, and decreased arterial oxygen saturation. Pneumothorax can expand to the point of tension pneumothorax, which is characterized by hypotension, tracheal shift, and cardiovascular collapse. If sufficient time is available, a chest radiograph is obtained to confirm diagnosis.

Management entails placement of a chest tube for evacuation of intrapleural air. In a spontaneously ventilating patient, the indications for chest tube placement are pneumothorax occupying at least 15% of the hemithorax or the presence of symptoms. Because mechanically ventilated patients are at risk for increasing size of the pneumothorax, they usually require placement of a chest tube. In emergency situations, decompression of the hemothorax can be accomplished by placement of a 14-gauge IV catheter into the second intercostal space in the anterior axillary line.

Torsion of Residual Lobe

Pulmonary torsion refers to lung rotation on its bronchovascular pedicle. If uncorrected, it will result in pulmonary infarction. Patients undergoing lung resection are at increased risk for torsion of the remaining lobe. The right middle lobe and lingula are at greatest risk for torsion after right upper or left upper lobectomy.[307] Chest radiograph reveals an area of atelectasis or an expanding intrathoracic mass. If suspected, bronchoscopy should be performed, followed by immediate surgical reexploration. A double-lumen endotracheal tube should be placed to allow for complete pneumonectomy or untwisting of the rotated bronchial vascular pedicle.

Postoperative Respiratory Failure

The risks of postoperative respiratory dysfunction increase as the incidence of coexisting disease increases and the economic pressure to extubate and streamline the postoperative period continues to grow. Patients with chronic lung disease have an increased incidence of pulmonary complications. The increase in risk is related to the decrement in preoperative pulmonary function. The postoperative respiratory complications associated with smoking may be reduced with cessation of smoking at least 8 weeks before operation.[308,309]

The importance of factors such as age, obesity, and malnutrition are less clear. Advanced age alone does not appear to be a risk factor, but it may be a confounding variable. Respiratory mechanics and pulmonary functions are altered in obese patients.[310,311] The accumulation of fat in respiratory structures reduces compliance and increases the work of breathing. Although obesity may influence the risk of postoperative pulmonary complications, its importance is minor except in morbidly obese patients. Malnutrition is not a major risk factor for postoperative pulmonary complications, although it impairs immunity, decreases diaphragmatic muscle function, and diminishes the ventilation response to hypoxia.[312] Even though aggressive nutritional support improves biochemical parameters, it has not been shown to improve pulmonary function.[313,314]

Pulmonary Edema

Pulmonary edema occurs because of altered balance of the Starling forces, resulting in a net movement of fluid into the interstitial space. Risk factors for pulmonary edema include cardiac, pulmonary, and anatomic reasons.

Pneumonectomy or reexpansion of atelectatic lung is associated with postoperative pulmonary edema. The etiology of these complications most likely is multifactorial and involves changes in hydrostatic pressure, oncotic pressure, cardiac output, and vascular permeability. Reexpansion pulmonary edema is unilateral and follows the reinflation of atelectatic lungs caused by removal of effusions, evacuation of a pneumothorax, or reinflation after use of a double-lumen endotracheal tube.[315,316] This type of edema has been related to increased vascular permeability caused by an inflammatory reaction to the endothelium and mechanical changes to the blood vessels.[317,318] To avoid mechanical damage caused by excess stretching and increased pressure gradients, the lung should be expanded slowly and gradually.[319] The factors associated with postoperative pulmonary edema are more complicated. Postpneumonectomy pulmonary edema has been commonly attributed to increased cardiac output and fluid overload. Pneumonectomy dramatically decreases the cross-sectional area of the vascular bed, increasing hydrostatic pressure. During normal conditions, the vascular bed can accommodate the increased flow without dramatic increase in pulmonary arterial pressure, although the presence of preexisting cardiac disease combined with aggressive fluid replacement and reduction of lymphatic drainage may predispose to the transudation of edema fluid. More recently, it has been recognized that a change in permeability is a major contributing factor to edema after pneumonectomy.[319] Occurrence of acute reexpansion pulmonary edema can be severe and result in mortality.[316] Patients become tachypneic, tachycardic, and hypoxic. These patients often remain intubated and require postoperative ventilatory support. Therapy is generally supportive. Mechanical ventilation with PEEP, diuresis, and hemodynamic support may be appropriate.[320] Patient positioning may be therapeutic when pulmonary edema is unilateral. Lateral decubitus positioning with the affected side up will reduce intrapulmonary shunting and improve oxygenation.[321]

Neurologic Injuries

Phrenic Nerve Injury

The phrenic nerve originates from C3, C4, and C5, passing into the chest anterior to the hilum of the lung within the pericardium. It is susceptible to damage during median sternotomy or thoracotomy. Phrenic nerve injury manifests as respiratory failure or failure to wean from mechanical ventilation. Diagnostic tests include chest radiography and fluoroscopic examination of diaphragmatic movement. Chest radiography shows a clear lung with an elevated hemidiaphragm, whereas fluo-

roscopy documents paradoxical movement of the diaphragm during inspiration. Most patients with normal lung function can tolerate unilateral phrenic nerve injury, although patients with preexisting lung disease or those who have undergone extensive pulmonary resection may be debilitated. If lung function does not return within 2–9 months, alternative therapies, including diaphragmatic pacing and diaphragmatic plication, can be considered.

Recurrent Laryngeal Nerve Injury

The left recurrent laryngeal nerve is susceptible to injury during hilar dissection and mediastinoscopy. Unilateral laryngeal nerve injury usually is asymptomatic or manifests as hoarseness of voice, although bilateral nerve injury can result in apposition of the vocal cords and inspiratory obstruction requiring emergent reintubation of the trachea. If vocal cord function does not return after several months, the involved vocal cord can be injected with Teflon to improve its function.

Spinal Cord Injury

Spinal cord injury is a rare complication after thoracic surgery.[322] The mechanisms of injury include nerve compression and vascular ischemia. Epidural hematomas and nerve compression can result from placement of epidural catheters or from surgical bleeding into the epidural space. Disruption of the major intercostal artery supplying the anterior spinal artery can result in anterior spinal artery syndrome, leading to paralysis.

Brachial Plexus Injury

The brachial plexus is susceptible to injury caused by surgical trauma and indirectly caused by positioning.[323] Stretch injury of the plexus can occur with extreme abduction, external rotation, and dorsal extension of the arm (for further discussion, see Chap. 26).

POSTOPERATIVE PAIN MANAGEMENT

The pain that accompanies thoracic surgery is notable for its intensity and duration. Acutely, moderate to severe levels of pain may not decrease substantially over the course of hospitalization and the first postoperative month.[324] Noxious input associated with thoracic surgery is conveyed to the CNS along the intercostal, vagus, and phrenic nerves. Afferent phrenic activity is believed to be the source of the shoulder pain that frequently accompanies thoracic procedures because this is curtailed by phrenic[325] but not suprascapular or epidural blockade.[326] Intercostal nerve dysfunction resulting from incision, retraction, trocar placement, or suture is common[327] and likely plays a significant role in the pain accompanying thoracic surgery. Although used with increasing frequency, thoracoscopic approaches have not had the favorable impact on pain that many had anticipated.[328,329]

Postoperative pain control is one of the most important management goals for preventing postoperative respiratory complications. Inadequate pain control leads to shallow respirations, tachypnea, inability to cough effectively, retention of secretions, and atelectasis. These symptoms contribute to postoperative hypoxia, hypercapnia, and respiratory failure in postthoracotomy patients. Effective postoperative pain management decreases these deleterious effects. We are strong advocates of epidural analgesia using local anesthetic and opioid that is initiated intraoperatively and continued postoperatively. This therapy can be supplemented with NSAIDs, acetaminophen, α_2-adrenergic agonists, and ketamine. Other options are patient-controlled analgesia, intercostal nerve blocks, cryoanalgesia, intrapleural catheters, and paravertebral block.

Intercostal Nerve Block

Intercostal nerve block is an effective technique to provide postoperative analgesia without central respiratory depression and to attenuate the decrease in pulmonary function after thoracic surgery.[330] Postthoracotomy pain is not completely managed with intercostal analgesia; it requires supplemental use of parenteral opioids or NSAIDs. Complications of this technique are few but include pneumothorax, local anesthetic toxicity, and neuroaxonal spread of local anesthetics that can result in unintentional hypotension.[83,331]

Intercostal nerve block can be performed intraoperatively by intrathoracic injection or percutaneously by the anesthesiologist. Nerve blocks are performed at the levels above and below the site of chest tube insertion and incision (Fig. 53–44). Nerve blocks are performed by injection of 2–3 mL of bupivacaine 0.5% with epinephrine (1:200,000 concentration). Because the average duration of these nerve blocks is 4–8 hours, placement of indwelling catheters in the intercostal space is used to provide analgesia up to 6 days.

A variation in providing postoperative intercostal analgesia is cryogenic analgesia. The efficacy of this technique is debatable compared with epidural or IV anesthesia.[138,332] Problems associated with cryoanalgesia of the intercostal nerves include long-term neuralgias, prolonged paresthesia, dysesthesias, and loss of intercostal muscle tone. Another possible option is paravertebral analgesia, which is a variation of intercostal nerve block.

Thoracic Paravertebral Block

An alternate method for achieving multiple intercostal nerve blockade is placement of a thoracic paravertebral block, either by single injection or continuous catheter.[333,334] Unilateral analgesia is achieved by depositing local anesthetic in the paravertebral space, which is the locus of the primary ramus of the intercostal nerve. Although this technique avoids some of the disadvantages of intrapleural analgesia, such as loss through chest tube and risk of rapid absorption, it has not gained widespread popularity. No studies to date have documented an improvement in respiratory function equal to or exceeding that reported with use of epidural analgesia.

Epidural Anesthesia

Epidural anesthesia is commonly used for management of postthoracotomy pain and has potential benefits for the pulmonary and cardiovascular systems.[335–337] Surprisingly, VATS is associated with postoperative pain and a prevalence of chronic pain comparable to that of open procedures, with rates of pain ranging from 22–63%,[328,329] which probably due to intercostal nerve and muscle damage from trocar insertion. Consequently, epidural analgesia is strongly recommended for patients undergoing VATS who are deemed high risk during preoperative evaluation.

Epidural analgesia lessens the postoperative reduction in pulmonary function (FVC, FEV_1, peak exploratory flow rate) and improves arterial oxygenation compared with use of parenteral opioids. In addition, administration of epidural opioids attenuates postoperative sympathetic stimulation and conse-

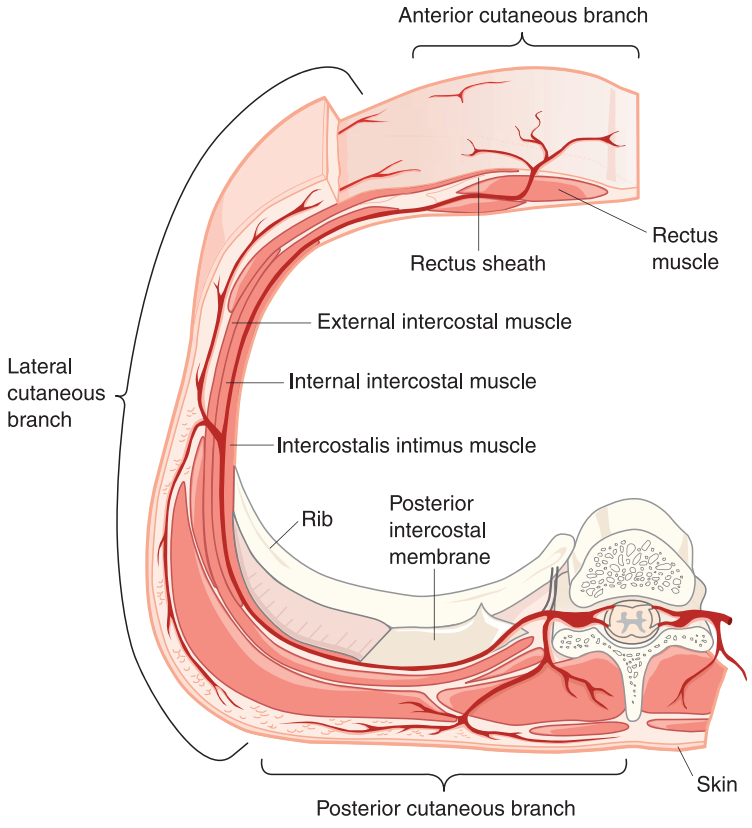

FIGURE 53–44. Intercostal nerve and its branches, and approximate area of skin supplied by the branches. There is evidence that local anesthetic injected near the lateral cutaneous branch diffuses posteriorly to reach the posterior cutaneous branch. Note also the spinal nerves and dorsal root ganglia in the region of intervertebral foramen, with risk of perineural spread into spinal fluid after intraneural injection in this region. Direct injection into an intervertebral foramen may reach spinal fluid by means of a dural cuff. Local anesthetic may gain access to epidural space by diffusing into an intervertebral foramen. Close to the midline, the intercostal nerve lies directly on the posterior intercostal membrane and pleura. (From Cousins MJ, Bindenbough PO, eds. Neural Blockade. 2nd ed. Philadelphia: JB Lippincott, 1988, pg. 247, with permission.)

quent hypertension and tachycardia.[338] Use of local anesthetics may be cardioprotective by producing sympathetic blockade, resulting in vasodilatation of epicardial vessels, improving left ventricular function during ischemia, and decreasing adrenergic outflow.[141] Animal studies that evaluated the effects of thoracic epidural analgesia have shown a lessening of myocardial ischemia and a reduction in the area of infarction.[339]

Effective postoperative analgesia can be obtained by placing the epidural catheter in either the thoracic or lumbar regions.[340–345] The efficacy of the site of epidural opioid administration may depend in part on the hydrophobicity of the opioid. Some investigators have proposed that epidural administration of lipophilic opioids produces analgesia predominantly by systemic absorption and not at the level of the spinal cord.[335,345]

It is the clinical practice in many institutions to combine the use of epidural opioids with local anesthetics. Theoretically, the combination of the two agents act synergistically to provide better analgesia while minimizing the side effects of either agent. The combination of epidural bupivacaine plus morphine or fentanyl provides better analgesia than does local anesthetic alone.[346]

Side effects associated with neuraxial administration of local anesthetics include hypotension and bradycardia, caused by sympathectomy and peripheral vasodilatation, and blockade of the cardiac accelerator nerve fibers at T1–T4. Administration of opioids is associated with side effects such as nausea, vomiting, pruritus, urinary retention, central narcosis, and respiratory depression. The incidence of respiratory depression from neuraxial administration of opioids varies from 0.1–3%.[335] Depending on the agent used, respiratory depression from opioids may peak from 4–10 hours after bolus injection but may persist up to 24 hours. Patients at increased risk for developing respiratory depression include older, sicker patients undergoing lengthy surgical procedures and those receiving major parenteral opioids perioperatively or > 6 mg of epidural morphine or 0.5 mg of intrathecal morphine (Box 53–14).[335] To decrease complications associated with respiratory depression, the patient should be monitored and cared for by knowledgeable staff with clear instructions for management of respiratory depression.

BOX 53–14.

Factors Predisposing to Development of Respiratory Depression after Epidural Opioids

- Drug factor
  - Hydrophilic drug (e.g., morphine)
  - Large doses
  - Repeated doses
  - Concomitant administration of parenteral opioids or other CNS depressants
- Patient factors
  - Elderly or debilitated
  - Coexisting respiratory disease
  - Thoracic epidural
  - High sensitivity to opioids (i.e., no previous exposure to opioids)
  - Intrathecal administration
  - Increased intrathoracic pressure (e.g., controlled ventilation, coughing, vomiting)

From Etches et al.[335] with permission.

The acute and chronic pain that accompanies thoracic surgery is significant but often underappreciated, with a well-established level of significant physiologic and functional impact and unknown social and economic costs. An appropriate perioperative analgesic regimen, apart from its more immediate benefits with respect to comfort and pulmonary function, likely will lead to reductions in longer-term pain. Therefore, we strongly recommend thoracic epidural analgesia in all patients scheduled for open thoracotomy and serious consideration of epidural analgesia in patients undergoing VATS. Epidural analgesia can be combined with NSAIDs and/or acetaminophen to reduce pain as much as possible to reduce risk and promote well-being. Patients whose pain is not well controlled (visual analogue pain score ≥ 3 out of 10) must be assessed for epidural func-

tion and the need for additional alternate analgesics, including IV opioids, ketamine, and α_2-agonists. These regimens should be directed by physicians trained in pain management who will be immediately available to best care for these high-risk patients.

CHAPTER 54

Anesthesia for Major Vascular Surgery

Alina Nicoara, MD, and
Madhav Swaminathan, MD

The management of anesthesia for surgery of the aorta and its major branches, including carotid endarterectomy (CEA), aortic aneurysm and occlusive repair, and lower-extremity vascular bypass grafting is both challenging and dynamic. The pathologic processes that give rise to aneurysmal and occlusive disease are largely systemic, and thus patients presenting for major vascular surgery usually have either overt or occult involvement of several organ systems. Coexisting coronary artery disease (CAD) is of particular concern because myocardial ischemia, myocardial infarction (MI), and myocardial failure constitute most of the perioperative morbidity. The stress response of surgery must also be aggressively controlled in both the intraoperative and the postoperative periods to minimize complications.

Vascular surgery necessitates the temporary interruption of arterial blood flow by isolation of the diseased vessel segment with occluding clamps, resulting in dramatic physiologic changes superimposed on complex disease states.

Minimally invasive techniques were developed to reduce morbidity and mortality and to provide an alternative to patients who are at high risk of postoperative complications with standard surgical therapy. The success of intraluminal and hybrid (both intra- and extraluminal) techniques has increased over the last decade and these treatment options are becoming more widely used, changing the role of the anesthesiologist.

This chapter details the fundamental considerations surrounding the perioperative evaluation, preparation, and management of major vascular surgery.

Portions of this chapter were previously published in Beattie C, Frank SM, Walker GV, Siex NW. Anesthesia for major vascular surgery. In: Longnecker DE, Tinker JH, Morgan E, Jr, eds. Principles and Practice of Anesthesiology. 2nd ed. St. Louis: Mosby, 1998:1841–1880, and are used here with permission.

KEY POINTS

1. Atherosclerosis is a multifactorial disease. Besides traditional risk factors (age, sex, elevated blood pressure, smoking, high levels of low-density lipoprotein [LDL] cholesterol, and low levels of high-density lipoprotein [HDL] cholesterol), newer risk factors have been described, such as fasting glucose, triglycerides and triglyceride-rich lipoprotein remnants, lipoprotein (a), homocysteine, and high-sensitivity C-reactive protein.
2. The precise mechanism of final injury caused by atherosclerosis is one or more of the following: (a) plaque enlargement reducing blood flow; (b) arterial embolism of plaque-associated platelet thrombi or atheromatous debris; and (c) complete occlusion of arteries at sites of advanced plaques.
3. Patients presenting for major vascular surgery usually have either overt or occult involvement of several organ systems. The vascular patient population has a high incidence of significant coronary artery disease (CAD); for example, left ventricular systolic dysfunction (left ventricular ejection fraction less than 40 percent) is five times more common in patients with cerebrovascular disease or peripheral arterial disease compared with matched controls.
4. The current standards for preoperative cardiac evaluation of these patients are the guidelines published by the American College of Cardiology (ACC) and the American Heart Association (AHA), initially in 1996 and updated in 2002, which provide an 8-step algorithm stratifying patients' risks based on the integration of major, intermediate, and minor predictors of cardiac risk, including functional capacity, the surgery-specific risk, and, when indicated, the results of stress testing.
5. Perioperative myocardial ischemia can result from increases in myocardial oxygen demand secondary to increases in blood pressure and heart rate, anemia, elevated preload, or increased contractility, or from decreases in oxygen supply as a consequence of hypotension, tachycardia, increased filling pressure, anemia, hypoxemia, and obstructed coronary blood flow because of acute thrombosis or spasm.
6. The ACC/AHA guidelines for perioperative cardiovascular evaluation for noncardiac surgery in 2002 recommend that patients previously on β-blockers should continue these agents perioperatively and whenever possible β-blocker should be started days or weeks before elective surgery in high-risk patients in whom there are findings of ischemia on preoperative testing, and the dose should be titrated to achieve a resting heart rate between 50 and 60 beats/min.
7. Invasive monitoring should be chosen and implemented based on patient's condition, ancillary diseases, and anticipated hemodynamic changes associated with the surgical procedure.
8. Monitoring of the awake patient during carotid endarterectomy (CEA) is the gold standard for neurologic assessment and may allow for prompt identification of patients who would benefit from shunt placement. This method of monitoring requires the absolute cooperation of surgeon, anesthesiologist, and patient.
9. One goal of anesthesia for CEA is to avoid hemodynamic extremes during induction, incision, surgical manipulation, emergence, and extubation. The blood pressure during carotid occlusion should be maintained at or up to 20% higher than the patient's highest recorded resting blood pressure when awake so as to maintain adequate collateral blood flow. The patient should be sufficiently responsive immediately after surgery to obey commands and thereby facilitate neurologic evaluation.
10. The estimated annual rupture risk according to abdominal aortic aneurysm (AAA) diameter is 0.5–5% for those 4.0–4.9 cm, 10–20% for those 6.0–6.9 cm, 20–40% for those 7.0–7.9 cm, and 30–50% for those greater than 8.0 cm in diameter.
11. The physiology of aortic cross-clamping includes changes in blood pressure, cardiac output, myocardial perfusion, pH, and tissue perfusion of the spinal cord, kidneys, and viscera.

Continued

Key Points–continued

12. The degree of hypertension caused by application of an aortic cross-clamp depends on the location of the clamp, the degree of collateralization, and the preocclusion aortic flow.
13. The main hemodynamic pathophysiologic factors involved in the response to the aortic cross-clamping are an increase in afterload caused by an increase in the impedance to aortic flow and an increase in preload caused by blood volume redistribution from the veins distal to the aortic occlusion to the proximal vasculature.
14. Multiple interventions have been proposed to counteract the effect of increased afterload and preload secondary to aortic cross-clamping such as arteriolar dilation, venodilation, and passive and active shunts.
15. As the incidence of acute renal failure during aortic aneurysm repair varies from 3–13%, preservation of renal function is a primary concern during aortic aneurysm surgery.
16. Modalities of spinal cord protection during aortic surgery include identification of ischemia by monitoring evoked potentials (somatosensory evoked potential and motor evoked potential), reimplantation of segmental vessels, sequential aortic clamping, maintaining aortic distal aortic perfusion through shunt or bypass, cerebrospinal fluid drainage, epidural cooling or hypothermic cardiopulmonary bypass, and circulatory arrest.
17. Unclamping leads to an acute fall in blood pressure as a result of a decrease in systemic vascular resistance. Gradual release of the aortic clamp and its reapplication has been recommended to allow time for volume replacement and washout of the vasoactive and cardiodepressant mediators from the ischemic tissues.
18. Endovascular repair of the aorta has steadily gained popularity as a reliable alternative to conventional surgical repair of aortic aneurysms. The concept of endovascular repair of abdominal aneurysms developed from the desire to reduce morbidity and mortality and to provide an alternative to patients who cannot undergo standard surgical therapy.
19. Various types of anesthesia can be used for stent repair, specifically general anesthesia, regional anesthesia, and monitored anesthesia care with local anesthetic infiltration at the incision site. Goals of an anesthetic plan should be to provide hemodynamic stability and adequate oxygenation and ventilation, to preserve organ function, and to maintain normothermia.

PATHOPHYSIOLOGY OF VASCULAR DISEASE

Pathogenesis of Atherosclerosis

The arterial wall response to hypertension, diabetes, and the stimuli of elevated blood lipids and cigarette smoke occurs predominantly in men and demonstrates a genetic susceptibility. The cellular response includes macrophage migration from blood to intima, intimal macrophage lipid accumulations, smooth muscle cell migration from media to intima, intimal smooth muscle cell proliferation, lipid-laden macrophage necrosis, and organic calcium precipitation. In addition to these considerations, complexities of the blood-surface arterial interface implicate the factors of velocity, shear stress, pulsatility, elasticity, and microbiochemical environment at the endothelial surface.[1]

Multiple factors contribute to the pathogenesis of atherosclerosis including endothelial dysfunction, dyslipidemia, inflammatory and immunologic factors, plaque rupture, and smoking. Dyslipidemia, especially high levels of low-density lipoprotein (LDL) and low levels of high-density lipoprotein (HDL), play a crucial role in the development of atherosclerosis.

Endothelial dysfunction induced by dyslipidemia is an initial step in atherosclerosis, is induced by oxidized LDL, can be worsened by cigarette smoking, and can be reversed with correction of hyperlipidemia by diet and/or therapy. Accelerated accumulation of oxidized LDL in cholesterol-enriched macrophages leads to mitochondrial dysfunction, apoptosis, and necrosis, with resultant release of cellular proteases, inflammatory cytokines, and prothrombotic molecules.[2] The presence of inflammation plays an important role in the development of atherosclerosis. Among the inflammatory markers for atherosclerosis risk that have received attention are interleukins and C-reactive protein. Interleukin-6, a circulating cytokine has been identified as a marker of inflammation in coronary atherosclerotic plaques. Interleukin-6 stimulates platelet aggregation and the expression of tissue factor, macrophage LDL receptors, C-reactive protein, and fibrinogen. Interleukin-6 also regulates the expression of other inflammatory cytokines, such as interleukin-1 and tumor necrosis factor-α. C-reactive protein, one of many human acute-phase reactants, is produced in the liver in response to interleukin-6, interleukin-1β, and tumor necrosis factor-α. It activates the classic complement cascade, mediates phagocytosis, regulates inflammation, and is a nonspecific but sensitive marker of infection and tissue inflammation.[3] Plaque hemorrhage and plaque rupture may also contribute to the progression of the atherosclerotic lesion.

Pathophysiology of Atherosclerosis

Atherosclerosis is the primary process leading to MI, stroke, chronic mesenteric ischemia, renovascular hypertension, extremity ischemia, and aneurysmal disease. These pathologic states occur years after the slow onset of plaque formation in the vascular wall. The precise mechanism of final injury is one or more of the following: (a) plaque enlargement reducing blood flow; (b) arterial embolism of plaque-associated platelet thrombi or atheromatous debris; and (c) complete occlusion of arteries at sites of advanced plaques.

Atherosclerosis is a multifactorial disease. The impact of traditional risk factors such as age, sex, elevated blood pressure, smoking, high levels of LDL cholesterol, and low levels of HDL cholesterol on coronary heart disease risk has been demonstrated beyond any doubt. Newer risk factors, such as impaired fasting glucose, triglycerides and triglyceride-rich lipoprotein remnants, lipoprotein(a), homocysteine, and high-sensitivity C-reactive protein also contribute to an increased risk of coronary and cardiovascular diseases (Table 54–1).[4] Correction or modification of some of these may arrest or lessen the progression of the disease.

TABLE 54–1.

Old, Old/New, and New Risk Factors for Atherosclerosis

Old	Old/New	New
Sex (men > women)	High-normal blood pressure	Apolipoprotein B; apolipoprotein A-1
Age	Metabolic syndrome	Triglycerides, triglyceride-rich lipoprotein remnants
Family history of premature cardiovascular disease	Diabetes mellitus, impaired glucose tolerance, impaired fasting glucose	Small dense LDL, oxidized LDL, antibodies against oxidized LDL
Total cholesterol; LDL cholesterol; HDL cholesterol (negative risk factor)		Lipoprotein(a)
Hypertension		Homocysteine
Smoking		High-sensitivity C-reactive protein
Overweight/obesity		

HDL, high-density lipoprotein; LDL, low-density lipoprotein.
Fruchart JC, Neirman MC, Stroes ES, Kastelein JJ, Dureiz P. New risk factors for atherosclerosis and patient risk assessment. Circulation 2004; 109(23 Suppl 1):III15–III19.

The Committee on Vascular Lesions of the American Heart Association identifies 6 histologic types of atherosclerotic lesions. The initial (type I) lesion contains enough atherogenic lipoprotein to elicit an increase in macrophages and formation of scattered macrophage foam cells. Type II (fatty streak) lesions consist primarily of layers of macrophage foam cells and lipid-laden smooth muscle cells and include lesions grossly designated as fatty streaks. In addition to the lipid-laden cells of type II, type III (intermediate) lesions contain scattered collections of extracellular lipid droplets and particles that disrupt the coherence of some intimal smooth muscle cells. This extracellular lipid is the immediate precursor of the larger, confluent and more disruptive core of extracellular lipid that characterizes type IV (atheroma) lesions. Beginning around the fourth decade of life, lesions that usually have a lipid core may also contain thick layers of fibrous connective tissue (type V lesion-fibroatheroma) and/or fissure, hematoma, and thrombus (type VI-complicated lesion; Fig. 54–1).[5]

Fatty streaks are commonly observed in young adults and have been identified in the coronary artery intima of children. Isolated lipid-laden monocytes and macrophages, called *foam cells*, have been identified in the intima of infants as young as 1 month of age.[6]

Atherosclerosis is generally asymptomatic until the plaque stenosis exceeds 70 or 80%, which can produce a critical reduction in flow as with coronary blood flow to the myocardium. These large lesions can produce typical symptoms of angina pectoris. However, acute coronary and cerebrovascular syndromes (unstable angina, MI, sudden death, and stroke) are typically caused by rupture of plaques with less than 50% stenosis.[7]

Atherosclerotic plaques tend to occur in several specific anatomic locations, and plaque development at other sites is uncommon. The coronary arteries, the carotid bifurcation, the infrarenal abdominal aorta, the

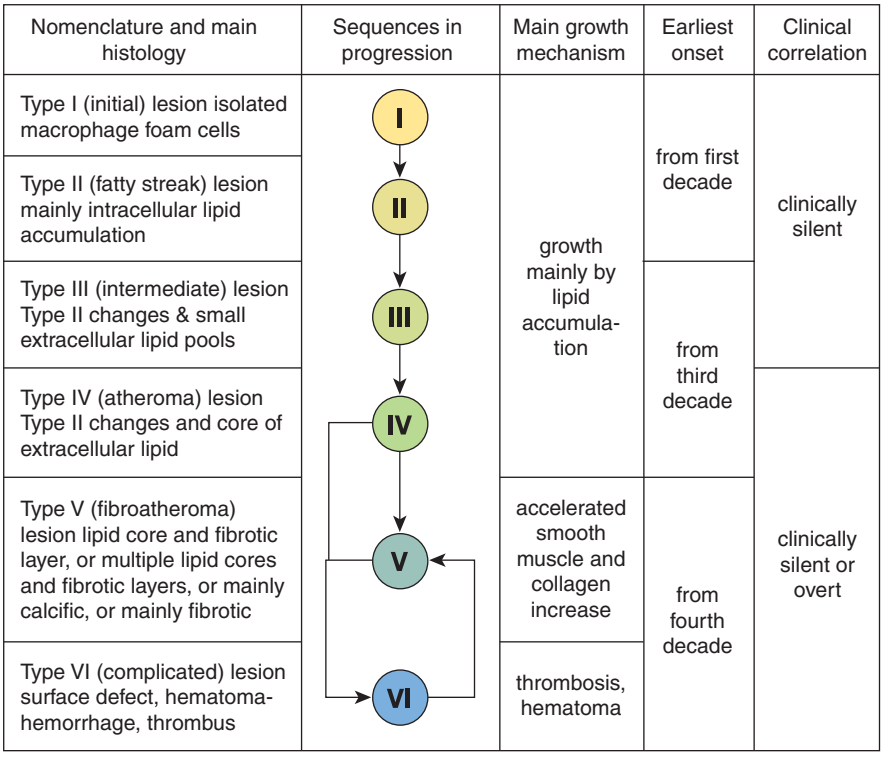

FIGURE 54–1. Flow diagram in center column indicates pathways in evolution and progression of human atherosclerotic lesions. Roman numerals indicate histologically characteristic types of lesions enumerated in the text and defined at left of flow diagram. The direction of arrows indicates sequence in which characteristic morphologies may change. From type I to type IV, changes in lesion morphology occur primarily because of increasing accumulation of lipid. The loop between types V and VI illustrates how lesions increase in thickness when thrombotic deposits form on their surfaces. Thrombotic deposits may form repeatedly over varied time spans in the same location and may be the principal mechanism for gradual occlusion of medium-sized arteries. Source: Stary HC, Chandler AB, Dinsmore RE, et al.[5]

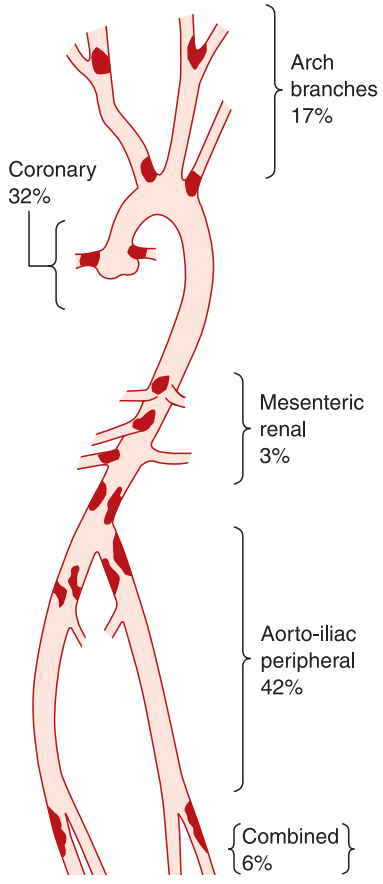

FIGURE 54–2. Distribution of atherosclerotic lesions. Source: Zwolak RM CJ.[1]

iliac arteries, and the superficial femoral artery are the most usual sites of development (Fig. 54–2).

Arterial emboli vary in significance, depending on the size of the embolus, the development of collateral circulation, and the metabolic rate of the ischemic tissue. Common sources of the embolic material are cardiac thrombosis (90%) from the left atrium or ventricle and atherosclerotic debris (10%) from an arterial plaque.[1] Emboli tend to lodge at bifurcations or at sites of vessel narrowing.

Additional comments on pathophysiology are presented at the beginning of the separate sections on carotid, lower-extremity, and aortic surgery.

PREOPERATIVE EVALUATION OF THE VASCULAR SURGERY PATIENT

Although occasionally the atherosclerotic process manifests itself in a discrete vascular segment, the more common presentation is diffuse involvement of several organ systems. The vascular patient population has a high incidence of significant CAD; for example, left ventricular systolic dysfunction (left ventricular ejection fraction less than 40 percent) is 5 times more common in patients with cerebrovascular disease or peripheral arterial disease than in matched controls.[8]

In addition, vascular patients often report a heavy smoking history, and some degree of pulmonary compromise is expected. Diabetes mellitus is frequently associated with vascular disease, necessitating appropriate evaluation and treatment in the preoperative period. Hypertension is both a predisposing factor for vascular disease and a consequence of its development.

Risk assessment will have value only if it leads to risk modification or otherwise influences the decisions regarding surgical or anesthetic procedures. A great deal of investigational activity has been conducted to evaluate preoperative testing procedures with the highest degree of sensitivity and specificity that identify patients at risk for perioperative cardiac morbidity and mortality.[9–11]

These risk-assessment models are based on findings from the history, physical, and electrocardiogram (ECG), and/or additional information from diagnostic studies. As cardiac complications pose one of the most significant risks to patients undergoing major vascular surgery, the continuing debate concerns the appropriate management sequence to be followed once the risk is predicted. That is, should other tests, such as dipyridamole-thallium imaging (DTI) or dobutamine stress echocardiography (DSE), be performed to select a subset of patients to be revascularized with percutaneous transluminal angioplasty[12] or coronary artery bypass graft (CABG) prior to vascular surgery, or should the patient proceed directly to vascular surgery with aggressive perioperative medical management in an attempt to reduce risk.

The current standards for preoperative cardiac evaluation of these patients are the guidelines published by the American College of Cardiology (ACC) and the American Heart Association (AHA) initially in 1996 and updated in 2002.[10] The guidelines provide an 8-step algorithm stratifying patients' risks based on the integration of major, intermediate, and minor predictors of cardiac risk (Box 54–1),[10] including functional capacity (i.e., metabolic equivalent[13]

BOX 54–1.

Clinical Predicators of Increased Perioperative Cardiovascular Risk (Myocardial Infarction, Heart Failure, Death)

Major
- Unstable coronary syndromes
  - Acute or recent myocardial infarction[a] with evidence of important ischemic risk by clinical symptoms or noninvasive study
  - Unstable or severe angina (Canadian class III or IV)
- Decompensated heart failure
- Significant arrhythmias
  - High-grade atrioventricular block
  - Symptomatic ventricular arrhythmias in the presence of underlying heart disease
  - Supraventricular arrhythmias with uncontrolled ventricular rate
- Severe valvular disease

Intermediate
- Mild angina pectoris (Canadian class I or II)
- Previous myocardial infarction by history or pathologic Q waves
- Compensated or prior heart failure
- Diabetes mellitus (particularly insulin-dependent)
- Renal insufficiency

Minor[b]
- Advanced age
- Abnormal ECG (left ventricular hypertrophy, left bundle-branch block, ST-T abnormalities)
- Rhythm other than sinus (e.g., atrial fibrillation)
- Low functional capacity (e.g. inability to climb one flight of stairs with a bag of groceries)
- History of stroke
- Uncontrolled systemic hypertension

ECG, electrocardiogram.
[a]The American College of Cardiology National Database Library defines recent myocardial infarction as greater than 7 days but less than or equal to 1 month (30 days); acute MI is within 7 days.
[b]May include "stable" angina in patients who are unusually sedentary.

or exercise duration; Box 54–2),[10] the surgery-specific risk (Box 54–3),[10] and when indicated, the results of stress testing (Fig. 54–3). Several studies have assessed the utility of the ACC/AHA guidelines for risk stratification. Licker et al. compared data from two consecutive 4-year periods (1993–1996 control period versus 1997–2000 intervention period). Introduction of ACC/AHA protocols was associated with increased preoperative myocardial scanning (44.3% vs. 20.6%) and coronary revascularization (7.7% vs. 0.8%), as well as a significant decrease in the incidence of cardiac complications (from 11.3% to 4.5%) and an increase in event-free survival at 1 year after surgery (from 91.3% to 98.2%).[14,15]

Application of these guidelines results in approximately 50% of all major vascular surgery patients undergoing noninvasive testing.[16] The results of such testing then lead to either the original vascular procedure when negative, or to angiography when positive with some patients requiring coronary revascularization prior to vascular surgery.

Many tests have been both supported and refuted over time as valuable predictors of perioperative cardiac morbidity. However, the cost of these tests is a limiting factor. For example, it has been estimated that annual medical costs would rise $100 million should DTI be used in half of the vascular surgery patients.[17]

Clinical Predictors of Perioperative Risk

Peripheral vascular surgery is associated with greater cardiac morbidity and overall mortality than other forms of noncardiac surgery.[18,19] Perioperative MI is reported to occur in 4–15% of patients undergoing peripheral vascular surgery and accounts for more than 50% of perioperative mortality.[19]

Hertzer showed that only 8% of 1000 vascular surgery patients in whom coronary angiography was performed had normal coronary arteries.[20] Severe and surgically correctable CAD was documented in 14% of patients who had no clinical criteria to suggest this degree of disease. Depending on the screening test employed, the incidence of significant CAD in patients with abdominal aneurysms, claudication, or carotid artery disease varies from 25% to 90%.[20,21]

Physiologic factors associated with surgery predispose to myocardial ischemia, which is more pronounced in patients with underlying coronary disease. Myocardial ischemia can result from increases in myocardial oxygen demand secondary to increases in blood pressure and heart rate, anemia, elevated preload increased contractility, or from decreases in oxygen supply as a result of hypotension, tachycardia, increased filling pressure, anemia, hypoxemia, and obstructed coronary blood flow as a consequence of acute thrombosis or spasm. Acute coronary and cerebrovascular syndromes (unstable angina, MI, sudden death, and stroke) are typically caused by rupture of plaques with less than 50% stenosis[7] and perioperative cardiovascular testing may not clearly identify these patients.

Several studies have looked at adverse cardiac events related to type of surgery. L'Italien et al. investigated 547 patients who were undergoing vascular surgery from two medical centers. These patients underwent clinical evaluation, DTI, and either aortic, infrainguinal, or carotid vascular surgery. Perioperative MI occurred in 6% of patients who underwent aortic and carotid artery surgery

BOX 54–3.

Cardiac Risk[a] Stratification for Noncardiac Surgical Procedures

High (reported cardiac risk often greater than 5%)
- Emergent major operations, particularly in the elderly
- Aortic and other major vascular surgery
- Peripheral vascular surgery
- Anticipated prolonged surgical procedures associated with large fluid shifts and/or blood loss

Intermediate (reported cardiac risk generally less than 5%)
- Carotid endarterectomy
- Head and neck surgery
- Intraperitoneal and intrathoracic surgery
- Orthopedic surgery
- Prostate surgery

Low (reported cardiac risk generally less than 1%)
- Endoscopic procedures
- Superficial procedures
- Cataract surgery
- Breast surgery

[a]Combined incidence of cardiac death and nonfatal myocardial infarction.

[b]Do not generally require further preoperative cardiac testing.

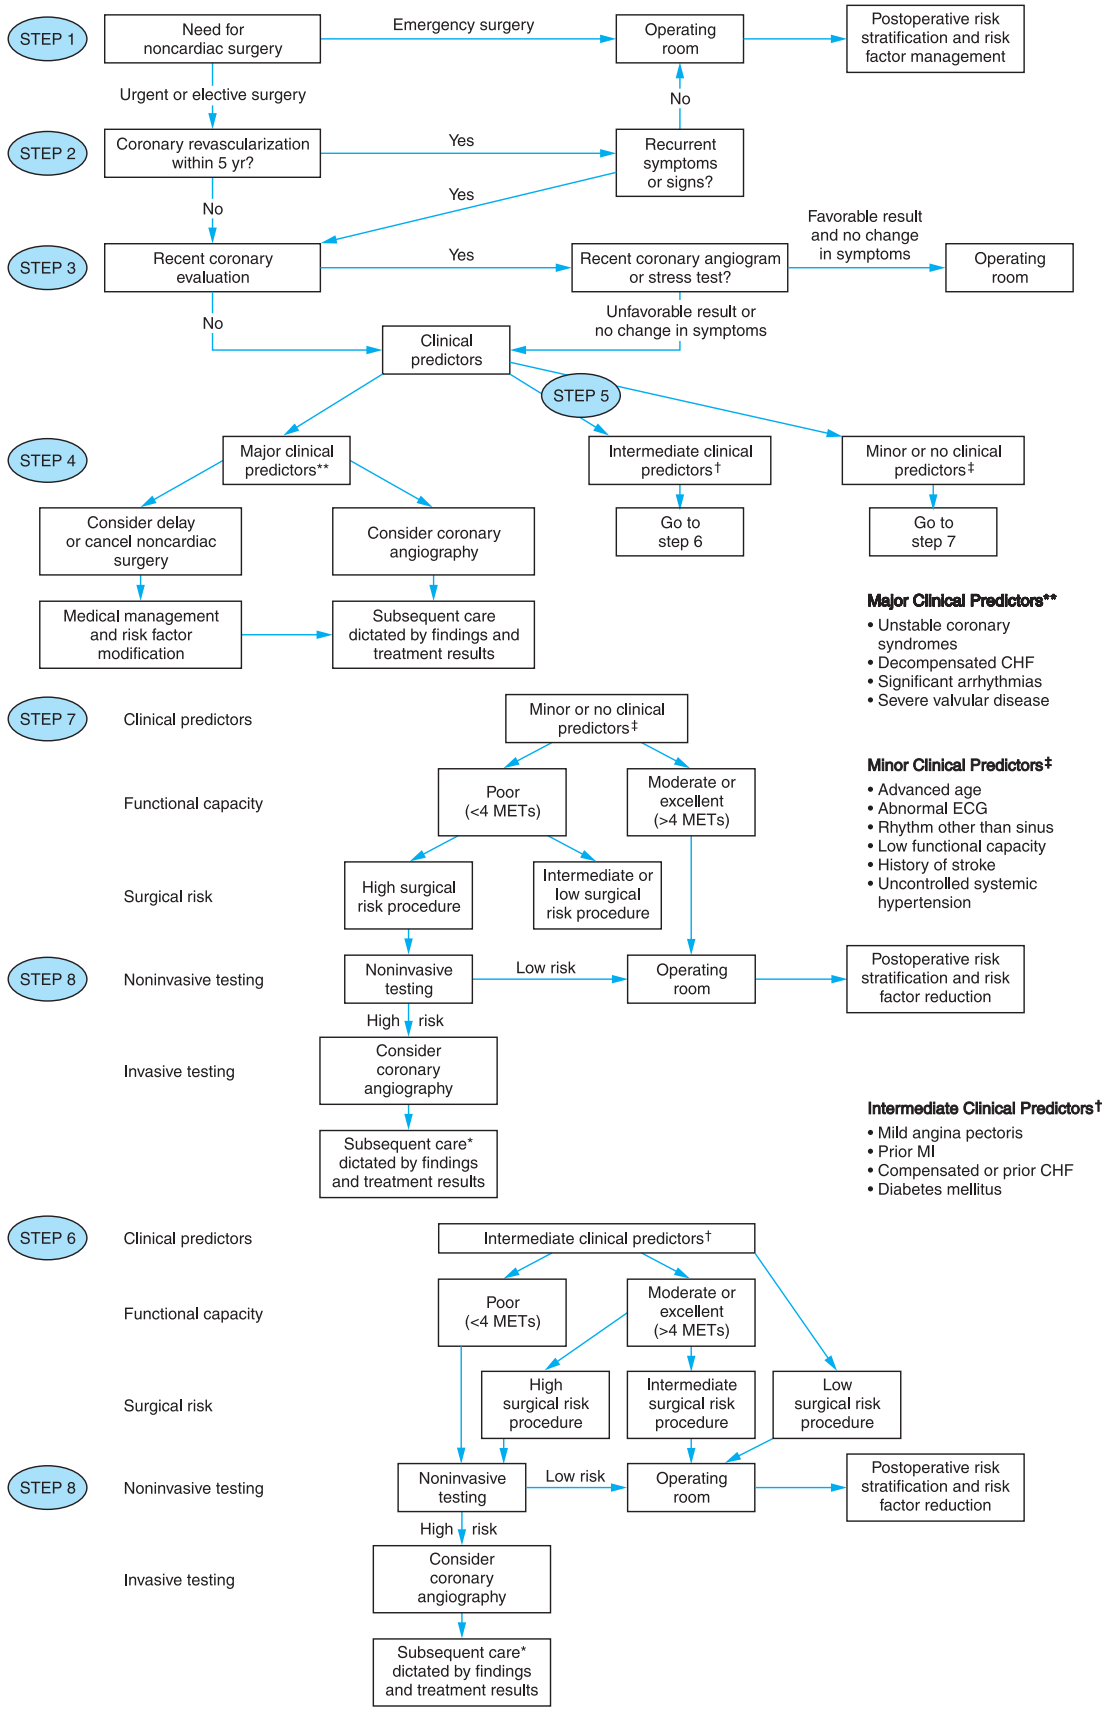

FIGURE 54–3. Stepwise approach to preoperative cardiac assessment. Steps are discussed in text. *Subsequent care may include cancellation or delay of surgery, coronary revascularization followed by noncardiac surgery, or intensified care. Eagle KA, Berger PB, Calkins H. ACC/AHA Guideline Update for Perioperative Cardiovascular Evaluation for Noncardiac Surgery-Executive Summary A Report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Committee to Update the 1996 Guidelines on Perioperative Cardiovascular Evaluation for Noncardiac Surgery). Circulation 2002;105:1257.

and in 13% of patients who underwent infrainguinal procedures ($p = 0.019$). Significant ($p < 0.05$) predictors of MI were history of angina, fixed and reversible dipyridamole-thallium defects, and ischemic ST depression during testing. Although patients who underwent infrainguinal procedures exhibited more than twice the risk for perioperative MI of patients who underwent aortic surgery (relative risk: 2.4 [1.2–4.5, $p = 0.008$]), this value was reduced to insignificant levels (relative risk: 1.6 [0.8–3.2, $p = 0.189$]) after adjustment for comorbid factors.[16]

Thirty-day mortality after elective aneurysm repair was 5.8% and 2.7% in the United Kingdom Small Aneurysm trial and the Aneurysm Detection and Management (ADAM) trial, respectively.[22,23] Perioperative mortality is much higher with emergency surgery, occurring in 37% of 81 patients in a large screening trial.[24]

Using multivariable analysis, the revised Goldman cardiac risk index identified 6 clinical factors that predicted major cardiac complications in a cohort of 2893 patients who underwent elective noncardiac surgery. These factors were high-risk surgery, history of CAD, no history of revascularization, history of congestive heart failure, preoperative use of insulin, and preoperative serum creatinine greater than 2 mg/dL. These predictors were then validated in a cohort of 1422 patients. The predictive value was significant in all types of elective major noncardiac surgery except for abdominal aortic aneurysm surgery. Cardiac event rates for zero, 1, 2, and ≥ 3 of the 6 factors were 0.4%, 0.9%, 7%, and 11%, respectively.[25]

Recent Myocardial Infarction and Angina

Patients with prior MI are at greater risk for perioperative reinfarction. Traditionally, risk assessment for noncardiac surgery was based on the time interval between the MI and the surgery. Older studies found as much as a 36% risk of reinfarction or cardiac death when patients underwent surgery within 3 months of a previous MI. The risk fell to 15–25 percent at 3–6 months, and to 5% when surgery was performed after more than 6 months after a previous MI.[26] However, the risk was lower in later studies because of preoperative optimization and intensive perioperative monitoring.[12]

The American College of Cardiology National Database Library defines recent MI as greater than 7 days but less than 1 month since the occurrence. The ACC/AHA guidelines for perioperative evaluation of the cardiac patient undergoing noncardiac surgery categorizes those who have had a MI within the past 6 weeks as being in the group of highest risk; after that 6-week period risk stratification is based on the presentation of the disease.[10] Risk stratification of patients with acute coronary syndromes such as unstable angina predict those who are at high risk for further ischemic events or adverse outcomes. Such patients should not undergo noncardiac surgery except in the most emergent of circumstances.

Valvular Diseases

Although severe valvular disease is considered by the ACC/AHA guidelines as a major clinical predictor of increased perioperative cardiovascular risk, studies show that when the clinician is aware of the pathophysiologic implications of the disease and manages the patient accordingly, patients with severe aortic stenosis even if symptomatic, can undergo surgery with a risk that is not so high, and may not be different from controls.[27,28]

Diabetes

Diabetes has been strongly suggested as a predictor for perioperative cardiac morbidity after vascular surgery.[29] Altered autonomic function in diabetes may predispose to greater intraoperative risk of blood pressure lability, variation of heart rate, gastroparesis, and decreased esophageal sphincter tone. Diabetic autonomic neuropathies can obscure symptoms of myocardial ischemia, thus adding to the already high incidence of "silent" ischemia seen in the perioperative period. The presence of diabetes in vascular surgery patients may identify a population in whom DTI is useful.[30]

Assessment of Pulmonary Status

Many vascular patients are chronic smokers, and cigarette smoking increases the risk for postoperative pulmonary complications. The risk of pneumonia is twice as high in smokers as in nonsmokers, and the development of hypoxemia in the postoperative period occurs more frequently and more severely in smokers as compared with nonsmokers. Pulmonary function tests are indicated only when clinical assessment suggests severe compromise of pulmonary function, and may be useful in identifying patients who would benefit from perioperative care and those who are likely to require mechanical ventilation postoperatively. Arterial blood gases may be used to evaluate the degree of pulmonary disease and provide a baseline for subsequent clinical decisions. A persistently elevated $PaCO_2$ greater than 45 mm Hg reliably predicts a high risk for pulmonary complications.[31]

Assessment of Renal Function

A comprehensive preoperative evaluation of a vascular surgical patient should include an assessment of renal function as this patient population is at increased risk for renal failure.

Causes of baseline renal insufficiency include atherosclerosis of the renal arteries, hypertension, diabetic nephropathy, and depressed myocardial function. Contrast-enhanced imaging studies performed before surgery also alter renal function by both a direct toxic effect and by a hyperosmolar-induced diuresis that reduces the intravascular volume. Intravascular volume expansion before, during, and after the angiographic study minimizes renal effects.

In the vascular patient who is undergoing abdominal aortic surgery, there are several causes of renal impairment superimposing on an already precarious renal function, such as wide fluctuations in the intravascular volume and cardiac output, altered neuroendocrine milieu with increased epinephrine, norepinephrine, and renin secretion, emboli shower dislodged by the aortic clamp, and dysfunctional effects on renal hemodynamics from aortic cross-clamping.

Evolving technology and progress in surgical and anesthetic management has decreased the incidence of renal failure.

Diagnostic Testing

Electrocardiogram

Preoperative ECG abnormalities are observed in 40–70% of patients with CAD who are undergoing noncardiac surgery. ST-segment and T-wave abnormalities are noted (65–90%) and Q waves occur in 0.5–8% of patients. The presence of Q waves or significant ST-segment elevation or depression is associated with an increased incidence of cardiac complications.[30]

Exercise Electrocardiography

Noninvasive diagnostic tests have been proposed to evaluate the extent of CAD before noncardiac surgery and to permit further stratification in patients who are deemed to be at intermediate risk after clinical evaluation. One caveat of interpreting stress testing in the overall preoperative evaluation of the patient is that for the purpose of predicting perioperative cardiac events, stress testing has a high negative predictive value (90–100%) but low positive predictive value (6–67%); consequently, it is more useful in reducing estimated risk if negative (or normal) than for identifying patients who are at very high risk if positive.[32]

Exercise ECG without myocardial imaging has been the traditional method for evaluating CAD, and is the standard method for determining functional capacity and detecting myocardial ischemia with a sensitivity of 68–81% and a specificity of 66–77%. Exercise tolerance appears to be more important than the ECG response to exercise. Inability to perform moderate exercise or to achieve greater than 85% of predicted maximal heart rate during treadmill exercise testing is associated with a high risk of a postoperative cardiac event, even in the absence of diagnostic ischemic ECG changes.[33] In patients who cannot exercise and who have abnormalities on the baseline ECG that interfere with interpretation, pharmacologic stress testing is warranted. The two most common used tests are DTI and DSE.

Dipyridamole-Thallium Myocardial Perfusion Imaging The two vasodilators used for pharmacologic myocardial perfusion imaging are adenosine and dipyridamole. Adenosine and dipyridamole are equally effective, but adenosine has the advantages of very short half-life, rapid reversal of side effects after the test is completed, and possibly more predictable vasodilatation. Thallium-201 is taken up by cells similarly to potassium and is readily assimilated by healthy myocardial cells; consequently, infarcted, ischemic, and hypoperfused areas appear as defects. After injection of thallium or 99-technetium, normal myocardium will show up on initial imaging whereas areas of infarction or hypoperfusion distal to a stenosis will appear as a defect. After dissipation of the dilatory effect and after a second injection of technetium, defects caused by ischemia will resolve whereas those caused by scarred infarcted tissue will persist.

In a 1995 review of the 5 largest series of 1410 selected patients referred for dipyridamole-thallium myocardial perfusion imaging prior to vascular surgery, the sensitivity and specificity for a major cardiac event was 85% and 60%, respectively. The negative predictive value of dipyridamole-thallium imaging was 98%, but the positive predictive value was only 18%.[34] The ability to identify patients who are at risk may be improved when taking into account the extent of ischemia rather than only its presence. A recent meta-analysis showed that the probability of MI or cardiac death without reperfusion ranged from 3–4% in patients with no or only fixed defects, to 9% with reversible defects involving less than 20% of the left ventricle, to 18% with reversible defects involving 30–49% of the left ventricle, and to 45% with reversible defects involving more than 50 percent of the left ventricle.[35] There are, however, differences in predicted values reported between consecutive and selective series of patients.[36] Eagle et al. studied 200 patients who were undergoing vascular surgery, and found that DTI was most helpful in stratifying patients who had already been identified as high risk by clinical markers alone (e.g., angina, age >70 years, ventricular ectopy, diabetes, Q waves on ECG). These experts suggest using DTI to further delineate risk in patients with 1 or 2 of these clinical markers. In this subset of patients, a positive DTI was associated with a 10-fold higher incidence of cardiac morbidity. The study recommends proceeding with coronary angiography in these patients, as well as in any patient with 3 or more markers, in which case the DTI is unnecessary.[30] Conversely, Baron et al. studied a large consecutive population of patients who were undergoing abdominal aortic surgery, and were unable to demonstrate an association between thallium redistribution and perioperative cardiac morbidity.[9]

Dobutamine Stress Echocardiography Dobutamine stress echocardiography is preferred in patients with bronchospastic lung disease and in those with severe carotid stenosis because dipyridamole can induce bronchospasm and a decrease in blood pressure. It also provides information about left ventricular function or valvular heart disease. As opposed to DTI, which is limited in its methodology by not increasing myocardial oxygen consumption, the administration of dobutamine mimics intraoperative conditions by increasing heart rate. The predictive value appears to vary with patient risk. This was illustrated in a recent analysis of 1097 patients who were assigned 1 point for each of the following clinical risk factors: age older than 70 years, current angina, MI, congestive heart failure, prior cerebrovascular event, diabetes mellitus, and renal failure (Eagle criteria). The study showed that the additional predictive value of DSE is limited in clinically low-risk patients who are receiving β-blockers such that DSE may be avoided in a large number of patients who can proceed safely for surgery without delay. In clinically intermediate- and high-risk patients who are receiving β-blockers, DSE may help identify those who can undergo surgery and those in whom cardiac revascularization should be considered.[37] Some studies suggest that DSE is superior in its ability to predict morbidity in vascular surgery but, unfortunately, the test is also the most expensive noninvasive technique.[11,38]

Transthoracic Echocardiography Transthoracic echocardiography may add predictive information regarding left ventricular function and valvular lesions in certain patients who are undergoing noncardiac surgery. Although it has been shown that depressed ventricular function assessed by left ventricular ejection fraction may be predictive of postoperative heart failure,[9] data do not support the use of transthoracic echocardiography for the noninvasive assessment of left ventricular function to predict preoperative cardiac risk before noncardiac surgery, as stated in a position paper of the American College of Physicians.[39]

Ambulatory ECG Monitoring Preoperative ambulatory ECG monitoring provides a means of monitoring continuously for significant ST-segment changes. Some studies correlated the duration and severity of preoperative ST-segment changes with perioperative cardiac morbidity in patients who were undergoing vascular surgery.

Raby et al. showed that 12 of 32 (37%) patients with preoperative ischemia detected by ambulatory ECG suffered a MI, unstable angina, or pulmonary edema during or after major vascular surgery, whereas only 1 postoperative myocardial event occurred among 144 patients who did not exhibit preoperative ischemia.[40] Baseline ECG changes are found in a significant number of vascular patients and limit the use of this test. In addition, the test provides binary outcomes and cannot further stratify high-risk patients.[41]

Coronary Angiography In the perioperative setting many infarctions are the result of acute thrombosis of a noncritical stenosis, which limits the value of routine angiography prior to major noncardiac surgery. The ACC/AHA guidelines' class I recommendations state that coronary angiography should be considered in patients with suspected or known CAD with at least 1 of the following findings: (a) evidence for high risk of adverse outcome based on noninvasive test results, (b) angina unresponsive to adequate medical therapy, (c) unstable angina, particularly when facing intermediate-risk or high-risk noncardiac surgery, and (d) equivocal noninvasive test results in patients at high clinical risk who are undergoing high-risk surgery.[10]

PREOPERATIVE THERAPY

Preoperative Coronary Artery Bypass Grafting

Some patients who present for major surgery have unstable coronary syndromes that are sufficiently high risk to mandate coronary revascularization. For most patients, however, the issue is considerably less clear.

The results of the Coronary Artery Revascularization Prophylaxis (CARP) trial were recently published. This study prospectively randomized 510 patients with stable coronary disease to either coronary revascularization by CABG surgery, percutaneous coronary intervention (PCI), or medical therapy before undergoing major vascular surgery. Two-thirds of the enrolled patients had either one- or two-vessel disease. Excluded from the study were patients who had unstable coronary disease, left main coronary artery stenosis, severe left ventricular dysfunction, or severe aortic stenosis. Potentially beneficial medications, including β-blockers, antiplatelet agents, angiotensin-converting enzyme inhibitors, and statins were widely used in both groups. β-Blockers were given to 84% of the patients in the revascularization group and to 86% of the patients in the medical therapy group. The study found no significant difference in long-term outcome. After 2.7 years, mortality was 22% in the revascularization group and 23% in the nonrevascularized group. These data support the current ACC/AHA perioperative cardiovascular recommendations that the decision to perform coronary revascularization should be based on the same well-proven indications used in the nonoperative setting. However, the study was also not large enough to provide a conclusive analysis of the potential benefit of revascularization in high-risk subgroups, such as those with a large stress-induced defect on myocardial perfusion imaging (MPI) or those with three vessel disease plus left ventricular dysfunction.[42]

In contrast to these findings, other reports suggest that surgical revascularization may provide a net reduction in perioperative and, in particular, long-term morbidity and mortality in selected patients with coronary disease who undergo major noncardiac surgery. A retrospective cohort analysis evaluated 1834 patients with both coronary and peripheral arterial disease. A significant long-term survival benefit was seen in patients who underwent CABG compared with medical therapy, regardless of the need for vascular surgery. Subgroup analysis suggested that the survival benefits with CABG were limited to patients with three-vessel disease, and were inversely related to the left ventricular ejection fraction.[43]

Preoperative Percutaneous Coronary Intervention

PCI can be performed either through stenting or angioplasty (percutaneous transluminal coronary angioplasty [PTCA]). Drug-eluting stents are now implanted in the great majority of PCI procedures because of a much lower expected rate of restenosis and target-vessel revascularization than seen with angioplasty alone or bare-metal stents. However, recent studies have questioned whether long-term outcomes, including stent restenosis, MI, and cardiac death are lower with drug-eluting stents than with bare-metal stents.[44–46]

The role of PCI in the preoperative management of patients who are undergoing noncardiac surgery is less-well established. One study looking at an administrative database of patients who were undergoing surgery in Washington State found that, compared with patients who did not undergo PTCA preoperatively, the procedure led to a lower incidence of perioperative cardiac complications. The benefit of revascularization was most apparent in the group that underwent PTCA at least 90 days before undergoing noncardiac surgery. In contrast, when revascularization was performed less than 90 days before noncardiac surgery, PTCA was not associated with an improved outcome. This finding suggests that PTCA should not be used solely as a means of reducing perioperative risk.[47]

Coronary stenting poses unique challenges related either to perioperative bleeding because of postprocedural antiplatelet therapy or to stent thrombosis that may be associated with withholding or reducing antiplatelet therapy so as to minimize bleeding. The authors of the ACC/AHA guidelines recommend a delay of at least 2 weeks, ideally 4–6 weeks, before noncardiac surgery to allow 4 full weeks of dual antiplatelet therapy and complete reendothelialization of the stent.

Perioperative Medical Therapy

Nitrates, β-blockers, and calcium channel blockers are common chronic medications in vascular surgery patients. Because perioperative discontinuation of these therapies may lead to perioperative ischemia, dysrhythmias, MI, and cardiac death, it is recommended to continue all significant cardiovascular medications up to and including the morning of surgery.

The focus on perioperative β-blockade has led to mounting evidence that their prophylactic use reduces cardiac mortality and morbidity. β-Blockers reduce ischemia by decreasing myocardial oxygen demand as a result of increased stress and catecholamine release in the perioperative period, and may decrease the incidence of plaque rupture by reducing mechanical stress via hemodynamic effects.[48] β-Blockers are the most studied and advocated perioperative medical therapy. Clinical studies show that perioperative β-blockade can reduce mortality and

cardiovascular complications in high-risk patients who must undergo noncardiac surgery.[49,50] The 2002 ACC/AHA guidelines for perioperative cardiovascular evaluation for noncardiac surgery recommend that patients previously on β-blockers should continue these agents perioperatively. The guidelines also suggest that, whenever possible, β-blocker should be started days or weeks before elective surgery in high-risk patients in whom there are findings of ischemia on preoperative testing, and that the dose should be titrated to achieve a resting heart rate between 50 and 60 beats/min. The use of β-blockers is also recommended in patients with known risk factors for coronary disease who are undergoing noncardiac surgery (a class II indication).[10]

Although evidence supporting the routine use of α_2-agonists such as clonidine is not as compelling as that for perioperative β-blockade, the ACC/AHA guidelines introduced the use of α_2-agonists as a class IIb recommendation for perioperative control of hypertension or risk reduction in patients with known CAD or major risk factors for CAD.[10]

GENERAL CONSIDERATIONS

Modern developments in risk assessment, surgical risk modification, physiologic monitoring, antiischemic therapies, techniques of anesthesia and analgesia, and postoperative intensive care and rehabilitation can all produce clinical pathways that truly optimize patient care. Full realization of this potential requires an integrated approach and collaboration between vascular surgery, cardiac surgery, cardiology, anesthesiology, and critical care medicine to a degree not easily achievable in most institutions.

Vascular surgery patients require intensive perioperative monitoring for two primary reasons: (a) these patients often have systemic manifestations of atherosclerotic vascular disease and are at risk for cardiac, cerebral, renal and spinal cord ischemia, all of which can be diagnosed and treated using appropriate monitors; and (b) vascular procedures involve major physiologic changes, including significant third-space losses, blood loss, and the complications of transfusion (coagulopathies, hypocalcemia, hypothermia, and acidosis). There can also be significant changes in the hemodynamic profile associated with the application and release of vascular clamps.

To reduce cardiac morbidity, appropriate ECG monitoring is mandatory. One study showed that monitoring the standard leads II and V_5 detects 80% of ST-segment changes caused by ischemia, although V_4 is preferable to V_5, and the concomitant monitoring of 3 leads increases the sensitivity to 95% or higher.[51] The following discussions assume that the American Society of Anesthesiology (ASA) standards of basic monitoring are met, including employing pulse oximetry, capnography, ECG and body temperature measurement.

CAROTID ENDARTERECTOMY

Pathophysiology of Carotid Disease

Occlusive disease of the carotid system is commonly caused by atherosclerosis and involves the origins of both the internal and external carotid arteries as well as the bifurcation of the common carotid artery. Carotid atherosclerosis is usually most severe within 2 cm of the bifurcation of the common carotid artery, and predominantly involves the posterior wall of the vessel. The plaque encroaches on the lumen of the internal carotid artery and often extends caudally into the common carotid artery. Various theories have been proposed to explain atheromatous plaque formation at the carotid bifurcation. Impedance mismatch, with altered hemodynamic conditions that accompany division of a vessel into conduits of substantially different sizes, may be implicated in the vessel injury.[52] Plaque formation may produce symptoms either through low flow as a result of the stenosis with inadequate collateral compensation or by exhibiting degenerative changes that lead to atheromatous emboli and thromboemboli.

Indications

Although successful CEA may reduce the risk of stroke in selected patients, it is always important to balance the risk of operation with the risk of stroke from the unoperated lesion.

Three major trials have investigated the efficacy of CEA in selected patients with symptomatic carotid atherosclerosis: the North American Symptomatic Carotid Endarterectomy Trial (NASCET), the European Carotid Surgery Trial (ECST), and the Veterans Affairs Cooperative Trial 309. These major clinical trials defined symptomatic carotid disease as focal ischemic symptoms that are referable to the appropriate carotid artery distribution, including one or more transient ischemic attacks characterized by focal neurologic dysfunction or transient monocular blindness or one or more minor (nondisabling) ischemic strokes.[53] A recent pooled analysis of these three trials using the same measurements and definitions yielded highly consistent results. CEA is of some benefit for patients with 50–69% symptomatic stenosis, and highly beneficial for those with 70% symptomatic stenosis or greater but without near-occlusion. Benefit in patients with carotid near-occlusion is marginal in the short-term and uncertain in the long-term. CEA was not beneficial for symptomatic carotid stenosis of 30–49%, and was harmful for symptomatic patients with less than 30% stenosis.[54]

Three high-quality major trials—the Veterans Affairs Cooperative Study Group, the Asymptomatic Carotid Atherosclerosis Study (ACAS), and the Asymptomatic Carotid Surgery Trial (ACST) have evaluated the efficacy of CEA in patients with asymptomatic high-grade carotid stenosis (60% or greater). A meta-analysis of these three trials showed that despite approximately a 3% perioperative stroke or death rate, CEA for asymptomatic carotid stenosis reduces the risk of any stroke by approximately 30% over 3 years. However, the absolute risk reduction is small for the first few years of followup. The ACST showed that significant benefit for the population is not evident until 2 years after surgery. Early after CEA, perioperative morbidity outweighs the modest, although significant, reduction in stroke risk that accompanies this procedure.

Data from several studies identified clinical predictors for adverse outcome. Although not validated in other studies, one or more of the following characteristics are associated with an increased risk of poor outcome (stroke, MI, or death) at 30 days after CEA: age older than 80 years, congestive heart failure, chronic obstructive pulmonary disease, renal failure (serum creatinine concentration >2.0 mg/dL), contralateral ca-

rotid artery occlusion, and recurrent ipsilateral carotid artery stenosis.[55]

Intraoperative Monitoring

Monitoring for Cerebral Ischemia

The beneficial effects of CEA over medical therapy are partially dependent on low perioperative morbidity. It is recommended that perioperative stroke and death rate be less than 6% for symptomatic patients and less than 3% for asymptomatic patients so as to maintain this benefit.[56]

The carotid artery must be temporarily completely occluded by a cross-clamp in order to perform the CEA. Although 80–85% of patients tolerate clamping of the carotid artery without symptoms, assessment of collateral circulation occurring contralaterally via the circle of Willis is needed in all patients. The most common technique to restore flow across the carotid artery is a temporary Javid shunt, which is inserted through the arteriotomy distally in the internal carotid artery and proximally in the common carotid artery. Although beneficial in restoring blood flow, shunt insertion may cause an embolism-associated stroke, can be associated with intimal dissection leading to acute occlusion, and may affect the adequacy of the endarterectomy by limiting exposure of the plaque. Several authorities argue that any monitoring modality that could reliably indicate inadequate cerebral blood flow would allow a more conservative use of the shunting procedure.

Electroencephalography Electroencephalography is the gold standard for monitoring patients under general anesthesia. Cerebral ischemia produces neuronal dysfunction, leading to slowing of frequencies or reduced amplitude in the electroencephalogram (EEG) tracing. These changes may be generalized (global ischemia) or regional (focal ischemia). The depth of ischemia is associated with the severity of EEG changes. Electroencephalography cannot assess the whole cerebral cortex and is less reliable at assessing subcortical structures. In the setting of CEA, the focal EEG changes after cross-clamping the carotid artery may be defined as none, mild (<25% increase in theta waves or >50% decrease in amplitude), moderate (>25% increase of theta waves or <25% increase of delta waves), or severe (>25% increase of delta waves and severe flattening of amplitude or isoelectric curve).[57] A recent study evaluated the efficacy of continuous intraoperative EEG monitoring in a group of 1661 CEA operations in which the EEG was the sole criterion for shunt insertion.[58] Intraoperative stroke rate in the study group was 0.3% (5 strokes). A statistically significant increase in intraoperative stroke rate was associated with the development of an abnormal EEG, a contralateral internal carotid artery occlusion, and the combination of both an abnormal EEG and a contralateral internal carotid occlusion.[58] One explanation for the high sensitivity of the EEG monitoring in this study may be the technique used (16-channel EEG interpreted by experts). In less-experienced hands, the sensitivity for detection of ischemia decreases.[59] Patients who have preexisting neurologic deficits should be monitored with caution. One study showed that 4 (3%) of 124 patients who had strokes or reversible neurologic deficits before CEA awoke with new deficits despite an unchanged EEG during the procedure.[60]

Electroencephalography is affected by anesthetic agents and changes in temperature and blood pressure. Additionally, the value of EEG monitoring is limited by the fact that the majority of neurologic deficits after CEA is caused by thromboembolism rather than occlusion of blood flow during carotid clamping.

Processed electroencephalography, such as compressed spectral array, density spectral array, and spectral edge frequency, is easier to monitor and interpret. Although there is still insufficient data, studies so far show that these techniques have a lower sensitivity than raw electroencephalography.

Somatosensory Evoked Potentials The most commonly used electrophysiologic technique to monitor functional continuity of nerve, spinal cord and brain is somatosensory evoked potentials (SSEPs). The use of SSEP monitoring during CEA is still inconclusive. While some studies found similar sensitivity in their ability to detect postoperative neurologic defects when compared with electroencephalography[61] others found SSEP to be less sensitive than electroencephalography in predicting the need for shunting.[62] Under general anesthesia the cortical SSEP is depressed, amplitude is decreased, and there is increased latency in a dose-dependent manner by inhalational agents. It can be obtained, however, in most patients with 0.5 minimum alveolar concentration of a volatile anesthetic supplemented by intravenous medications, usually narcotics or intravenous hypnotics. Furthermore, the technique is dependent on availability of specialized equipment and trained staff.

Transcranial Doppler Transcranial Doppler (TCD) provides noninvasive assessment of the middle cerebral artery (MCA) by insonating the MCA through the temporal bone using a specially designed Doppler probe. As long as fluctuations in arterial blood pressure and arterial CO_2 content are small, changes in flow velocity reflect changes in cerebral blood flow. Hemodynamic compromise is indicated by a reduction in mean flow velocities or when there is slow flow acceleration. In addition, TCD has the unique capability to detect cerebral microembolic signals, reflecting the presence of gaseous or particulate matter in the insonated cerebral artery, which occur most commonly during the dissection phase, during shunting and unclamping, during wound closure, and in the first few hours postoperatively.[63]

Data regarding the reliability of TCD in monitoring for cerebral ischemia is controversial. Emboli during dissection and wound closure, as well as greater than 90% decrease of MCA peak systolic velocity at cross-clamping or greater than 100% increase of the pulsatility index of the Doppler signal at clamp release, were independently associated with stroke.[64] Belardi et al. concluded that neither TCD nor the stump pressures are reliable in predicting the need for carotid shunting.[65] TCD may be used as a complementary monitoring technique to electroencephalography. Although there is high overlap between low-flow velocities and ipsilateral EEG slowing, neither technique alone may identify all candidates for shunting or prevent all strokes.[57] Technical difficulties or inappropriate visualization window make TCD difficult to interpret in 15–20% of cases.

Near-Infrared Spectroscopy Near-infrared spectroscopy (NIRS) is a noninvasive technique that allows continuous monitoring of regional cerebral oxygenation saturation (rSO_2) through the scalp and skull.

Although easy to use and interpret, noninvasive NIRS has several limitations related to the fact that NIRS primarily measures venous oxygen saturation at the level of the frontal lobes, and there is a wide range of values that are not associated with a clinically detectable neurologic dysfunction. Samra et al. noted that although there was a significant change in ipsilateral rSO_2 during carotid cross-clamping as compared with preclamping and postclamping values, there was a highly variable patient-to-patient change in rSO_2 after carotid cross-clamping, with no relation to neurologic dysfunction.[66]

NIRS is a simple and noninvasive method to indirectly assess cerebral perfusion in patients undergoing CEA. Although it correlates with the development of clinical and EEG signs of cerebral ischemia, it should not be used alone to predict the need for shunt placement because of its low sensitivity and specificity.[67]

The Awake Patient Monitoring of the awake patient is the gold standard for neurologic assessment and may allow for prompt identification of patients who would benefit from shunt placement. Change in contralateral strength or consciousness in the setting of adequate mean arterial pressure is an indication for shunt placement. Intraoperative neurologic changes in the awake patient may predict a sixfold increase in the incidence of postoperative stroke (Fig. 54–4).[68] A study reporting the synchronous use of EEG monitoring with mental status evaluation in patients undergoing CEA under regional anesthesia showed that EEG monitoring yielded a significant number of false-positive (6.7%) and false-negative (4.5%) results in the detection of neurologic deficits when compared with mental status evaluation alone in the awake patients.[69] This method of monitoring requires the absolute cooperation of surgeon, anesthesiologist, and patient.

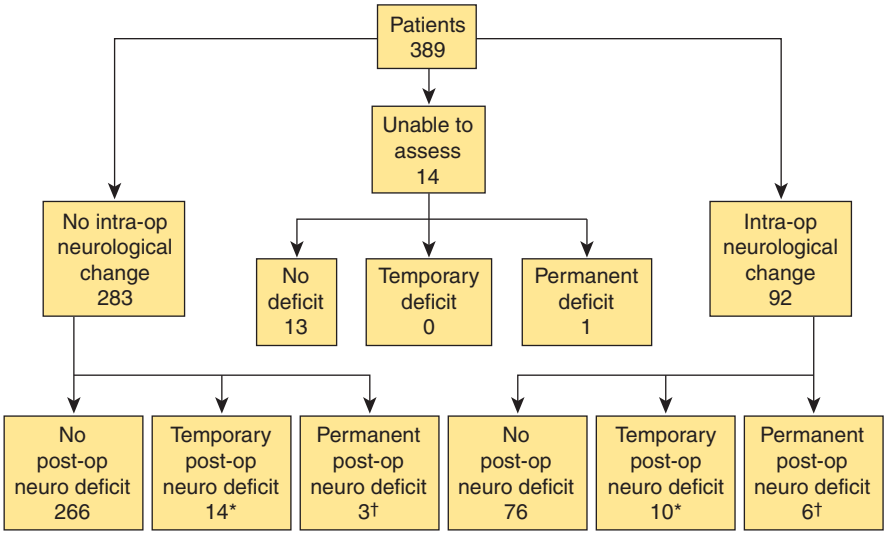

FIGURE 54–4. Correlation of intraoperative neurologic change and postoperative neurologic outcome. Number of patients is shown in each box. *p <0.05 for temporary neurologic complication. †p <0.01 for permanent neurologic complication. Source: Stoughton J, Nath RL, and Abbott WM.[69]

GENERAL CONSIDERATIONS

Standard cardiovascular monitoring should include continuous ECG with two leads displayed (usually II and V_5) and invasive continuous measurement of arterial blood pressure.

The 2003 ASA revised practice guidelines for the use of pulmonary artery catheters (PACs) do not support the use of PACs in peripheral vascular surgery unless indicated by comorbidities.[70] As changes in pulmonary capillary occlusion pressure are relatively insensitive to myocardial ischemia some advocate continuous use of transesophageal echocardiography (TEE) in patients with severe CAD.

Intravenous access may be limited to large-bore peripheral intravenous catheters. The use of central venous catheters should be parsimonious, weighing in risks and benefits. It may be more appropriately reserved for patients with documented or suspected severe CAD or valvular heart disease. The contralateral internal jugular vein should be preferably and cautiously cannulated under ultrasound guidance to avoid carotid puncture.

Anesthetic Techniques

The goals of anesthesia, with balanced concerns for both brain and heart, may be summarized as follows:

- Hemodynamic extremes should be avoided during induction, incision, surgical manipulation, emergence and extubation.
- The patient should be sufficiently responsive immediately after surgery to facilitate neurologic evaluation.

Clearly, these two objectives narrow the range of acceptable anesthetic options and require clinical expertise.

Because the impact of the anesthetic technique on outcome remains controversial, both regional and general anesthesia techniques have proponents. Some investigators have found that regional anesthesia by cervical plexus block obviates the use of a shunt in more than 80% of patients, and facilitates safe, simple, and effective intraoperative cerebral function monitoring.[71–73] Regional anesthesia may be associated with shorter hospital stays, decreased intensive care costs, and less cardiovascular morbidity.[74–76]

A meta-analysis of the available randomized clinical trials comparing CEA under local anesthesia versus general anesthesia[77] showed that although local anesthesia was associated with a significant reduction in local postoperative hemorrhage, there were no significant differences in morbidity and mortality outcomes. These results should be interpreted with caution because of small sample sizes and insufficient power. Results from a large, ongoing, randomized trial (general anesthetic versus local anesthetic for carotid surgery [GALA]) are awaited before recommendations can be made regarding favoring one type of anesthesia over another.

Regional anesthesia is performed by blocking the superficial and deep cervical plexus formed from C2 to C4 anterior rami of the ipsilateral spinal roots. Proponents of this technique believe that an awake patient is the best monitor of neurologic function during carotid surgery. To achieve this goal the patient must be minimally sedated; the procedure requires a high degree of patient cooperation, a profound block-

ade, and an expeditious surgeon. Intraoperatively, the internal, external, and common carotid arteries are clamped sequentially followed by neurologic assessment. If neurologic deficit is noted by monitoring speech and upper-extremity motor function, surgery may proceed either with elevation of systemic blood pressure, reocclusion and reassessment of the patient, or with placement of a Javid shunt that bypasses the operative area.

Complications associated with regional anesthesia include infection, hematoma, local anesthetic toxicity, nerve injury, inadvertent spinal anesthesia, and phrenic nerve blockade, which can result in loss of function of the ipsilateral hemidiaphragm and consequent respiratory insufficiency, especially in patients with chronic respiratory disease.[78]

Disadvantages of regional anesthesia include patient discomfort and loss of cooperation, confusion, panic, and seizures. Management of intraoperative problems may be more difficult and, theoretically, associated with increased morbidity.

General anesthesia allows reliable airway control, better control of ventilation, nearly eliminating the possibility of hypoxemia and hypo- or hypercapnia, and optimal operating conditions for the surgical team. A potential benefit of using general anesthesia is the ability to monitor with TEE to detect wall-motion abnormalities and to guide therapy in patients with severe CAD.

Induction of general anesthesia should proceed slowly with medications titrated to the desired effect. Sodium thiopental, propofol, and etomidate are the induction agents employed most frequently because of their neuroprotective effects. Addition of a short- or intermediate-acting narcotic, depending on the proposed duration of surgery, is recommended. Moderate doses of narcotic allow for better hemodynamic control during intubation and incision, and permit a lower dose of inhalational agent to be used for anesthetic maintenance. The choice of neuromuscular blocking agents is unimportant as long as the duration of action of the agent does not delay emergence and it is not associated with hemodynamic disturbances related to the vagolytic or histamine release effects. Vecuronium seems to be the ideal muscle relaxant for procedures lasting ninety minutes or less.

The use of a laryngeal mask airway may lessen perioperative hemodynamic responses associated with airway management during intubation and extubation, but this decision must be based individually on the pros and cons related to the use of either an endotracheal tube or laryngeal mask airway.

Maintenance of general anesthesia can be achieved with various agents depending on hemodynamic stability provided, rapidity of emergence, and interference with the methods of monitoring employed. The rapid elimination of desflurane and sevoflurane may allow earlier postoperative neurologic assessment compared with isoflurane. However, desflurane may be associated with tachycardia and hypertension and therefore may increase cardiovascular risk. A study investigating hemodynamic and recovery characteristics in patients scheduled for CEA anesthetized with isoflurane, sevoflurane, or desflurane found no significant perioperative differences were noted in cardiac index or ST-segment analysis. The times to extubation, movement on command, and consciousness were shorter after desflurane and sevoflurane than after isoflurane.[79] As mentioned in the paragraphs above, moderate amounts of opioids can be used to enhance hemodynamic stability during maintenance of anesthesia, with care not to compromise rapid emergence at the end of the procedure. Researchers have found that although fentanyl, sufentanil, and remifentanil offered similar intra- and postoperative hemodynamic stability, remifentanil allowed faster recovery and earlier neurologic examination and was superior in blunting the sympathetic response to intubation.[80,81]

Blood pressure and heart rate changes during and after CEA surgery are quite variable and can even be extreme.[82] Surgical manipulation of the carotid sinus can cause an increase in afferent impulses to the brainstem and trigger an abrupt bradycardic response and hypotension. This may be prevented by infiltration of the sinus with local anesthetic by the surgeon. If infiltration has not been performed, then clamp application may cause hypertension and tachycardia because the sinus now senses a low pressure. The reverse may or may not be observed with unclamping. The variability between individuals in this reflex behavior may be a result of differences in sinus insensitivity secondary to the atherosclerotic process.

Control of the arterial partial pressure of carbon dioxide in the arterial blood is controversial. Hypocapnia produces nondiscriminatory bilateral cerebral vasoconstriction whereas hypercapnia may induce a "steal" phenomenon. Consequently, most authors recommend the maintenance of normocarbia during CEA.[82]

A number of animal studies of traumatic brain injury, focal cerebral ischemia, and global cerebral ischemia demonstrate that glycemic control is a critical factor in terms of outcome.[83] Glycemic control with insulin improves neurologic outcome in patients who are critically ill and in those who are undergoing cardiac surgery.[84] Although there is relative lack of evidence to support the tight control of glucose in diabetic patients who are undergoing CEA, the adverse impact of hyperglycemia on cerebral ischemic injury suggests that the perioperative management of glucose is vital in these patients.

It is universally accepted that blood pressure during carotid occlusion should be maintained at or up to 20% higher than the patient's highest recorded resting blood pressure when awake so as to maintain adequate collateral blood flow. This may be achieved by titration of vasoconstrictors or inotropes, or by infusion of intravenous fluids. Although many recommend using dilute continuous infusions of an α-agonist to achieve this goal, Smith et al. showed a higher incidence of myocardial ischemia when phenylephrine was used to achieve blood pressure goals in patients who were under moderately deep levels of inhalational anesthesia. Interestingly, despite the high incidence of intraoperative myocardial ischemia, no patient in this study suffered perioperative MI. It is noteworthy that this investigation used an anesthetic procedure that did not include short-acting narcotics as a supplement to the inhalational agent.[85] No evidence is available to help choose one intervention over another.[82]

Nowhere are emergence issues more important and complex than in CEA. Although it is desirable to have the patient alert and responsive immediately after the procedure to permit neurologic assessment, hypertension, which can stress and rupture the surgical anastomosis, is an ever-present

threat. Patients are frequently smokers with hyperreactive airways and copious airway secretions. Unless thorough precautions are taken, stimulation from the endotracheal tube at the time of emergence from general anesthesia will cause coughing and straining and can result in severe hypertension. Residual effects from previously administered narcotics are particularly helpful at this time. Early extubation could be considered in selected patients. Careful evacuation of oropharyngeal secretions, instillation of 60–80 mg of 2% lidocaine in the endotracheal tube during the surgical closure, and careful adjustment to minimal pressure in the endotracheal tube cuff, are partially effective techniques to blunt hypertension caused by the presence of the endotracheal tube. Aggressive pharmacologic intervention may be necessary with short-acting agents.

Postoperative Considerations

There are several potential complications that may occur postoperatively, notably stroke, MI, and respiratory dysfunction. Hypertension is common, can have a multifactorial etiology, and is associated with increased incidence of cardiac and neurologic complications. An avoidable consequence of poorly controlled hypertension is wound hematoma necessitating prompt evaluation and possible wound exploration.

Patients with severe hypertension are at risk of developing hyperperfusion syndrome, which is an abrupt increase in blood flow with loss of autoregulation in the surgically reperfused brain. Reports describe a spectrum of findings, including severe headache, transient ischemia, seizures, and intracerebral hemorrhage, which presents as headache, seizures, or cerebral edema, and often occurs several days after surgery.[86]

Hypotension and bradycardia may occur secondary to carotid sinus hypersensitivity after plaque removal. Carotid body injury may persist for up to 10 months postoperatively. Recurrent laryngeal, hypoglossal, and marginal mandibular nerve injury may result in hoarseness, tongue deviation on protrusion, and drooping of the corner of the mouth. Superior laryngeal nerve injury may present as impaired phonation. Spinal accessory nerve injury may result in ipsilateral shoulder weakness.[87]

LOWER-EXTREMITY VASCULAR SURGERY

An Overview of Peripheral Arterial Disease

Peripheral arterial disease (PAD) is a growing clinical problem in the United States and its prevalence is only likely to increase as the population ages. Between 1999 and 2000 the National Health and Nutrition Examination Survey examined the population older than age 40 years and found that PAD affected more than 5 million adults in the United States. PAD prevalence increases dramatically with age from 0.9% between the ages of 40 and 49 years to 14.5% in those age 70 years and older. African American ethnicity, current smoking, diabetes, hypertension, hypercholesterolemia, and low kidney function were significantly associated with prevalence of PAD.[88]

Atherosclerosis is the most common etiology of PAD. Other, less-common causes are acute arterial disease (embolism, thrombosis, dissection, trauma), adventitial cystic disease, arterial fibrodysplasia, occluded limb aneurysms, and tumors. Of the cases of embolism to the lower extremities, 90% are caused by emboli that originated in the heart in patients with cardiac dysrhythmias, recent MIs or ventricular aneurysms with intracardiac thrombus, or diseased or prosthetic cardiac valves.

Patients are candidates for elective surgery to correct peripheral occlusive disease if they exhibit (a) intermittent, activity-limiting claudication; (b) ischemic rest pain; (c) ischemic ulceration; or (d) gangrene. According to the ACC/AHA and TransAtlantic Inter-Society Consensus (TASC) guidelines, certain issues have to be considered before revascularization: morphology of the lesions, projected natural history and prognosis of the patient, projected improvement in quality of life from alleviation of claudication, and inadequate response to exercise rehabilitation and medical therapy.[89,90]

Patients with intermittent claudication have normal flow to skeletal muscle at rest but markedly impaired flow to meet metabolic demands during exercise. The location of pain varies with the anatomic site of obstruction: buttock and hip pain is usually caused by aortoiliac disease, thigh pain is caused by common femoral artery disease, calf pain is caused by either superficial femoral artery or popliteal artery disease, and foot pain is caused by tibial or peroneal artery disease. Over time PAD affects skeletal muscle neurologic and metabolic functions, leading to further impairments in muscle performance and patient functional status.[89]

Modifiable atherosclerotic risk factors for PAD include smoking, diabetes, obesity, hyperlipidemia, hypertension, and homocysteine elevation.[89] Although more than 70% of the patients with PAD have no progression of symptoms with conservative management such as smoking cessation, exercise rehabilitation, and antiplatelet therapy,[90] the remainder have progression of their symptoms that mandate revascularization. When revascularization is required, the options are percutaneous interventional procedures and surgery.

Percutaneous transluminal angioplasty results in a "controlled" dissection of the arterial media. Percutaneous transluminal angioplasty traditionally has been limited to the treatment of focal, short segmental stenoses or occlusions. With advancements in technology, percutaneous transluminal angioplasty is now routinely applied to more extensively diseased segments to attempt limb salvage before a distal surgical bypass. Percutaneous transluminal angioplasty can also be used in patients who are poor surgical candidates. The TASC group recommends endovascular treatment for single lesions less than 3 cm in the common or external iliac artery (type A lesions) and surgical treatment for complete common femoral artery, superficial femoral artery or popliteal artery occlusions and proximal trifurcation occlusions (type D lesions). For lesions of intermediate severity there is insufficient evidence to make recommendations and these may be treated on an individual basis.[89]

Individuals who are undergoing lower-extremity vascular surgery present a dilemma to the anesthesia provider. The procedure itself is associated with far less (intraoperative and postoperative) nociceptive stimulation than aortic surgery, less hemodynamic fluctuation than carotid or aortic surgery and can be performed with a pure regional anesthetic. On the other hand, patients may have severe CAD and other systemic disorders, the

former undiscovered because of mobility limitations, placing these patients at high risk for perioperative complications. In a large study, patients undergoing infrainguinal bypass had a 30-day mortality rate of 5.8% and a 1-year mortality of 16.3%.[91] Thus the perioperative management of this group, including the anesthetic technique, must proceed with considerable caution.

Anesthetic Considerations

Monitoring

Standard monitoring should include continuous ECG with two leads displayed (usually II and V_5), pulse oximetry, noninvasive blood pressure capnography, and temperature. In patients with cardiac risk factors who are undergoing noncardiac surgery, the perioperative maintenance of normothermia is associated with a reduced incidence of morbid cardiac events and ventricular tachycardia.[92]

Arterial cannulation and continuous pressure monitoring are considered standard. If a radial line is not technically feasible, the axillary approach is recommended. Central venous pressure (CVP) monitoring is frequently helpful. Volume status can be difficult to judge, especially in long, complicated cases that can evolve unpredictably. Improved response time to the administration of vasoactive agents is often sufficiently important to justify central venous cannulation.

Pulmonary artery catheterization is not routinely employed. Although monitoring with PACs provides more hemodynamic data, its benefit has not been demonstrated in several outcome studies, so is not routinely employed.[93,94] The 2003 ASA revised practice guidelines for the use of PACs do not support their use in peripheral vascular surgery unless indicated by comorbidities.[70] As changes in pulmonary capillary occlusion pressure are relatively insensitive to myocardial ischemia, some advocate continuous use of TEE in patients with severe CAD.

Anesthetic Techniques

Because of their especially high-risk status, and because the nature of the surgery permits a pure regional technique, lower-extremity vascular surgery patients have been the subject of several studies comparing regional and general anesthesia.

Spinal and epidural anesthesia using local anesthetic agents have long been believed to provide overall better operative conditions for a variety of reasons, including avoidance of exposure to airway and pulmonary morbidity, lower blood loss, and ablation of the surgical stress response. The latter effect presumably produces more stable hemodynamics, reduced hypercoagulability, better wound healing, and less immune suppression. Furthermore, vasodilatation secondary to sympathetic blockade should be particularly helpful in sustaining graft patency.

A recent meta-analysis of 141 randomized trials compared neuraxial anesthesia with general anesthesia for all types of patients and demonstrated that neuraxial blockade reduced the odds of deep vein thrombosis by 44%, pulmonary embolism by 55%, transfusion requirements by 50%, pneumonia by 39%, and respiratory depression by 59% (all $P < 0.001$). There were also reductions in MI and renal failure.[95]

Serious difficulties have plagued many published investigations, including both prospective, randomized clinical trials and retrospective studies. The failure to adequately address these issues has produced findings that vary widely and therefore must be carefully interpreted.

The landmark study by Yeager et al. showed much less morbidity and mortality in a group of patients who underwent diverse major surgical procedures and who were given regional anesthesia and analgesia postoperatively, compared with those who received general anesthesia followed by on-demand parenteral narcotics. Only a few vascular surgery subjects were included in this study and the morbidity and mortality in the general anesthesia group was much higher than reported in other studies. No management techniques were specified and the general anesthesia group actually received a wide variety of techniques.[96] Tuman et al. randomized patients undergoing lower-extremity vascular surgery or aortic abdominal aneurysm surgery to receive either epidural-supplemented general anesthesia followed by postoperative epidural analgesia or general anesthesia followed by on-demand parenteral narcotics.[97] The investigators found somewhat higher cardiac morbidity in the general anesthesia group, but the difference was much less dramatic than in the study by Yeager et al. The most remarkable outcome was a larger number of reoperations for inadequate lower-extremity flow in the general anesthesia group (20%). Tuman has speculated that the mechanism for this morbidity was attributable to perioperative hypercoagulability in the general anesthesia group that was not seen in the regional anesthesia group. It has been long believed, with some hard data, that regional blockade with local agents blunts certain components of the surgical stress response, including procoagulant activity. Although establishing the ability of regional anesthesia to attenuate this phenomenon would be significant, caution is warranted in the attribution of prevention of hypercoagulability to the reduced revascularization rates because other possibilities include sympathetic blockade as well as other aspects of management. Two other studies that compared regional and general anesthesia,[98,99] in which neuraxial analgesia was not continued in the postoperative period, found no benefit in terms of vascular graft patency.

Christopherson et al. conducted a randomized trial, called the Perioperative Ischemia Randomized Anesthesia Trial (PIRAT), of 100 patients who were undergoing lower-extremity grafts under epidural or general anesthesia. Postoperative analgesia included epidural fentanyl in the regional group and IV patient-controlled analgesia in the general group. Cardiac morbidity and mortality in each group was low, and the revascularization rate was high in the general anesthesia group.[100] Rosenfeld et al. using patients from the PIRAT study, reported an increase in plasminogen activator inhibitor in the general patients, but not in the regional patients, on the morning after surgery (Fig. 54–5).[101] This finding confirms the hypercoagulable state found by Tuman et al. postoperatively in the general anesthesia group, as well as the ability of regional anesthesia and analgesia to prevent the phenomenon. Also reporting from the PIRAT study, Breslow showed that norepinephrine levels rise at the end of surgery in the general, but not the regional, anesthesia group, and remain elevated throughout the postoperative period. Clearly, in this study, regional anesthesia/analgesia was effective in blocking the stress response after surgery.[102]

Source: Rosenfeld BA, Beattie C, Christopherson R, et al.[101]

Bode et al. conducted a trial larger than the previous studies. In their trial, 423 patients who were undergoing lower-extremity grafts were randomized to either regional (spinal or epidural) or general anesthesia. They found low cardiac morbidity and mortality and low revascularization rates in both groups. In this study, however, all patients were monitored with pulmonary artery catheters intraoperatively and for the first 48 hours postoperatively. This permitted aggressive optimization of hemodynamic status and probably contributed to the excellent results in both groups.[103]

Anticoagulant therapy is an important adjunct in the perioperative period in the maintenance of vascular graft patency. As this has implications in the choice of anesthetic technique, the American Society of Regional Anesthesia and Pain Medicine has issued guidelines regarding neuraxial anesthesia and anticoagulants.[104] A few of these recommendations are as follows:

1. Unfractionated heparin should not be given for at least 1 hour after needle placement. Epidural catheters should be removed at least 1 hour before a heparin dose and at least 2–4 hours after a heparin dose after evaluation of patient's coagulation status. There should be careful monitoring of the patient's neurologic status in the postoperative period and minimal concentration of local anesthetic should be used.
2. There are no current contraindications to using neuraxial techniques in patients who are on subcutaneous heparin prophylaxis.
3. For patients who are on low-molecular-weight heparin, needle placement should occur at least 12 hours after the last thromboprophylactic dose of low-molecular-weight heparin and at least 24 hours after the last therapeutic dose.
4. Warfarin therapy should be discontinued 4–5 days before block placement, and coagulation status should be checked.
5. There are no contraindications to giving a neuraxial anesthetic to patients who are on nonsteroidal anti-inflammatory drugs.
6. Clopidogrel should be discontinued for 7 days, and ticlopidine for 14 days, prior to neuraxial anesthesia.

Although regional anesthesia has desirable effects, there is insufficient data to recommend one technique over another. With the advent of new anesthetic agents, general anesthesia can be safely employed with attention to detail throughout the perioperative period and aggressive management of hemodynamic changes.

ANEURYSMS

Pathophysiology and Management

Aneurysms are arterial expansions that occur as the vascular wall becomes weakened from atherosclerosis or other degenerative processes. The abdominal aorta is the most common site of arterial aneurysm. Abdominal aortic aneurysms (AAAs) most often occur in the segment of aorta between the renal and inferior mesenteric arteries. Approximately 5% involve the renal or visceral arteries. Thoracoabdominal aneurysms involve the thoracic and abdominal aorta together.

Recently, the role of atherosclerosis in the pathogenesis of aneurysms has become less clear and the underlying cause of aneurysmal aortic dilation is uncertain in most patients. A genome scan of 36 families with abdominal aortic aneurysm identified a possible gene locus for this disease on chromosomes 19q13 and 4q31.[13] Other investigators suggested that destruction of elastin in the aortic wall is a key event that shifts the load produced by blood pressure on collagen. This is exacerbated in the presence of hypertension. Smoking and age are other important factors. The location of the aneurysm is also important, as elastic lamellae are relatively less common in the abdominal aorta. Once the shielding effect of elastin is lost, further dilation and rupture of the aorta depend on the physical properties of the collagen present.[105]

Although the infrarenal portion may exhibit atherosclerosis, the suprarenal aorta often shows degenerative changes of the media called *mucoid degeneration, myxomatous degeneration*, or *cystic medial necrosis*.[106]

The natural progression of untreated aneurysm is expansion and eventual rupture. This is because with equal distending pressure within a vessel, the wall tension is higher when the vessel radius is larger, as described by the Laplace law. This physical principle states that the tension (T) sustained by a vessel wall because of blood pressure (P) is directly proportional to the vessel radius (R) as given by the following relationship: $T \sim P \times R$.

Perioperative mortality after elective aneurysm repair is low (5.8 and 2.7% in the United Kingdom Small Aneurysm and the ADAM trials, respectively).[22,23] In contrast, perioperative mortality is much higher with emergency surgery, occurring in 37% of 81 patients in a large screening trial.[24] Consequently, it is important to identify individuals who are at greatest risk for rupture and appropriately time the surgical repair.

The likelihood that an aneurysm will rupture is influenced by a number of factors, including aneurysm diameter, rate of expansion, and gender. According to a statement from the Joint Council of the American Association for Vascular Surgery and Society for Vascular Surgery, the estimated annual risk of rupture, according to AAA diameter, is 0.5–5% for AAAs that are 4.0–4.9 cm in diameter; 10–20% for AAAs that are 6.0–6.9 cm in diameter; 20–40% for AAAs that are 7.0–7.9 cm in diameter; and 30–50% for those AAAs that are greater than 8.0 cm in diameter.[107] Other factors include continued smoking, uncontrolled hypertension, increased wall stress, and rate of expansion (a rate of growth of more than 0.5 cm in 6 months).[90]

Two randomized trials, the United Kingdom Small Aneurysm and the ADAM trials, investigated the management of medium-size aneurysms (4.0–5.5 cm), comparing early surgery with ultrasound surveillance. Both trials showed no long-term difference in mean survival between the early surgery and surveillance groups, although in the United Kingdom Small Aneurysm trial, after 8 years there was a lower total mortality in the early surgery group, probably attributable to changes in lifestyle adopted by patients in this group.

In 2005 the ACC/AHA, published guidelines on the diagnosis and management of peripheral arterial disease in collaboration with major vascular medicine, vascular surgery, and interventional radiology societies. Some of the recommendations are as follows:

1. Aneurysms 4.0–5.4 cm in diameter should be monitored by ultrasound or tomographic scanning every 6–12 months.
2. Aneurysms 3.0–4.0 cm in diameter should be monitored by ultrasound every 2–3 years.
3. Aneurysms with diameter larger than 5.5 cm should be repaired.
4. Earlier repair may be beneficial in patients with aneurysms that increase in diameter more than 0.5 cm in 6 months.
5. Patients with symptomatic aneurysms should undergo repair, regardless of aneurysm diameter.

Anesthetic Considerations

Monitoring

All patients undergoing aortic surgery should have continuous intravascular monitoring of arterial pressure. As with other types of surgery, the first site considered is the radial artery of the arm with the highest pressure, determined by sphygmomanometry. Reasons for choosing other sites include inadequate collateral flow to the hand (the Allen test), poor radial pulsations caused by previous trauma or proximal vascular disease, and site of cross-clamping above the left subclavian. The axillary artery offers an excellent alternative. Cannulation of the axillary artery is usually performed with the Seldinger technique. Caution is warranted in flushing an axillary artery catheter because the tip is rather more proximate to the carotid and vertebral system, and air or particulate matter could enter these vessels.

In addition to radial or axillary pressure monitoring, a femoral arterial cannula should be strongly considered in thoracic or thoracoabdominal aneurysm surgery where shunt or bypass procedures are employed. Knowledge of arterial pressure distal to the cross-clamp permits a considerably more rational approach to hemodynamic manipulations during surgery. Although embolization and arterial occlusion can occur, studies show that complication rates are similar for ulnar, brachial, axillary, femoral, and dorsalis pedis cannulation and are very low.[108]

The use of PACs in the perioperative setting and their impact on morbidity and mortality is still under intense scrutiny and debate. Although some clinicians advocate the use of PACs in all patients who are undergoing an aortic cross-clamp procedure, others moderate their use based on the cross-clamp level and extent of comorbid disease. Several clinical trials have compared outcomes in vascular surgical patients monitored with CVP only versus PACs. Sandison et al. compared the outcome of patients undergoing nonelective AAA repair at two hospitals under the care of a single vascular surgeon and found that the hospital that used fewer PACs and less intervention (in the form of colloid and inotropes) had lower mortality. One other prospective trial randomized abdominal aortic reconstructive surgery patients to monitoring with a central venous catheter or with a PAC, and showed that the choice of central venous catheter or pulmonary artery catheter monitoring made little difference in outcome.[109] Sandham et al. and the Canadian Critical Care Trials Group published a landmark study that looked at the routine use of PACs and found no benefit to therapy directed by PAC over standard care in elderly, high-risk surgical patients who required intensive care. They also found a higher rate of pulmonary emboli among the catheter group.[110] A rational approach is to use a PAC in those cases requiring a suprarenal (or above) cross-clamp and reserve its use in infrarenal aneurysms and occlusive disease to those individuals with significant cardiac, renal, or pulmonary pathology. This endorsement presumes that the venous cannulation and balloon flotation are initiated safely; the pressure transducers are properly leveled, zeroed, and calibrated; thermodilution cardiac outputs are technically sound; calculated and measured parameters are interpreted correctly; and therapeutic interventions reflect appropriate understanding of physiology and pharmacology. If any one of these requisites is missing, PACs are best omitted.[111]

TEE is a valuable tool, increasingly available in the noncardiac operating rooms. According to the 2003 guidelines issued by the American College of Cardiology and the American Society of Echocardiography, class I and class II indications for intraoperative TEE use in vascular surgery are intraoperative evaluation of severe hemodynamic instability unresponsive to treatment; perioperative monitoring of patients who are at increased risk of myocardial ischemia or with severe ventricular dysfunction; perioperative assessment of thoracic aortic aneurysms and stent placement; intraoperative evaluation of aortic atheroma; and monitoring of the placement and function of intracardiac and intravascular devices.[112] TEE is a sensitive monitor for detecting myocardial ischemia, considered by many to be more sensitive than ECG, PACs, or other means of hemodynamic monitoring.[113] Smith et al. determined that intraoperative TEE could successfully demonstrate myocardial ischemia by revealing acute segmental wall-motion abnormalities. He also found that when new segmental wall-motion abnormalities continued until the end of the operation, MI was likely to have occurred.[85] There are certain risks involved with a TEE examination, such as anatomic damage from insertion

and manipulation of the probe, incomplete examination, and incorrect interpretation of the images, which can lead to decisions detrimental to the patient. TEE may prove particularly useful in patients who are undergoing supraceliac cross-clamping procedures.[114]

Despite tremendous development in surgical and anesthetic techniques, resection of the thoracic and thoracoabdominal segments of the aorta remains associated with the risk of paralysis. Procedures that require aortic cross-clamping above the celiac axis or more cephalad incur a progressively higher risk of major neurologic sequelae. The number of reported incidents of paraplegia following aortic surgery varies from approximately 1 in 1000 for elective repair of uncomplicated abdominal aortic aneurysm to 30% when the entire thoracic aorta is replaced emergently.[115] Monitoring of functional continuity of the spinal cord would allow for implementation of hemodynamic or cytoprotective interventions to minimize spinal cord injury. The perioperative use of SSEPs to monitor spinal function is well established. Cunningham et al. reported that ischemic periods associated with less than 30 minutes of SSEPs loss did not result in paraplegia, whereas longer periods of ischemia resulted in a 71% incidence of paraplegia.[116] However false-positive and false-negative results have been reported with the use of SSEPs. SSEPs monitor only the posterior column of the spinal cord, are very sensitive to anesthetic agents (especially volatile agents), can be influenced by temperature, hypoxia, hypotension, ischemia of the peripheral nerves, or peripheral neuropathies.[115] To complement SSEPs in monitoring spinal cord functional integrity, motor evoked potentials (MEPs) were introduced. MEPs are produced by stimulation of the motor cortex. The response typically is recorded near the muscle as a compound muscle action potential. Transcranial MEPs are exquisitely sensitive to anesthesia. Total intravenous technique with propofol/ketamine and opioid continuous infusions is favored when MEP monitoring is employed.

Blood loss during aneurysm surgery is highly variable. Central venous access and large-bore peripheral venous access for the administration of large blood volumes is necessary. A rapid infusion system that can administer up to 1500 mL/min of warmed fluids, should be available. Blood-salvaging techniques for autotransfusion have proven useful in aortic aneurysm repair. Systems that use cell separation and return only red blood cells result in fewer coagulation abnormalities than systems that return whole blood. Given the high cost of current technology, it becomes cost-effective (when compared to the cost of providing allogeneic blood) when 2 or more units of blood can be salvaged and reinfused. Major vascular surgery offers the best opportunity for appropriate employment of blood-scavenging units. Although no randomized, prospective studies of efficacy have been reported, it is obvious that the use of these devices would decrease the exposure of multiple donors. One study showed a 25–57% reduction in the number of different donors for patients having vascular procedures.[117]

Some degree of hypothermia is commonly observed in patients who are undergoing aneurysm surgery. This is caused by the exposure of abdominal contents, the administration of large amounts of fluid, and disturbances in thermoregulatory mechanism caused by both inhaled and intravenous anesthetics. Whereas hyperthermia is associated with increased metabolic rates with deleterious cerebral and spinal cord effects, hypothermia is associated with adverse myocardial events, coagulopathy, wound infection, and delayed wound healing. In a review of patients who underwent elective AAA repair, Bush et al.[118] noted significantly more organ dysfunction (53% vs. 29%) and higher mortality rate (12% vs. 1.5%) in hypothermic patients (temperature less than 94.1°F [34.5°C]) than in normothermic patients. Active measures should be taken to maintain normothermia. However, during aortic cross-clamping, the lower body should not be actively warmed.

Physiology of Cross-Clamping

The hemodynamic and metabolic alterations caused by acute interruption of aortic blood flow have been the subject of both animal and human investigations for many years.[119–121] Features of particular relevance to anesthetic management include changes in arterial blood pressure, cardiac function, myocardial perfusion, and acid–base status, as well as tissue integrity of the kidneys, viscera, and spinal cord. Conflicting findings have been obtained and likely reflect species variation, patient characteristics, degree of collateralization, location of the cross-clamp, baseline cardiac function, type of anesthesia, the use and type of vasodilators, and the presence or absence of CAD. This section reviews the classic and conflicting findings from the literature and presents plausibility arguments for making rational clinical decisions.

Blood Pressure The degree of hypertension caused by application of an aortic cross-clamp depends on the location of the clamp, the degree of collateralization, and the preocclusion aortic flow. Thus an infrarenal clamp in a patient with aortic occlusive disease may cause virtually no elevation in the blood pressure because distal preclamp flow was minimal. Also, aortic clamping above a thoracic coarctation may result in no pressure change proximal (or distal) to the clamp because of adequate collateral flow. In the case of AAA repair, runoff is usually good and collateralization minimal. Therefore, an increase in blood pressure should be expected, the magnitude of which is proportional to how proximal the location of cross-clamp is in relation to the heart. Clamping below the renal arteries is common and usually produces only a small increase in blood pressure,[121] but supraceliac occlusion can result in significant hypertension.[119] Other factors may contribute to the observed hypertension. During proximal aortic occlusion, increased concentrations of catecholamines, angiotensin, and renin have been observed. These agents, as well as other mediators released from ischemic tissues below the clamp, may influence the vascular tone above the clamp.[122]

Venous Return and Cardiac Output Although it may seem intuitive that cardiac output should decrease with acute occlusion of a major arterial conduit caused by an increase in afterload, reflex mechanisms, venous return, and left-heart function may modify this response. For example, location of the cross-clamp is important. If the clamp is placed in the supraceliac region, evidence suggests that venous return and cardiac output actually increase. This is probably a result of splanchnic venous collapse distal to the cross-clamp and blood volume redistribution above the level

of the clamp with increased filling pressures (central venous pressure, pulmonary capillary wedge pressure, or left ventricular end-diastolic pressure). However, an infrarenal cross-clamp may redistribute blood volume back to the compliant splanchnic bed, decrease preload, and cause a decrease in cardiac output.[120]

Other mechanisms have been suggested to explain an increase in cardiac output with thoracic aortic clamping, including an aortic–cardiac reflex,[123] which increases contractility and elimination of slow time-constant vascular beds (splanchnic) from the circulation.[124,125] Conversely, an increase in aortic pressure should stimulate baroreceptors to depress heart rate, contractility, and vascular tone. Previous studies showed a decrease in cardiac output with aortic occlusion, and this finding has come to represent the common understanding.[114,126] How is it possible to obtain such opposing results? Paradoxically, infrarenal and suprarenal cross-clamps eliminate fast time-constant vascular beds (lower extremities, kidneys) and thus could reduce cardiac output, whereas higher thoracic clamps remove the slow time-constant visceral circulation, thereby increasing cardiac output. Figure 54–6 summarizes the issues surrounding blood volume distribution during application of supra- and infraceliac cross-clamps.

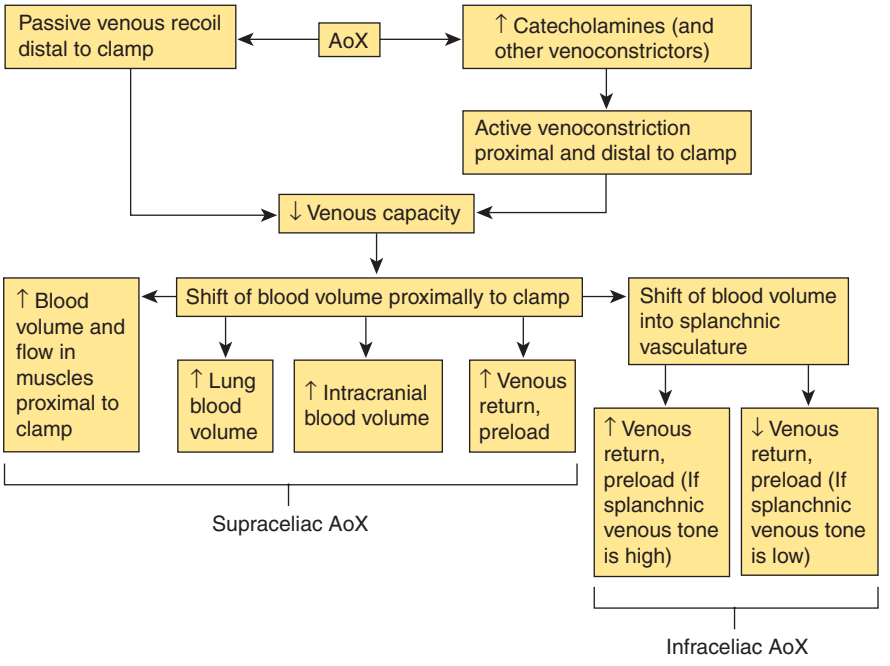

FIGURE 54–6. Blood volume redistribution during aortic cross-clamping. This scheme depicts the reason for the decrease in venous capacity, which results in blood volume redistribution from the vasculature distal to aortic occlusion to the vasculature proximal to aortic occlusion. If the aorta is occluded above the splanchnic system, the blood volume travels to the heart, increasing preload and blood volume in all organs and tissues proximal to the clamp. However, if the aorta is occluded below the splanchnic system, blood volume may shift into the splanchnic system or into the vasculature of other tissues proximal to the clamp. The distribution of this blood volume between the splanchnic and nonsplanchnic vasculature determines changes in preload. ↑, increase; ↓, decrease; AoX, aortic cross-clamping. Source: Gelman S.[120]

Myocardial Effects The effects of aortic cross-clamping on cardiac function and myocardial perfusion have been the subject of several investigations. In the absence of any underlying disorder of contractility or coronary flow, the heart can generate and withstand very high arterial pressures. However, serious deterioration of pump function could be produced if a high afterload is superimposed on a myocardium depressed by cardiomyopathic processes. Moreover, myocardial ischemia itself could be precipitated during clamping, leading to regional wall motion abnormalities or infarction if afterload elevation occurs in the presence of coronary artery stenosis.[114] The presumed mechanism for this ischemia is subendocardial hypoperfusion caused by the high intercavitary pressures during diastole and systole, in conjunction with impaired inflow caused by stenotic coronary lesions.

One investigation used TEE monitoring and determined that occlusion of the aorta at the supraceliac level caused major increases in left ventricular end-systolic and end-diastolic dimensions, decreases in ejection fraction, and frequent wall-motion abnormalities. These changes were not detected by conventional monitoring devices. Occlusion at the suprarenal–infraceliac level caused similar but smaller changes, and occlusion at the infrarenal level caused only minimal cardiovascular effects. The hemodynamic effects of clamping the aorta were managed by administration of vasodilating drugs, anesthetics and fluids to keep systemic and pulmonary arterial pressures normal. The same study reported the onset or worsening of regional wall abnormalities during aortic occlusion, which did not resolve with modification of the loading conditions using vasodilators and inhalational agents.[114]

It is quite possible that aortic occlusion could have effects on ventricular function even if mean arterial pressure and systemic vascular resistance were normalized to baseline. The blood pressure wave form, as observed in the ascending aorta, is created by characteristics of ventricular ejection and vascular resistance and compliance, as well as by pressure waves returning retrograde from major reflecting sites in the periphery. If sufficiently delayed, reflected waves may appear in diastole, thus augmenting myocardial perfusion. Return during systole, however, would add to wall stress during ejection and increase myocardial oxygen demand.[127] By moving the major reflecting site closer to the heart, aortic cross-clamping could thus cause myocardial dysfunction in the face of a mean aortic pressure normalized by therapy.

Aortic cross-clamping is associated with increases in preload and afterload, leading to an increase in myocardial oxygen demand. The intact coronary vasculature responds to this increase in demand by an increase in flow. In one set of experiments, cross-clamping of the aorta was associated with a greater than 65% increase in the coronary blood flow, which probably represents coronary blood flow autoregulation and increases in myocardial oxygen demand and consumption.[119]

Responses to cross-clamping differ in patients with and without CAD. In

conditions of increased systolic left ventricular pressure and left ventricular dilation, the normal ventricle responds with a positive inotropic effect (the "Anrep effect").[120] In contrast, in the presence of CAD, left ventricular decompensation ensues because of the inability to increase subendocardial blood flow in response to an increase in intraventricular pressure.

Metabolic Changes Two fundamental interconnected metabolic effects characterize aortic cross-clamping: (a) lowered total-body oxidative metabolism (VO_2) and (b) conversion to anaerobic metabolism of the hypoperfused body mass distal to the clamp. Gelman et al.[120] showed that application of an infrarenal cross-clamp caused a 16% decrease in VO_2. Presumably, a suprarenal occlusion would cause a reduction similar to the infrarenal occlusion because the kidneys do not consume oxygen in proportion to their flow.

The effects of aortic cross-clamping on mixed venous oxygen saturation and partial pressure depend on the therapeutic modalities used to control blood pressure. If arteriolar dilation is the dominant therapy, then aerobically functioning tissue will be overperfused, its extraction will decrease, and the saturation and partial pressure of oxygen of mixed venous blood will increase substantially. Conversely, preload reduction techniques maintain both oxygen extraction ratio and mixed venous saturation at approximately their preclamp values.

Anaerobic metabolism by tissue below the aortic cross-clamp produces lactic acid that reaches the proximal circulation by collaterals, leading to progressive rise in blood lactate. For infrarenal cross-clamps, the buildup in systemic lactate during occlusion, as well as its release with unclamping, is noticeable but rarely clinically significant.[121] Exceptions to this occur with grossly prolonged ischemic times.

Cross-clamps above the celiac axis not only produce a larger anaerobically functioning tissue mass but also, by excluding the liver and kidneys, greatly attenuate the elimination of lactate.

Therapeutic Strategies

Most clinicians view the physiologic problem of aortic cross-clamping as a consequence of increased left ventricular afterload, and propose interventions that reverse this effect. Vasodilators, notably sodium nitroprusside, are routinely used to control hypertension.[129]

Arteriolar dilation in vessels supplying organs proximal to the clamp can, in most circumstances, cause them to accommodate a sufficient increase in blood flow to maintain blood pressure within an acceptable range. Obviously, this produces a relative over-perfusion of the affected organs. Problems with this method include (a) partial failure (e.g., inability to adequately control pressure); (b) the need for high doses of sodium nitroprusside; and (c) exceedingly low pressures in the circulation distal to the lowest clamp.

Alternate strategies involve manipulating the venous return. During the period of cross-clamp, that portion of the body supplied by the occluded arterial flow is unavailable for oxidative metabolism. Thus, the heart does not need to maintain its preclamp output, and interventions that would reduce output seem appropriate.[120] Simultaneous interventions to decrease the venous return and minimize blood redistribution may solve the problem.

Venodilation with nitroglycerine, sufficient to lower filling pressure and reduce cardiac output, appears to be the most attractive alternative. In experimental aortic cross-clamping in animals, despite the severe myocardial depression observed, nitroglycerin maintained transmural distribution of flow favoring the endocardium. The benefit probably reflected decreased ventricular wall tension resulting from an increase in venous capacitance and subsequent preload reduction.[130]

Although nitroglycerin is an attractive alternative given its coronary vasodilatory and preload reduction effects, it is a weak arteriodilator and may not be sufficient in controlling blood pressure in situations of high aortic occlusion.[122] The use of a combination of low-dose nitroprusside along with nitroglycerine as a titratable technique to control pressure will benefit from both afterload and preload reduction with rapid termination of the pharmacologic effects before aortic unclamping.

Isoflurane, which mildly depresses contractility and causes vasodilatation of both resistance and capacitance vessels, has been safely used for anesthesia and blood pressure control in patients with good myocardial function who are undergoing thoracic aneurysm repair.[131]

Bypass and shunting techniques that divert flow from the left atrium, left ventricle, or proximal aorta to the aorta distal to the lowest clamp have been used to blunt the effects of cross-clamping. Because these methods are not devoid of complications, they are usually reserved for surgery that necessitates thoracic aortic clamping.

Femoral vein–femoral artery bypass uses femoral venous inflow by gravity to a reservoir/oxygenator, and roller-pump-generated outflow to a femoral artery, thus perfusing retrograde vasculature below the most distal clamp (femoral–femoral bypass). Hypertension caused by clamp application is quickly resolved by increasing volume in the venous reservoir, which reduces venous return to the heart and lowers cardiac output.[132] The requirement for full systemic anticoagulation can be a disadvantage in terms of postoperative bleeding. Technical problems with cannula size and placement that limit the venous return will decrease the bypass pump flows and will limit the distal perfusion and the effectiveness of the circuit in controlling proximal blood pressure.[122]

A Gott shunt is a heparin-coated conduit that passively shunts blood from the proximal to the distal aorta without the need of systemic coagulation. One end of the conduit is placed in the ascending aorta or in the aortic arch and the distal end is placed in the distal descending aorta.[133] Although it is a simple and inexpensive technique, distal flow is limited by the size of the shunt, and dislodgement of atheromatous plaque, vessel injury, bleeding, kinking, and malpositioning of the conduit can occur.

Partial left-heart bypass uses extracorporeal circulation to shunt flow from the left atrium to the distal circulation. The left atrium is commonly cannulated via a left pulmonary vein and oxygenated blood is diverted either through a centrifugal pump or through an oxygenator/reservoir and a roller pump to the femoral artery. Whereas using a reservoir requires full systemic anticoagulation, using a centrifugal pump requires minimal or no heparin. Bypass flow rates ranging from 25–40 mL/kg/min seem sufficient to normalize proximal aortic pressures and maintain adequate distal perfusion.[122,134]

Renal Protection As the incidence of acute renal failure during aortic aneurysm repair varies from 3–13%,[122] preservation of renal function is a primary concern during aortic aneurysm surgery. Clearly, procedures that require cross-clamping of the aorta above the renal arteries will result in a temporary period of renal ischemia, with the potential for inducing some degree of renal injury.

In animal experiments, preischemia administration of mannitol exerts a protective effect on renal function.[135] Because the mechanisms that produce acute tubular necrosis are complex, it is not surprising that controversy exists regarding the exact manner in which mannitol and other agents might prevent acute tubular necrosis. It is possible that mannitol, a potent osmotic diuretic, exerts its protective effect by the scavenging of free radicals produced upon reperfusion of the kidney with cross-clamp release and by shifting blood flow to the renal cortex by its vasodilatory properties. As there is some evidence to support a beneficial effect of intravenous mannitol given before aortic clamping,[136] it is common clinical practice to administer 12.5 g/70 kg 10–15 minutes before aortic cross-clamping.

The use of furosemide is more controversial. Although a protective effect of furosemide has not been established per se, it is generally believed that this agent may result in a conversion of low-output-to-high-output renal failure, the latter being much easier to manage in the postoperative period. When diuretics are used, increased fluid requirements and hypokalemia should be anticipated throughout the perioperative period.

For the more common infrarenal aneurysms, where cross-clamp application would not seem to impede renal perfusion, renal vascular resistance increases and renal blood flow decreases.[120,135,137] The distribution of renal blood flow is altered during infrarenal aortic cross-clamping, and this phenomenon can result in impairment of function.[137] Renal blood flow is reduced not only during cross-clamping, but after cross-clamping blood flow does not immediately return to normal.[120] All of these factors combine to increase the risk of postoperative renal dysfunction. Patients with preoperative renal insufficiency are at greatest risk of developing renal failure.[136]

Maintenance of adequate intravascular volume[138] and a short cross-clamp time, usually less than 30 minutes,[122] are the most important factors for avoiding renal dysfunction postoperatively. Many clinicians advocate the use of low-dose dopamine (3 μg/kg/min) to increase renal blood flow during aneurysm surgery, although there is no evidence to support this approach.[139] Fenoldopam mesylate, a highly selective dopamine type-1 agonist that preferentially dilates the renal and splanchnic vasculature, has renoprotective effects and is associated with a relatively rapid return of renal function to baseline values in this setting.[140]

Other methods of renal protection include partial left heart bypass or renal cooling with selective cold crystalloid perfusion.[141,142]

Spinal Cord Ischemia and Protection The spinal cord receives blood via radicular arteries that supply the anterior spinal artery and the posterolateral spinal arteries. The upper part of the spinal cord receives most of its blood supply via the vertebral arteries and in a small proportion via the ascending and deep cervical arteries and through the costovertebral arteries. The lower half of the spinal cord is supplied entirely by branches of the intercostals, lumbar, iliolumbar, and lateral sacral arteries. The paired posterior arteries supply the posterior one-third of the spinal cord while the anterior spinal artery supplies the anterior two-thirds of the spinal cord.

The single anterior artery commences from the spinal branches of the vertebral arteries and receives variable blood supply through radicular arteries derived from ascending cervical, intercostal, lumbar, and iliolumbar arteries. The largest and most developed radicular artery is the arteria radicularis magna, or the artery of Adamkiewicz, which can originate from T9 to L3 levels, but most commonly arises from T9 to T12.[115]

Based on anatomic distribution of segmental vessels supplying the spinal cord, the tenuous collateral flow to the anterior spinal artery in the midthoracic region makes the spinal cord vulnerable to ischemia during aortic occlusion or hypotension.

Aortic cross-clamping, which either incorporates the artery of Adamkiewicz between clamps or exposes it to hypoperfusion, may lead to paraplegia or paraparesis.[143] Because the incidence of these complications increases from 1% in the low abdominal aortic aneurysms to 7–40% for thoracic and thoracoabdominal aneurysm repair,[144] several modalities to provide spinal cord protection have been developed, including identification of ischemia by monitoring evoked potentials (SSEP and MEP), reimplantation of segmental vessels, sequential aortic clamping, maintaining aortic distal aortic perfusion through shunt or bypass, cerebrospinal fluid drainage, epidural cooling, or hypothermic cardiopulmonary bypass and circulatory arrest.[145]

Unclamping

Release of the aortic cross-clamp results in metabolic and hemodynamic changes that vary in magnitude according to (a) the extent and nature of the tissue reperfused; (b) the total occlusion time; (c) administration of fluids and therapeutic agents during the cross-clamp period and at the moment of unclamping; and (d) the use of shunts or bypass. The most consistent cardiovascular response to clamp release in the absence of shunts or bypass is an acute fall in systemic blood pressure. The dominant influence is a decrease in systemic vascular resistance caused by opening of the previously minimally perfused vascular beds, which may be maximally dilated due to reactive hyperemia.

Release of an infrarenal clamp usually causes a small drop in blood pressure that is transient and well-tolerated, although treatment with fluid infusion or small increments of a vasopressor may be occasionally necessary. Removal of a supraceliac cross-clamp can result in profound hypotension, which should be anticipated by vigorous prerelease intravascular volume administration, and frequently requires transient vasopressor support (Fig. 54–7). However, indiscriminate use of vasopressors may result in excessive vasoconstriction above the aortic clamp compared with below the clamp because the former, which is nonischemic, would respond better to vasopressors than the latter, which is acidotic. This would promote redistribution of blood volume from the upper to the lower part of the body, further reducing the flow above the aortic clamp.[120] Figure 54–8 summarizes the hemodynamic responses to aortic unclamping.

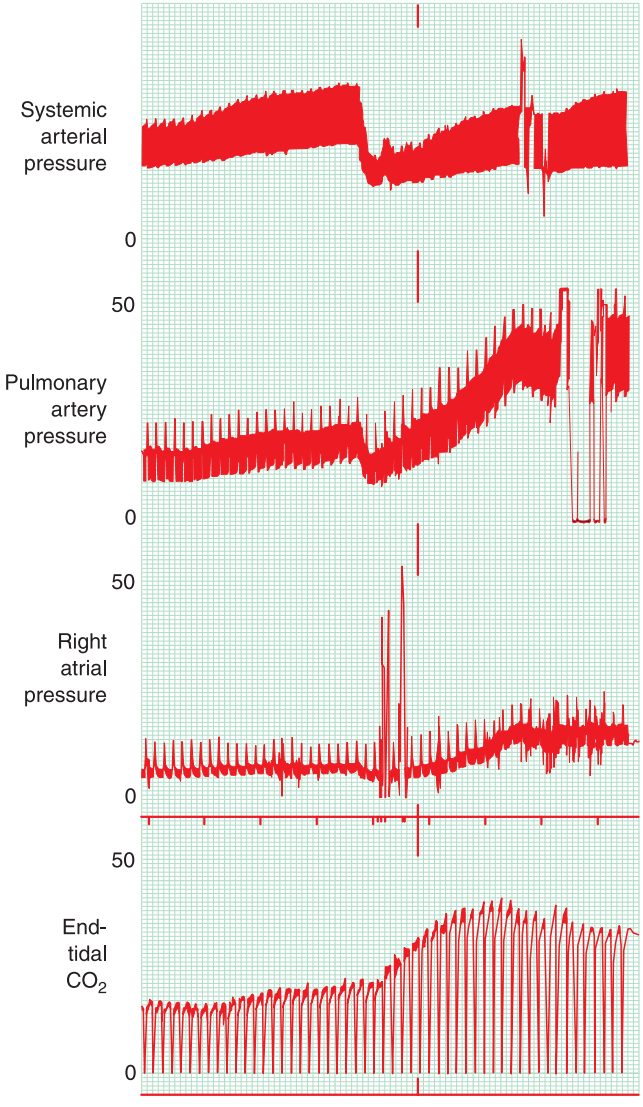

FIGURE 54–7. Continuous chart recording of arterial, pulmonary artery (PA), and right arterial pressures and end-tidal CO_2 around the time of release of a supraceliac cross-clamp. Note the prerelease rise in pressures as vasodilatation is reduced. Fall of pressures with release is followed by rapid return resulting from administration of vasopressors and volume. Elevation of CO_2 may contribute to rise in PA pressures.

Several different mediators have been suggested as being responsible for the hemodynamic effects seen after the release of the aortic cross-clamp including acidosis, lactate production, renin–angiotensin system, oxygen free radicals, prostaglandins, complement activation, and myocardial depressant factors.[120] Unless the myocardium becomes ischemic or fails, stability usually returns within several minutes with conservative therapy. Disseminated intravascular coagulation is an unusual but devastating complication.[146] The etiology of the condition is largely unknown, but is likely related to cross-clamp duration and intestinal ischemia.

Total body oxygen consumption increases with unclamping as below-clamp tissues return to aerobic metabolism. Mixed venous blood shows an abrupt desaturation within minutes after release of a supraceliac clamp, and rapidly returns to preclamp values. The transient rise in oxygen extraction implied by this finding may only reflect "reloading" of oxygen-depleted hemoglobin, myoglobin, and cytochromes, rather than actual energy production. Investigators have addressed the issue of "oxygen debt," wherein reperfusion of a previously ischemic tissue mass may result in an overshoot of oxygen consumption to "repay" a deficit incurred during the anaerobic period.[147]

Carbon dioxide is elevated in arterial and venous blood within moments of unclamping, and this is reflected in the end-tidal partial pressure (see Fig. 54–7). Two principal sources contribute to the appearance of CO_2: (a) as the end product of aerobic metabolism and (b) from the buffering (through carbonic acid) of organic acids that are washed out during reperfusion. It was formerly common clinical practice to administer a bolus of sodium bicarbonate just before unclamping in an attempt to buffer the expected fall in pH. Unfortunately, additional CO_2 produced by the exogenous sodium bicarbonate buffering adds to the CO_2 produced by aerobic metabolism and dramatically increases $Paco_2$ levels. Carbon dioxide readily diffuses across cell membranes and could worsen intracellular acidosis, resulting in organ dysfunction (e.g., cardiac conduction and contractility disturbances).[148] Bicarbonate should be administered, if desired, before unclamping when volume resuscitation, perfusion and ventilation are adequate.

Blood lactate levels often increase after release of the aortic clamp. Higher concentrations occur with prolonged ischemia and higher levels of clamping. Lactate levels rapidly return to normal after complete restoration of hepatic and liver flow and elimination of continued excess production. It is uncommon for significant lactate elevation to persist into the postoperative period.

Gradual release of the aortic clamp and its reapplication has been recommended to allow time for volume replacement and washout of the vasoactive and cardiodepressant mediators from the ischemic tissues.[120]

Anesthetic Techniques

The anesthetic plan should take into consideration the comorbidities of the patient and knowledge of intraoperative physiologic changes, as well as specific plans for postoperative care.

General Anesthesia After institution of appropriate monitoring, induction of general anesthesia can be induced with sodium thiopental, etomidate, or propofol while avoiding hemodynamic extremes. Intravenous opioids, such as fentanyl and sufentanil, can be titrated to blunt the hemodynamic effects of endotracheal intubation. Neuromuscular blockade may

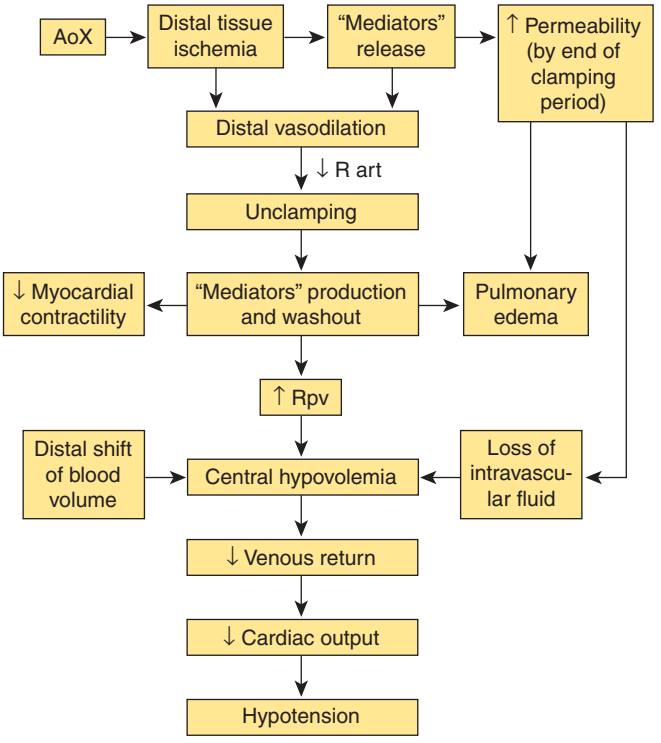

FIGURE 54–8. Systemic hemodynamic response to aortic unclamping. ↑, increase; ↓, decrease; AoX, aortic cross-clamping; Cven, venous capacitance; R art, arterial resistance; Rpv, pulmonary vascular resistance. Source: Gelman S.[120]

be introduced at any time during this process after the loss of consciousness. Tachycardia and/or hypertension that may be triggered by laryngoscopy and intubation can be controlled with short-acting β-blockers such as esmolol. Brisk fluid administration may be necessary during induction to prevent hypotension. Preoperative antihypertensive medications, recent use of intravenous contrast agents, and fasting can result in intravascular volume depletion. The generalized withdrawal of sympathetic tone that accompanies anesthetic induction can then lead to hypotension. Anesthesia may be maintained with volatile agents in combination with opioids and neuromuscular blocking agents. The choice of volatile agent may be based on their secondary effects. Isoflurane causes mild vasodilatation and minimal myocardial depression and seems to be the agent of choice. More importantly, both isoflurane and sevoflurane protect the myocardium from ischemia by means of preconditioning.[149]

Total intravenous anesthesia can be used with titrated, continuous infusion of propofol and short-acting opioids such as remifentanil and alfentanil. Total intravenous anesthesia should be considered when intraoperative neurologic monitoring with SSEP and MEP is employed. This technique is also appealing in patients who have renal insufficiency or in cases involving suprarenal aortic clamping because of the lack of dependency of these agents on renal clearance for recovery. Additionally, it allows rapid emergence and extubation. Although there may be concerns with total intravenous anesthesia because of its tendency to cause hypotension, this can be prevented by ensuring euvolemic status before induction.[150]

Combined Techniques The introduction of intrathecal and epidural narcotics for both intraoperative and postoperative analgesia has proved to be a major advance in perioperative anesthetic management. When patient-controlled analgesia is combined with classic methods of regional anesthesia, a variety of intraoperative and postoperative strategies using local anesthetics and opioids are possible. A comprehensive discussion of postoperative analgesic techniques is beyond the scope of this chapter, but certain pertinent issues relating to major vascular surgery are outlined. First, intraoperative and postoperative management issues clearly should be separated. Improved clinical outcome for regional or combined regional/general techniques compared with general anesthesia may be attributable to differences in postoperative pain management rather than intraoperative technique. Studies disagree on the influence of anesthetic technique on perioperative morbidity in this patient population.[151] Second, although the value of neuraxial narcotics in moderating postoperative stress is increasingly clear, intraoperative use of this modality influences anesthetic management. Any significant dose of parenteral opiates given to blunt the stimuli of intubation and incision may act synergistically with the neuraxial narcotic to produce prolonged or delayed respiratory depression at the end of the procedure, thereby delaying emergence. Epidural anesthesia using local anesthetic agents is an attractive adjunct to general anesthesia and has been advocated for vascular surgery.[96] With noxious stimuli blocked at the level of somatic afferents, only those systemic agents necessary to produce unconsciousness, amnesia, and reflex suppression are required. Experience shows, however, that extreme hypotension can result in patients who are undergoing aortic surgery when combined regional and general anesthesias are used. The drop in blood pressure that accompanies removal of an aortic cross-clamp is exacerbated by any degree of sympathetic blockade. Adequate fluid resuscitation before cross-clamp or the use of vasopressors with declamping may be required. Although excessive fluid administration may predispose to hypervolemia in the postoperative period, the use of vasopressors may cloud clinical judgment when organ or limb perfusion is in doubt. Hypotension can be minimized by optimizing intravascular volume and by administering much smaller volumes of local anesthetics in the epidural space than normally required for a "pure" regional anesthetic.

It is increasingly evident that the postoperative period is associated with a high risk of morbidity in patients with cardiac disease undergoing noncardiac surgery.[19,34] Several possible sequelae of major vascular surgery, including "third-space" fluid accumulation, postoperative pulmonary dysfunction, coagulopathy, hypothermia and renal failure, may make emergence and extubation problematic. The ideal is to have an extubated, comfort-

able, well-oxygenated, ventilating patient who is normothermic and normovolemic, with good renal function and stable vital signs.

Postoperative Care

Even with the wide variation in clinical practice, emergence technique, need for mechanical ventilation, and postoperative analgesia are critical determinants of postoperative morbidity. Relevant issues to consider are the anesthetic technique, extent of aneurysm repair, and patient stability with regard to certain physiologic parameters, including body temperature, pulmonary function, urine output, blood loss, and intravascular volume.

Many patients will be ready for extubation at the termination of surgery. Several factors, however, may complicate what would otherwise appear to be a simple decision. Patients with a significant smoking history may have respiratory compromise. Postoperative deterioration of pulmonary function superimposed on preexisting dysfunction can result in poor oxygenation immediately after surgery. Furthermore, varying degrees of fluid shift commonly occur during aortic aneurysm repair and continue postoperatively. Even if intravascular volume has been carefully maintained, extravascular fluid must be mobilized and eliminated over time. It is not always possible to monitor and control this process with a sufficient degree of precision. Thus patients who seem to be doing well may develop problems several hours after the procedure and require reintubation after an apparently "normal" recovery.

Several authors have recommended the use of epidural narcotics and local anesthetics for postoperative pain control.[96,152] The benefits of epidural analgesia include efficient pain management, a decrease in adrenocortical stress response, and a reduction in protein catabolism, immunosuppression, and pulmonary and cardiac morbidity.[97,122,153,154] However, other investigations have found no difference in morbidity or mortality rates when pure general anesthesia was compared with a combined regional/general technique.[155,156]

Myocardial ischemia is common in the postoperative period, although much of it may be "silent" and require careful surveillance to detect. There is also a strong association between postoperative ischemia and adverse outcome.[34]

Postoperative care of vascular surgery patients can be challenging. Coagulopathy in the perioperative period can become a major problem requiring reexploration. Hypothermia may persist and require treatment with heating blankets. Electrolytes and blood gases should be followed closely and hemodynamic profiles optimized. Patients who have experienced a ruptured aneurysm and/or prolonged suprarenal cross-clamping are at high risk of acute renal failure. Adequate attention to these details is essential for ensuring a successful outcome.

Anesthetic Considerations for Endovascular Aneurysm Repair

Endovascular aortic repair (EVAR) has steadily gained popularity as a reliable alternative to conventional surgical repair of aortic aneurysms. Endovascular repair of abdominal aneurysms was developed to reduce morbidity and mortality and to provide an alternative for patients who cannot undergo standard surgical therapy.

To define the role of EVAR in the management of aortic abdominal aneurysms, two randomized trials investigated both short- and long-term outcome of patients who were considered suitable candidates for either elective open surgery or endovascular repair. The EVAR 1 (endovascular aortic repair) trial included 1082 patients with aneurysms at least 5.5 cm in diameter who were at least 60 years of age and found that the 30-day mortality was significantly lower with endovascular than with open repair (1.6% vs. 4.6%). However, overall survival was comparable in both groups 4 years after randomization.[157] The Dutch Randomized Endovascular Aneurysm Management (DREAM) trial evaluated 345 patients with aneurysms of at least 5 cm in diameter, and found a significant trend toward lower operative mortality with EVAR than with conventional surgery (1.2% vs. 4.6%). There was no difference in cumulative survival at 2 years of follow-up (89.7% vs. 89.6% with surgical repair), an effect that was present at 1 year.[158] The short-term survival advantage of EVAR appears to be much greater when it is limited to patients who are at highest risk from open surgery.[159] EVAR avoids the hemodynamic lability associated with major abdominal incision and aortic cross-clamping and unclamping, and also presents other subtle benefits, such as significantly smaller changes in plasma catecholamine levels, improved acid–base homeostasis,[160] and a decreased metabolic stress response.[161]

In 2005, the ACC/AHA published practice guidelines for the management of patients with peripheral arterial disease (lower extremity, renal, mesenteric, and abdominal aortic).[90] The following 3 recommendations were made with regard to the type of intervention:

1. Open surgical repair for patients at low or average risk of operative complications.
2. EVAR in patients who are at high risk of complications from open operations.
3. EVAR for patients who are not at high surgical risk; however, evidence of benefit is less-well established in this setting.

For the deployment of the graft, a femoral or iliac arteriotomy is performed, and a sheath is passed into the aorta over a guidewire. The endovascular stent is threaded over the guidewire and is positioned under fluoroscopic guidance. An inflatable balloon catheter is positioned inside the proximal attachment system. The balloon is inflated for a period of 30–60 seconds during which time aortic blood flow is occluded. This expands the stent and imbeds the hooks into the normal arterial wall. Newer, approved devices are self-expanding once released from the sheath and use a trilobed balloon for stent fixation. This combination results in less hemodynamic stress as the aorta is never totally occluded during balloon expansion.

Endovascular repair is suitable for patients who meet certain anatomic criteria: at least 1.5 cm of aneurysmal neck below the renal arteries; at least 1 cm of aneurysmal neck above the aortic bifurcation; femoral artery free from limiting occlusion and at least 8 mm in diameter; and, if the distal attachment is the iliac artery, a minimal length and maximum diameter of healthy artery as specified by the manufacturer.

Surgical complications can include damage to iliofemoral vessels (dissection, ischemia), distal embolization of atheromatous debris, adverse reactions to radiographic contrast, rupture of aneurysm, and displacement of the proximal stent to occlude the renal or mesenteric arteries or other arteries in repair of the thoracic aorta.

Endoleak is defined as the persistence of blood flow outside the lumen of the endograft but within an aneurysm sac. Endoleak may occur as a consequence of misplacement or poor sizing of an endograft (technical error), fatigue, displacement or distortion of the endograft material (device failure), or by reactions to the endograft within the aneurysmal sac environment. Endoleaks are classified based on location/mechanism and timing of occurrence. Type I endoleak is a persistent flow around the attachment sites (proximal or distal) of the endograft as a result of inadequate or ineffective seal at the graft ends. Type II endoleak is a result of retrograde flow into the aneurysmal sac from a patent collateral branch vessel. Type III endoleak is defined as flow into the aneurysmal sac because of a tear or defect in the endograft fabric or because of leakage between modular segments of an endograft. Type IV endoleak is flow detected in the aneurysmal sac as a consequence of the highly porous graft material.[162]

Anesthetic Techniques

General anesthesia, regional anesthesia and monitored anesthesia care with local anesthetic infiltration at the incision site have all been used successfully for EVAR. Goals of an anesthetic plan should be to maintain hemodynamic stability, provide adequate oxygenation and ventilation, preserve organ function, and maintain normothermia.[163]

Certain concerns related to the procedure should be addressed. Careful positioning of the device over guidewires for accurate deployment and the use of fluoroscopy require the patient to be perfectly still, sometimes for longer periods of time than anticipated. Care must be taken to ensure that tachycardia and hypertension are avoided. During the transient balloon occlusion of the aorta, the surgeon may request that the mean blood pressure be maintained at about 60 mm Hg so that the force pushing the stent distally is minimized. Also at this time the patient may experience significant hemodynamic stress, especially if baseline cardiac function was poor. Vasopressors and inotropes must be available at hand to manage hemodynamic emergencies. Preparation must be made for sudden massive blood loss, following major disruption of the aorta, and immediate laparotomy with aortic cross-clamping.

Blood loss can be difficult to quantify, as it is often lost around the sheaths and catheters, and can be retroperitoneal in the case of injury to femoral or iliac vessels. Hemoglobin should be checked during the procedure, especially if the patient becomes unstable. Endovascular procedures involve the liberal use of radiographic contrast to assist in appropriate deployment of the graft, ensure exclusion of the aneurysmal sac and determine branch vessel patency. It is important to ensure that patients are adequately hydrated during the procedure and in the postoperative period to minimize contrast induced nephropathy.

At the time of instrumentation of the aorta the patient must be anticoagulated with intravenous heparin. This, however, should not restrict the use of regional anesthesia as long as the recommendations made by the American Society of Regional Anesthesia and Pain Medicine regarding neuraxial anesthesia and anticoagulation are followed.

Various studies have compared anesthetic techniques. A recent retrospective analysis based on the European registry of patients who underwent EVAR (the European collaborators on stent/graft techniques for aortic aneurysm repair [EUROSTAR] registry) showed that a benefit in systemic complications, hospital stay, and admission to the intensive care unit could be documented for both local and regional anesthesia compared with general anesthesia.[164] DeVirgilio et al. compared cardiopulmonary morbidity and mortality rates in a retrospective study of 200 patients who underwent infrarenal EVAR and found no overall difference.[165] This study, as well as other studies, noted lower fluid requirements and less need for vasopressor support associated with local anesthesia.[166] Also, by avoiding mechanical ventilation, patients with pulmonary comorbidities may benefit from a regional or local anesthesia technique.

From the preceding discussion, it is apparent that a variety of anesthetic techniques may be used, as long as specific goals of EVAR are met. Future randomized trials are needed, however, to further assess the impact of anesthetic technique on outcomes.

CONCLUSION

The patient who is undergoing major vascular surgery can be both challenging and rewarding for the anesthesiologist. The pathophysiology of vascular disease is complex and involves several organ systems. Predictive factors for vascular disease such as smoking, hypertension, and diabetes must also be considered when planning perioperative anesthesia management. Temporary flow interruption of major diseased vessels may induce dramatic physiologic changes that can be a challenge during the intraoperative phase. Adequate knowledge of the pathology of vascular disease, operative technique, and the available monitoring modalities is essential in ensuring favorable outcomes in this high-risk patient population.

CHAPTER 55

Anesthesia for Gastrointestinal Surgery

Martin Slodzinski, MD, PhD,
and
William T. Merritt, MD, MBA

In recent years, technical advances and increased experience with these techniques have led to remarkable changes in gastrointestinal (GI) surgical practice. These include the routine use of laparoscopy and the increasing use of robot-assisted surgery.

The GI tract is a fascinating organ system with a complex neurochemical organization.[1] GI surgery occupies a major percentage of the operative time in any general hospital setting. Anesthesia for such procedures likewise represents a major portion of the anesthesiologist's responsibilities. Many of these procedures are done so frequently that they may become routine. Others are sufficiently sophisticated that they may only be performed in tertiary care and teaching institutions. This chapter includes illustrations of some typical procedures and discusses preoperative, intraoperative, and postoperative considerations. It begins with a discussion of issues pertinent to the effects of anesthesia administration on GI function. Subsequent sections deal with surgical and anesthetic considerations of specific areas regarded as GI in nature.

OROPHARYNX

Digestive physiology begins with mastication. Pulmonary aspiration of oropharyngeal, esophageal, or gastric contents is a high concern for anesthesiologists caring for patients with gastrointestinal disorders/symptoms. Local and general anesthesia depress sensation of the upper digestive system, beginning with trigeminal innervation of the nasopharynx. The posterior third of the tongue and oral pharynx are innervated by the glossopharyngeal nerve, which accompanies the carotid sheath emerging from the jugular foramen. The superior laryngeal nerve innervates the tongue base and inferior epiglottis to the vocal cords. The recurrent laryngeal nerve innervates from the vocal cords distally. The remaining larynx and trachea are innervated by penetrating branches of the vagus. Any specific or general (i.e., stroke) pathology affecting the innervation of these areas increases risks of perioperative mishandling of oropharyngeal secretions and fluids, and an increased potential for aspiration.

ESOPHAGUS AND STOMACH

Proper function of the esophagus and the lower esophageal sphincter (LES) is a concern during anesthesia care. If the esophagus is dilated because of obstruction by tumor, destruction of neural mechanisms (e.g., achalasia), or existence of a diverticulum, particulate matter will remain for hours (if not days) after ingestion, and secretions will not pass normally to the stomach. *If the LES is not functioning properly, or if a hiatal hernia exists, stomach contents may reflux into the esophagus and even*

KEY POINTS

1. Diseases of the gastrointestinal system frequently result in abnormal gastric function, with potentially increased anesthetic risk caused by increased intragastric pressure, delayed gastric emptying, gastric dilation, and increased gastric secretion.
2. The volume, pH, and amount of particulate matter in the aspirate appear to be the three most important factors determining the severity of the pulmonary insult.
3. Extensive bowel, pancreatic, or esophageal resections entail considerable morbidity, with potential serious postoperative complications such as hemorrhage, coagulopathy, and hepatic, renal, pulmonary, or cardiovascular failure.
4. Laparoscopy entails the installation of gas (usually CO_2) into the peritoneal cavity with physiologic changes resulting from this gas under pressure and subsequent surgical positioning. Hemodynamic compromise can occur, which, although rare, can be catastrophic.
5. The systemic inflammatory response syndrome/multiorgan dysfunction syndrome continuum is often accompanied by GI mucosal ischemia and the release of mediators that further compromise both splanchnic and systemic perfusion. Anesthetic care of these patients is especially challenging.
6. If the lower esophageal sphincter is not functioning properly, or if a hiatal hernia exists, stomach contents may reflux into the esophagus and pharynx during anesthesia and surgery, increasing the potential for serious aspiration pneumonia.
7. Narcotics have intestinal side effects that are well recognized. Lower esophageal sphincter tone is decreased. Gastric emptying is impaired because of decreased propulsive motility and increased tone in the antrum of the stomach.
8. During laparoscopy, the development of pneumothorax and/or pneumomediastinum is a serious and/or potentially life-threatening complication. When either is suspected, from hemodynamic deterioration or from the presence of subcutaneous emphysema, especially of the neck and face, aggressive investigation (auscultation, chest radiograph) and management (e.g., chest tube for tension pneumothorax) should be undertaken. Procedures on the lower esophagus may be more likely to result in these complications.
9. Approximately 40% of patients with gastroesophageal reflux have delayed gastric emptying, and in approximately one-third of these, the delay is clinically significant.
10. Maneuvers necessary for blunt esophagectomy are capable of causing serious hemodynamic and ventilatory compromise and require appropriate monitoring of blood pressure and respiration.
11. Bariatric surgery patients may have significant medical problems and their perioperative care can be quite challenging. Newer procedures continue to lessen morbidity and mortality.

the pharynx during anesthesia and surgery, increasing the potential for serious aspiration pneumonia. Placement of a cuffed endotracheal tube during surgical procedures largely protects the airway from such materials. When obstructions are present, endotracheal intubation should occur with the patient awake (e.g., direct oral, blind nasal, or fiberoptic bronchoscopy) or via a rapid sequence method with the patient anesthetized. With the awake method, sedation should be limited or avoided altogether, especially in patients with a "full" stomach, proximal obstruction, esophageal diverticulum, or altered consciousness. Emptying the gastric or esophageal contents (e.g., nasogastric tube, Sengstaken-Blakemore tube) should decrease the volume and nature of any fluid available for reflux.[2,3] In any patient with known hiatal hernia or LES dysfunction, or when the stomach or esophagus is suspected to contain fluid or particulate matter, an attempt should also be made to aspirate the material before emergence from anesthesia. In addition, extubation should occur only after swallowing, adequate strength, and the ability to follow commands are apparent.

Many surgical approaches to the esophagus require a thoracotomy and a laparotomy, the lateral position, and a method of collapsing one lung. In addition, a temporary esophageal dilator may be requested intraoperatively by the surgeon; a nasogastric or naso-"intestinal" tube will need to be positioned at some point during the procedure to maintain continuity above and below the anastomosis. Such procedures can be demanding and require considerable preoperative planning.

MANAGEMENT OF ACID REFLUX

Abdominal surgery has been associated with as much as 75% of the perioperative mortality related to aspiration pneumonitis.[4] In addition, fasting gastric volume can be large in patients with GI disorders, especially duodenal ulcer disease.[5] Many other conditions, some directly related to the GI tract, are associated with some risk of regurgitation of esophageal or stomach contents and ultimate pulmonary aspiration (Box 55–1). In these conditions, an inadequate initial clearance or the return of a substance to the pharynx may be followed by ineffective removal with subsequent passage through the glottic opening into the lungs.[6] Mortality associated with aspiration ranges from 3–70%,[7–10] and the true incidence and morbidity are not well quantified. A large European study suggests the actual incidence is considerably lower, approximately 0.05%.[11] Unrecognized or "silent" regurgitation typically occurs, as does subsequent aspiration.[12–15]

The volume, pH, and amount of particulate matter in the aspirate appear to be the three most important factors determining the severity of the pulmonary insult. Particulate matter obstructs airways and quickly leads to ventilation and perfusion mismatching, hypoxia, hemorrhagic edema, and sometimes acute pulmonary hypertension.[16] Traditionally, gastric volumes greater than 25 mL and pH less than 2.5 have been associated with the most severe pneumonitis,[17,18] although more recent data suggest that greater volumes of nonparticulate aspirated fluid would be tolerated when the pH is greater than 2.5.[16,19,20]

In addressing the problem of aspiration during the delivery of anesthesia, anesthesiologists have focused on four areas: (a) reduction of the acid content and volume of the stomach contents, (b) improvement of intestinal motility, (c) prevention of reflux into the pharynx, and (d) a better understanding of gastric emptying.

Although antacids increase gastric pH, particulate (i.e., opaque) antacids produce severe aspiration damage similar to that of gastric acid.[19] The use of clear antacids is just as effective in increasing pH but is associated with only mild pulmonary changes if aspirated.[21–23]

Histamine-2 (H_2)-blocking agents are effective in reducing the acidity and, to a lesser extent, the volume of gastric fluid. Three agents are currently used: cimetidine and ranitidine are backed by extensive clinical experience; famotidine is a more recent introduction.[24,25] None of these agents has much effect on the acidity of material already present in the stomach (e.g., that found in the trauma patient or patients requiring other emergency surgery) but may decrease intraoperative acid production if given before surgery. Oral therapy seems to be as effective (and considerably less expensive) as intravenous (IV) or intramuscular forms when premedication by the oral route is suitable. Administration the night before and the morning of surgery consistently increases gastric pH to above 2.5. Rapid administration of cimetidine is associated with hypotension,[26–28] bradycardia,[29] and cardiac arrest.[30] Ranitidine appears to have a lesser incidence of similar side effects.[31,32] Mechanisms may include blockage of the inotropic and chronotropic responses of stimulation of myocardial H_2 receptors.[33,34] These agents alter metabolism or kinetics of various drugs, including the cytochrome P450 system,[35,36] lidocaine,[37] nifedipine,[38] theophylline,[39,40] warfarin,[41] and phenytoin.[42] Although atropine and glycopyrrolate decrease gastric acid production somewhat, they generally are not used for this specific purpose because they also decrease LES tone.

Rapid-acting intravenous proton pump inhibitors are effective in reducing gastric volume and increasing gastric pH. In a prospective, randomized, controlled trial, proton pump inhibitors were compared with H_2 antagonists. After intravenous administration 1 hour prior to surgery, pantoprazole 40 mg (Protonix) and ranitidine 50 mg (Zantac) were compared. Gastric aspirate pHs were 5.3 and 4.8 and residual volumes 8 mL and 15 mL, respectively, measured just after induction of anesthesia. This was compared with an IV saline control. Patients receiving pantoprazole and ranitidine had statistically greater gastric pH and less gastric volume than control patients (5 mL IV saline with gastric aspirate pH 3.7 and 29 mL volume), but

BOX 55–1.

Conditions Associated with Aspiration Pneumonia

- Altered state of consciousness
- Inadequate pharyngeal reflexes
- Anesthesia induction, intubation
- "Full" stomach
- Abnormal esophageal function
- Abnormal LES
- Intestinal obstruction, dysmotility
- Abdominal distension
- Pregnancy
- Obesity
- Inadequate muscle relaxant reversal
- Poor cough
- Abdominal infection
- Abdominal trauma
- Pain
- Recent extubation (dysfunctional vocal cords/hypopharynx/sedation)

there was no statistical difference between the pantoprazole and ranitidine groups.[43] Although both proton pump and H_2 inhibition may be used to reduce perioperative gastric acid, neither seems to be superior.

Gastric and intestinal motility are stimulated by metoclopramide, which acts centrally by inhibiting dopamine and in the gut by releasing acetylcholine. LES tone also increases, but the pylorus and duodenum relax.[44,45] Metoclopramide usually is administered concurrently with an H_2 blocker.

Preventing refluxed material from reaching the pharynx is the goal of cricoid pressure (the Sellick maneuver) and rapid sequence intubation. When properly performed, cricoid pressure should provide a barrier for at least 100 cm H_2O of esophageal pressure.[46] Pressure should not be released until the cuff is inflated and until correct placement has been verified by appropriate observations, including auscultation and capnometry. However, a meta-analysis of 241 peer-reviewed articles found little evidence that rapid sequence intubation provided protection against aspiration. Furthermore, in a controlled, blinded, randomized, crossover study comparing the Sellick and BURP (backward, upward, and right-sided pressure on the thyroid cartilage) maneuvers, the BURP maneuver and cricoid pressure worsened the laryngoscopic view in 30% of cases, cricoid pressure alone worsened the view in 12.5% of cases, and there was no difference in 65% of cases.[47,48]

As more is learned about the physiology of gastric emptying, the tradition of overnight fasting for elective surgery has come into question.[49–53] Residual gastric volumes may be acceptable after 2–4 hours of fasting, and the addition of H_2 blockers lowers pH as well. One should not extrapolate from such information directly to the emergency patient or the patient with a full stomach. *The aspiration of particulate matter produces such a devastating insult in the lung that, except for the most urgent situations, 6–8 hours of fasting after solid foods is recommended.* Even after this waiting period, the stomach often still contains food and large amounts of fluid.

BOWEL DISTENSION

Nitrous oxide (N_2O) administration is associated with an increase in intraluminal gas volume. Experimentally, in dogs, bowel gas volume increases approximately 75–100% after 2 hours of 70–80% N_2O, and by 100–200% after 4 hours.[54] Normally, luminal contents include approximately 100 mL of gas, mostly swallowed air; aerophagia or bowel obstruction greatly increases this volume. Clinically, N_2O use results in a slow increase in bowel distension and intraluminal pressure. The principal surgical consequence is difficulty with abdominal closure at the completion of a procedure. During extreme conditions (e.g., obstruction with distended bowel), increased intraluminal pressure may lead to bowel ischemia. N_2O use during abdominal surgery, if needed, should be limited to the initial 10–15 minutes at induction and intubation and during the period of abdominal wall closure at the completion of the surgical procedure. (See Endoscopic Procedures below for issues regarding N_2O during laparoscopy.)

BOWEL MOTILITY

Neostigmine is representative of anticholinesterase drugs necessary for the reversal of residual nondepolarizing muscular blockade. These drugs have a history of relative safety, although their parasympathetic stimulation leads to undesirable side effects. Bradycardia occurs so often that it is anticipated and managed before its occurrence by the administration of a parasympatholytic drug (e.g., atropine or glycopyrrolate) at reversal of neuromuscular blockade. This parasympathetic stimulation also affects intestinal motility, increasing the frequency and pressure of peristaltic waves, especially in the colon. For unknown reasons, diseased colon (e.g., from ulcerative colitis, diverticulitis[55]) appears to be more susceptible to this effect. This has led to considerable debate over the potential for cholinesterase inhibitors to cause breakdown of colonic anastomoses.[56–59] Fortunately, residual anesthetic agents and pretreatment with parasympatholytic agents (atropine, glycopyrrolate) attenuate this response. Inadequate perfusion of the anastomotic site, infection, and underlying tissue abnormality are now thought to be more significant issues.

Thiopental increases electrical and mechanical activity of the duodenum and jejunum in experimental studies, and atropine premedication decreases the response.[60] Ketamine has little effect on GI motility, and oral diazepam reduces gastric emptying and increases small bowel transit time.[61]

Narcotics have significant intestinal side effects. LES tone is decreased.[62] *Gastric emptying is impaired*[63] *because of decreased propulsive motility and increased tone in the antrum of the stomach.* The duodenum and the small intestine undergo a decrease in propulsive contractions, whereas the amplitude of rhythmic segmental nonpropulsive contractions often is enhanced, which results in an increase in resting tone and can cause peristaltic spasms. The proximal small bowel is more affected than the distal part, and the tone of the ileocecal valve is increased. Parasympatholytic agents can partially abolish these effects. In the large intestine, the effects can be more pronounced; peristaltic waves are decreased or absent. The amplitude of rhythmic nonpropulsive contractions is increased, often to the point of spasm. Anal tone also is increased. Again, diseased bowel appears more susceptible to such effects.[64]

High spinal or epidural anesthesia promotes hyperperistaltic activity because of blockade of sympathetic innervation. The unopposed parasympathetic activity may cause nausea and vomiting in approximately 20% of patients, for whom atropine may be effective.[65] Because of the increased peristaltic activity, controversy has arisen over the effects of spinal or epidural anesthesia on anastomotic breakdown, especially in colon surgery. Some data suggest that this problem is not significantly increased with regional anesthesia[66] and that colonic blood flow is improved by spinal or epidural anesthesia.[67] Others disagree with these findings.[68,69]

Postoperative ileus is probably associated with the manual trauma during laparotomy or from increased splanchnic nerve discharge in other procedures. Gastric peristalsis returns within 24–48 hours, and colonic activity returns after 48 hours, beginning at the cecum and progressing caudally. Small bowel motility returns more rapidly, and sometimes enteral tube feedings can be initiated within 24 hours. This ileus can lead to mild abdominal distension and absent bowel sounds for as long as 48–72 hours. Passage of flatus, cramping, and return of appetite suggest the return of normal peristaltic activity.[70,71]

Although neuraxial narcotics generally are recommended for pain relief in

most patients, the side effects of pruritus, urinary retention, and especially respiratory depression are problematic in some. Effects are presumably through local spinal cord receptors and via more central mechanisms after rostral spread in the cerebrospinal fluid or systemic absorption. Although used extensively and successfully in patients undergoing all forms of surgery, including many varieties of abdominal surgery,[33,72] there are animal data that document alterations in intestinal motility associated with neuraxial narcotics,[73] and at least one note of caution in humans.[74] Most studies conclude that postoperative epidural anesthesia and analgesia directed by an anesthesiologist, compared with intravenous anesthesia administered by a surgeon, provides superior analgesia, but does not reduce mortality or major morbidity, especially after major abdominal and cardiac surgical procedures.[75]

BILIARY EFFECTS

Therapeutic doses of the opioids can cause a marked increase in biliary tract pressure in susceptible patients. For example, 10 mg of subcutaneous morphine can produce a 10-fold increase in common bile duct pressure within 15 minutes that can last 2 or more hours.[76] This effect results from opiate receptor-mediated mechanisms that cause spasm of the sphincter of Oddi. Fentanyl and alfentanil also increase common bile duct pressure.[77,78] The general importance of this effect on intraoperative cholangiograms is uncertain, but fentanyl-supplemented anesthesia is associated with a 3% surgical failure rate.[79] Meperidine increases biliary tract pressure via mechanisms that are not receptor-mediated.[80] Opiate antagonists (e.g., naloxone) can reverse this opiate-related increase in biliary tract pressure (except for that caused by meperidine)[81] but also may reverse general analgesic effects. Sublingual nitroglycerin (0.6 mg) decreases the elevated intrabiliary pressure, but atropine only partially attenuates the response. Glucagon (1–3 mg), titrated to effect, also reverses opiate-related biliary spasm.[82]

RESPIRATORY FUNCTION

Because abdominal surgery is performed with the patient in the supine position, the anesthesiologist should remember several points. Functional residual capacity (FRC) is decreased by 0.5–1.0 L in the supine position, and the relationship of FRC to closing volume contributes to the alveolar–arterial oxygen difference and shunt.[83–85] This augments the 15–20% decrease in FRC associated with general anesthesia,[86] which continues postoperatively.[87] The Trendelenburg position aggravates this problem even further[88] because more of the lung assumes zone III conditions. Patients with elevated pulmonary arterial pressure (e.g., mitral stenosis) generally do not tolerate the Trendelenburg position. Diaphragmatic impairment and abdominal pain contribute to the potential for major respiratory embarrassment after abdominal surgery and, at least initially, are intensified by any negative effects from residual inhalation agents, IV anesthetics, and neuromuscular blockade. After upper abdominal surgery, vital capacity remains abnormal for more than 1 week.[89,90] Experimental data demonstrate that excessive fluid administration contributes to hypoxemia if fluid accumulates in the lungs and leads to increasing arteriovenous shunting.[91] However, no rigorous evidence exists favoring either the amount or type (colloid vs. crystalloid) of intravenous fluid, in spite of decades of controvery.[92,93]

ANESTHESIA FOR ENDOSCOPIC PROCEDURES

Endoscopic abdominal procedures leave inconspicuous scars, result in less postoperative pain with shorter hospitalizations, decreased hospital costs,[94,95] and even immunologic advantages.[96] As "minimally invasive" surgical techniques, reduced risk is implied, but endoscopic surgery involves the instillation of gas under pressure into a "closed" cavity, a process that may initiate unique physiologic responses and potential complications.

Diagnostic examination, cholecystectomy, vagotomy, appendectomy, adrenalectomy, nephrectomy, bariatric procedures, liver resection, pancreatic surgery, colectomy and hiatal, diaphragmatic, and inguinal hernia repair are among the abdominal procedures being performed with laparoscopic equipment. Each procedure has its own indications and conversion rates to an open method (e.g., 1.0–6.9% conversion to laparotomy with laparoscopic cholecystectomy).[97]

The physiologic changes associated with laparoscopy include those associated with tilting the patient to facilitate instrumentation and surgical exposure, the pressure effects of instilled gas, and the systemic effects of the gas—almost universally CO_2—that is instilled (and absorbed or embolized).

The head-down position (i.e., Trendelenburg) reduces vital capacity because of the increased weight of the abdominal contents on the diaphragm.[98] This effect is more pronounced in elderly, obese, and debilitated patients. In those undergoing *open* procedures, it is made worse by the placement of retractors and surgical packing under the diaphragm. In addition to this encroachment on lung expansion, right mainstem bronchial intubation can occur. Either of these can be associated with hypoxemia.[99] In contrast, the head-up position redistributes central blood volume peripherally and further aggravates any impairment of venous return created by the pneumoperitoneum.

The instillation of CO_2 to create an intentional pneumoperitoneum carries with it a number of physiologic side effects and complications (Box 55–2). Mechanical injury at the time of trocar insertion can lead to bleeding or bowel perforation. Bleeding also can occur from injury to vessels encountered during surgical instrumentation and dissection. With current laparoscopic

BOX 55–2.

Reported Complications with Laparoscopy

- Hemorrhage
- Hypotension, decreased cardiac output
- Acidosis
- Pneumothorax
- Pneumomediastinum
- Mainstem intubation
- Subcutaneous emphysema
- Airway obstruction
- Retroperitoneal CO_2
- Venous stasis
- Bradycardia, increased vagal tone
- Cardiac arrest
- Increased sympathetic activity secondary to increased CO_2
- Venous CO_2 embolism, fatal
- Regurgitation and aspiration

equipment, intraabdominal pressure is maintained between 12 and 15 mm Hg (17–22 cm H_2O). Because of leaks around the various cannulae, enormous gas volumes (≥50 L)[100] may be required during the course of the procedure to generate this relatively low pressure. Such pressures and the resulting abdominal distension may disturb the protective function of the gastroesophageal junction. The hemodynamic changes associated with this pneumoperitoneum depend on a number of factors, including the resulting intraabdominal pressure, the amount of CO_2 absorbed, the patient's level of hydration, the type of ventilation, and the nature of the surgery. Cardiac function during insufflation of peritoneal CO_2 has been studied primarily in healthy (e.g., no known cardiac disease) patients using a variety of cardiac function measurements (dye dilution, impedance cardiography, transesophageal echocardiography, and pulmonary artery catheters). Unfortunately, none of the studies have controlled well for the level of anesthesia at the various stages of the procedures and have managed hypercapnia differently. Most studies,[101–105] but not all,[106–109] report a decrease in left ventricular function and cardiac output (cardiac output decreased 7–24%). Similarly, most studies found an increase in central venous pressure (redistribution of abdominal blood volume?), with an increase in systemic vascular resistance and mean arterial pressure. In addition, with assumption of the reverse Trendelenburg position, cardiac index may decrease by 50% of preanesthesia and preinsufflation values.[103,110] Left ventricular enddiastolic, right atrial, and pulmonary capillary wedge pressures dramatically decrease after assumption of reverse Trendelenburg position.[111] Venous stasis of the lower extremities also occurs, with attendant concerns for embolic phenomenon.[112,113] Patients with cardiovascular disease will have responses to laparoscopy that are affected by the extent of cardiac reserve, baseline medications, level of hydration, and their response to the anesthesia medications used.[110,114] The potential deleterious effects of hypercapnia on cardiac function (e.g., increased sympathetic activity, myocardial depression) may further complicate laparoscopy in those with cardiovascular disease.[115]

During retroperitoneoscopic adrenalectomy (prone–jackknife position or lateral), a small (<10 cm) cavity in the lumbodorsal fascia is created with a distension balloon trocar. CO_2 is insufflated to a pressure of 15–20 mm Hg. Unlike laparoscopy, stroke volume and cardiac output appear to increase with insufflation, as do mean arterial pressure, central venous pressure, and pulmonary artery pressure. No change was noted in pulmonary capillary wedge pressure, heart rate, and systemic vascular resistance.[116]

Relatively small CO_2 emboli have been detected by transesophageal echocardiography in 69% of patients, classified by the American Society of Anesthesiologists as physical status P1 to P3, who undergo laparoscopic cholecystectomy.[117] Fatal massive CO_2 embolism has been reported,[118] including a report of death from delayed CO_2 embolism associated with gas trapping in the portal circulation.[119] With time, subcutaneous or mediastinal emphysema and pneumothorax may develop, with associated hypoxemia, hypotension, and cardiovascular collapse. The incidence of extraperitoneal insufflation of CO_2 has been reported to range from as little as 0.4–2%[120] to 20–64%,[121] and is more likely during lengthy procedures such as fundoplication.[122] *The development of pneumothorax and/or pneumomediastinum during endoscopic surgery is a serious and potentially life-threatening complication. When either is suspected, from hemodynamic deterioration or from the presence of subcutaneous emphysema, especially of the neck and face, aggressive investigation (auscultation, chest radiograph) and management (e.g., chest tube for tension pneumothorax; conversion to an open procedure) should be undertaken. Procedures on the lower esophagus are more likely to result in these complications.*[121]

Ventilation and pulmonary function are important concerns during laparoscopy. With conventional open laparotomy, it is well accepted that upper abdominal surgery is associated with postoperative pulmonary dysfunction in approximately 50% of patients.[123] This dysfunction is related to impaired diaphragmatic function, pain, type of incision, and decreased FRC.[124–126] *Pulmonary function is also impaired after laparoscopic cholecystectomy, with sustained decreases in forced vital capacity, peak expiratory flow, and forced expiratory volume in 1 second (FEV_1) noted 24 hours after surgery; fortunately, these changes are only approximately 50% of those seen in conventional open cholecystectomy.*[127]

The exogenous CO_2 insufflated during laparoscopy is soluble in blood and after transperitoneal absorption is presented to the lungs for excretion. Endtidal CO_2 ($ETCO_2$) increases from 0–30%[128–130] when minute ventilation is held constant. Increasing ventilation by as much as 30% may be necessary to keep the $ETCO_2$ in the mid-30s (mm Hg) range.[131]

During laparoscopy, an overriding anesthetic concern is the preservation of ventilation, which tends to be impaired by surgical positioning and abdominal distension. This almost always means general anesthesia with endotracheal intubation.[132,133] Not only does this provide protection for the airway,[134] but it permits adequate measurement of $ETCO_2$ and manipulation of ventilation as needed. Routine intraoperative monitoring ($ETCO_2$, pulse oximetry, blood pressure, airway pressure) should be adequate for the expected physiologic changes encountered in most patients. The anesthesiologist should be aware of the insufflating pressure being used and should be alerted if an unusual amount of CO_2 is required.

It is theoretically sound to avoid N_2O for at least two reasons. First, it diffuses into the abdominal cavity in concentrations sufficient to support combustion of intestinal gas[135,136]; second, it will diffuse into CO_2 bubbles and emboli, increasing their size and the potential for an obstructive event.

Adequate muscle relaxation is required during laparoscopy so that spontaneous respiratory effort does not impair the surgical procedure or risk increasing the gradient for embolic gas to enter the central circulation.

Despite the limited surgical incision(s), postoperative muscle pain remains a problem, even in children.[137] This has not been eliminated by avoiding succinylcholine or by manipulation of other anesthetic regimens.[138] Nausea and vomiting is common after laparoscopy, especially in women, and it appears that women are at increased risk for this during their menses.[139] Droperidol, a dopamine receptor antagonist, has been found to decrease nausea and vomiting in nonmenstruating women, but not during menses. Because serotonin has been implicated

in several premenstrual syndromes, serotonin antagonist therapy (e.g., ondansetron) can be beneficial.

In the rare event of catastrophic hemodynamic collapse during laparoscopy, several possible causes should be considered. *During laparoscopy, hemorrhage can be obvious or occult (e.g., retroperitoneal). Pneumothorax, massive CO_2 embolus, and pneumomediastinum may occur. Initial therapy includes releasing the pressurized pneumoperitoneum (i.e., conversion to open procedure). For pneumothorax, a thoracentesis should be performed. If massive embolization occurs, N_2O, if employed, should be discontinued immediately and cardiopulmonary resuscitation should be performed.* The patient should be placed in the left lateral position. Attempts at embolus retrieval should be made through central venous access, if available. If these measures do not provide sustained benefit, even cardiopulmonary bypass may be necessary.

GASTROINTESTINAL ENDOCRINOLOGY

Understanding of GI endocrine tumors has expanded dramatically since original descriptions of the *carcinoid syndrome* several decades ago. That clinical syndrome (including flushing, diarrhea, telangiectasias, bronchoconstriction, fibrous endocardial plaques) has traditionally been said to originate from metastatic carcinoid tumors in the GI system, pancreas, biliary vessels, bronchi, ovaries, and testes via release of vasoactive hormones into systemic circulation. Cardiac involvement (primarily right-sided valvular) is actually noted in more than 50% of patients by echocardiography and may require valvular surgery.

It is now recognized that there are at least 14 different endocrine cell types in the gastrointestinal tract that produce numerous peptide hormones such as gastrin, glucagon, somatostatin, secretin, and vasoactive intestinal peptide (VIP). They may have hormonal and/or neurotransmitter functions. Their interactive biology is complex and tumor presentation uncommon; excellent references detail their complexity, management, and uncommon clinical syndromes.[140–142] Most produce small amounts of neuroendocrine substances and do not result in clinical symptoms until late stages of disease. These tumors tend to have an indolent course, and aggressive malignancy is relatively infrequent. An increasing number of such lesions are being discovered before biochemical clinical symptoms. In addition to these endocrine/neuroendocrine tumors (terms considered synonymous), there are also pancreatic islet cell tumors. Duodenal gastrinomas can be associated with multiple endocrine neoplasia type-1 and may or may not result in the Zollinger-Ellison syndrome. Somatostatinomas may be associated with neurofibromatosis.

These gastroenteropancreatic neuroendocrine tumors have a yearly incidence of 1.0–2.6 per 100,000 population from gastrointestinal origin, with an additional 0.2–0.4 per 100,000 population from the pancreas. Since only approximately 10% of the 100,000 population produce bioactive hormones, diagnosis often occurs late after metastasis has occurred. There is emerging evidence of distinct molecular genetic differences between GI and pancreatic neuroendocrine tumors.[143]

Therapy of functional tumors involves controlling symptoms, which includes somatostatin analogues for carcinoid syndrome, watery diarrhea syndrome ("VIPomas"), and hyperglucagonemia. For those with gastrinoma (Zollinger-Ellison syndrome), proton pump inhibitors have improved therapy of high acid production. In addition to true insulinomas, some other neuroendocrine tumors may secrete a chemical that behaves like insulin.

Surgical treatment includes attempts to discover/remove the primary tumor, regional lymph nodes, and appropriate distant metastases, for example, liver tumors. This includes liver resection and both cryoablation and radiofrequency ablation. Impressive improvements in symptomatology can occur, and depending on cell type, meaningful 5-year survival may result.[144]

Anesthesia management of this broad group of patients requires an understanding of the biochemical abnormalities noted, the clinical/potential clinical manifestations, medical therapy being used, the surgical/diagnostic procedure(s) contemplated, and the ability to monitor hemodynamics and lab values (e.g., glucose) closely in the operating room/perioperative environment.

For the carcinoid syndrome, a nonhistamine releasing anxiolytic can be employed to reduce the catecholamine levels. The somatostatin analogue, octreotide,[145] odansetron (5-HT_3 antagonist),[146] and remifentanil[147] have been found useful in perioperative suppression of carcinoid signs and symptoms.

MEDICAL AND SURGICAL CONCERNS IN GI ILLNESS

The Esophagus

The esophagus extends from the pharynx at the level of C6 to the gastroesophageal junction. The hypopharynx courses from the level of the epiglottis to the upper border of the esophagus and funnels food into the esophagus. Swallowing begins as a voluntary process as food and liquid pass through the mouth, which initiates a complex and normally coordinated sequence of involuntary discharges through cranial nerves V, VII, X, and XII to the oropharynx and the esophagus. The upper third of the esophagus contains striated musculature, the lower third has smooth muscle, and the middle third has a mixed muscular supply. Motor innervation is supplied by the vagus nerves. Striated muscle is innervated by preganglionic fibers and smooth muscle by postganglionic fibers from the Auerbach plexus.

In adults, the upper esophageal sphincter (UES) is approximately 3 cm in length and consists of the cricopharyngeal muscle (striated), a portion of the inferior constrictor muscle superiorly, and circular esophageal muscles inferiorly.[148,149] The primary function of the UES is controlled by the swallowing mechanism in general, but its resting tone is increased in response to esophageal distension or acid from gastroesophageal reflux[150] and decreases during sleep.[151]

The lower end of the esophagus (3–5 cm in length) acts as a functional LES. Thickness of the smooth muscle layers increases in this area, and circular fibers develop considerable tension. Control of the LES tone is complex and chiefly results from vagal cholinergic and myogenic mechanisms, although prostaglandins,[152] neuropeptides (e.g., vasoactive intestinal peptide),[153] GI hormones (e.g., gastrin, motilin),[154] the progesterones and estrogens of pregnancy, and thyroid-stimulating hormone[155] are among substances known or suspected of affecting LES tone. Material enters the esophagus after voluntary propulsion by the tongue into the hypopharynx. With relaxation of the UES (resting tone, ap-

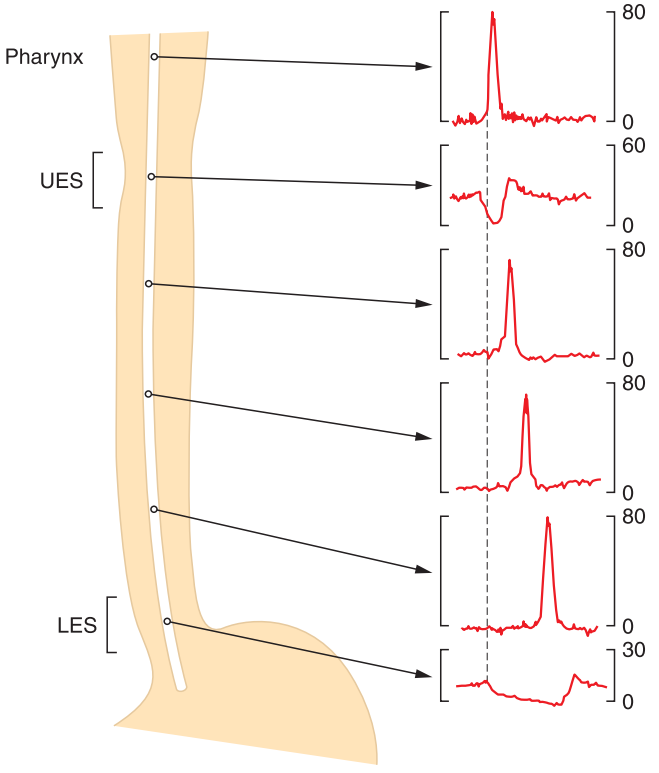

FIGURE 55–1. Esophageal manometry. Simplified representation of normal physiologic pressures in pharynx, upper esophageal sphincter (*UES*), esophagus, and lower esophageal sphincter (*LES*). On right, high-pressure zones are noted as the pressure catheter is withdrawn from stomach. On left, normal peristalsis occurs after a swallow, with relaxation followed by contraction and return to resting tone for UES and LES.

proximately 20–60 mm Hg), food enters the esophagus and is moved along by primary peristaltic waves (25–80 mm Hg). LES relaxation (resting tone, 10–20 mm Hg) occurs, and the bolus enters the stomach. This whole process takes only 4–8 seconds. Secondary peristaltic waves serve to move residual matter through and into the stomach. Figure 55–1 depicts normal esophageal motility.

Acid Reflux and Hiatal Herniation

Reflux of material from the stomach into the esophagus is a complex topic and is covered in depth in other texts.[156] Criteria for diagnosis include those of reflux symptoms (Box 55–3) and the results of various tests, including radiographic studies, endoscopy, biopsy, manometry, and prolonged esophageal pH monitoring. The pH test demonstrates that virtually all healthy subjects have episodes during daily activity when their esophagus is exposed to pH less than 4. This exposure is increased during awake upright activity, especially after eating, and occurs during supine sleep activity,[157] when swallowing frequency is diminished and less effective (Table 55–1). Reflux is associated with pressure gradients between the abdomen (positive pressure) and the thorax (intermittently negative pressure) and with poorly understood episodes of "transient lower esophageal relaxation."[158–163] pH testing also detects those patients with reflux of alkaline duodenal material into the stomach and esophagus.[164]

The etiology for increased exposure of the esophagus to acid material and ultimately to the risks of acid and particulate matter aspiration can involve one of several mechanisms (Box 55–4). The mechanical competence of the LES depends on intrinsic tone (normally greater than 5 mm Hg[165]), the overall length of the LES muscular segment (normally 3 cm or longer), the portion of that segment that is intra-abdominal (at least 1 cm), and interaction with the cardia of the stomach, which should transmit intraabdominal pressure to the distal LES.[164,166–168] The most common abnormality is decreased LES tone, but even normal LES tone can be affected by the other mechanisms.[169]

Esophageal clearance of reflux material depends on swallowing, gravity, intrinsic motor activity, salivation, and whether a hiatal hernia is present. Although the frequency of acid reflux may be greater during the day, the duration of episodes is longer when the patient is in the supine position because of loss of gravitational effects. Additionally, any disease that affects the motor activity of the esophagus may lead to impaired clearance of acid material (Box 55–5), with resultant ef-

BOX 55–3.

Symptoms of Acid Reflux

- Water brash
- Heartburn
- Anginal type of chest pain
- Dysphagia
- Regurgitation with bending or in supine position
- Coughing or wheezing from aspiration
- Vagally induced bronchoconstriction

TABLE 55–1.

Exposure of Esophagus to pH <4 (n = 50)[a]

Segment of 24 hour pH test	Mean	SD	95%
Total time (%)	1.51	1.36	4.45
Upright time (%)	2.34	2.34	8.42
Supine time (%)	0.63	1.0	3.45
Number of episodes/24 hours	19.00	12.76	46.90
Number of episodes >5	0.84	1.18	3.45
Longest episode (usually in supine position)	6.74	7.85	19.80

95%, asymptomatic volunteers; SD, standard deviation.

[a]This represents a "normal" level of reflux in healthy subjects. Those with gastroesophageal reflux disease have more "frequent" and longer episodes (>5 min) representing a greater % of time.

fects on the esophageal mucosa and potential for aspiration.[170] Saliva is important in neutralizing the small amounts of acid refluxed with peristalsis even in healthy persons, and clearance of this acid is prolonged when saliva is removed by suctioning.[171] The salivation stimulated by heartburn (termed *water brash*) can lead to repetitive swallowing, aerophagia, and gastric distension with further reflux.[172] Perioperatively, the presence of a nasogastric/orogastric tube may contribute to reflux of gastric contents and the risk of aspiration, and has been challenged as a routine practice.[173,174]

The presence of a hiatal hernia is associated with additional abnormalities (Fig. 55–2). The hernia produces a defect in esophageal propulsion that results in inadequate acid clearance and longer transit time.[175] The retreat of all or part of the distal LES into the chest impairs the ability of the lower third of the LES, in concert with the cardia of the stomach, to impart extrinsic abdominal pressure and enhance sphincter function. If intrinsic LES tone also is decreased, a setup exists for major reflux of acid material and, ultimately, for the development of aspiration pneumonia. Despite this, most patients with hiatal hernias are asymptomatic.[176]

Certain abnormalities of gastric function also can result in acid reflux through a normal gastroesophageal junction or by exacerbating preexisting LES abnormalities (Box 55–6). Normally, the body and fundus of the stomach are able to adapt to a large volume of material with minimal increases in pressure, although a previous vagotomy interferes with the active relaxation necessary for this to occur, and greater intragastric pressures occur with lesser volumes.[177] Outlet obstruction of the stomach more obviously leads to increases in pressure, which occurs normally with vomiting, but also with pyloric stenosis in newborns and obstructing ulcers or tumors in patients of any age.

Delayed gastric emptying leads to persistence of gastric acid and foodstuffs. The causes are varied[156] (Box 55–7) but yield a similar effect. As larger volumes accumulate and persist for a longer period, the potential for reflux through either a normal or abnormal LES increases. Approximately 40% of patients with gastroesophageal reflux have delayed gastric emptying,[178,179] and in approximately one third of these, the delay is clinically significant. Those rare patients with postviral gastroparesis also may have serious autonomic neuropathy.[180] Patients with various neurologic illnesses may manifest a variety of GI motility abnormalities.[181]

Myogenic abnormalities
Diabetic gastric atony
Diffuse neuromuscular disorders
Postviral gastroparesis
Postvagotomy
Pyloric dysfunction
Altered duodenal motility

As the stomach dilates from any cause, the relationship between the cardia and abdominal portion of the LES changes, which results in decreased maintenance of proper LES tone and increased risk of reflux. In addition to the conditions already mentioned, aerophagia from several causes also may lead to gastric distension. Normally, each pharyngeal swallow results in several cubic centimeters of swallowed air. Patients with reflux may habitually swallow (some even chew gum to stimulate saliva) to clear acid and can develop air-induced gastric distension, which can exacerbate their reflux. Other patients with decreased saliva formation (e.g., with Sjögren syndrome) or after head and neck irradiation may swallow excessively with resultant aerophagia. Loss of secondary peristalsis, which can occur with diabetes mellitus and collagen vascular diseases, also leads to inordinate swallowing in an effort to propel food along, again with resultant aerophagia.

Gastric acid hypersecretion plays a role in some patients with gastroesophageal reflux who have a mechanically normal LES, and is a complicating factor in other patients with abnormal LES function.[182–184]

The most serious acute consequence of acid reflux is the risk of aspiration of stomach contents. Chronic complications include esophagitis, stricture formation, Barrett esophagus (with risk of esophageal cancer), and chronic pulmonary disease from repeated episodes of aspiration. Aspects of surgical management are discussed next.

Surgical Procedures of the Esophagus

Several surgical procedures for patients with esophageal disease are worthy of specific mention, but an extensive discussion of all approaches is beyond the scope of this text.[185,186] Patient positioning, site of incision, and whether the esophagus will be transected are important to the anesthesiologist in all esophageal procedures.

Several approaches exist for the management of reflux disease.[187] The Nissen-type (360° gastric fundoplication) procedure may be approached abdominally (open or more commonly via laparoscopy) or through a left posterolateral thoracotomy. During the abdominal approach, severe liver retraction typically occurs, and the reverse Trendelenburg position is useful to the surgeon. The transthoracic approach may be used for repeat procedures, in obese patients, and when esophageal shortening is suspected. The Belsey-type (240° fundoplication) procedure also is approached from a left lateral chest incision. For any of these procedures, the anesthesiologist may be asked to pass a bougie through the pharynx into the distal esophagus to the area of surgical manipulation so that the repair can be sized. Should the restoration tend to slide back into the chest because the esophagus is too short, a lengthening procedure (e.g., colon interposition) may be required. Except for this latter maneuver, the esophagus is not transected for these procedures. Laparoscopic and robotically assisted laparoscopic surgeries have increased in quantity and complexity.[188] Because of restrictions in patient positioning and the shear mass of the robotic devices, access to the patient during these procedures may be suboptimal. Heightened awareness of the operative field is required by the anesthesiologist since the surgeon may be viewing only the video projection at a platform physically removed from the patient.

Several techniques are used for patients with esophageal cancer. For lesions of the distal esophagus, the Ivor-Lewis/McKeown-type repair (Fig. 55–3) includes an anterior abdominal incision followed by a right thoracotomy. The McKeown-type is similar but adds a right neck incision to facilitate the anastomosis of the stomach to the cervical esophageal remnant. Either procedure may include extensive node dissection in the chest, entry into the pericardium or the opposite chest, and thoracic duct ligation. Single-lung ventilation may facilitate operative exposure. Blunt esophagectomy (Fig. 55–4) is used for cervical esophageal disease, for lower-third esophageal carcinoma, and in early noninvasive disease. Abdominal and left cervical incisions are made, and extensive, "blind" bimanual dissection through the chest is performed. Bleeding or tracheal injury may necessitate an emergent thoracotomy. Postoperative recurrent nerve injury is described in 10% of patients.[189]

Peptic Ulcer Disease and Duodenal and Gastric Carcinoma

Millions of Americans have symptoms of acid and peptic ulcer disease,[190] and annual direct and indirect costs exceed $3.4 billion.[191] Duodenal ulcer disease (DUD) occurs 2–3 times more often in men than in women, and mortality rates may be somewhat greater in nonwhites ages to about 65 years. Genetic (e.g., family history, blood group O, human leukocyte antigen [HLA] types B_5 and B_{12}) and environmental (e.g., smoking, aspirin, nonsteroidal antiinflammatory drugs [NSAIDs]) factors are involved in DUD. Chronic pulmonary disease, cirrhosis, renal transplantation, and possibly high psychological stress also may increase the incidence of ulcer disease. Resting and stimulated secretion of acid are increased[192,193] in common DUD, and in patients with gastrinoma (Zollinger-Ellison syndrome—see Gastrointestinal Endocrinology). The

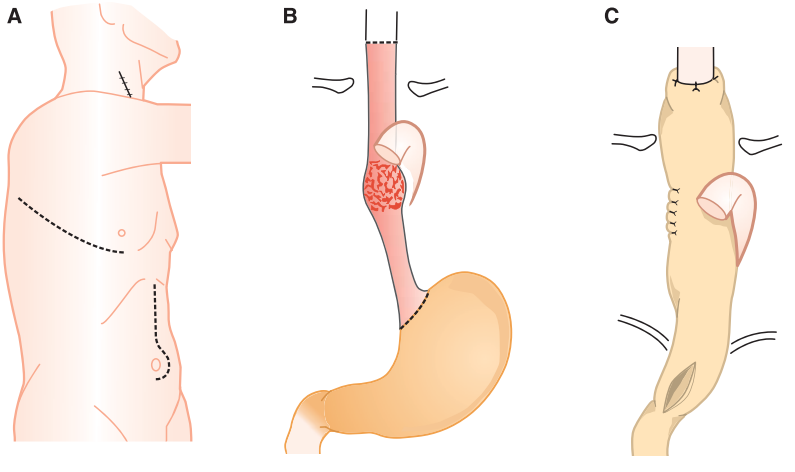

FIGURE 55–3. Ivor-Lewis/McKeown-type esophagectomy. After abdominal mobilization of stomach, the chest and neck are explored concurrently to allow total esophagectomy and cervical esophagogastrostomy.

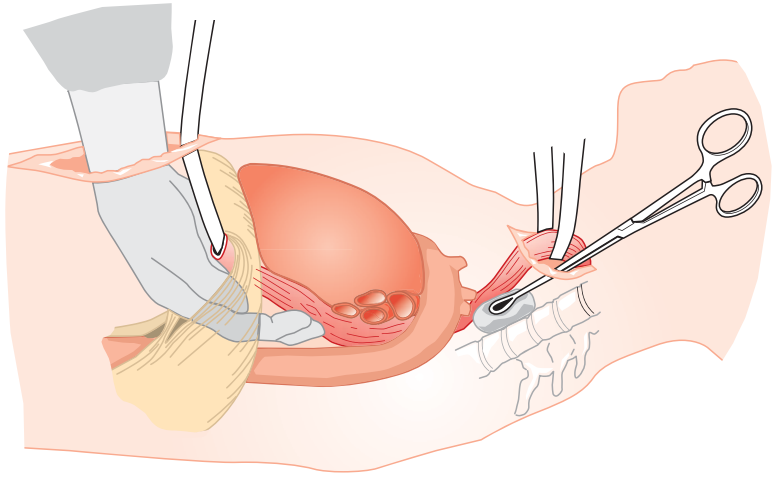

FIGURE 55–4. Blunt esophagectomy. Maneuvers necessary for this procedure are capable of causing serious hemodynamic and ventilatory compromise and require appropriate monitoring of blood pressure and respiration.

number of parietal cells secreting acid may be increased. The rapid emptying of stomach contents in some patients with DUD may overwhelm duodenal buffering and clearance mechanisms. Because these patients appear to have reduced duodenal bicarbonate secretion,[194] they are predisposed to ulceration.[195]

Gastric ulcers occur only one third to one fifth as often as duodenal ulcers, and causal factors in gastric ulcer disease (GUD) are largely unrelated to those for DUD. Genetic, psychological, and hypersecretion of acid are not factors for most patients. The largest group of patients with GUD have normal-to-low secretion of acid and evidence of decreased gastric mucosal defenses against acid and pepsin-related endothelial injury. GUD tends to occur in older patients, and possibly as a result, this mortality rate is higher. GUD is associated with gastritis and with gastric carcinoma. Aspirin is clearly a risk factor,[196] as may be NSAIDs; both are thought to work via inhibition of prostaglandin synthesis. Pyloric function may be defective in patients with GUD, permitting reflux of duodenal, biliary, and pancreatic secretions into the stomach, initiating gastritis, and, ultimately, ulcerations.[197] Smoking reduces pyloric sphincter tone and increases the risk of bleeding from ulcers.[198] DUD and GUD are associated with *Helicobacter pylori* infection[199] and elimination of *H. pylori* is a focus of treatment.

Medical Treatment

The medical treatment of patients with ulcer disease involves dietary and environmental restrictions (e.g., avoiding aspirin, NSAIDs, smoking, alcohol; limiting caffeine, anxiety) and medication. Antacids, H_2-receptor antagonists, and coating agents (e.g., sucralfate) are useful in patients with DUD or GUD. Protein pump (H, K-ATPase) inhibition (e.g., omeprazole) has become important as an extremely potent inhibitor of gastric acid secretion in the patient with DUD. Exogenous prostaglandins ultimately may have a role. Bleeding patients undergo endoscopic procedures with the potential for cauterization. At arteriography, selective administration of vasopressor (e.g., vasopressin into the left gastric artery) or embolization may be warranted. Multiple trials support the suppression of acid production in the critically ill patient, especially those receiving anticoagulation or on mechanical ventilation. However, there is insufficient data to support proton pump inhibitors over H_2 antagonists, but in the acutely bleeding patient, proton pump inhibitors are quite effective as prophylaxis and superior to H_2 antagonists.[200]

Surgical Treatment

Several procedures and variations are performed for the management of DUD (Box 55–8). Duration of symptoms, gastric outlet obstruction, perforation,[201] and hemorrhage impose specific considerations, as do various known complications of these procedures (Box 55–9). For example, after a truncal or selective vagotomy, approximately 20% of patients will have clinically impaired gastric emptying if a drainage procedure also is not performed. [202]

BOX 55–8.

Surgical Management of Duodenal Ulcer Disease

- Vagotomy with drainage via pyloroplasty or gastrojejunostomy
- Vagotomy with antrectomy (hemigastrectomy) and gastroduodenostomy (Billroth I) or gastrojejunostomy (Billroth II)
- Subtotal gastrectomy and Billroth I or II

Erosive gastritis is a common problem. Therapy involves appropriate blood and volume resuscitation, gastric irrigation with saline, and instillation of antacids. When bleeding does not stop or recurs, endoscopic evaluation and cauterization may suffice. If not, angiography may allow visualization of the damaged vessel for embolization or continuous infusion of intraarterial vasopressin.[203] Surgical procedures for hemorrhagic gastritis are required in 10–20% of patients. No single technique is considered the procedure of choice, and decisions regarding the nature of the procedure selected may require open visualization of the focal versus diffuse nature of the bleeding. Total gastrectomy, partial gastrectomy with vagotomy, vagotomy and pyloroplasty, devascularization, and simple oversew procedures all have advocates.[204–206]

Surgical therapy for patients with gastric ulcer generally involves ulcer removal and antrectomy (i.e., distal gastrectomy) with direct anastomosis to the duodenum (Billroth I procedure). Unless features of hypersection of acid exist, a vagotomy generally is not performed. Perforation can be managed with excision and simple closure in debilitated elderly patients or more definitively in younger stable patients. If malignancy is encountered, an appropriate procedure should be performed.

BOX 55–9.

Complications of Procedures for Duodenal Ulcer Disease

- Abdominal fullness and pain
- Nausea
- Heartburn
- Reflux and regurgitation
- Bile and food emesis
- Dumping syndrome
- Diarrhea

Gastric carcinoma generally is divided into two broad categories. Early carcinoma is confined to the gastric mucosa or submucosa, regardless of size or of lymph node seeding. Many of these patients are curable surgically. A subtotal gastrectomy is warranted for localized disease, and a total gastrectomy is needed for more extensive involvement. Surgical therapy for advanced gastric carcinoma is generally less successful because less than 10% of patients survive 5 years.[207] Procedures vary as to the extent of gastric resection and to the aggressiveness of lymph node and adjacent organ resection.[208–211] Some studies suggest improved survival for patients undergoing palliative resections even when a cure is not possible.

Cholecystitis, Gallstone Disease, Cholecystectomy, and Biliary Disease

Approximately 20 million Americans have cholelithiasis, and another 800,000 are diagnosed with it each year.[212] Many predisposing factors exist (Box 55–10). The three basic types of gallstones are cholesterol, pigment, and mixed. The last category represents approximately 75% of all affected patients. Catalysts for stone formation include decreased gallbladder motility with stasis, increased gallbladder mucous secretion, altered epithelial ion transport, and possibly increased gallbladder synthesis of prostaglandins[213] and increased biliary calcium.[214,215]

Diagnosis

Clinical cholecystitis is classically associated with obstruction of the cystic duct (e.g., from stone, edema, sludge, fibrosis) and subsequent epithelial injury, enzyme release, and inflammatory response.[216] In approximately 75% of patients, cholecystitis is self-limiting and resolves over approximately 1 week, but 5–10% of patients develop serious complications, including empyema, cholangitis, gangrene, or perforation. Positive cultures are found in approximately 20–30% of patients younger than 50 years of age, in greater than 50% of patients older than 70 years of age,[217] in 20–40% of those with chronic disease, and in 60–70% of those with acute cholecystitis.[218,219] Gram-negative organisms predominate. An overriding focus in evaluating patients is detecting cystic duct obstruction. Abdominal ultrasonography is extremely useful in detecting cholelithiasis and technetium scans in detecting cystic duct obstruction (even in patients with elevated bilirubin levels). Plain abdominal films, oral cholecystography, and IV cholangiography are more limited as diagnostic tools.

BOX 55–10.

Factors Associated with Increased Incidence of Gallbladder Disease

- Increased age
- Female sex
- Pregnancy
- Obesity
- Hemolysis
- After truncal vagotomy
- Long-term parenteral nutrition
- Pima Indian

Treatment

Oral therapy using deoxycholic acid analogues results in cholelitholysis because of their ability to decrease the rate-limiting enzyme in cholesterol synthesis, coenzyme A reductase.[83] This is effective in some patients. Although it is recognized that asymptomatic gallstones frequently exist, management options are debated. Some studies document that about one third of these patients will develop complications requiring urgent surgery.[220,221] Others note that morbidity and mortality are lower after elective procedures in younger patients,[181,222] although most suggest that routine prophylactic cholecystectomy for asymptomatic disease is not required.[223]

Cholecystectomy generally is performed within several days of onset of symptoms. Approximately 25% of patients develop recurrent cholecystitis if surgery is delayed, and 1 in 8 will require emergency cholecystectomy.[224–226] Despite the risks associated with older patients, conservative management (e.g., delayed surgery) in the elderly population may be inadvisable; gallbladder empyema, perforation, sepsis, and cardiovascular complications occur more often in this group.[227–229]

Lithotripsy with high-frequency shock waves disintegrates some gallstones. General anesthesia usually is not needed, but sedation and analgesia with appropriate monitoring are required.[230] Although laparoscopic cholecystectomy[25] has become the staple of gallbladder removal, management considerations are similar to those of any laparoscopic procedure (Box 55–11).

BOX 55–11.

Effects and Complications Associated with Laparoscopy

- Altered ventilatory dynamics caused by large volume of intraabdominal carbon dioxide (CO_2)
- Hypercapnia from CO_2 absorption
- Decreased venous return from increased intraabdominal pressure/patient position
- Venous CO_2 embolism, intraoperatively and in early postoperative period
- Abnormal gastroesophageal junction competence from high intraabdominal pressure
- Effects of patient positioning

Open laparotomy is generally reserved for more complicated considerations (e.g., abscess, perforation, need for intraoperative cholangiogram or bile duct exploration, suspected anatomic abnormalities, obesity). In addition, laparotomy remains the back-up procedure for other procedures that fail or for patients with complications. Surgical manipulation of the abdominal viscera has been associated with various circulatory changes, including bradycardia and hypotension.

Biliary Tract Cancer

As many as 2000 new cases of gallbladder carcinoma may be seen in the United States annually. Patients are likely to be elderly women who have associated gallstones. Because of early metastasis, most patients are unresectable at presentation, and their 5-year survival rate is extremely low. Patients with microscopic disease have a much better prognosis. Palliative procedures are difficult for those with advanced disease; biliary decompression stents are placed for bile drainage.

Extrahepatic bile duct cancer survival rate depends on the location of the tumor. Survival improves from proximal to distal common duct sites and is best with a papillary morphology. Patients may undergo one or more laparotomies before arrival at a tertiary/definitive treatment center. Surgical management generally involves some form of biliary-enteric anastomosis (e.g., Roux-en-Y hepaticojejunostomy, Roux-en-Y choledochojejunostomy, Whipple procedure, palliative Silastic tube drainage) depending on the tumor's location.

Strictures of the Biliary Tract and Sclerosing Cholangitis

Benign strictures of the biliary tract result from various causes, including surgical trauma, inflammation from calculi, biliary tract infection (e.g., bacterial cholangitis), blunt or penetrating abdominal trauma, toxic injury during hepatic arterial infusion therapy, and sclerosing cholangitis. Eighty percent of patients have symptoms within 1 year of the associated surgery or trauma.[231] Symptoms and signs include abnormal biliary drainage or bile leakage immediately postoperatively and variable evidence of biliary obstruction and abnormal liver function in all patients. Painless jaundice and cholangitis are seen less often. Cholangiography should define biliary tree anatomy, and the placement of a ring catheter permits drainage and management of infection preoperatively.

When patients have an acute stricture after surgery, operative treatment may consist of the resection of a short segment of bile duct or a segmental duct ligation. More involved injuries usually demand creation of a Roux-en-Y jejunal limb and T-tube of transhepatic drainage catheters. Later in the postinjury period, extensive adhesions often are present, necessitating tedious dissection. Again, surgical management requires creation of a Roux-en-Y loop and decompression via T-tube, ring catheter, or a transhepatic Silastic stent.

BARIATRIC PROCEDURES

Ten percent of all health costs in the United States are related to treating obesity and obesity-related complications.[232] Perioperative care of the extremely obese (body mass index [BMI] $>40\ kg/m^2$) presents multiple challenges. A myriad of comorbidities including obstructive sleep apnea, diabetes, dyslipidemia, hypertension, atherosclerosis, cardiomyopathy, colicystitis, nonalcoholic steatohepatitis, and certain cancers[233] make this a formidable group of patients.

Bariatric surgery refers to procedures of the stomach or intestines designed to result in weight loss. Initial attempts at such surgery (e.g., jejunoileal bypass) induced malabsorption and rapid weight loss, but the resulting blind loop syndrome limited its long-term acceptability. Some advocate adjustable gastric banding, whereas others advocate a procedure involving the so-called duodenal switch. Variations on the theme of a Roux-en-Y gastric bypass may be the most frequently employed method in the United States. With the advent and increasing use of laparoscopic approaches, the early postoperative course and recovery have been greatly improved. Ultimately, the goal has been to balance restriction of food intake and malabsorption for enhanced patient acceptance and success of therapy.[234] Even endoluminal and transgastric procedures are now being performed.[235]

Peripheral venous access is often difficult or impossible and central venous access is required. Central access can be very challenging because of an inability to properly appreciate anatomical landmarks; however, such access has been greatly facilitated by use of ultrasound guidance.[236,237] Measurement of an accurate blood pressure usually requires invasive access. Unsurprisingly, the physical mass of the extremely obese patient requires appropriate bed selection and positioning because of the risk of compression neurologic injuries.[238]

One misconception associated with anesthesia for the extremely obese involves airway management; with increasing bariatric surgical experience, extreme obesity no longer is an independent risk factor for difficult intubations. In more than 750 patients without airway pathology, no correlation between BMI and difficult intubation was noted.[239] In fact, of 100 direct laryngoscopies of patients with BMI $>40\ kg/m^2$, only 1 intubation failed and only 12 intubations were deemed challenging (not significantly different from the general population).[240] Morbidities associated with obstructive sleep apnea include hypoxemia, pulmonary hypertension, and cor pulmonale.

Extreme obesity is associated with significant cardiovascular perioperative risks. More than 50% of these patients are hypertensive.[241] (See Chap. 22 for a detailed discussion of the preoperative assessment of the obese patient.) The Framingham study indicated that for every increased increment in body mass index (weight in kg/height in m^2), a 5–7% increase risk of congestive heart failure exists.[242] An "X" syndrome of massive obesity that includes glucose intolerance, hypertension, hyperlipidemia, and microalbuminemia has been described; it is strongly associated with coronary artery disease.[24] Such findings suggest the potential positive benefits of bariatric surgery: for example, for every kilogram of weight loss, systolic pressure decreases 0.5%, serum glucose decreases 0.2 mM, low-density lipoprotein cholesterol decreases 0.7%, and high-density lipoprotein cholesterol *increases* 0.25.[244] In spite of these potential long-term benefits, bariatric surgery still contains significant perioperative risk: mortality 1.5%, pulmonary embolism 1.14%, and small bowel obstruction and anastomotic leaks 3% each.[245] In addition, there are both short- and long-term metabolic and nutritional issues that vary with the procedure type and can be of concern.[246,247]

Mean weight loss for patients undergoing all forms of bariatric surgery has been reported to be approximately 61% of excess body weight, and maintenance of weight loss far exceeds that from medical treatments alone. Significant improvements in diabetes, hyperlipidemia, hypertension, and obstructive sleep apnea are usually expected. Improvements in other comorbidities, such as fatty infiltration of the liver, respiratory and asthmatic symptoms, and cardiomyopathy are more modest. Emerging studies suggest a reduction in mortality associated with bariatric surgery and a clear improvement in quality of life.[234,248] and many consider such surgery the only cure for morbid obesity (Fig. 55–5).

The Pancreas and Surgery

Pancreatitis

Although the treatment of acute pancreatitis is primarily medical, surgery may be required for such conditions as draining an abscess. Emerging evidence suggests that early surgery may not be as high a risk as previously thought.[249] Patients with pancreatitis are extremely ill with severe abdominal pain and may have fever, nausea and vomiting, jaundice, hypotension, ileus, and external distortion of the stomach on radiographs. Management includes nasogastric suction, maintenance of intravascular volume, anticipation of respiratory insufficiency,[250–252] analgesia, and nutritional support.

The patient with chronic pancreatitis may have incapacitating upper abdominal pain radiating to the back, which can be continuous or intermittent, especially after eating. Forty percent of pa-

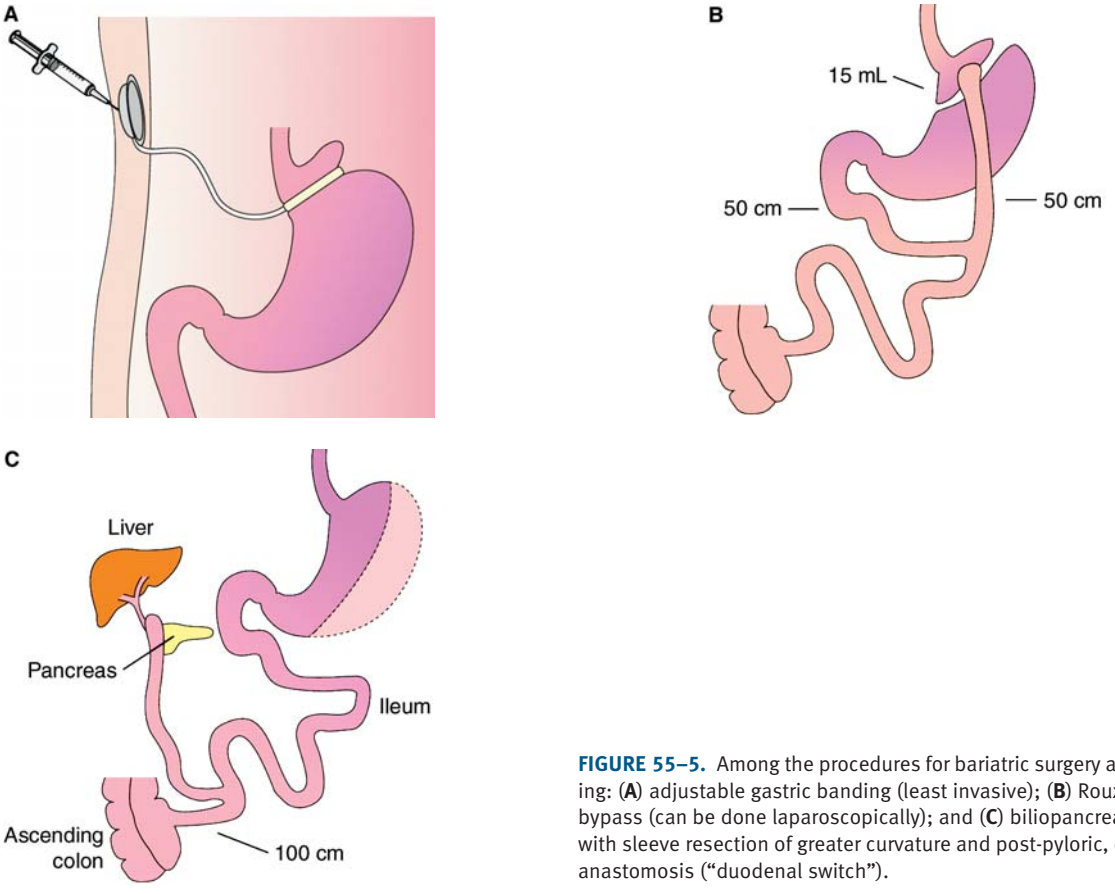

FIGURE 55–5. Among the procedures for bariatric surgery are the following: (**A**) adjustable gastric banding (least invasive); (**B**) Roux-en-Y gastric bypass (can be done laparoscopically); and (**C**) biliopancreatic diversion with sleeve resection of greater curvature and post-pyloric, duodenoileal anastomosis ("duodenal switch").

tients have diabetes from loss of pancreatic tissue.[253] Exocrine function may be sufficiently abnormal to require pancreatic enzyme replacement. Obstructions, strictures, and dilations of the pancreatic ductal system are thought to produce the pain through sympathetic pathways. Several surgical procedures have evolved to decompress the ducts and remove damaged pancreas. A caudal pancreatojejunostomy[254] uses a Roux-en-Y loop to decompress the tail of the pancreas. With the Puestow-type[255] procedure (Fig. 55–6), the Roux-en-Y limb envelops the pancreas distally, allowing pancreatic ducts to be opened longitudinally for drainage into the loop. For both of these procedures, a splenectomy and excision of the tail of the pancreas are necessary for technical reasons. A modification of the Puestow procedure[256] (Partington procedure) allows the tail of the pancreas and the spleen to be spared. Postoperatively, some patients require insulin and pancreatic enzyme replacement. Other patients with severe chronic pancreatitis require a near-total pancreatectomy or a pancreatoduodenectomy to remove sufficient tissue to relieve pain. Patients with pseudocyst of the pancreas require drainage of the cyst through a Roux-en-Y loop or directly into the stomach. Alternatively, a distal cyst may be removed by a partial pancreatectomy.

Other Conditions

Cancer of the pancreas and periampullary area is a frequently diagnosed problem with, unfortunately, an increasing incidence. Approximately 25,000 patients are diagnosed each year in the United States. Diagnosis usually is suggested by ultrasonography or computed tomography. Magnetic resonance imaging, endoscopic retrograde cholangiopancreatography, or percutaneous transhepatic cholangiography may yield information concerning the site and etiology of bile duct obstruction. Percutaneous fine-needle aspiration biopsy may be performed with the aid of ultrasound examination or computed tomography. Despite this array of tests, determination of the extent of disease and often the tissue diagnosis should await a thorough intraoperative examination. Only then can the necessary procedure be decided. The cure rate is 5% or less, largely because of relatively vague and general symptoms before

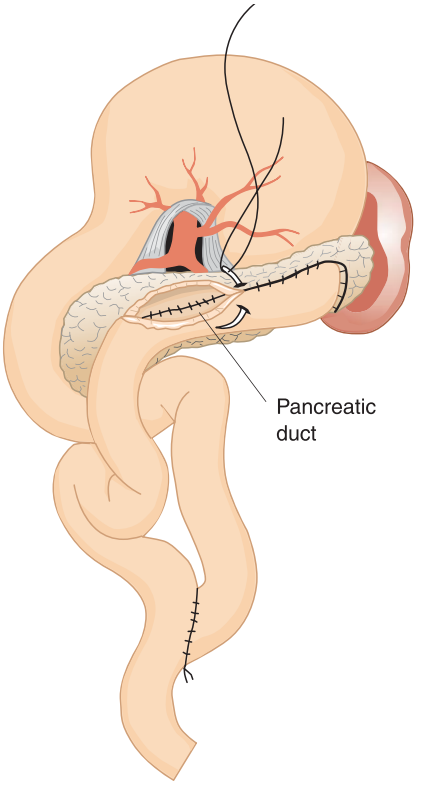

FIGURE 55–6. Puestow procedure: lateral or longitudinal pancreatojejunostomy. Roux-en-Y limb of jejunum is sutured to open pancreatic duct along its length.

the onset of jaundice, which greatly narrows the diagnostic possibilities. By the time the diagnosis is suspected, the lesion may be unresectable. Because only small lesions of the head of the pancreas or ampullary area are resectable and because many of the remaining patients still require a palliative procedure to relieve obstructive jaundice, a considerable number of these patients undergo laparotomy.

Most procedures aimed at a cure are termed a *pancreatoduodenectomy* (Fig. 55–7; i.e., Whipple procedure). Variations include total pancreatectomy, regional pancreatectomy, and similar procedures that preserve the pylorus of the stomach. *These are long, extensive bowel resections that cause considerable morbidity. Serious postoperative complications include hemorrhage, coagulopathy, and hepatic, renal, pulmonary, and cardiovascular failure.*

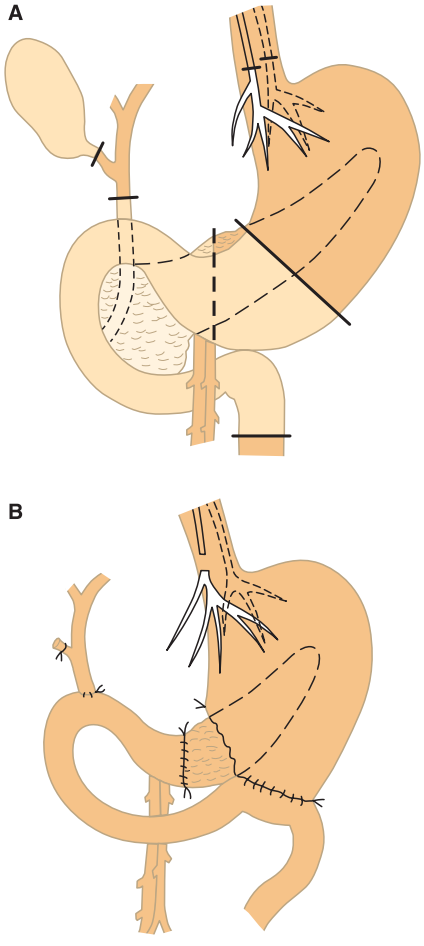

FIGURE 55–7. Pancreatoduodenectomy (Whipple procedure). **A.** Presurgical anatomic relationships. **B.** Reconstruction demonstrating biliary, pancreatic, and gastric anastomoses. If distal stomach and pylorus are preserved, truncal vagotomy is unnecessary. Gallbladder is removed if diseased.

Endocrine disease of the pancreas also is managed surgically. An insulinoma is the most common of these diseases. Because this tumor secretes insulin autonomously, spontaneous hypoglycemia is seen, with symptoms caused by decreased blood sugar levels and the resultant burst of catecholamine release. The differential diagnosis for hypoglycemia is extensive, but once insulinoma is diagnosed, management is surgical. Benign tumors are either enucleated or resected with a margin of pancreas. When no tumor is found at laparotomy, a distal or near-total pancreatectomy is performed, depending on the histology. Malignant disease may be surgically debulked with subsequent chemotherapy.

The Zollinger-Ellison syndrome results from a pancreatic or duodenal tumor (gastrinoma) that secretes excessive gastrin. Symptoms usually are abdominal pain and possibly diarrhea. Associated endocrinopathies include multiple endocrine neoplasia syndrome type 1 (MEN 1: parathyroid, pituitary, adrenal) and MEN 2 (medullary carcinoma of the thyroid, parathyroid adenoma, pheochromocytoma). Medical management involves H_2-receptor antagonists or proton pump blocker therapy. Surgical management involves vagotomy and pyloroplasty when no tumor is discovered at laparotomy or major resection procedures when a localized tumor is found. The presence of metastatic disease and MEN syndromes dictates medical therapy.

Other endocrine tumors of the pancreas include VIP (VIPoma), glucagonoma, and somatostatinoma. Surgical considerations are similar to those for insulinoma and gastrinoma (see Gastrointestinal Endocrinology).

Pancreas Transplantation

Pancreas transplantation (PTX)[257] has become a surgical treatment for type 1 diabetes mellitus.[258] Most patients receive their PTX with or shortly after a renal transplantation, although some have received a pancreas before becoming uremic (such treatment is controversial).[259]

Evaluation of patients before PTX includes extensive assessment of the cardiovascular system because the incidence of coronary artery disease in young diabetic patients with end-stage renal disease is high.[260] Active infection (e.g., dental abscess, peritonitis, osteomyelitis, decubitus ulcers) should be sought and managed before transplantation. Secondary diabetic complications (e.g., retinopathy) should be documented and quantified in an effort to gauge the effects of the transplant process on their progression. Recipient contraindications include malignancy and active infection, with concern for those with blindness, advanced cardiovascular disease, and major amputation.

Donor organs typically come from patients younger than 55 years of age without major atherosclerosis of the celiac axis, abdominal contamination, pancreatic injury or pancreatitis, or diabetes. Neither donor serum glucose nor amylase appear to have predictive value for ultimate function in the recipient.[261] Earlier competition between harvesting teams for the liver or pancreas has been largely resolved by techniques permitting simultaneous retrieval of the liver and the pancreas.[262,263]

There are several approaches to implanting the pancreas. Some drain the pancreas enterically via a Roux-en-Y loop.[264,265] Reexploration is frequent with this procedure because of a high incidence of complications. Assessment of organ function and rejection is difficult.[266] Other centers perform PTX via a bladder drainage procedure (Fig. 55–8). Some use direct draining of the pancreatic duct into the ureter or bladder, whereas others use a small "button" of duodenum or a closed duodenal segment for union with the bladder. Vascular anastomoses are with the iliac vessels, similar to a renal transplantation. Hypertension, abnormal renal function, and all the sequelae of diabetes mellitus and its management make this a challenging group of patients.

Perioperatively, patients undergoing PTX need to have appropriate cardiovascular monitoring and a regimented approach to managing serum glucose levels. This may entail insulin infusion protocols and frequent intraoperative glucose determinations in an attempt to prevent hypoglycemia and hyperglycemia. Glucose-containing solutions are avoided unless the glucose level is lowered to less than 60 mg/dL. With reperfusion of the new pancreas, a dramatic increase occurs in blood sugar levels for reasons not entirely understood, so it is also prudent to monitor glucose levels frequently for

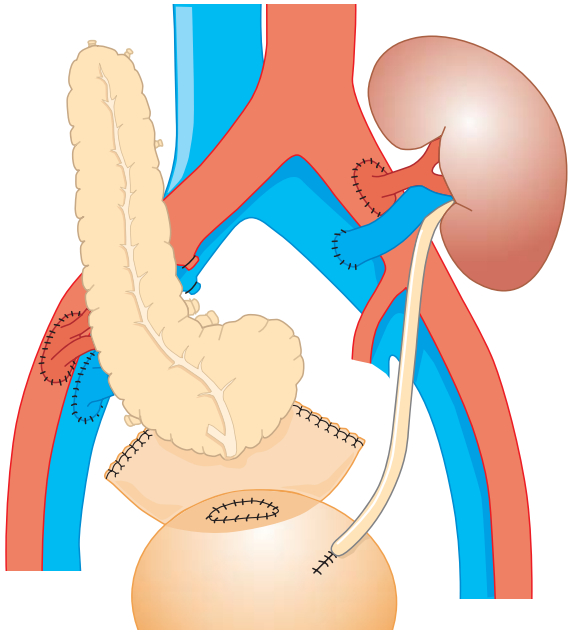

FIGURE 55–8. Pancreas transplantation. Pancreas transplanted with bladder drainage via a pancreatic duodenocystostomy. Concurrent renal transplantation also is depicted.

the first hour or so after reperfusion. Postoperatively, the patient is treated in an intensive care setting.[267–269] (See Chap. 58 for an in-depth discussion of pancreas transplantation.)

SMALL BOWEL TRANSPLANTATION

Because of extremely poor outcomes in patients with extensive bowel resection for acute and chronic disease and because of success in other solid-organ transplantation, small bowel transplantation has been pursued by a few selective academic centers. Candidate patients have intestinal failure and have significant complications from total parenteral nutrition. Furthermore, these patients have one of the highest mortality rates of any patients waiting for solid organs.[270] Candidate organs are difficult to acquire because the intestine is sensitive to pressor-induced ischemia that may occur during aggressive intensive care both before and after brain-death declaration. (See Chap. 58 for a detailed discussion of small bowel transplantation.)

Small bowel transplantation may be coupled with liver or en bloc visceral organ transplantation. Anesthesia for small bowel transplantation with liver or en bloc visceral transplantation is similar to orthotopic liver transplantation. (See Chap. 56 for a detailed discussion of liver transplantation.) For isolated small bowel transplantation, significant lysis of adhesions and vascular anastomoses require adequate perfusion pressure and fluid resuscitation.[271]

Surgical technique of en bloc visceral transplantation and the exclusion of the colon aided the improvement of small bowel transplantation.[271] But the greatest advances, as with other solid-organ transplantation, have occurred because of improvements in immunosuppression, which have lead to longer organ and patient survival. Tacrolimus, mycophenolate, rapamycin, daclizumab, alemtuzumab, interleukin-2 antagonists, and steroids represent novel increments in immunosuppression developed in the last 20 years. Others have used donor bone marrow infusion with ex vivo graft irradiation as adjuvant therapies to improve small bowel survival.[271,272]

Preoperative screening and aggressive therapy for cytomegalovirus and Epstein-Barr virus are also important considerations for extending organ and patient survival.[273,274]

Gastrointestinal Bleeding

GI bleeding often represents a major diagnostic and therapeutic challenge. Initial signs may be hematemesis, melena, hematochezia, or occult blood in the stool. As little as 60 mL loss per day can result in a black stool, and less than 10 mL can result in a positive Hemoccult test. Many patients with GI bleeding are elderly or debilitated, and symptomatic hemorrhage causes major stress to other organ systems (e.g., cardiac, renal, central nervous).

Upper Tract Bleeding

The list of potential etiologies for upper GI hemorrhage is lengthy, but the four most common causes appear to be peptic ulcer disease, erosive gastritis, esophageal varices, and Mallory-Weiss tears of the esophagus.[275] Other causes include malignancy, blood dyscrasias, hemostatic disorders, aortoenteric fistulas, Dieulafoy syndrome, and collagen vascular diseases. In one series, 12% of patients with upper GI bleeding had chronic renal failure and bled from angiodysplastic lesions of the stomach and duodenum.[276] *It usually is stated that if the patient's systolic pressure is less than 100 mm Hg, with a pulse greater than 100 beats/min (i.e., a loss of 2 or 3 units or more of blood) and red or maroon stools, then the mortality rate is greater than 20% and surgical intervention is necessary in more than 50% of patients.*[277] Chronic lung, renal, cardiac, and liver disease and age older than 60 years add to this burden.

Diagnosis is aided by esophagogastroduodenoscopy in the first 24 hours. Management includes volume replacement and attention to illness in other systems. Some patients may receive parenteral vasopressin, such as an arterial infusion after angiography locates a bleeding ulcer or Mallory-Weiss tear, or an IV infusion for variceal bleeding. Varices often can be controlled with a Sengstaken-Blakemore tube, usually in preparation for more definitive management, such as sclerotherapy. Vasopressin often is still infusing when patients arrive for surgery to control bleeding. Vasopressin increases splanchnic and hepatic arteriolar resistance while decreasing portal venous pressure and hepatic blood flow. After a bolus dose, effects may last for approximately 1 hour.[278] Worrisome side effects of vasopressin include coronary artery vasoconstriction with myocardial infarction, a potential complication of its use in patients with myocardial ischemia.[279] Intestinal and extremity ischemia also can occur.[280,281]

Lower-Tract Bleeding

The more frequent causes of lower GI bleeding are anorectal polyps, colonic polyps, colorectal cancer, inflammatory bowel disease, submucosal angiodysplasia, and diverticular disease. In children, juvenile polyps, Meckel diverticulum, and arteriovenous malformations are additional causes. Because the bleeding often is intermittent, diagnostic evaluation may be frustratingly negative. Endoscopy, radiographic examinations, and selective angiography are among the diagnostic and therapeutic (e.g., electrocoagulation, embolization) modalities. Technetium-99m–labeled erythrocyte scans appear to be useful for slow, recurrent, lower GI bleeding.[282] Surgical procedures are directed toward the suspected diagnosis. Infrequently, when troublesome and symptomatic bleeding persists without a diagnosis, laparotomy may be undertaken for intraoperative endoscopy.

Obstructive Disease

Impaired GI transit results from various conditions causing pseudoobstruction (i.e., decreased motility) and paralytic ileus and those producing varying degrees of mechanical obstruction (Box 55–12). Considerable variation exists within each of these broad categories, and associated illness can be extensive.

Pseudoobstruction and paralytic ileus generally represent intestinal motility disorders, and the list of causes is long (Box 55–13).[283] Patients with pseudoobstruction usually have an insidious clinical course that evolves over months and years for the primary disease and for any coexisting GI manifestations. In general, remissions and exacerbations often occur.

Paralytic ileus tends to be acute in onset and to develop in patients with no suspected predisposing disease process. Although probably caused by neurohumoral mechanisms, paralytic ileus is not well understood. *The most common ileus is that seen after intraabdominal operations.*[56] Length of hospitalization following abdominal surgery depends on several factors including pain control, presence of mechanical devices (drains, catheters, and intervenous tubes) and postoperative ileus. In 2000, the Health Care Financing Administration demonstrated that 161,000 Medicare patients underwent major intraabdominal operative procedures costing more than $1 billion. Postoperative ileus has the potential to play a significant role in length of hospitalization, morbidity, mortality and cost.

BOX 55–12.

Causes of Impaired Intestinal Transit

Impaired motility
Pseudoobstruction
Paralytic ileus
Mechanical obstruction

Normal gastrointestinal motility is an integration of smooth muscle contraction, neural input, hormonal signals, and an enteric nervous system. The digestive system has as many neurons (Auerbach and Meissner plexus) as the spinal cord. After an intraabdominal operation, the electrical disorganization and ineffective coordination of propulsion characterizing an ileus usually resolves after 4–5 days.[284] *The small intestine usually recovers motility within a few hours.*[285] *The stomach resumes its ability to empty after about 24 hours, but the colon may not regain effective motility for 48 hours or longer.*[286–289]

Physical manipulation of the abdominal viscera, opioids, catecholamines, and inhalational anesthesia decrease bowel motility.[290] To date, there is no specific treatment for postoperative ileus. Nasogastric tubes historically have been inserted to reduce pulmonary complication, hasten bowel function return, increase patient comfort, and shorten hospital stay. In fact, a Cochrane analysis (4194 patients, 2108 routine nasogastric tube, 2087 no or selective tubes) demonstrated that *not* having a nasogastric tube after a procedure hastened return of bowel function ($P < 0.001$) and marginally decreased pulmonary complication ($P = 0.07$).[291] Early ambulation is an inexpensive therapy that decreases risk of thromboembolism and may be psychologically helpful for patients, but does not appear to benefit patients in resolution of postoperative ileus.[292] In 1928, Steinbrok et al. reported treatment of ileus by splanchnic epidural anesthesia. Although there have been suggestions that sympathectomy from epidural anesthesia will cause an increase in anastomotic leaks, an analysis of 12 trials with 562 patients failed to find an association between epidural anesthesia and anastomotic breakdown.[293] Furthermore, when compared with patients who were receiving patient-controlled parenteral opioids, epidural analgesia provided better postoperative pain control.[293]

Although neostigmine, metoclopramide, cisapride, erythromycin, ceruletide, somatostatin, laxatives, and nonsteroidal antiinflammatory agents have theoretical advantages for enhancing GI

motility, investigations have not demonstrated useful effects in humans.[284] It is well established that opioids acutely and chronically slow gastrointestinal motility. Administration of peripheral opioid antagonists appears to lead to a faster return of bowel function, faster hospital discharge, without an increase in readmissions, and with *no difference* in pain scores.[294,295]

Other abdominal causes of paralytic ileus include blunt trauma, bowel perforation, bile peritonitis, and intraabdominal sepsis. Nonabdominal causes include lobar pneumonia, myocardial infarction, massive trauma, generalized sepsis, and electrolyte abnormalities such as hypophosphatemia and hypokalemia.

Mechanical obstruction is a vexing diagnostic problem that generally requires surgical intervention. Simple obstruction implies adequate blood flow to the obstructed area, whereas strangulation connotes insufficient circulation to the area. Obturated obstruction is caused by an intraluminal foreign body. Mechanical obstruction tends to be acute, with fairly rapid progression to complete obstruction.

Approximately 60–80% of obstruction occurs in the small intestine.[296] Pain, distension, emesis, and obstipation typically are present. Volume loss, tachycardia, and electrolyte disturbances can occur from severe vomiting and the massive volumes that are sequestered in strangulated bowel.

Approximately 7–9 L of fluid are presented to the gut daily[297] from varied sources (Table 55–2). With obstruction, not only is reabsorption hindered, but intestinal fluid secretion may be increased.[298] In addition, rapid infusion of IV fluids, which may be necessary for hemodynamic support, has been reported to increase secretion.[299] Once intraluminal pressure exceeds approximately 20 cm H_2O, reabsorption fails.[300]

Because intestinal fluid has a tonicity and electrolyte composition similar to extracellular fluids, acid–base and electrolyte disturbances generally are not severe. Duodenal obstruction can lead to hypokalemic alkalosis resulting from severe emesis. In addition, once strangulation occurs (and no definitive criteria exist for this diagnosis), necrosis of bowel and bacterial proliferation contribute to rapid sequestration of fluid and colloid in the affected bowel and peritoneal cavity. Together with vomiting, this can produce marked depletion of intravascular volume and the potential for renal and cardiovascular instability.

Bile	1000
Pancreatic juice	2000
Succus entericus	1000

Other conditions can mimic small bowel obstruction (Box 55–14), making the diagnosis difficult. This especially applies to elderly patients, who often have only minimal evidence of peritoneal irritation.

Acute, large bowel obstruction is associated with pain, distension, vomiting, and obstipation, although large bowel obstruction can be more insidious than small bowel obstruction and may present without pain but with "overflow" diarrhea. Fifty percent or more of large bowel obstructions result from colorectal cancer, with much of the rest caused by diverticulitis, volvulus, and fecal impaction.[301] Small bowel obstruction may occur concurrently. An incompetent ileocecal valve may permit the eventual development of feculent vomiting.

Management includes decompression of the stomach, appropriate IV fluids, and attention to conditions in other systems (e.g., infection, renal and cardiovascular problems). Depending on the patient's age and the severity of illness or suspected intervention, invasive hemodynamic monitoring may be warranted.

Patients with GI motility disorders and those with obvious obstruction are at risk for regurgitation and aspiration during the induction and maintenance of anesthesia and postoperatively. The anesthesiologist should be aware of the potential for such difficulty with this group of patients and treat appropriately. At the least, this would include the omission of oral premedication and the use of postoperative (and preoperative when indicated) nasogastric suctioning. Anesthesia should be induced using awake intubation or rapid sequence considerations.

Conditions Mimicking Small Bowel Obstruction

Diabetic ketoacidosis
Sickle crisis
Porphyria
Pancreatitis
Ureteral and biliary colic
Food poisoning
Pseudoobstruction

The Systemic Inflammatory Response Syndrome–Multiple Organ Failure Continuum

Many severely ill patients require emergency surgical intervention for life-threatening conditions such as abdominal trauma, resection of nonviable bowel, relief of obstruction or strangulation, drainage of an abscess, or removal of a severely inflamed gallbladder. In addition to their abdominal disorder, they may be intubated in an intensive care unit, may have evidence of organ system failure (e.g., pulmonary, renal, central nervous system and major metabolic changes), or may be older with serious cardiac and vascular disease. Many behave as if they have a severe infection whether or not one is eventually discovered. In the past, varying etiologies have been suggested, including gram-negative sepsis, endotoxemia, sepsis syndrome, and multiple system organ failure. Because of the many similarities among such patients, even for those whose clinical course falls outside these diagnoses (e.g., patients with gram-positive sepsis, viral or fungal infection, or no infection at all), other explanations have been sought.

Common to many of these patients is evidence of major inflammatory mediator production and release by polymorphonuclear leukocytes, macrophages, monocytes, platelets, and the endothelium. The cyclooxygenase pathway has important effects. More than 30 such mediators have been identified, with cytokines such as tumor necrosis factor, interleukins 1, 6, and 8, substance P, granulocyte-macrophage colony-stimulating factor, interferon, and platelet-activating factor among the most studied.[302,303]

It has been suggested that the *systemic inflammatory response syndrome* represents the earliest, fairly nonspe-

*Two or more should be present for a diagnosis to be made.

cific, phase of a process that may lead to organ dysfunction and ultimately, organ failure. Currently, the diagnosis of SIRS requires that two of the findings in Box 55–15 be present.[304] *Systemic inflammatory response syndrome and multiple organ failure appear to be the ends of a hierarchical continuum with an increasing inflammatory response to infectious and noninfectious stimuli;*[305] while initially *organ dysfunction is more functional than permanent, organ failure and mortality increase with increasing inflammatory response.*[306,307]

The GI tract is a vulnerable organ system. Any insult to adequate core tissue perfusion (e.g., hemorrhage, cardiac arrest, cardiopulmonary bypass) may result in severe or relative hypotension, with ensuing GI mucosal ischemia. Endogenous vasoconstrictors may be released[308] (Box 55–16), which may affect the splanchnic bed more consistently than others.[309–313] Reperfusion after shock may be associated with oxygen and free radical mucosal damage. In addition, so-called myocardial depressant factors can be released from the pancreas and possibly the small intestine, which further contribute to tissue hypoperfusion and low cardiac output syndrome. As much as 15–65% of the circulating volume can redistribute to damaged bowel during this process. While inadequate perfusion limits delivery of oxygen for cellular processes, other mechanisms that directly affect mitochondria may have similar effects even with relatively adequate (or increased) perfusion. A host of factors affect the mitochondria, including reactive oxygen species, local PO_2, levels of adenosine triphosphate, and hormonal influences such as thyroid, catecholamines, corticosteroids, and leptins. Nitric oxide is a strong inhibitor of mitochondrial electron transport. If insufficient energy is available to fuel metabolism, critical thresholds of adenosine triphosphate result and cellular dysfunction and death ensue.

Although the systemic cardiovascular response demanded by these conditions usually is hyperdynamic, it often is inadequate, either because metabolic requirements are too high (or because of end-organ inability to use oxygen) or because of limitations imposed by evolving or underlying myocardial dysfunction. Management of these patients is beyond the scope of this chapter. When the anesthesiologist encounters these patients, they frequently are already receiving vasopressor and inotropic support. Intraoperative care includes intensive evaluation of oxygen delivery, optimization of volume and cardiovascular function, and avoidance of drugs and agents that will further compromise their already tenuous status.[314,315]

SUMMARY

The complex physiologic and metabolic interactions of the GI tract and other organ system functions can present fascinating challenges for the anesthesiologist. Because GI surgery often can seem so benign, it is perhaps more difficult to remain "tuned in" to such concerns. The rewards of good patient care should be sufficient incentive to reexamine important issues in GI surgery and anesthesia from time to time.

CHAPTER 56

Anesthesia for Liver Surgery and Transplantation

Warren S. Sandberg, MD, PhD, and Douglas E. Raines, MD

INTRODUCTION

Anesthesiology is an ever evolving field, and anesthesia for surgery of the hepatobiliary system is no exception. Over the past 3 decades, hepatic surgery has developed as a separate subspecialty, and this development has paralleled the evolution of hepatic surgery from a risky and heroic enterprise to a more routine undertaking. Better understanding of hepatic anatomy, better diagnostic imaging capabilities, better patient selection and risk stratification, better surgical techniques, and better anesthetic techniques have at once improved the morbidity and mortality profiles of liver surgery while extending the limits of what can safely be accomplished.

This chapter describes the anesthetic management of patients undergoing hepatic surgery, ranging from minimally invasive procedures, such as transjugular intrahepatic portosystemic shunting, to orthotopic liver transplantation. Patients presenting for hepatic surgery can generally be divided into two groups, each of which provides unique challenges for the anesthesiologist:

1. Patients presenting for hepatic surgery who do not have significant liver disease—for example, the patient with isolated hepatocellular carcinoma. These patients can generally be evaluated and managed as patients presenting for other types of major intraabdominal surgery.
2. Patients with significant liver disease presenting for hepatic surgery for either amelioration of the liver disease itself or, more rarely, treatment of a distinct hepatobiliary problem. Hepatobiliary operations performed on patients with liver disease include portosystemic shunts, hepatic resection, and orthotopic liver transplantation.

Patients with liver disease who require nonhepatic surgery are a broader group unified by a common derangement. In these individuals, the liver disease must be taken into account and will shape preoperative preparation, anesthetic technique, and postoperative care (for more details on the evaluation and general anesthetic management of the patient with liver disease presenting for nonhepatic surgery, see Chap. 14).

The general principles evinced in Chap. 14 apply as well to patients with liver disease presenting for hepatobiliary surgery. In this chapter, we first review the relevant anatomy, physiology, and hepatobiliary pathophysiolo-

KEY POINTS

1. Patients with chronic liver dysfunction and cirrhosis have a hyperdynamic circulation with low peripheral vascular resistance and an increased cardiac index.
2. Coagulopathies, edema and ascites, renal dysfunction, portopulmonary hypertension, hepatopulmonary syndrome, and autonomic neuropathies are common in patients with liver disease.
3. The cause of hepatic encephalopathy is believed to be multifactorial. Hepatic encephalopathy resembles, and must be differentiated from, many other nonfocal neurologic conditions, such as hypoglycemia, hyponatremia, intracranial hemorrhage or mass lesions, and meningitis.
4. Patients scheduled for hepatic resection should be evaluated as any patient scheduled for major noncardiac surgery. Plans for monitoring, vascular access, induction and maintenance of anesthesia, postoperative pain control, and postoperative care should take into account a large subcostal incision and the potential for sudden massive hemorrhage and severe physiologic derangements during and after surgery.
5. The most common indication for liver transplantation is chronic hepatocellular disease because of alcohol and/or hepatitis. Hepatitis C is increasingly important, representing a unique and growing health risk for anesthesiologists.
6. Cardiac assessment of the patient being considered for liver transplantation focuses on functional and invasive tests of cardiac performance that assess ischemic potential and the search for cardiac structural anomalies that might compromise outcome from orthotopic liver transplantation.
7. Liver transplantation comprises three phases. During the *preanhepatic* phase, a complete hepatectomy is performed. During the *anhepatic* phase, vascular anastomoses between the donor liver and the recipient's vessels are constructed. During the *neohepatic* phase, the hepatic arterial and biliary anastomoses are constructed, and the wound is closed.
8. The two common techniques for liver transplantation are the en bloc technique with interruption of vena caval flow and the piggyback technique with preservation of vena caval flow.
9. The goals of hemodynamic management are to provide sufficient circulating volume, vascular tone, and cardiac output to perfuse the vital organs. This is not guided by any single parameter but rather by a synthesis of all available data.
10. Most livers made available for transplantation come from heart beating cadaveric donors. When caring for organ donors, the focus of care has shifted from preserving the patient to preserving the function of graft organs. Because of the shortage of cadaveric donors, the use of living donors is growing. In these cases, donor safety is a primary concern because the donor derives no physical benefit from the surgery.
11. The effects of portal hypertension and ascites are alleviated by nonshunting and shunting procedures. Nonshunting procedures are aimed at controlling hemorrhage from portosystemic varices. Shunting procedures redirect the portal venous flow into the systemic venous circulation via a nonvariceal conduit, thus relieving portal hypertension, decompressing varices, and at the same time relieving ascites.

gy that affect the anesthetic management of patients presenting for hepatic surgery. Next, we describe at a high level the surgical considerations informing the various groups of hepatic operations, followed by detailed consideration of the consequent anesthetic management goals.

ANATOMY AND PHYSIOLOGY

Anatomy of the Liver

The liver contains two lobes (right and left) that are separated on the anterior side by the falciform ligament and supplied by right and left branches of the portal vein and the hepatic artery. Two smaller additional lobes can be visualized on the posterior aspect of the liver, the caudate and quadrate lobes. The liver is subdivided into eight segments that are defined by secondary and tertiary branching of the blood supply. The caudate lobe contains segment 1, the left lobe contains segments 2 and 3, the quadrate contains segment 4, and the right lobe contains segments 5 though 8.

Blood flow to the liver is 1 L/min/kg of hepatic tissue, or approximately 25% of the cardiac output. Most of this blood supply is via the portal vein (75%), which delivers approximately 45–50% of the hepatic oxygen supply, with the balance coming via the hepatic artery. Portal venous blood flow is controlled primarily by the arterioles within upstream splanchnic organs and, to a more limited extent, by resistance within the liver. Hepatic artery blood flow is controlled directly via arterial smooth muscle under autonomic regulation. In addition, metabolic factors such as blood pH and/or oxygen content can modulate hepatic arterial resistance and, hence, blood flow. After coursing through the liver, blood drains via the hepatic veins and into the inferior vena cava.

Overview of Liver Functions

The liver is among the most complex organs in the body and is responsible for a wide range of important synthetic and metabolic processes. A detailed review is beyond the scope of this chapter, but a brief overview is provided here.

Albumin Synthesis

The liver synthesizes more albumin than any other protein, in the range of 10–20 g/day. As the most abundant plasma protein, it serves an important role in maintaining the normal oncotic pressure of plasma. A decrease in albumin synthesis can allow transudation of fluids into extravascular spaces, producing edema and ascites. Albumin has a half-life of approximately 20 days; therefore, it is not a good indicator of liver function in patients with acute hepatic disease. Because many drugs, including barbiturates and benzodiazepines, are bound by albumin in the blood, the hypoalbuminemia frequently observed in patients with significant hepatic dysfunction can lead to an increase in the free or active concentrations of the drugs. This may account, in part, for the increased sensitivity of patients with severe hepatic disease to sedatives and anesthetics.

Coagulation Factor Synthesis

The liver is the major site of synthesis of most procoagulant and inhibitory clotting factors, including fibrinogen, factors II, V, VII, IX, XII, and XIII, plasminogen, antithrombin, and proteins C and S. Consequently, loss of hepatic parenchymal cells can lead to clotting factor deficiencies with resultant coagulopathy. Systemic fibrinolysis, which is found in 30% of patients with end-stage liver disease, may contribute to clotting factor deficiencies.[1] Although the pathogenesis of this fibrinolysis is not clearly defined, studies suggest that it involves altered tissue plasminogen activator activity, impaired synthesis of the inhibitors of plasminogen and plasmin, α_2-antiplasmin, and histidine-rich glycoprotein.[2–5] Additionally, patients with advanced liver disease exhibit an exaggerated fibrinolytic response to major surgery, such as liver transplantation, predisposing them to significant perioperative hemorrhage.[6]

Carbohydrate Metabolism

Regulation of blood glucose concentrations is controlled largely by the liver and is under hormonal control. In response to lowered concentrations of glucose in the portal vein, glycogen stored in the liver is broken down to glucose for use by other tissues (glycogenolysis). During periods of fasting when glycogen stores have been depleted, the liver can also generate glucose from noncarbohydrate sources, such as lactate, amino acids, and glycerol (gluconeogenesis). Ingestion of carbohydrates replenishes glycogen stores and allows fatty acids to be synthesized by the liver.

Bile Acid Synthesis

Bile acids are important compounds required for elimination of cholesterol and absorption of vitamins and fats. The liver converts approximately 500 mg/day of cholesterol into bile acids in processes that involve 17 different enzymes and are regulated by many factors, including nutrients and hormones.[7] Bile acids are stored in the gallbladder and released into the small intestine to emulsify lipids, cholesterol, and the fat-soluble vitamins A, D, E, and K. Most (90–95%) of the secreted bile acids are reabsorbed by the liver and recycled.

Drug Metabolism

A number of enzymatic pathways are involved in the metabolism of drugs by the liver, each can be placed into one of two reaction categories. Phase 1 reactions use the chemical processes of oxidation, reduction, and hydrolysis; occur in the hepatocyte smooth endoplasmic reticulum; and are mediated primarily by the cytochrome P450 family of enzymes. Phase 2 reactions increase the water solubility of drugs by coupling (conjugating) drugs with polar moieties, thereby facilitating biliary excretion. Often, phase 2 reactions follow phase 1 reactions because the products of phase 1 reactions may not be sufficiently water soluble to be readily excreted.

PATHOPHYSIOLOGY RELEVANT TO ANESTHESIA FOR LIVER SURGERY

In this section, we briefly review the disease entities leading to liver failure (for a more complete description and a discussion of the Child-Turcotte-Pugh classification scheme for evaluating the surgical risk associated with progressive worsening of liver disease, see Chap. 14). Later in this section, we describe the pathogenesis and medical management of organ system derangements that are associated with acute and chronic liver disease.

Chronic Liver Disease

Chronic liver disease may result from a variety of conditions, including infection, biliary obstruction, toxicity, and inborn errors of metabolism (Box 56–1). These conditions can progress to

BOX 56–1.

Major Causes of Chronic Liver Disease

- Intraparenchymal disease
  - Viral infections
    - Chronic active hepatitis B
    - Chronic active hepatitis C
    - Hepatitis D
  - Toxins
    - Ethanol
  - Miscellaneous
    - Cystic fibrosis
    - Hemochromatosis
    - Wilson disease
    - α_1-Antitrypsin deficiency
    - Metabolic errors of carbohydrate, lipid, protein
  - Cholestatic disease
    - Primary biliary cirrhosis
    - Primary sclerosing cholangitis

BOX 56–2.

Major Causes of Fulminant Hepatic Failure

- Toxins
  - Acetaminophen
  - Ethanol
  - *Amanita phalloides*
  - Halothane
  - Phosphorus
- Viral infections
  - Hepatitis A
  - Hepatitis B
  - Hepatitis C
  - Hepatitis D
- Miscellaneous
  - Budd-Chiari syndrome
  - Acute fatty liver of pregnancy
  - Wilson disease

BOX 56–3.

Hemodynamic Derangements in Cirrhotic Liver Disease

- Decreased systemic vascular resistance due to:
  - Peripheral vasodilatation
  - Arteriovenous shunting
- Redirection of blood flow:
  - Increased pulmonary, splanchnic, muscle, skin blood flow
  - Decreased portal vein flow to liver
  - Normal or increased hepatic arterial flow
  - Normal to decreased renal blood flow
- Increased blood volume
  - Decreased serum albumin
  - Decreased plasma oncotic pressure
- Increased cardiac output
  - Apparent cardiomyopathy despite increased output
- Decreased arteriovenous O_2 content difference
  - Increased venous O_2 content
- Decreased responsiveness to catecholamines

cirrhosis, which is characterized by hepatic cell death, fibrosis, and formation of regenerative nodules. This process is essentially irreversible and leads to important physiologic disturbances. Elevation of the blood pressure within the portal venous system (i.e., portal hypertension) is common in patients with significant chronic liver disease and results from increased portal blood flow and/or intrahepatic resistance. It is associated with the formation of ascites, esophageal varices, hepatic encephalopathy, and splenomegaly. Ascites is a hallmark of decompensated liver cirrhosis, and its cause is multifactorial. These factors include alterations in portal blood flow dynamics, activation of the renin–angiotensin–aldosterone system, and reduction in plasma oncotic pressure. The primary treatments of ascites are sodium and water restriction, administration of diuretics, and abdominal paracentesis, which can lead to intravascular fluid depletion.

Esophageal variceal bleeding is a potentially lethal complication of cirrhosis. Treatment options depend on the severity of the bleeding and include the administration of β-blockers, variceal banding, sclerotherapy, and portosystemic shunting. However, an important potential complication of portosystemic shunting is that it may cause or worsen existing hepatic encephalopathy.[8]

Fulminant Hepatic Failure

Fulminant hepatic failure is generally defined as severe hepatic dysfunction that occurs either in the absence of preexisting liver disease or in the presence of well-compensated liver disease. Drug toxicity, most frequently by acetaminophen, is the most common cause of fulminant hepatic failure (Box 56–2), followed by viral hepatitis. However, not uncommonly (17%), no causative agent is identified.[9] Acute hepatic encephalopathy is a prominent clinical feature of fulminant hepatic failure and is associated with progressive brain swelling and an increase in intracranial pressure (ICP) that can result in brain herniation and death. Brain herniation is also the most commonly identifiable cause of death found at autopsy.[10] In patients who are awake and responsive, regular neurologic examinations can be used to exclude dangerous brain swelling. However, neurologic examinations cannot detect dangerous increases in ICP when patients are comatose because of encephalopathy or in patients during general anesthesia. Therefore, some centers regularly institute ICP monitoring during major surgery. However, such monitoring is controversial because patients with fulminant hepatic failure commonly are coagulopathic, and placement of ICP monitors is associated with a significant (10–20%) risk of intracranial bleeding.[11,12]

Treatment of fulminant hepatic failure is supportive, and many patients recover. However, some patients do not recover and thus require liver transplantation. Regardless of the final path to resolution, supportive care aims to reduce the impact of severe encephalopathy and brain swelling. Mild hypothermia appears to be protective in patients with encephalopathy during acute liver failure awaiting liver transplantation, but this has not been unequivocally demonstrated by randomized studies.[13] Similarly, barbiturates can be used to lower brain oxygen consumption as an additional temporizing measure.

Bacterial infection develops in up to 80% of patients with fulminant hepatic failure.[14,15] These infections most commonly involve the respiratory and urinary systems.[15] Acute infection may prevent transplantation.

Hemodynamic Changes in Liver Disease

Patients with chronic liver dysfunction and cirrhosis commonly have a hyperdynamic circulation (Box 56–3) with a low peripheral vascular resistance and an increased cardiac index.[16] It has been suggested that a low systemic vascular resistance results from an increase in circulating endogenous vasodilators, including nitric oxide, calcitonin gene-related peptide, and substance P, the metabolism of which is reduced by the presence of intrahepatic and extrahepatic arteriovenous shunts.[17–19] Cardiac output is frequently elevated in cirrhotic patients, attributable to increased sympathetic

nervous system activity, increased blood volume and preload, and reduced systemic vascular resistance.[20,21] However, even in the setting of increased cardiac output, patients with cirrhosis may have significant cardiac dysfunction. Typical features of "cirrhotic cardiomyopathy" include impaired cardiac contractility, conduction abnormalities, impaired excitation–contraction coupling, and decreased β-adrenergic receptor function.[22] Some patients with a hyperdynamic circulation develop significant left ventricular failure after liver transplantation. The condition has been suggested to result from increased peripheral vascular resistance after relief of vasodilatation by transplantation. With inotropes, mechanical ventilation, and close monitoring, results from small series suggest that these patients will survive.[23]

Renal Function in Patients with Liver Disease

Renal dysfunction is common in patients with liver disease and has at least three major causes.[24] First, prerenal azotemia resulting from overaggressive use of diuretics used to control ascites can result in rising blood urea nitrogen (BUN) and creatinine concentrations indicating worsening renal function. These elevations usually respond to reduction of the diuretic dose and gentle hydration. The second common cause of renal dysfunction in patients with liver disease is acute tubular necrosis in the setting of another acute, precipitating factor. In patients with liver disease, a common scenario is the development of a low-tone, sepsis syndrome in the setting of an infection, such as spontaneous bacterial peritonitis, followed by renal failure. Renal failure commonly develops in the setting of infection in patients with liver disease. For example, it has been reported that 27% of patients with cirrhosis and sepsis progressed to renal failure.[25] Of these patients, renal failure was reversible in 76%,[25] demonstrating that renal function tends to recover with removal of the inciting insult. However, the mortality rate for patients with high Model of End-Stage Liver Disease (MELD) scores (i.e., severe liver disease) was high.[25] The third common cause of renal failure in the cirrhotic patient is hepatorenal syndrome.[26] The diagnostic criteria for hepatorenal syndrome are given in Box 56–4.

Hepatorenal syndrome is marked by worsening of renal function as the liver disease progresses. Renal function will not recover unless liver function improves.[24] Temporizing measures to treat hepatorenal syndrome are based on theories of its pathophysiology. One such theory is that the inciting factor is the peripheral vasodilatation that characterizes late cirrhosis.[27] Decreased peripheral vascular resistance activates vasoconstrictor systems (e.g., renin–angiotensin–aldosterone, antidiuretic hormone, and sympathetics), leading to renal vasoconstriction. This in turn leads to sodium and water retention and the formation of ascites. Another theory is that portal hypertension reduces blood flow to hepatocytes,[28] which sense the reduced flow as a manifestation of inadequate blood volume and activate a hepatorenal reflex causing vasoconstriction and sodium and water retention. Thus, the temporizing therapies for hepatorenal syndrome include both renal vasodilators and splanchnic vasoconstrictors. Splanchnic vasoconstrictors, such as vasopressin and its longer-lived relatives, are sometimes coadministered with a plasma expander such as albumin.[24] This is the preferred treatment for patients with liver transplantation as an option, and renal function typically recovers after transplantation.[24] However, transplantation is complicated by the presence of renal failure, and renal replacement therapy for control of pH, serum potassium, and intravascular volume is frequently required for these patients.

BOX 56–4.

Diagnostic Criteria for Hepatorenal Syndrome[a]

- Major Criteria
  - Low glomerular filtration rate, as indicated by serum creatinine >1.5 mg/dL
  - Exclusion of shock, ongoing bacterial infection, volume depletion, or use of nephrotoxic drugs
  - No improvement in renal function after stopping diuretics and volume repletion with 1.5 L of normal saline
  - No proteinuria or evidence of obstructive uropathy or parenchymal renal disease
- Minor Criteria
  - Urine volume <500 mL/d
  - Urine sodium <10 mEq/L
  - Urine osmolality > plasma osmolality
  - Urine red blood cells <50 per high-power field
  - Serum sodium <130 mEq/L

[a]Only major criteria are needed to establish the diagnosis.

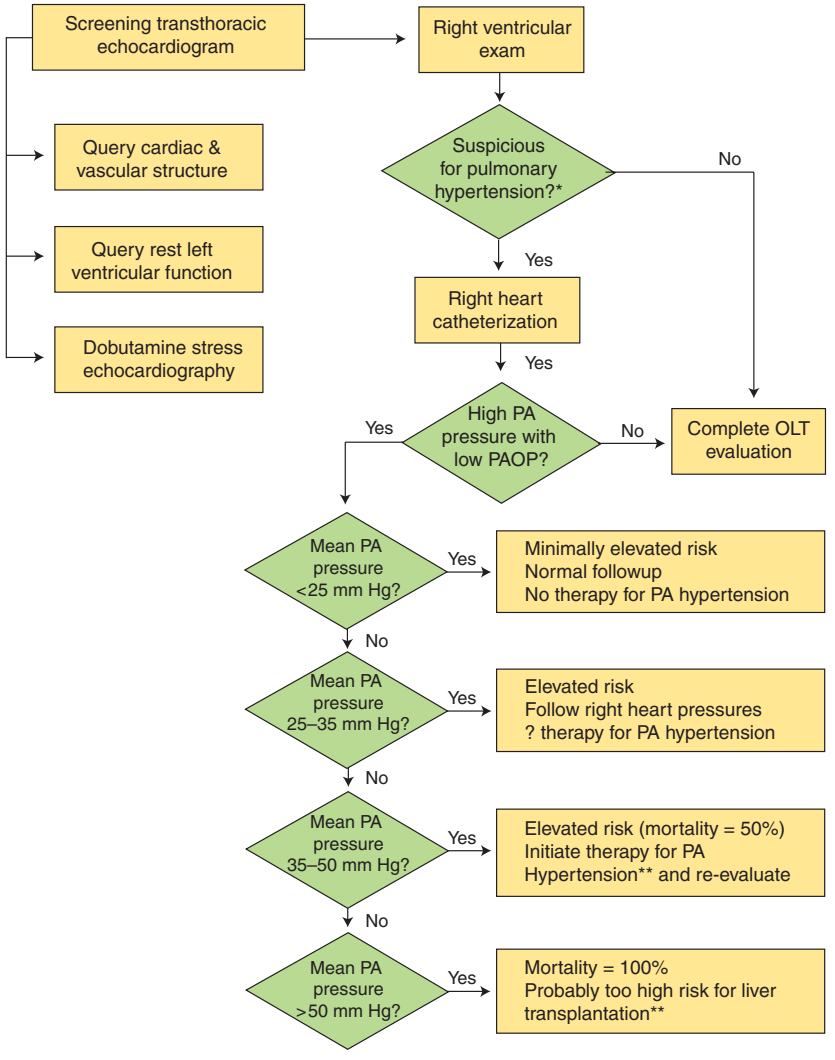
Pulmonary System in Liver Disease

Some patients with chronic liver disease and portal hypertension develop alterations in pulmonary physiology leading to two clinically distinct syndromes: portopulmonary hypertension and hepatopulmonary syndrome. Management depends on appreciating the difference between portopulmonary hypertension and hepatopulmonary syndrome and the therapeutic approaches to each.[29]

Portopulmonary Hypertension

Portopulmonary hypertension occurs most frequently in patients with advanced liver disease. In one study of patients with cirrhosis and refractory ascites, the prevalence of portopulmonary hypertension was 16%.[30] Portopulmonary hypertension is characterized by mean pulmonary arterial pressure >25 mm Hg with normal pulmonary capillary wedge pressure (<15 mm Hg) and elevated pulmonary vascular resistance (>120 dyne/sec/cm^5) in the setting of portal hypertension.[29] Multiple factors have been implicated in the etiology of portopulmonary hypertension, including (1) increased pulmonary arterial blood flow secondary to the increase in cardiac index frequently observed in cirrhosis, (2) increased circulating blood volume, and (3) vasoconstriction and progressive pulmonary vascular remodeling due to proliferation of endothelial and smooth muscle cells with or without thrombotic change.[29,31] The most common symptom of portopulmonary hypertension is dyspnea on exertion, with fatigue, palpitations, chest pain, and syncope being less frequent.[32,33]

Evidence of portopulmonary hypertension can be obtained noninvasively using transthoracic Doppler echocardiography. Fig. 56–1 outlines the diagnostic approach to pulmonary hypertension. Although transthoracic echocardiography is a useful screening tool for portopulmonary hypertension, it frequently overestimates right ventricular pressure,[34] producing a large number of false–positive results as determined by direct pressure measurements at subsequent



* Right ventricular systolic pressure estimate > 40 mm Hg, right ventricular hypertrophy or right ventricular dilation.

**Provocative testing during right heart catheterization, e.g., inhaled nitric oxide by face mask or intravenous epoprostenol, may predict treatment efficacy.

FIGURE 56–1. Suggested diagnostic paradigm for excluding or monitoring pulmonary hypertension. Although many variations exist, it is important to complete the process with a detailed knowledge of the patient's pulmonary hemodynamics. Normal follow-up: repeat transthoracic echocardiogram or right-heart catheterization 1 year after previous test. Elevated risk implies high risk of perioperative mortality (see text for details). OLT, Orthotopic liver transplantation; PA, pulmonary artery.

cardiac catheterization.[34,35] For example, a right ventricular systolic pressure estimate ≥ 40 mm Hg obtained from transthoracic echocardiography is associated with significant pulmonary hypertension (i.e., mean pulmonary arterial pressure >25 mm Hg) at right-heart catheterization in only approximately 65% of cases.[35] Conversely, the sensitivity of Doppler echocardiography for detecting portopulmonary hypertension is sufficiently high that a normal study rules out portopulmonary hypertension.[35] Because of the severe consequences of failing to diagnose and manage portopulmonary hypertension during later liver surgery or transplantation, the best current approach is to screen with transthoracic echocardiography and perform pulmonary artery catheterization to confirm or exclude portopulmonary hypertension in patients with high right ventricular systolic pressure estimates at transthoracic echocardiography.

Effective management of portopulmonary hypertension is important because reducing pulmonary arterial pressures, unloading the right heart, and allowing time for pulmonary vascular remodeling may allow patients who are not liver transplant candidates to become potential recipients.[36] Pulmonary vasodilator treatment also may allow a marginal patient to receive a transplant with reduced mortality.[36] Vasodilators, such as epoprostenol, sildenafil, and nitric oxide, can reduce pulmonary vascular resistance[37,38] and are used for this purpose by programs that consider liver transplantation in patients whose pulmonary pressures can be satisfactorily lowered. Whether these interventions improve survival at liver transplantation is unclear given the current level of evidence. How long pulmonary arterial pressures must be lowered to confer the benefit (if any) of the intervention at subsequent transplantation also is unclear. Case reports of patients with good response to pulmonary vasodilators who subsequently had poor outcomes of transplantation temper enthusiasm for the prospects of such patients.[39]

Experience with pulmonary vasodilators is greatest with IV epoprostenol. Epoprostenol appears to be effective in reducing pulmonary arterial pressures, although it can lead to splenomegaly.[40] Epoprostenol use was more common in patients with pulmonary hypertension who survived liver transplantation than in nonsurvivors with the same degree of pulmonary hypertension, although the difference was not significant.[41] Unfortunately, IV epoprostenol requires continuous IV access for infusion, with all of the attendant complications of permanent venous access and pump failures.

The difficult logistics of continuous epoprostenol use have prompted a search for more convenient routes of administration and/or longer-lived prostaglandin analogues. For example, early reports indicate that continuous subcutaneous administration of treprostanil[42] reduces the symptoms of pulmonary hypertension and lowers pulmonary arterial pressures. Oral beraprost[43] also reduces symptoms of pulmonary hypertension, but the reductions in pulmonary arterial pressures were modest and did not achieve statistical significance despite a relatively large sample size. Inhaled iloprost quickly reduces right-heart pressures and is easy to deploy (and should be pulmonary selective).[44–46]

Of note, none of these alternatives to IV epoprostenol produces more than a few millimeters of mercury reduction in mean pulmonary arterial pressure. Consequently, these drugs may have limited effectiveness in the preparation of patients with pulmo-

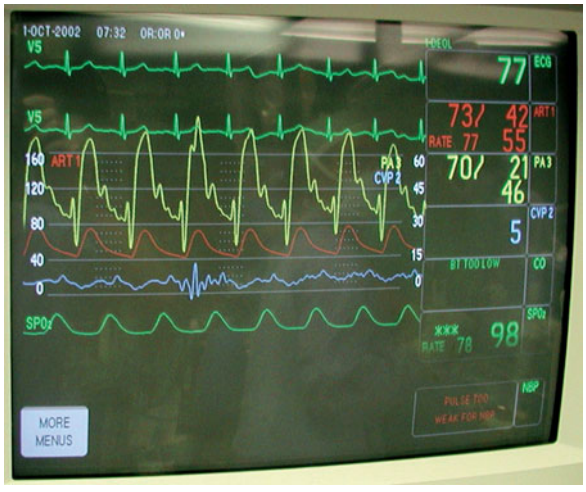


FIGURE 56–2. Pulmonary and systemic pressures immediately after pulmonary artery catheter placement during liver transplantation in a patient with apparent pulmonary hypertension.

nary hypertension for liver transplantation. Conversely, results from individual patients indicate that IV epoprostenol can lower mean pulmonary arterial pressure from approximately 50 to 25 mm Hg.[37,47]

The discovery that nitric oxide can induce pulmonary vasodilatation has provided another approach to lowering pulmonary arterial pressures. Inhaled nitric oxide is a selective pulmonary vasodilator that lowers pulmonary arterial pressures in patients with portopulmonary hypertension.[38] Nitric oxide administered by face mask can be used as a diagnostic tool to assess pulmonary arterial pressure response to vasodilators during right-heart catheterization.[48]

When pulmonary hypertension is discovered unexpectedly in the operating room at the beginning of a transplant, reversible causes of pulmonary hypertension, such as hypoventilation-induced hypercarbia, should be ruled out or reversed. Fig. 56–2 illustrates apparently severe pulmonary hypertension, with pulmonary pressures equal to systemic pressure. Reversing hypercarbia attributable to hypoventilation and lightening the anesthetic lowered the pulmonary pressures and raised the systemic pressures, after which the patient had an uneventful liver transplant.

When newly discovered apparent pulmonary hypertension does not respond to such simple maneuvers, inhaled nitric oxide may be very effective in lowering the pulmonary arterial pressures acutely, without the systemic effects of a nonselective vasodilator such as epoprostenol. Pulmonary arterial pressures (and consequently central venous pressure) should be lowered as effectively as possible, both to minimize hemorrhage and to avoid acute graft congestion that could cause early graft compromise in the operating room.[29] Also of importance is extending treatment of pulmonary hypertension well into the postoperative period because graft failure due to poor blood flow remains a concern. Thus, as the patient moves toward extubation, it is necessary to transition from inhaled nitric oxide to an IV agent (e.g., epoprostenol) or oral agent (e.g., sildenafil) as part of weaning from the ventilator, with the lowest achievable pulmonary arterial pressure being the goal.

Sildenafil is an inhibitor of phosphodiesterase-5 that blocks degradation of cyclic guanosine monophosphate, the second messenger of nitric oxide. Sildenafil also produces selective pulmonary vasodilatation.[49] There are early anecdotal reports of its use as a pulmonary vasodilator in patients prior to liver transplant.[50,51] Oral sildenafil is a useful adjunct to inhaled iloprost, a prostacyclin analogue.[52] To date, far less evidence supports the efficacy of sildenafil, particularly as monotherapy, than IV epoprostenol as therapy for portopulmonary hypertension, but early reports are encouraging.

Hepatopulmonary Syndrome

Hepatopulmonary syndrome is defined by the presence of hepatic dysfunction or portal hypertension, an elevated alveolar–arterial oxygen gradient, and intrapulmonary vasodilatation.[29,53] Thus, although portopulmonary hypertension is associated with pulmonary vascular vasoconstriction, hepatopulmonary syndrome results from vasodilatation and pulmonary vascular remodeling. Patients may present with digital clubbing, spider angiomata, arterial hypoxemia, and dyspnea that worsens upon moving from a recumbent to an upright position (orthodeoxia and platypnea).[53] Early diagnostic criteria required ruling out the presence of other cardiopulmonary abnormalities. However, it now is apparent that hepatopulmonary syndrome may contribute to hypoxemia even when other cardiopulmonary abnormalities are present.[54,55] Intrapulmonary vasodilatation may reflect true anatomic shunt, physiologic shunt, and precapillary or capillary dilation leading to alterations in oxygen diffusion.[56] Nitric oxide level is elevated in the exhaled breath of patients with hepatopulmonary syndrome, suggesting a causative role.[57,58] Interestingly, a case of normalization of exhaled nitric oxide accompanied by return to normoxia after liver transplantation has been reported.[58]

The diagnosis of hepatopulmonary syndrome depends on documenting the presence of arterial desaturation and pulmonary vasodilatation in patients with liver disease. Other causes of hypoxia in patients with liver disease must be excluded (Box 56–5). Pulse oximetry is a sensitive, noninvasive screening tool for detecting low arterial oxygen saturation, the results of which can be confirmed using arterial blood gas analysis.[59] Pulmonary

BOX 56–5.

Major Causes of Hypoxia in Patients with Liver Disease

- Ventilation–perfusion mismatching
  - Premature airway closure
  - Pulmonary vasodilatation
  - Impaired hypoxic pulmonary vasoconstriction
  - Diffusion–perfusion deficit
  - Pulmonary emboli
- Compression of lung tissue
  - Impaired diaphragmatic function due to ascites
  - Pleural effusion
- Pulmonary edema
  - Pulmonary manifestations of specific liver disease (e.g., α_1-antitrypsin deficiency)
- Acute exacerbations of intercurrent chronic lung disease

vasodilatation can be documented using a variety of modalities, including contrast echocardiography, lung perfusion scanning, or pulmonary artery catheterization.[29,53] During contrast echocardiography, late appearance (i.e., 3–6 cardiac cycles) of contrast in the left heart suggests intrapulmonary shunting, whereas early appearance (immediate to one cardiac cycle) indicates intracardiac shunting.[29] Pulmonary angiography is rarely indicated but may be useful to exclude or embolize arteriovenous malformations causing large right-to-left shunts.[29] A flowchart outlining the assessment for hepatopulmonary syndrome is shown in Fig. 56–3.

No effective medical therapies for hepatopulmonary syndrome are available, although selective inhibition of nitric oxide production shows theoretical promise.[29,53] For patients with end-stage liver disease, liver transplantation frequently leads to reduced intrapulmonary shunting and improved oxygenation.[60] Transplantation in patients with hepatopulmonary syndrome is no riskier than is transplantation in patients without hepatopulmonary syndrome; the outcomes of transplantation are the same whether or not the recipients have the condition.[61,62] Among patients with hepatopulmonary syndrome, orthotopic liver transplantation leads to longer survival than does medical management without transplantation.[63] Furthermore, cirrhotic patients with hepatopulmonary syndrome are more likely to die while receiving medical therapy alone (as opposed to transplantation) than are matched cirrhotic control patients without hepatopulmonary syndrome.[63,64] Transplantation must be performed early in patients with hepatopulmonary syndrome; delaying transplant until patients are profoundly hypoxemic is associated with mortality as high as 30%.[65,66]

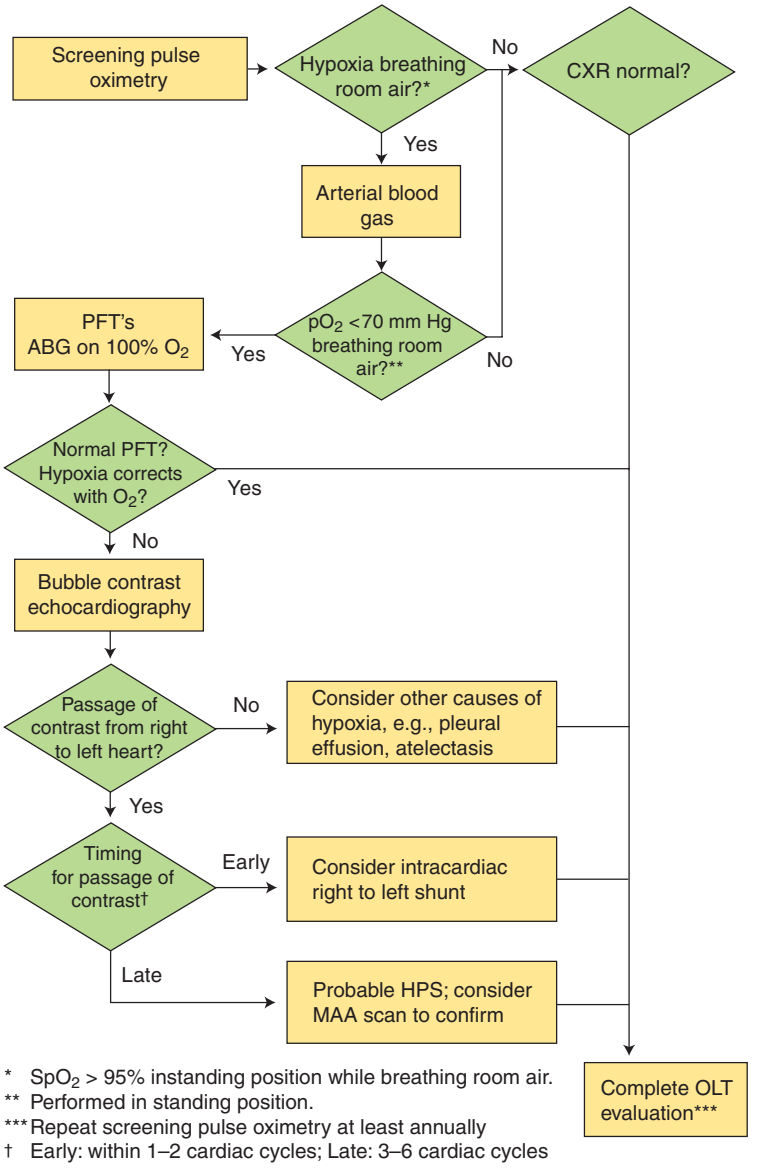

FIGURE 56–3. Diagnostic algorithm for hepatopulmonary syndrome. Some centers extend this algorithm by the routine performance of ^{99}Tc macroaggregated albumin scanning, which is very sensitive to intrapulmonary shunts when other possible right–to-left shunts have been excluded. Screening pulse oximetry should be carried out at every clinic visit and at least annually because development of hepatopulmonary syndrome shortens life expectancy and is accorded additional Model of End-Stage Liver Disease (MELD) points when discovered. ABG, Arterial blood gas; HPS, hepatopulmonary syndrome; MAA, technetium-99 (^{99}Tc) macroaggregated albumin; PFTs, pulmonary function tests.

Nervous System in Liver Disease

Hepatic Encephalopathy

The cause of hepatic encephalopathy is generally believed to be multifactorial. Elevated ammonia levels are frequently, but not always, found in patients with hepatic encephalopathy, and ammonemia is traditionally believed to play a role in its development. Activation of γ-aminobutyric acid (GABA) receptors in the brain also may contribute to hepatic encephalopathy, as evidenced by the ability of the $GABA_A$ receptor antagonist flumazenil to produce a short-term improvement in hepatic encephalopathy.[67,68] Interestingly, ammonia has been shown to enhance GABA-ergic currents, perhaps explaining its role in hepatic encephalopathy.[69] Hepatic encephalopathy resembles many other nonfocal neurologic conditions (Box 56–6) from which it must be differentiated. Many of these are comorbid conditions in patients with liver failure. The severity of encephalopathy contributes to the Child-Turcotte-Pugh system for stratifying severity of hepatic disease (see Chap. 14).

Autonomic Neuropathy

Autonomic neuropathies are found in up to 50% of patients with chronic liver disease.[70,71] They most commonly manifest as impaired cardiovascular function[71] and gastric motility.[72] Patients with autonomic neuropathies experience a higher incidence of hypotension during general anesthesia.[73]

BOX 56–6.

Conditions Resembling Hepatic Encephalopathy

- Metabolic disorders
  - Hypoglycemia
  - Hyponatremia
  - Hypernatremia
- Intracranial processes
  - Subdural hematoma
  - Intracranial hemorrhage
  - Intracranial mass lesion
- Infectious diseases
  - Meningitis

More importantly, autonomic neuropathy predicts increased mortality in cirrhotic patients relative to cirrhotic controls without autonomic neuropathy.[74] The development of autonomic neuropathies is not dependent on the etiology of the liver disease, and studies have not consistently found a correlation between the severity of liver disease and the incidence of autonomic neuropathies. Importantly, autonomic neuropathies resolve with the return of normal liver function after transplantation.[71,75]

HEPATIC RESECTION

Indications and Patient Characteristics

Hepatic resection is performed to remove lesions in the liver by resecting either an entire hepatic lobe, one or more anatomic segments of the liver, or nonanatomic wedges of liver tissue. Such operations were first reported in the 1950s and for the next 30 years were considered to be high risk. For example, the rate of mortality from hepatic resection reported in 1977 was 13–20%, depending on the extent of the resection.[76] Many of these deaths were due to hemorrhage. However, during the 1990s, improved surgical and anesthesia techniques, along with a growing operative experience and an increased ability to plan resections, have reduced perioperative mortality. The current perioperative mortality for hepatic resections performed in high-volume centers is estimated to be 1–7%.[77–81] In addition, multiple trends in morbidity and mortality are developing. In one center, the number of hepatic segments resected declined during the 1990s, and a concomitant decline in mortality was demonstrated.[77] At the same time, high-volume centers performing hepatic resections are liberalizing their acceptance criteria for patients, operating on older patients with more comorbid illnesses, including liver dysfunction, all while sustaining reductions in morbidity and mortality.[81] Advanced age (>70 years) is no longer a contraindication to hepatic resection for primary hepatocellular carcinoma or for metastases from other cancers.[82–84] Even patients with significant cirrhosis and liver dysfunction tolerate hepatic resections, in part because operative approaches now allow shorter hepatic ischemic time and removal of less liver tissue, all while achieving satisfactory surgical margins.[85] Even in patients with cirrhosis, morbidity from hepatic resections ranges from 20–50% (comparable with the rate reported in noncirrhotic cohorts), and mortality ranges from 0–10%.[85]

Long-term outcomes after hepatic resection are reasonable. After resection of hepatocellular carcinoma, the 3-year survival rate ranges from 40–70%, whereas the 5-year survival rate ranges from 40–50%.[85] Even hepatic resections for metastatic cancer (e.g., colon) have 1-, 3-, and 5-year survival rates of 90%, 54%, and 34%, respectively.[86]

Most patients present for hepatic resection because of malignancy (Box 56–7). In the United States, approximately 90% of patients in one large series had a malignancy; 69% of these lesions were metastatic, and 80% were colorectal in origin, making metastatic colon cancer the leading cause for hepatic resection.[77] In Asia, the ratio of malignant to benign indications for hepatic resection is similar, but three fourths of the malignancies are hepatocellular carcinoma,[81] reflecting the regional heterogeneity of the distribution of this cancer. Together, these two studies report on more than 3000 patients undergoing hepatic resection between approximately 1990 and 2000.[77,81] With such large numbers, the authors were able to conduct multivariate analyses to detect factors associated with increased risk of morbidity and mortality in the perioperative period after hepatic resection. Multivariate analysis yielded the following factors associated with elevated morbidity: blood loss, number of hepatic segments resected, added major biliary procedure, low preoperative albumin, presence of one or more comorbid conditions, male gender, elevated serum creatinine level, added major vascular procedure, and thrombocytopenia.[77,81] Risk factors for elevated mortality include blood loss, number of segments resected, preoperative bilirubin, complex hepatic resection, preoperative platelet count, low preoperative albumin, and patient age.[77,81]

BOX 56–7.

Potentially Resectable Hepatic Lesions

- Benign lesions
  - Hemangioma
  - Focal nodular hyperplasia
  - Liver cell adenoma
  - Cysts
  - Hydatid disease
- Malignant lesions
  - Primary hepatobiliary cancers
    - Hepatocellular
    - Cholangiocarcinoma
    - Hepatoblastoma
    - Angiosarcoma
    - Lymphoma
  - Cancers with local invasion of liver
    - Gallbladder and extrahepatic bile ducts
    - Colon
    - Stomach
    - Duodenum
    - Adrenal
  - Metastatic cancers
    - From possibly "isolated hepatic" spread
      - Colorectal
      - Rectum
      - Pancreatic islet cell
      - Carcinoid
      - Sarcoma
    - From possibly widespread metastases
      - Lung
      - Breast
      - Esophagus
      - Stomach
      - Pancreas
      - Other GI tract
      - Melanoma

Currently, the majority of hepatic resections are performed for cancer. However, the major modes of therapy are in flux. State-of-the-art therapy for hepatocellular carcinoma includes radiofrequency ablation, hepatic resection, and orthotopic liver transplantation, depending on the number, size, and location of the lesions. Thus, minimally invasive destructive therapies may significantly reduce the need for major hepatectomy in the future.[85]

Operative Considerations for Hepatic Resection

After the incision for hepatic resection is made, the abdomen is explored for metastases. If previously unsuspected widely metastatic disease is found, the operation ends quickly. Therefore, large doses of long-acting opioids and paralyzing agents should be avoided in the initial stage of surgery. If a large volume of ascites is drained immediately after the incision, hemodynamic instability may ensue because of sudden shifts of fluid out of the intravascular system.

After the initial exploration, a self-retaining retractor (Bookwalter or equivalent) is placed to assure good exposure. The placement of the retractor itself can depress splanchnic venous return and compromise respiratory mechanics by compressing the lung and overlying ribs.

The liver is dissected free of its attachments as needed to gain exposure, first to establish control of the vasculature and then to complete the hepatic resection. This involves moving the liver to gain exposure to the vascular structures underneath, which may twist the liver on its vascular pedicle or compress the vena cava, both leading to sudden changes in venous return with consequent hemodynamic effects. After gaining vascular control, the surgeon usually attempts to create anatomic planes (i.e., those that will bleed relatively little) between liver segments, or a dissection for a formal hepatic lobectomy is performed.

An understanding of the techniques for hepatic vascular occlusion during hepatic resection is important because uncontrolled and massive blood loss is a major risk of the operation. Multiple hepatic vascular occlusion techniques are available, each with its own implications for the anesthesiologist (Figs. 56–4 through 56–6).[87] In one common vascular exclusion maneuver, a clamp is placed on the portal triad. In this case, "portal triad" encompasses the hepatic artery, portal vein, and common bile duct Fig. 56–4).

Total vascular exclusion techniques allow for "bloodless" surgery. In addition to clamping the portal triad, clamps are placed on the inferior vena cava above and below the liver (Fig. 56–5). This combination of clamps prevents both inflow of blood and backflow from the vena cava. In one report using total vascular exclusion, the average red cell transfusion was 2.2 units.[88] Selective techniques have been described for total vascular exclusion in which the hepatic veins, rather than the inferior vena cava, are clamped.[89] Portal triad clamping is accompanied by venous outflow clamping of either all of the hepatic veins or only those draining the resected territory (Fig. 56–6). In the report of the technique, most patients received no transfusion.[89] Vascular exclusion techniques were first described by Pringle and are collectively described as the "Pringle maneuver." During vascular exclusion, the liver is warm and ischemic, so great attention is paid to keeping track of and minimizing "Pringle time."

At the conclusion of the resection, hemostasis is obtained, and the incision is closed. These portions of the procedure can be lengthy and deserve attention, because control of hemorrhage is the key to a successful early postoperative period. During the latter phases of the operation, the anesthesia team should make plans for postoperative disposition, either to the recovery room or to an intensive care unit (ICU) if the insult from surgery has been severe.

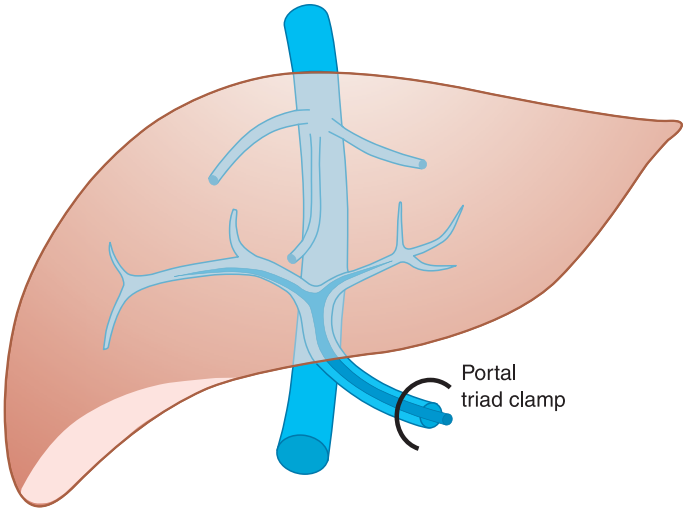

FIGURE 56–4. Location of vascular clamp for the classic "Pringle" maneuver, in which portal vein (*purple*) and hepatic artery (*red*) inflows to the liver are temporarily occluded to reduce blood loss during hepatic resections. The liver still is exposed to the vascular system by the hepatic veins (*blue*) draining into the inferior vena cava. Thus, bleeding is strongly influenced by central venous pressure.

Anesthesia for Hepatic Resection

Anesthesia for hepatic resection has been reviewed,[90,91] and the anesthetic approaches are appropriately changing over time to correspond to the

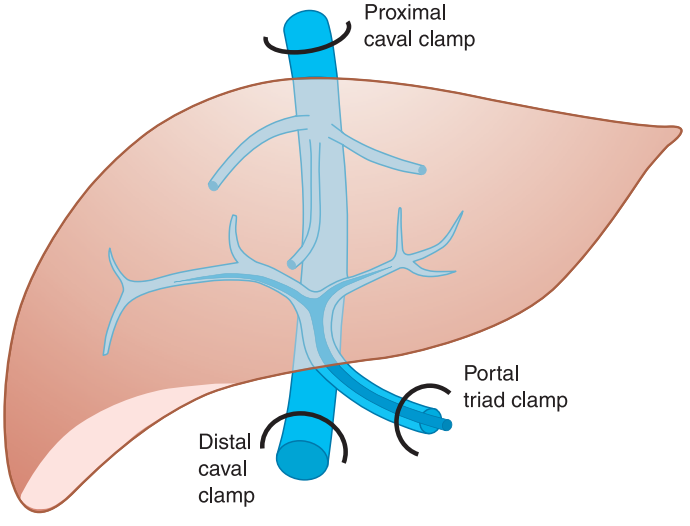

FIGURE 56–5. Total vascular exclusion of the liver. Portal vein (*purple*) and hepatic artery (*red*) inflows to the liver are temporarily occluded. Additionally, the inferior vena cava (*blue*) is cross-clamped above and below the hepatic veins to exclude the liver from central venous circulation.

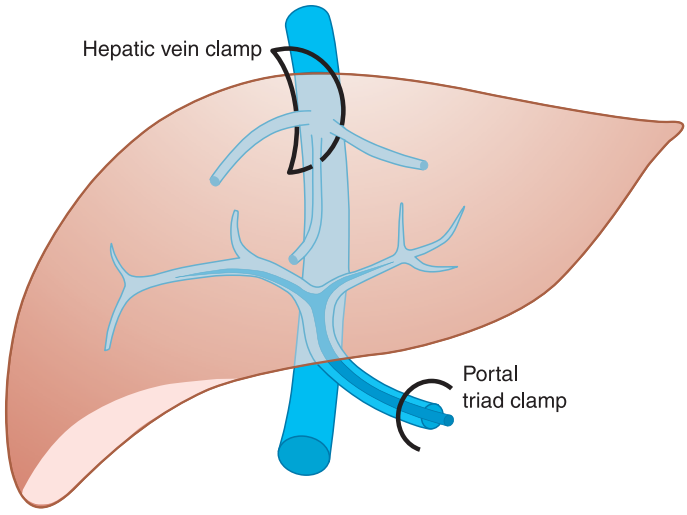

FIGURE 56–6. Total vascular exclusion of the liver with preservation of vena cava flow. Portal vein (*purple*) and hepatic artery (*red*) inflows to the liver are temporarily occluded. Additionally, the hepatic veins (*blue*) are clamped to exclude the liver from central venous circulation. Hepatic venous clamping can involve the entire liver or only the territory to be resected.

improvements in surgical technique and changes in patient selection. In general, patients scheduled for hepatic resection should be evaluated as any patient scheduled for major noncardiac surgery. Plans for monitoring, vascular access, induction and maintenance of anesthesia, postoperative pain control, and postoperative care should take into account a large subcostal incision and the potential for sudden massive hemorrhage and severe physiologic derangements during and after surgery.

The history and physical examination include a typical preanesthetic history, including questions directed to assess hepatic synthetic function, as well as global and focal neurologic status. For example, evidence of hepatic encephalopathy should be sought, both from the patient and from any persons accompanying the patient. Significant encephalopathy predicts worsened postoperative neurologic status if hepatic resection or portal diversion is planned. Focal neurologic deficits (i.e., sensory, motor, or pain abnormalities localized to a body part) should be sought and documented because the procedures require prolonged immobility, and positioning injuries may occur.

The assessment of cardiac ischemia risk cannot be overemphasized. Hepatic resections are frequently characterized by significant hemorrhage, leading to hypotension and tachycardia that may persist for some time as the anesthesia team restores intravascular volume. In addition to derangements in myocardial oxygen supply and demand during the case, the surgical stress induces a proinflammatory state. Major liver resection also leads to a hyperdynamic state with increased cardiac output and decreased systemic vascular resistance in the postoperative period.[92,93] Thus, the patient should be questioned in detail about risk factors pertaining to coronary artery disease as well as his or her level of physical activity and exercise tolerance. Symptoms of angina or anginal equivalents should be carefully sought.

The laboratory examination prior to hepatic resection includes an assessment of hepatic synthetic function [albumin, clotting factors as assessed by prothrombin time (PT), partial thromboplastin time (PTT), and fibrinogen measurement], metabolic function [aspartate aminotransferase (AST), alanine aminotransferase (ALT)], and excretory function (bilirubin). Assessment of coagulation function (PT, PTT, platelet count), oxygen-carrying capacity (hematocrit), and serum electrolytes completes the general picture of the patient. A chest x-ray film is useful for assessing lung volumes and the status of the lung parenchyma and in searching for preoperative pleural effusions (common in patients with significant liver disease but rare in others).

Preoperatively, a transthoracic echocardiogram may be useful for assessing resting atrial and ventricular function and valve performance and excluding (within the power of this relatively noninvasive test) septal defects that might allow paradoxical embolization. As mentioned, cardiac risk stratification begins with careful history taking but should include functional testing as indicated by the history and the guidelines of the American Heart Association.[94]

Preanesthetic Planning

Hepatic resections are almost always performed with the patient in the supine position through a right-sided subcostal incision. There may be extensions into the left subcostal region, superiorly in the midline, or both. The area of surgical preparation usually includes the entire abdomen and the lower chest up to the nipples. Monitor placement, warming strategies, and pain management planning should account for this area.

Typical monitoring consists of standard monitors and selected invasive monitors directed toward managing problems likely to arise during the case. An arterial catheter is useful for early recognition of hypotension and for obtaining blood samples. Central venous pressure measurement is useful to guide intravascular volume replacement and to assess right-heart pressures when a large hepatic resection is planned or when the dissection is expected to be bloody. Central venous access has the added benefit of providing a conduit for potent vasopressor administration. A pulmonary artery catheter is useful for measuring pulmonary arterial pressures, assessing left heart filling pressures, and guiding pharmacologic therapy. Transesophageal echocardiography can provide information regarding both intravascular volume status and cardiac performance and may replace invasive pressure measurements if the potential need for central venous access as a conduit for vasopressors is judged to be low.

Peripheral vascular access with sufficiently large catheters (14 gauge or larger) usually is sufficient for a hepatic resection. One helpful device is the rapid infusion catheter (RIC, Arrow International, Reading, PA, USA). The RIC is a 6.4 cm × 8.5 F peripherally inserted catheter useful for rapid infusion of large volumes. It can be placed in any large peripheral vein. Antecubital or cephalic veins are commonly chosen, but even distal veins on the forearm and hand can be used if they are large enough. The RIC alleviates the need for multiple central lines that

might be required to pass a pulmonary artery catheter, run multiple infusions, and accommodate high-flow administration of large volumes.

Induction and Maintenance of Anesthesia

Induction of anesthesia is readily accomplished using standard methods. Major considerations for induction are directed toward comorbidities (gastroesophageal reflux disease, coronary artery disease) rather than any unique feature of the liver disease. Patients with ascites should be considered to have a full stomach and receive a rapid sequence induction with cricoid pressure, if not otherwise contraindicated.

Maintenance of anesthesia is accomplished by standard methods, with attention to homeostatic control. Patient warming is important to maintain good clotting performance and minimize the risk of surgical site infection.[95,96] A single forced-air warming unit applied to the upper chest, arms, and head usually is sufficient. IV fluids should be either warm or actively warmed during infusion.

Because large hepatic resections may produce transient hepatic dysfunction, choosing drugs whose elimination is not completely dependent on hepatic metabolism may be preferable. In general, all the usual techniques for maintenance of general anesthesia are acceptable, although there are some minor differences between drugs commonly chosen for maintenance. Compared with isoflurane, sevoflurane was associated with smaller elevations in liver enzymes after hepatic segmentectomy.[97] These elevations were of uncertain clinical relevance, because no clinical liver damage was detected in either group. Cisatracurium, atracurium, and remifentanil might be more reliably eliminated than drugs that depend on hepatic hydrolysis and/or conjugation for termination of their effect. In practice, the dose-to-effect mode of administration almost always is sufficient to minimize the interaction between choice of anesthetic and the effect of liver resection.

If an epidural catheter has been inserted, it can be used intraoperatively with the understanding that the associated sympathetic blockade may cause hypotension. The severity of hypotension correlates with the concentration and volume of local anesthetic administered. Conversely, relatively dilute local anesthetic (e.g., 0.25% bupivacaine, 7–10 mL/h after a bolus) or dilute mixtures of local anesthetic combined with an opioid likely will provide significant analgesia during general anesthesia, with little hemodynamic effect. Hypotension resulting from local anesthetic-induced sympathetic blockade can be effectively treated with infusion of a vasopressor such as phenylephrine or norepinephrine.

Goals for Oxygenation and Ventilation

Changes in the fraction of inspired oxygen (FiO_2) and ventilation predictably result in changes in liver oxygenation and carbon dioxide (CO_2) elimination.[98] Vascular exclusion techniques to reduce bleeding create periods of hepatic ischemia. Thus, it seems prudent to provide normal systemic conditions by ventilating to keep the pH normal and the oxygen saturation high so that the liver is best prepared to tolerate these insults.

Hemodynamics

Clamping the portal triad reduces venous return, and cardiac output and blood pressure would be expected to fall. Cardiac output does indeed fall, but blood pressure increases because of an increase in systemic vascular resistance evoked by portal triad clamping. The increase in blood pressure appears to be a neurally mediated reflex, as the increase in systemic vascular resistance can be ablated by infiltrating the portal triad with lidocaine prior to clamping.[99] In contrast to portal triad clamping, total vascular exclusion of the liver via a vena cava cross-clamp does reduce blood pressure concomitant with a fall in cardiac output because the loss of venous return is so much larger.

Bleeding and Coagulation

Blood loss is affected by central venous pressure during surgery. When central venous pressure is maintained at <5 mm Hg, blood loss is predictably lower than when central venous pressure is ≥ 6 mm Hg. In the original publication describing low central venous pressure approaches to hepatic resection, median blood loss was only 200 mL, with most patients in the low central venous pressure study group not requiring transfusion.[100] In contrast, when central venous pressure was ≥ 6 mm Hg, median blood loss was 1 L, and half of the patients required transfusion.[100] Other centers practicing low central venous pressure techniques for hepatic resection report average estimated blood losses of approximately 1 L.[80]

Low central venous pressure approaches affect outcomes beyond transfusion and blood loss, as reflected in longer hospital stays for patients whose central venous pressure was >6 mm HG during hepatic resection.[101] Blood loss (and the subsequent requirement for transfusion) is associated with longer hospitalization, greater perioperative morbidity, and doubling of perioperative mortality (from 1.2% to 2.5%).[86] Reports in the surgical literature caution that extreme care must be taken during dissection of the liver so as not to make holes in the hepatic veins, which can lead to catastrophic hemorrhage or air embolism.[102] Obviously the risk of severe air embolism is elevated under low central venous pressure conditions, and the anesthesia team must be highly vigilant for such an event.

Low central venous pressure anesthesia apparently is safe with respect to renal function. Only 3% of patients experience any degree of permanent renal dysfunction after hepatic resection using a low central venous pressure technique.[80] This was lower than the historical incidence of renal failure complicating hepatic resection without the use of low central venous pressure.[80] However, these favorable outcomes are predicated on maintaining good renal perfusion pressure (typically believed to be $\geq$ 60 mm Hg) and renal blood flow throughout surgery.[91]

Control of Clotting

Multiple drugs that modify clotting are available to minimize blood loss during hepatic resection. Pharmacologic aids for minimizing blood loss are attractive given the concerns regarding transfusion in cancer surgery, but they are no substitute for good surgical technique. A complete discussion of the use of procoagulants during liver surgery appears in the Liver Transplantation section (see below). Briefly, three classes of agents are available: those that modify platelet and von Willebrand factor function (desmopressin and its analogues), the antifibrinolytics (aprotinin, ε-aminocaproic acid, and tranexamic acid), and replacements of specific clotting factors (e.g., recombinant factor VII).

Desmopressin increases factor levels and improves laboratory measures of clotting during hepatectomy but has no effect on blood loss.[103] The antifibrinolytic drug aprotinin reduces blood loss during elective liver resection,[104] as demonstrated in a small prospective trial. However, a large multicenter outcome study comparing aprotinin with the other antifibrinolytics and placebo in cardiac surgery demonstrated that the drug is not superior to ε-aminocaproic acid or tranexamic acid for reducing blood loss.[105] However, aprotinin is associated with excess renal failure and mortality compared with the other alternatives in cardiac surgery.[105] Therefore, routine use of aprotinin during hepatic resection must be questioned until studies demonstrating its safety in large numbers of hepatectomy patients are reported. Recombinant factor VII does not reduce blood loss or transfusion requirements in patients undergoing major hepatic resections,[106] but off-label use of this drug has been associated with unwanted thrombotic complications.[107]

Postoperative Planning

Postoperative planning after hepatectomy addresses three major concerns: immediate postsurgical airway management, postoperative disposition, and pain management.

Assessment of the airway after surgery and planning for extubation are guided by the same considerations as applied to any major case with the potential for large volume shifts and with a high abdominal incision. First, the magnitude of the operation and the patient's preoperative functional status are inventoried, followed by the magnitude of hemorrhage and the adequacy of its replacement, manifested by hemodynamic stability and acid–base status. Factors within the anesthesiologist's control (e.g., patient temperature, sedation, residual general anesthetics, and muscle strength) are considered. A physical examination of the face and upper airway assesses the degree of edema and swelling that might compromise the extubated airway. If all of these considerations are judged to be in satisfactory order, then it is reasonable to extubate the trachea at the end of a hepatic resection; otherwise the prudent course is a period of postoperative airway protection and support with mechanical ventilation.

Postoperative disposition is dictated by the patient's clinical condition. The same considerations that bore upon the decision to extubate the trachea apply to planning for disposition. A patient who has undergone an uncomplicated operation and uneventful extubation can be managed in the recovery room and discharged to the hospital floor. Intubated patients and those with important postoperative concerns should be managed in an ICU.

Analgesic requirements for patients after hepatic resection deserve careful consideration. Subcostal incisions typically are quite painful, and ineffective pain therapy will degrade the patient's ability to comply with postoperative pulmonary recruitment maneuvers and early ambulation. Regional anesthesia (e.g., epidural catheter) added to general anesthesia provides superior early postoperative pain control.[108] This must be balanced against the potential for postoperative hepatic synthetic failure and coagulopathy complicating subsequent removal of the epidural catheter. However, many practitioners opt to place the epidural catheter and monitor patients carefully for signs and symptoms of epidural hematoma.

Complications during Hepatic Resection

Intraoperative complications of hepatic resection almost always can be ultimately traced to excessive blood loss. Bleeding can result from either poor hemostatic control or coagulopathy. Coagulopathy rarely ensues during hepatic resection unless the patient had tenuous liver function at the start, the hemorrhage is severe, or patient warming was inadequate. Reversible causes of coagulopathy should be sought and corrected and the circulating blood volume supported by infusions of crystalloids, colloids, and transfusion as appropriate.

Air embolism is another common complication. Air embolism during hepatic resection (as well as transplantation) is problematic because it alters pulmonary vascular resistance, right-heart performance, and left-heart filling. The pathophysiology of venous air embolism has been studied in dogs.[109] Slow entrainment of air (rate 0.01–2.0 mL/kg/min), as might occur during surgery with small sites of venous opening, causes a progressive rise in central venous pressure, an early abrupt rise in pulmonary arterial pressure to a hypertensive plateau, and an unexplained decline in systemic vascular resistance. Air irritates the vascular endothelium, with resulting pulmonary edema, hypoxia, and reduced pulmonary compliance. Bolus infusion of air (1–13 mL/kg in a sudden bolus), as might occur with a major tear in the vena cava, causes increased central venous pressure. Because air fills the right ventricle, pulmonary and systemic pressures plummet, and cardiovascular collapse ensues.[109]

Air embolism apparently is a complication of many hepatic resections, although it is not always symptomatic. Some procedural approaches that may be advantageous from a surgical perspective may not be ideal from the anesthetist's viewpoint. For example, when comparing techniques for parenchymal dissection of the liver, the Cavitron ultrasonic aspirator (CUSA) is associated with less blood loss[110] than is a clamp-and-crush method. However, all CUSA patients had air emboli during hepatectomy, and in 44% of these patients the air filled more than half of the right ventricle. Air emboli occurred in 68% of patients undergoing clamp-and-crush hepatic resection as well, but to a much smaller extent. None of these emboli had pulmonary or hemodynamic effects on the patients, but this study suggests that air embolism is so common as to be considered ubiquitous during hepatic resection. Gas embolism from other commonly used devices (e.g., argon beam coagulators) has been described, in this instance with a fatal outcome.[111]

Air embolism is problematic during liver surgery and transplantation because of the risk of catastrophic paradoxical embolism.[112] Paradoxical embolism need not occur through an intracardiac right-to-left defect. Many patients presenting for hepatic resection (and certainly most liver transplant patients) have cirrhosis, and many cirrhotic patients have abnormal arteriovenous connections in the pulmonary circulation. Thus, venous air embolism should be minimized to lower the risk of paradoxical embolus. Massive venous embolism and/or paradoxical embolus must be high on the differential diagnosis of unexplained cardiopulmonary performance problems during hepatic resection. Fig. 56–7 shows the hemodynamic consequences of a large venous air embolism during a liver transplant. The

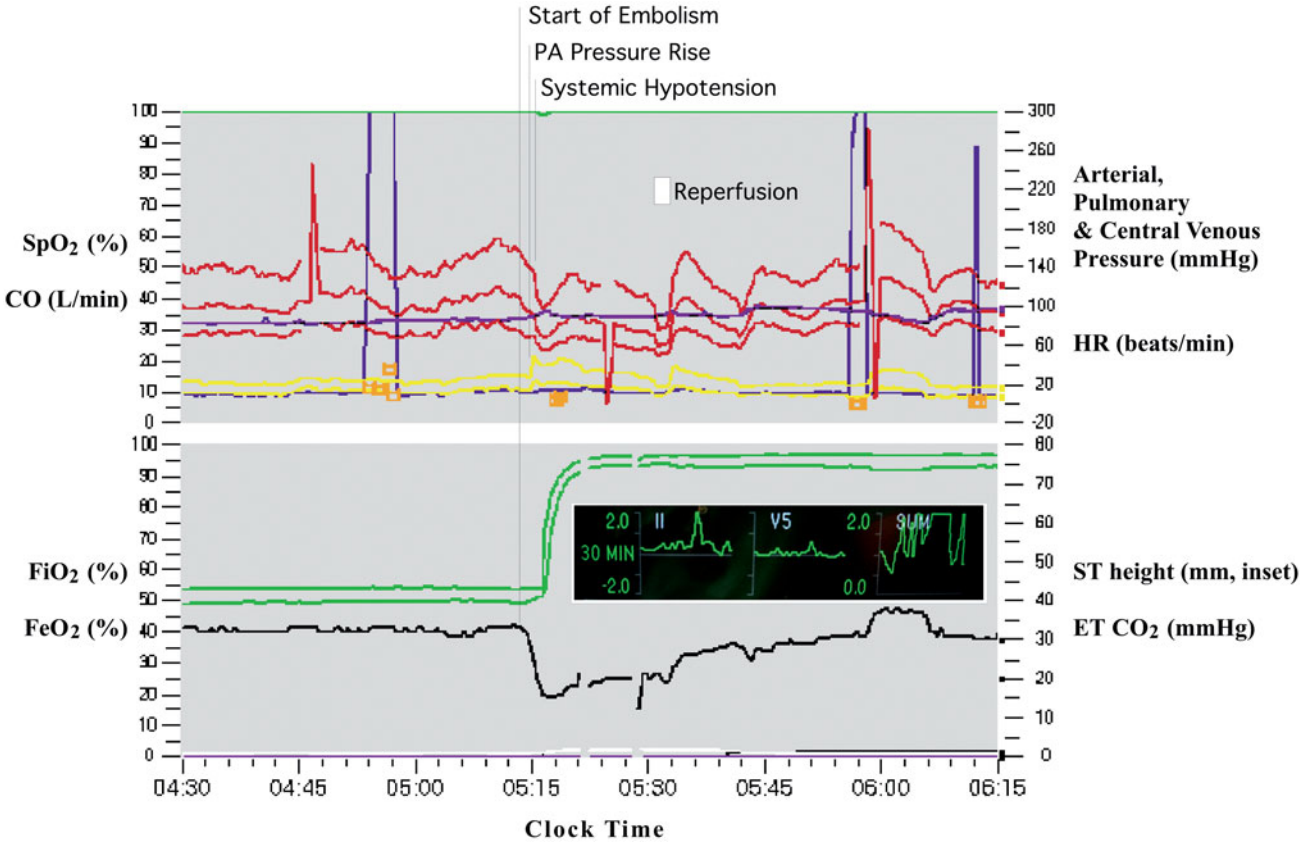

FIGURE 56–7. Screen shot of automated anesthesia information management system trend display marked by accidental venous air embolism. Inset (*black*) shows a trend display of the electrocardiographic ST segments, demonstrating inferior and lateral ST elevations.

first indication is an abrupt fall in end-tidal CO_2 (black trace), followed a few moments later by rising pulmonary arterial pressure (yellow trace). Systemic hypotension ensued (red trace). Inferior and lateral (see inset) ST-segment elevations accompanied systemic hypotension, caused by either coronary hypoperfusion or air in the coronary circulation. The circuit gas composition (green trace) was changed to 100% oxygen to minimize the size of gas bubbles. Cardiac output (orange rectangles) fell by 50% after the embolus.

Some practitioners recommend conducting hepatic surgery with the operating room table in a 15° head-down tilt to prevent embolized air from migrating cephalad,[113] but this may interfere with surgical exposure and may contribute to head and neck edema. If air embolism occurs, ventilation with 100% oxygen should be instituted. In severe embolism, placing the patient in the left lateral decubitus position with the head down may shift the gas bubble away from the right ventricular outflow tract and restore cardiac output. A central line placed into the right atrium can be used to aspirate gas from the heart. These measures must be undertaken while other supportive measures, including cardiopulmonary resuscitation and fluid/pressor administration, are continued. Cardiopulmonary bypass has been used successfully for resuscitation from gas embolism and should be considered if initial measures are unsuccessful.[114]

LIVER TRANSPLANTATION

Indications, Contraindications, and Patient Characteristics

The indications for liver transplantation are myriad in detail (Box 56–8), but all come down to liver failure sufficiently severe to preclude further survival without transplantation.

The most common indication for liver transplantation is chronic hepatocellular disease because of alcohol and/or hepatitis. Hepatitis C is an increasingly important indication for liver transplantation, representing a unique and growing health risk for anesthesiologists who provide care for these patients. Currently no vaccine against hepatitis C is available, and medical therapy is suboptimal. Thus, the most effective protection from the disease is avoiding exposure.

Hepatitis B and C both predispose patients to hepatocellular carcinoma. As the prevalence of hepatitis C in the population increases, so does the incidence of hepatocellular carcinoma. Thus, this tumor is becoming increasingly common as an indication for liver transplantation.

As surgical techniques, risk stratification of potential recipients, and management of intercurrent diseases (e.g., HIV infection) all improve, the contraindications to liver transplantation are becoming more nuanced. For example, advanced age is not necessarily considered a contraindication to transplantation. Instead, elderly patients are assessed using sophisticated testing of cardiopulmonary performance and rigorous assessment of nutritional status, body mass index (BMI), and exercise tolerance. Box 56–9 provides a general list of contraindications to liver transplantation, but each patient must be evaluated as an individual, with consideration of many extenuating and complicating factors.

BOX 56–8.

Indications for Liver Transplantation (Not Exhaustive)

- End-stage liver disease (chronic)
  - Hepatocellular disease
    - Chronic viral hepatitis (mostly hepatitis C)
    - Alcoholic liver disease
    - "Cryptogenic" cirrhosis
    - Chronic drug-induced liver disease
  - Cholestatic disease
    - Primary sclerosing cholangitis
    - Primary biliary cirrhosis
    - Biliary atresia (mostly children)
    - Other familial cholestatic syndromes
  - Vascular disease
    - Budd-Chiari syndrome
    - Venoocclusive disease
  - Polycystic liver disease
- Hepatic malignancies not amenable to other therapy
  - Hepatocellular carcinoma (often in setting of hepatitis C)
  - Cholangiocarcinoma
  - Carcinoid tumor
  - Other cancers (e.g., insulinoma)
- Fulminant hepatic failure
  - Drug induced
  - Acute viral hepatitis (A, B, C, D)
  - Metabolic diseases
    - Wilson disease, organic aciduria, other
- Metabolic diseases affecting the liver
  - α_1-Antitrypsin deficiency
  - Wilson disease
  - Hemochromatosis
  - Other rare diseases (e.g., Alagille syndrome, glycogen storage diseases, urea cycle deficiencies)

Patients with fulminant hepatic failure require particular attention because their status with respect to contraindications to transplantation may change on a daily or even hourly basis. As mentioned, acute infection is common in patients with fulminant hepatic failure but should be actively sought (or at least a high index of suspicion of considered) in any candidate who is high on the recipient list because acute infection is a clear contraindication to transplantation. Brain herniation (portending brain death) is another clear contraindication to transplantation. In critically ill, comatose transplant candidates, herniation is always a possibility, yet transplantation may avert this disastrous outcome. Incipient brain herniation is commonly assessed by serial head CT or, ideally, by ICP monitoring so that donor organs are not mistakenly allocated to patients who can no longer benefit from them. However, many neurosurgeons are reluctant to place ICP monitors because of the risk for hemorrhage (see above).

Patient Selection for Liver Transplantation

Liver transplantation is an arduous process before, during, and after the operation. Part of the evaluation aims to identify individuals who can comply with lifestyle requirements needed to maintain the health of the grafted organ. Recipients must be able to sustain lifelong abstinence from alcohol, illicit drugs, and diverted prescription narcotics. Lifelong immunosuppression is another requirement, and patients must have the means to obtain these necessary drugs and the personal organization and/or social supports to follow the complex medication regimen.

Evaluation seeks to identify individuals with sufficient psychological resilience, insight, and social supports who will be able to benefit over the long term from a resource as scarce as a donor liver. Thus, liver transplant listing committees are composed not only of surgeons and hepatologists, and, ideally, anesthesiologists, but also psychiatrists, addictions specialists, social services specialists, family therapists, and financial assistance experts.

Potential liver transplant recipients must be willing to accept massive blood transfusion during and after surgery. This requirement, formerly absolute, is being relaxed as some centers gain sufficient expertise to reliably perform liver transplantation with little or no requirement for transfused blood. For example, Jehovah's Witnesses formerly were excluded from orthotopic liver transplantation candidacy unless they were willing to accept blood product transfusion. However, case reports of successful transplants[115] have appeared, and some centers are willing to offer transplantation to Jehovah's Witnesses who refuse transfusion. Of note, Jehovah's Witnesses are allowed some latitude regarding their choice to receive or refuse transfusion, although the ultimate choices are personal ones made by the patient.

Potential recipients must be in the best possible physical condition within the context of hepatic failure and end-stage liver disease. For example, many programs require obese potential candidates to lose weight because obesity (BMI > 30) is associated with excess mortality in the perioperative period.[116] BMI > 30 is considered a relative contraindication to transplantation.

BOX 56–9.

Contraindications to Liver Transplantation

- Absolute Contraindications
  - Brain herniation/brain death
  - Sepsis outside the hepatobiliary tree (peritonitis)
  - Metastatic hepatobiliary tumors
  - Current extrahepatic malignancy
  - Advanced cardiopulmonary disease
    - Unrevascularized ischemic coronary disease
    - Recent drug-eluting stent placement
    - Critical aortic stenosis
    - Severe pulmonary hypertension (mean pulmonary arterial pressure >45 mm Hg)
  - AIDS (but not HIV infection)
- Relative Contraindications
  - Obesity (body mass index >30)
  - Moderate pulmonary hypertension (mean pulmonary arterial pressure >35 mm Hg)
  - Mild or moderate aortic stenosis
  - Revascularized coronary artery disease with depressed cardiac function
  - Advanced chronic renal failure
  - Severe hyponatremia
  - Portal vein thrombosis
  - Hepatitis (hepatitis B surface antigen or hepatitis Be surface antigen positive)
  - Prior open vascular portosystemic shunt
  - Prior complex hepatobiliary surgery
  - Hypoxemia with intrapulmonary shunts
  - Hepatic coma with intracranial hypertension
  - Active alcohol abuse
  - Active drug abuse
  - Cholangiocarcinoma or other aggressive tumor
  - Advanced age (no consensus on definition of "advanced age")
  - Poor social supports to assist with posttransplant medical compliance
  - Advanced malnutrition

TABLE 56–1.

Model for End-Stage Liver Disease (MELD) Scoring System

Prognostic Factor[a]	Regression Coefficient
Serum creatinine[b] ($\log_e$ value)	0.957
Serum bilirubin ($\log_e$ value)	0.378
INR ($\log_e$ value)	1.120

[a]Laboratory values < 1.0 are set to 1.0 for MELD score calculation.
[b]Maximum serum creatinine considered in the MELD score equation is 4.0 mg/dL (i.e., for patients with serum creatinine > 4.0 mg/dL, the serum creatinine level is set to 4.0 mg/dL). Patients on dialysis have their serum creatinine level automatically set to 4.0 mg/dL.
INR, International normalized ratio.

MELD Scoring System

The United Network for Organ Sharing (UNOS; *www.unos.org*) administers the allocation of donated organs in the United States. Liver transplant recipient candidates are priority ranked by application of the Model of End-Stage Liver Disease (MELD) scoring system. The MELD system ranks patients by expected mortality based on the severity of their liver disease. An analogous system for pediatric patients, the Pediatric End-Stage Liver Disease (PELD) scoring system, is applied for patients younger than 12 years. Thus, the MELD and PELD scores provide a method for ranking patients in descending order of disease severity (as reported by the likelihood of death from untreated disease), with higher scores indicating more severe disease burden.

The MELD scoring system uses a multivariate regression model to calculate risk of death from the patient's liver disease based on prognostic factors (laboratory values reflecting hepatic synthetic and excretory function) and regression coefficients (Table 56–1). Patients are assigned a MELD score based on the following calculation:

$$\text{MELD Score} = (0.957 \times \log_e[\text{creatinine mg/dL}] + 0.378 \times \log_e[\text{bilirubin mg/dL}] + 1.120 \times \log_e[\text{INR}] + 0.643) * 10, \quad (1)$$

where INR = international normalized ratio.

Scores are rounded to the nearest whole number. Thus, the risk score of a hypothetical patient with cirrhosis who has serum creatinine concentration = 1.9 mg/dL, serum bilirubin concentration = 4.2 mg/dL, and INR = 1.2 would be calculated as follows:

$$\text{MELD Score} = ([0.957 \times \log_e 1.9] + [0.378 \times \log_e 4.2] + [1.120 \times \log_e 1.2] + 0.643) * 10 \approx 20 \quad (2)$$

Recognizing that the MELD score does not fully encompass the unique characteristics of patients requiring liver transplantation, UNOS defines several exceptions and modifications to the MELD system. For example, patients with hepatocellular carcinoma are given additional MELD points, improving their likelihood of receiving a transplant. Similar adjustments are made for adult patients with hepatic metabolic syndromes. Finally, patients with acute liver failure can receive a special listing status—Status 1A—that puts them at the top of the waiting list. A candidate can be listed as Status 1A if he or she has fulminant liver failure with a life expectancy without a liver transplant of < 7 days, as defined by the following four categories:

1. Fulminant hepatic failure defined as the onset of hepatic encephalopathy within 8 weeks of the first symptoms of liver disease. The absence of preexisting liver disease is critical to the diagnosis. One of the following three criteria must be met in order to list an adult patient, who must be in the ICU, with fulminant liver failure: (1) ventilator dependence, (2) requiring dialysis or continuous venovenous hemofiltration or continuous venovenous hemodialysis, or (3) INR > 2.0, or
2. Primary nonfunction of a transplanted liver within 7 days of implantation, as defined by (a) or (b):
   (a) AST ≥ 5000 and one or both of the following:
   - INR ≥ 2.5
   - Acidosis, defined as pH ≤ 7.3 and/or lactate ≥ 2× normal

   (b) Anhepatic patient, or
3. Hepatic artery thrombosis in a transplanted liver within 7 days of implantation, with evidence of graft failure as defined in (2a) and (2b), or
4. Acute decompensated Wilson disease

Status 1 patients accrue additional points for time spent waiting for an organ while in that status. Each major blood group has a separate waiting list. To ensure the fair allocation of livers, adherence to the system is mandatory throughout the United States. Similar systems are in place throughout the developed world.

When a donor organ becomes available, it is offered to transplant programs in the following order of priority:

1. The organ is offered to Status 1 patients (in descending point order) in the same local area as the procuring center.
2. The organ is offered to transplant programs with Status 1 patients (in descending point order) in the same organ-sharing region as the procuring center.
3. The organ is offered to candidates with MELD/PELD scores ≥ 15 in descending order of MELD/PELD scores, first locally and then regionally.
4. The organ is offered to patients with MELD/PELD scores < 15, locally and then regionally.

If no transplant program has accepted the organ by the end of this list, then the organ is offered at the national level, first to Status 1 patients in rank order and then down the MELD/PELD waiting list.

Preanesthetic Evaluation of the Liver Transplant Candidate

Because of the prescreening process for listing a patient for liver transplantation, most patients are "well studied," that is, they have undergone extensive prior diagnostic and risk stratification assessment. Thus, on the day of surgery, the immediate preoperative evaluation of the patient for liver transplantation focuses on the history and physical examination relevant to the case immediately at hand. Furthermore, although technically elective surgery, liver transplantation is an unscheduled, urgent case with many surgical teams, recipient patients, and hospitals throughout the region preparing for synchronous receipt of donor organs. Thus, efficient and effective immediate preoperative care of the potential liver recipient is beneficial, both to the patients and to the medical system in general.

A typical preanesthetic history is taken, with attention to a few key points. Specific questioning pertinent to liver transplantation covers a variety of topics, as follows:

- Because liver transplants are unscheduled, patients are rarely fasting. However, the quality and quantity of recent oral intake help define the risk and potential consequences of regurgitation and aspiration of gastric contents.
- Liver transplantation requires ample vascular access for resuscitation and monitoring. A history of central venous and/or arterial catheter placement will alert the anesthesia team to possible difficulty with access because of occluded vessels, although in practice, ultrasonography used in catheter placement also shows vessel patency.
- Questions should also be directed to assess hepatic synthetic function, which may have deteriorated further since the patient's last reevaluation. A history of increasing abdominal girth or peripheral edema indicates failure to synthesize sufficient albumin and other plasma proteins to maintain plasma oncotic pressure. A history of easy bruising, bleeding during oral hygiene, or prolonged bleeding from minor injuries indicates insufficient hepatic function to maintain clotting factor levels at even a fraction of normal levels.
- The history should address neurologic status, searching for evidence of worsening encephalopathy, manifesting as loss of mental acuity, forgetfulness, fatigue, and somnolence. Also important is characterizing and documenting any preoperative focal neurologic deficits to establish the patient's status prior to the case. Positioning injuries with consequent neurologic deficits are not uncommon. If a patient complains of a deficit in the postoperative period, it is useful to know whether that deficit was present prior to surgery.
- The anesthesia team should reassess cardiac risk during the history, because many orthotopic liver transplant candidates wait months or years between rescreening tests of cardiac function and ischemic risk. Determining whether decreasing exercise tolerance is attributable to cardiac dysfunction or worsening liver disease can be difficult, so symptoms or signs of angina should be sought.

The physical examination should be as complete as that conducted for any patient undergoing major intraabdominal surgery. Special attention should be paid to the assessment of ascites. Ascites potentiates the possibility of regurgitation and aspiration. It also compromises pulmonary performance and may prevent the patient from being able to breathe while supine for central venous catheter placement. Finally, ascites pushes the diaphragm upward, causing atelectasis and diminishing functional residual capacity. Thus, ascites predisposes liver transplant patients to rapid and severe desaturation during induction of anesthesia, even after assiduous denitrogenation.

Attention should be paid to sites for vascular access. Large-bore (14 gauge or 8.5 F) venous cannulas are essential for volume resuscitation during the case, and they must be located above the diaphragm because the inferior vena cava will be cross-clamped at times. A femoral arterial catheter for pressure monitoring may be useful (see below). Landmarks for internal and external jugular cannulation, as well as subclavian access, should be examined, as well as peripheral venous and arterial sites on both arms.

Diagnostic Studies in the Liver Transplant Candidate

Laboratory tests obtained in the immediate preoperative period should include measures of hepatic synthetic and excretory function. Specifically, serum albumin and bilirubin should be measured. Routine coagulation studies (prothrombin time, partial thromboplastin time, fibrinogen, and platelet count) provide a measure of how hepatic synthetic failure has affected clotting factor levels. The platelet count can be low in the case of portal hypertension, as platelets are sequestered in the enlarged spleen.

Preoperative measurement of serum electrolytes is essential to provide baseline data about possible hyponatremia, hypokalemia or hyperkalemia, hypocalcemia, and hypomagnesemia. BUN and creatinine concentrations should be measured to assess the patient's renal function, which may, in turn, presage poor platelet function if uremia is present. This assessment of renal function (and acid–base status; see below) guides the possible use of intraoperative renal replacement therapy. Although rarely required, intraoperative renal replacement therapy may be needed if significant renal failure, electrolyte abnormality, or acid–base problems are found in the immediate preoperative laboratory investigation.

Hemoglobin should be measured to establish the preoperative baseline oxygen-carrying capacity. The patient's blood type should be redetermined, and a sample sent to the blood bank for antibody screening in anticipation of allogeneic transfusion. An electrocardiogram should be obtained in the immediate preoperative period to search for new changes suggestive of coronary artery disease. Finally, a preoperative chest x-ray film is obtained as a baseline for comparison of postoperative films.

Patients presenting for liver transplantation almost always have an extensive body of laboratory and diagnostic test results available to aid in perioperative risk assessment and anesthetic planning. Patients with acute liver failure may be exceptions to this generalization, being listed for transplantation and subsequently receiving grafts within a few days of their initial presentation.[9] However, in almost all cases, the following assessments either are repeated upon admission for transplantation or have been performed within the prior year.

Laboratory assessment of pulmonary function includes arterial blood gas measurement and pulmonary function testing. Blood gas measurement identifies patients with hypoxia, suggesting hepatopulmonary syndrome. Pulmonary function testing often reveals small lung volumes reflecting the effect of ascites. A superimposed obstructive pattern on spirometry may be seen in patients with a long history of smoking. These results are important, because the liver transplant patient is mechanically ventilated for a prolonged intraoperative period and perhaps for some time in the postoperative period.

Cardiac assessment of the patient being considered for liver transplantation focuses on functional and invasive tests of cardiac performance that assess ischemic potential and the search for cardiac structural anomalies that might compromise outcome from orthotopic liver transplantation.[117]

The incidence and severity of coronary artery disease increases with age

and with well-known risk factors, many of which are commonly found in patients with liver failure, such as diabetes, smoking, and obesity. Furthermore, better surgical and anesthetic techniques are allowing older patients, that is, patients with greater age-related risk of significant coronary disease, to be considered for liver transplantation. Flow-limiting coronary artery disease is of grave concern because liver transplantation is still a highly stressful operation. The potential for sudden, massive, ongoing blood loss complicated by extreme electrolyte derangements is still present, so all potential liver transplant recipients must be evaluated as if they are required to tolerate minutes to hours of a hypothetical state with heart rate >110 beats/min, mean arterial pressure <50 mm Hg, hemoglobin 7 g/dL, and pH <7.2. Only patients with ideal cardiac status are likely to survive this scenario unscathed.

To ensure that new and previously listed transplant candidates meet these criteria, the anesthesia liver transplant team periodically reviews the preoperative evaluation of individuals high on the liver transplant list. This task involves reviewing the echocardiogram, the results of functional stress testing, and, if performed, cardiac catheterization. This is not an academic exercise, because a significant fraction of patients being evaluated for liver transplantation has coronary artery disease, and with the coronary disease in many of these patients unsuspected prior to pretransplantation evaluation. For example, in a study applying coronary angiography to all potential liver transplant recipients older than 50 years, there was a 27% incidence of moderate-to-severe coronary artery disease, with 13.3% of the cohort having clinically unsuspected moderate or severe coronary disease.[118] Another study showed a 5.6% incidence of coronary artery disease in patients older than 40 years,[119] and the consensus seems to be that approximately 2.5–10% of patients have moderate to significant coronary artery disease.[120] Untreated significant coronary disease is potentially lethal in the setting of liver transplantation.[117] In one study, half of the patients with coronary artery disease who underwent liver transplantation died in the perioperative period, and the morbidity rate was 81%.[121]

Dobutamine stress echocardiography or possibly exercise stress thallium imaging appears to be the best screening test in patients with end-stage liver disease.[120,122–124] A recent meta-analysis indicates that dobutamine stress echocardiography has a superior negative predictive value in patients having elective noncardiac surgery.[125] Dobutamine stress is commonly used in pretransplant evaluation because it is considered to most closely mimic the state commonly found during liver transplantation and end-stage liver disease.[122] A negative dobutamine stress echocardiogram with adequate stress appears to predict a favorable perioperative cardiac outcome.[123,126] However, it is important to achieve at least 85% of the predicted maximal heart rate so that the dobutamine stress echocardiogram is diagnostic. Otherwise, the diagnostic value of the test is compromised.[127] In the aforementioned study, many patients were taking β-blockers, and more than half of the tests were nondiagnostic.[127] To achieve a diagnostic test, temporary withholding of β-blockade and use of supplemental atropine during testing may be necessary.

In the hyperdynamic state produced by the dobutamine stress echocardiography protocol, a significant number of patients develop a dynamic left ventricular outflow tract obstruction. However, despite the fact that more patients with dynamic left ventricular outflow tract obstruction developed intraoperative hypotension at transplantation, the overall outcomes (mortality) were the same between patients with obstruction and those without.[128]

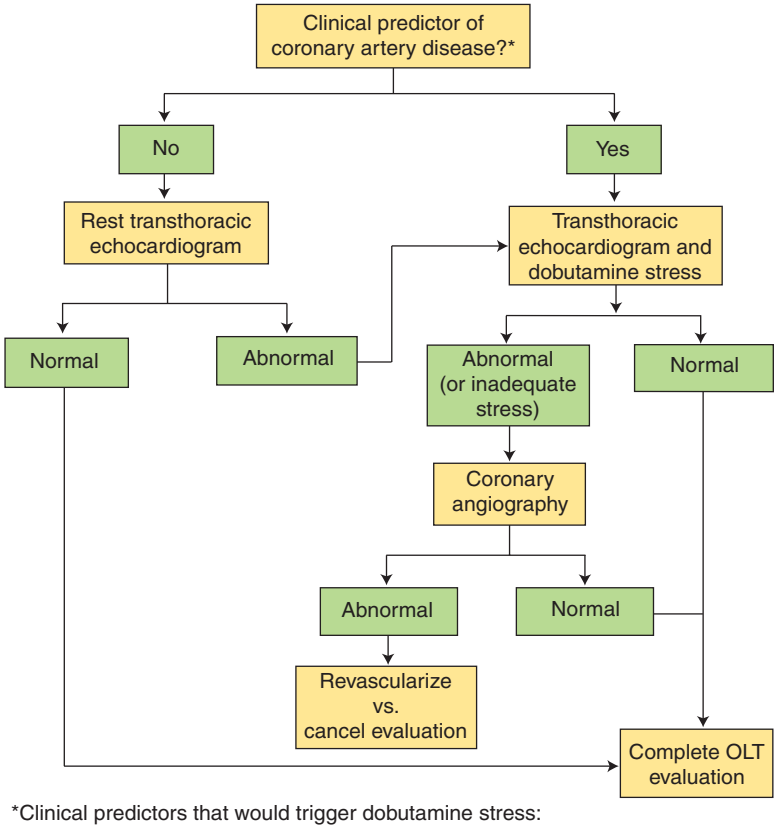
Most transplant programs use a cardiac risk stratification schema similar to that devised by Plevak.[122] The version used by our program is shown in Fig. 56–8.

The ideal management of potential liver transplant recipients with significant coronary disease is a difficult problem with little evidence to guide decision making. Patients with end-stage liver disease who undergo coronary artery bypass grafting have significant morbidity. In one study, patients with cirrhosis who underwent coronary artery bypass grafting had a 58% incidence of morbidity and significant complications.[129] Even patients with relatively mild liver disease (Child Class A and B liver disease) who underwent coronary artery bypass grafting had extremely high mortality and morbidity.[130] The benefit of an intervention, such as coronary angioplasty, stenting, or atherectomy, has not been formally studied on a large scale to show outcome compared with coronary artery bypass grafting.[120] Small series have reported good results with combined orthotopic liver transplantation and coronary artery bypass grafting,[119,131,132] but at present such a combined procedure is considered heroic in most transplant centers.

Independent of ischemic coronary artery disease, many patients with end-stage liver disease have a poorly understood disorder known as *cirrhotic cardiomyopathy* (a different entity from alcoholic cardiomyopathy) despite supranormal cardiac outputs.[22] This condition is multifactorial, and its mechanisms may include impairment of the β-adrenergic system, nitric oxide (overproduced in liver failure), cytokines, and prolonged hyperdynamic circulation.[133] Many patients with apparently normal ventricular function prior to surgery develop left ventricular failure in the postoperative period.[23,126] These patients, representing 1–6% of liver-transplanted individuals, may have had occult cirrhotic cardiomyopathy. Unfortunately, prospective diagnostic criteria for cirrhotic cardiomyopathy are lacking, and the diagnosis is commonly made only after a patient has suffered heart failure in the absence of any myocardial insult in the peritransplant period.

All patients being considered for liver transplantation should undergo a screening transthoracic echocardiogram. This is a good screening test to search for cardiac structural abnormalities as well as anomalies of the surrounding vasculature. Testing to exclude portopulmonary hypertension also is important.

Cardiac structural anomalies can affect outcome by impairing cardiac performance intraoperatively (e.g., functional or fixed valve stenoses) or by allowing passage of emboli from the right to the left side of the heart. Patent foramen ovale and other septal defects are a significant risk to orthotopic liver transplant patients and patients undergoing hepatic resection when fixed or transient right-to-left shunting occurs. Right-to-left shunt increases the possibility of paradoxical embolus of clot, air, or debris. Hepatic surgery can lead to large openings in the inferior vena cava, so the embolization problem can be severe. In fact, in two series, thrombus



*Clinical predictors that would trigger dobutamine stress:

- History of coronary disease or congestive heart failure
- Signs or symptoms of coronary disease or congestive heart failure
- Abnormal ECG
- Diabetes
- Current or prior smoking
- Hypertension
- Hyperlipidemia
- Obesity
- Age > 50 for males, > 55 for females even in absence of any of the above

FIGURE 56–8. Suggested algorithm for assessment of inducible myocardial ischemia. OLT, Orthotopic liver transplantation.

was detected in the right heart in between 1% and 6% of all patients undergoing orthotopic liver transplantation.[134,135] Because approximately 25% of all hearts in unselected autopsy subjects have patent foramen ovales,[136] the risk of injury due to paradoxical embolism may be greater than currently appreciated. Thus, in preparation for elective hepatic surgery and certainly in the evaluation for orthotopic liver transplantation, cardiac septal defects should be sought by echocardiography or MRI.

Transthoracic echocardiography can be used to interrogate the intraatrial septum using color flow Doppler mode. Additionally, bubble contrast echocardiography is a highly sensitive test for septal defects. Early passage (within 1–2 beats) of air from the right to the left heart indicates a septal defect, whereas later arrival of air on the left side indicates intrapulmonary shunting. This latter finding cannot be remedied, but when atrial defects are detected, consideration should be given to closing them.

Closure of patent foramen ovale prior to orthotopic liver transplantation is controversial, although it can now be accomplished percutaneously.[137] No controlled studies evaluating the usefulness of this intervention have appeared. Several factors favor closure: (1) embolism is common, particularly during the reperfusion period; (2) right-heart dysfunction with right-heart pressures greater than left-heart pressures is common during reperfusion; and (3) paradoxical embolism occurs in this setting.[138] On the other hand, the relationship between the presence or size of patent foramen ovale and the likelihood of paradoxical embolus is not clearly established. Although case series of paradoxical embolism have been documented by transesophageal echocardiography during liver transplantation,[138] whether these necessarily occur through a patent foramen ovale is not clear. Furthermore, closing a patent foramen ovale commits the coagulopathic patient with liver disease to months of therapy with antiplatelet agents.

MRI has recently been applied to the assessment of the intraatrial septum. Small studies comparing this technique with color flow Doppler echocardiography and bubble contrast studies indicate that MRI has similar sensitivity and specificity to these echocardiographic techniques.[139]

The final cardiopulmonary problem to be investigated in the prelisting evaluation is portopulmonary hypertension, the management of which was described above. Fig. 56–1 outlines the diagnostic and therapeutic decision approach to portopulmonary hypertension. Portopulmonary hypertension occurs in 2–4% of patients with end-stage liver disease and 5–10% of patients being evaluated for orthotopic liver transplantation.[36] The clinical predictors of pulmonary hypertension in liver transplantation include systemic hypertension, right ventricular dilation by echocardiography, estimated pulmonary artery systolic pressure ≥ 40 mm Hg by transthoracic echocardiography, right ventricular hypertrophy by echocardiography, or right ventricular heave.[140] The mortality associated with pulmonary hypertension during liver transplantation is significant. Half of patients with mean pulmonary pressures between 35 and 50 mm Hg died in the peritransplant period, and mortality was 100% in those with mean pulmonary arterial pressure > 50 mm Hg.[141] These results are similar in a multicenter retrospective review,[41] leading many centers to deny orthotopic liver transplantation to patients with more than mild portopulmonary hypertension. However, in some centers, mild portopulmonary hypertension (mean pulmonary arterial pressure < 35 mm Hg with good ventricular function) is not associated with poor early or late outcomes.[142]

Transesophageal echocardiography is rarely indicated in the preoperative assessment of orthotopic liver transplantation candidates. The procedure may require sedation, which can be complicated in the patient with end-stage liver disease. Furthermore, there is the risk of disrupting esophageal varices during the examination.

Operative Approaches for Liver Transplantation

Liver transplantation is conveniently divided into three phases: preanhepatic, anhepatic, and neohepatic. During the *preanhepatic* phase, a complete hepatectomy is performed. During the *anhepatic* phase, vascular anastomoses between the donor liver and the recipient's vessels are constructed. During the *neohepatic* phase, the hepatic arterial and biliary anastomoses are constructed, and the wound is closed.

A liver transplant begins like a hepatic resection, using the same incision and exposure and imposing the same hemodynamic consequences. The surgeon exposes and gains control of the hepatic vasculature. The hepatic artery, portal vein, and common bile duct are clamped and divided. Two different techniques are commonly used for controlling hepatic venous outflow and constructing the hepatic venous anastomosis: (1) an en bloc technique in which part of the recipient's vena cava is resected and replaced with a section of the donor vena cava, or 2) a "piggyback" technique in which the recipient vena cava is clamped with a side-biting clamp and a side-to-side anastomosis is constructed to the donor liver venous outflow. The choice of technique has important implications for anesthetic management and the expected course of the case (as described in the following paragraphs).

In the en bloc resection technique, the inferior vena cava must be clamped above and below the liver, with consequent severe reduction in venous return to the heart. Because both the portal vein and the inferior vena cava are clamped, the entire body below the caval cross-clamp, as well as the abdominal viscera, suffers venous congestion and ischemia unless an alternate route of venous return can be established. This massive loss of venous return, coupled with the insult of recirculating blood from such a large ischemic territory at the time of reperfusion, leads to profound hemodynamic instability requiring pharmacologic intervention, sudden hypothermia at reperfusion, and elevated potential for malignant cardiac arrhythmias. These difficulties have motivated the development and routine use of venovenous bypass techniques. This is commonly achieved via venovenous bypass from the lower half of the body to a great vein draining into the superior vena cava.

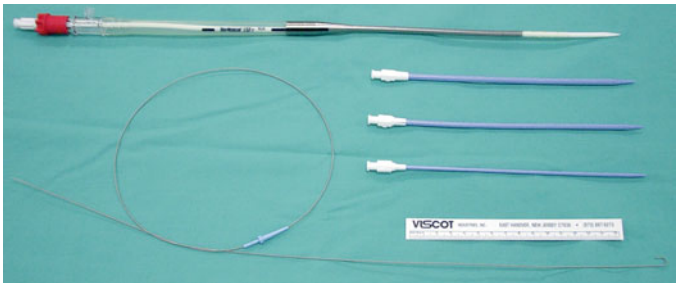


FIGURE 56–9. Large-bore venovenous bypass cannula with guidewire and dilators.

Venovenous bypass can be used to decompress the lower systemic venous circulation, the portal circulation, or both. The advantages and disadvantages of venovenous bypass have been reviewed.[143] Without the preserved venous return afforded by venovenous bypass, cardiac output and blood pressure may fall dramatically; often cardiac output falls by > 50%. Such falls in cardiac output are suggested to increase morbidity and mortality,[143] although primary research has failed to detect this association.[144,145]

Failure to decompress the lower systemic and portal venous systems leads to severe venous congestion below the caval cross-clamp. Above the clamp, reduced venous return reduces left ventricular preload and cardiac output, with a net result of reduced perfusion pressure for organs below the caval cross-clamp. Thus, without venovenous bypass, renal venous pressure is elevated, systemic arterial pressure is depressed, and renal perfusion pressure is degraded. Thus, venovenous bypass might be expected to afford some protection from renal failure in the perioperative period, but the net effect on renal function is equivocal. For example, venovenous bypass is not associated with improved postoperative renal function relative to matched patients whose liver transplant was performed without bypass.[146]

First described in 1984,[147] venovenous bypass is a technique wherein blood is actively pumped using a centrifugal pump from large-bore drainage cannulas to a similarly large return line (Fig. 56–9). The cannulas can be inserted percutaneously or via a cutdown procedure. A common drainage site for the lower systemic venous circulation is the left femoral vein. The portal vein, if drained, is accessed from the surgical field. Common return sites are the right internal jugular and left subclavian veins via percutaneous access or the left axillary vein via a cutdown technique.

Percutaneous insertion of the bypass cannulas can be performed by the surgical team or by the anesthesia team at the beginning of the case. An alternative approach is to prepare the left groin and axilla for possible cutdown access and then defer access until the need for venovenous bypass becomes clear. Percutaneous access appears to be quicker and to provide better flows,[148,149] but the cutdown technique persists. The bypass cannulas are very large and, when placed percutaneously, require multiple passes with successively larger sharp stiff dilators passed over a stiff guidewire to create a large enough skin entrance (Fig. 56–10).

Assiduous care should be taken to pass the dilators only deep enough to enlarge the skin punctures. Under no circumstance should the tip of any dilator be allowed to pass beyond the end of the guidewire. Exsanguinating hemorrhage into the chest and cardiac tamponade from cardiac puncture have occurred as mishaps of venovenous bypass cannula placement.[150] Every care should be taken to facilitate reliable cannulation of the target vein, including possible use of ultrasonography to guide initial venous access and manometry to confirm venous placement using a small, temporary catheter prior to beginning dilation. A postinsertion chest x-ray film to confirm vascular placement and correct insertion depth is mandatory prior to initiating venovenous bypass.

The bypass circuit should be carefully cleared of air as connections are made and all connections secured prior to initiating bypass. Systemic heparinization is not performed because the bypass circuit is heparin bonded.[151] Bypass flow rates of 1.5–5 L/min are typical. The initiation of bypass is a critical period, as malplacement of the return line becomes apparent with disastrous consequences almost immediately. For example, accidental placement of the tip of the return line through a cardiac

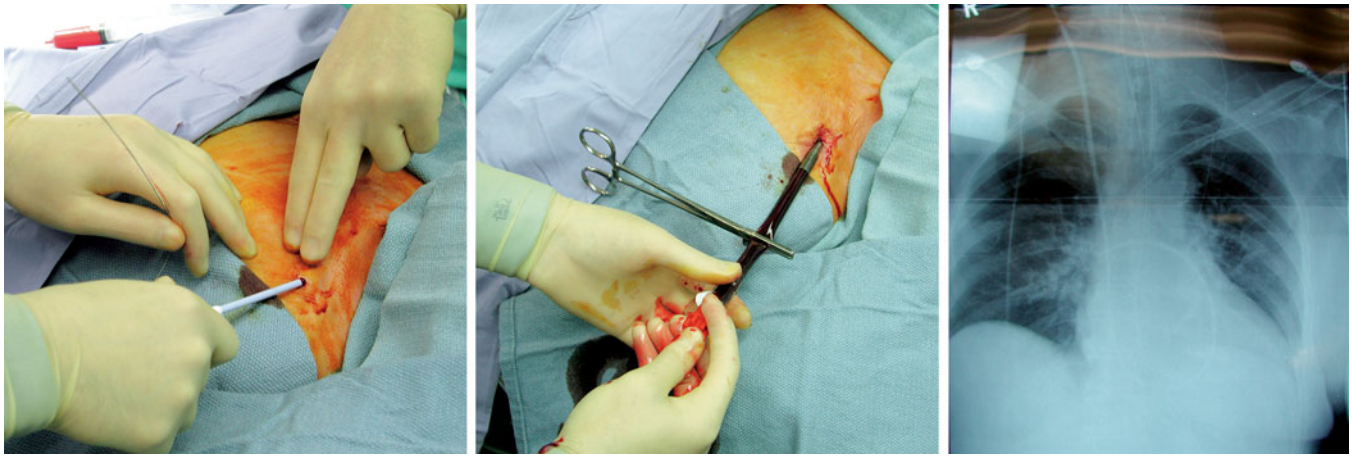

FIGURE 56–10. Subclavian placement of a percutaneous venovenous bypass cannula. **Left.** Use of a large-bore dilator after placement of the guidewire into the central circulation. **Center.** Cannula in place and clamped prior to connecting to the venovenous bypass pump tubing. **Right.** Portable chest x-ray film confirming intravascular placement.

chamber wall and into the pericardial sac will lead to nearly instantaneous, severe cardiac tamponade with initiation of flow. Fatal air embolism has occurred because of connection failure during venovenous bypass, so the pump and its circuit require constant attention by dedicated, specialized personnel.

Despite the improved conditions afforded during surgery, whether venovenous bypass improves long-term outcomes is not clear. Because of the potential for complications, coupled with improvements in surgical techniques (see next paragraph), some have questioned the usefulness of routine venovenous bypass.[143]

The alternative approach to liver transplantation, the vena cava preservation (or "piggyback") technique,[152] is designed to preserve vena cava flow for all but a few minutes of the transplant procedure. Portal venous and hepatic arterial control are obtained as in the en bloc technique. Instead of a cross-clamp, a "side-biter" clamp placed on the inferior vena cava isolates the liver from the systemic venous system. Figs. 56–6 and 56–11 illustrate this clamping method. In Fig. 56–11, a button of vena cava with the hepatic vein attachments has been removed, and the hole is held closed by the side-biter clamp at the bottom of the wound. The vena cava deep to this clamp is largely open to flow. This allows venous return from the lower systemic, but not the portal, venous system. Frequently, a brief period of total venous occlusion with a vena cava cross-clamp is needed to position the side-biter clamp. Vena cava distension due to overzealous volume replacement during the hepatectomy can make the piggyback technique more difficult for surgeons. Because the exposure made for hepatectomy is more difficult and the anastomosis is more complicated, the piggyback technique may take longer to perform. However, many programs now use this technique almost exclusively.[153] Piggyback transplantation is associated with a lower incidence of renal failure[154] and better gas exchange, acid–base status at reperfusion,[155] and intraoperative hemodynamic stability.

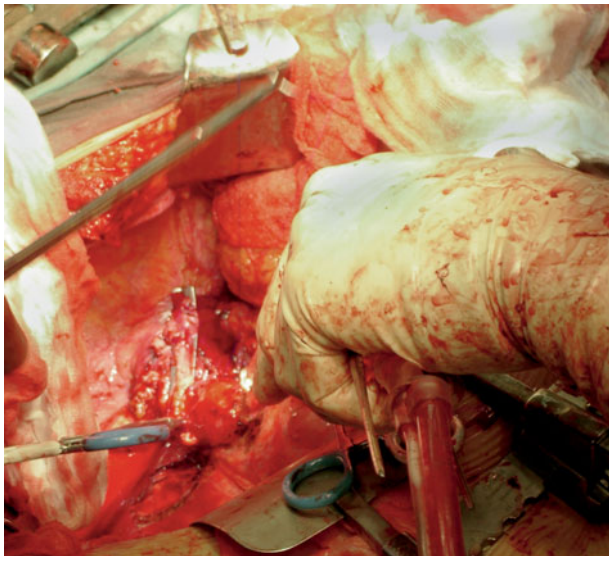

FIGURE 56–11. Photograph of a side-biting cross-clamp (*lower left*) on the inferior vena cava after removal of the liver. The patient's head is to the upper left.

Failure to decompress the portal system may lead to splanchnic congestion unless the recipient has large portosystemic shunts. Nevertheless, the piggyback technique reduces transfusion requirement as well as the need for vasoactive drugs during completion of the hepatectomy and construction of the venous anastomoses.[156] Temporary portocaval shunts have been described in association with piggyback technique. The temporary shunt appears to improve intraoperative hemodynamics and reduce transfusion requirements[157] but is not widely used. In general, use of the piggyback technique dramatically reduces the severity of problems during the anhepatic and reperfusion stages of the operation.

As the hepatectomy is being completed, a separate surgical team working at a different table prepares the donor liver for implantation. The graft vessels are trimmed to fit their counterparts in the recipient. Next, the graft is brought to the recipient surgi-

TABLE 56–2.

Major Foci of Intraoperative Management during Anesthesia for Orthotopic Liver Transplantation

Major Focus (Problem or Organ System)	Subtopics	Perturbing Factors
Cardiac	Ischemic potential	Hemorrhage (demand and carrying capacity)
	Dysrhythmias	Acid–base and electrolyte disturbances
	Right ventricular performance	Emboli, hepatic washout
Portal-to-central venous gradient	Graft perfusion is tenuous	Need to keep central venous pressure adequate to provide cardiac preload during vena cava cross-clamping
		Need to prevent venous air embolism
		Sudden hemorrhage
Renal performance	Urine output	Hypovolemia and hypotension
		Preexisting renal disease
		Need for intraoperative renal replacement therapy
Anesthesia	Hypnosis	
	Analgesia	
	Muscle relaxation	
Brain protection		
Immunosuppression		
Prophylaxis	Temperature management	Large incision, large prepared area
	Deep venous thrombosis prophylaxis	
	Preemptive antibiotics	Dilution due to massive hemorrhage
Glucose management	Coexisting diabetes	Steroid administration
		Absent gluconeogenesis during anhepatic phase
Coagulation	Hypocoagulable state due to liver failure	Massive hemorrhage
		Acute fibrinolysis at graft reperfusion
	Platelet sequestration	
	Platelet dysfunction due to uremia	
Electrolytes	Potassium	Elevated by potassium load in blood products
	Sodium	Hyponatremic patient at risk for central pontine myelinolysis (CPML) with massive infusions of sodium-rich fluids
	Calcium	Citrate in blood products chelates Ca^{2+}
Pulmonary performance	Ventilation	May be impaired by pleural effusions
	Oxygenation	May be impaired by intrapulmonary shunts
	Pulmonary vascular resistance	Acutely elevated in the face of acid load at graft reperfusion
Hemodynamics	Vasodilated hyperdynamic circulation	
	Massive hemorrhage	
	Vena cava compression	
	Possible venovenous bypass	

cal field, and the vascular anastomoses are constructed. The surgical goal during this phase of the operation is to construct patent, nonleaking anastomoses as efficiently as possible to minimize the warm ischemic time of the liver. Thrombosis of the recipient portal vein is a relatively common finding, either during the dissection or at the time of initial graft reperfusion. When discovered, portal venous thrombosis typically prompts an attempted thrombectomy using Fogarty catheters, a potentially bloody process. Typically, the donor hepatic to recipient vena cava and the donor portal to recipient portal venous anastomoses are constructed, flushed, and perfused as quickly as possible to establish a circulation in the graft. Then the hepatic arterial anastomosis is constructed, flushed, and opened, completing the graft blood supply.

Finally, a biliary drainage is constructed. This can be accomplished either by direct anastomosis of the graft bile duct to the recipient common bile duct or by a Roux-en-Y anastomosis using the jejunum.

Anesthesia for Liver Transplantation

Concerns and activities during anesthesia for liver transplantation mirror the major phases of the surgery. The anesthetic can be approximately divided into the following phases:

- Preinduction
- Induction, preparation for surgery, and maintenance
- Preanhepatic phase
- Anhepatic phase
- Venous reperfusion of the graft
- Neohepatic phase
- Emergence/transport to ICU

The anesthesia team attends to multiple homeostatic goals throughout the case (Table 56–2). Administration of

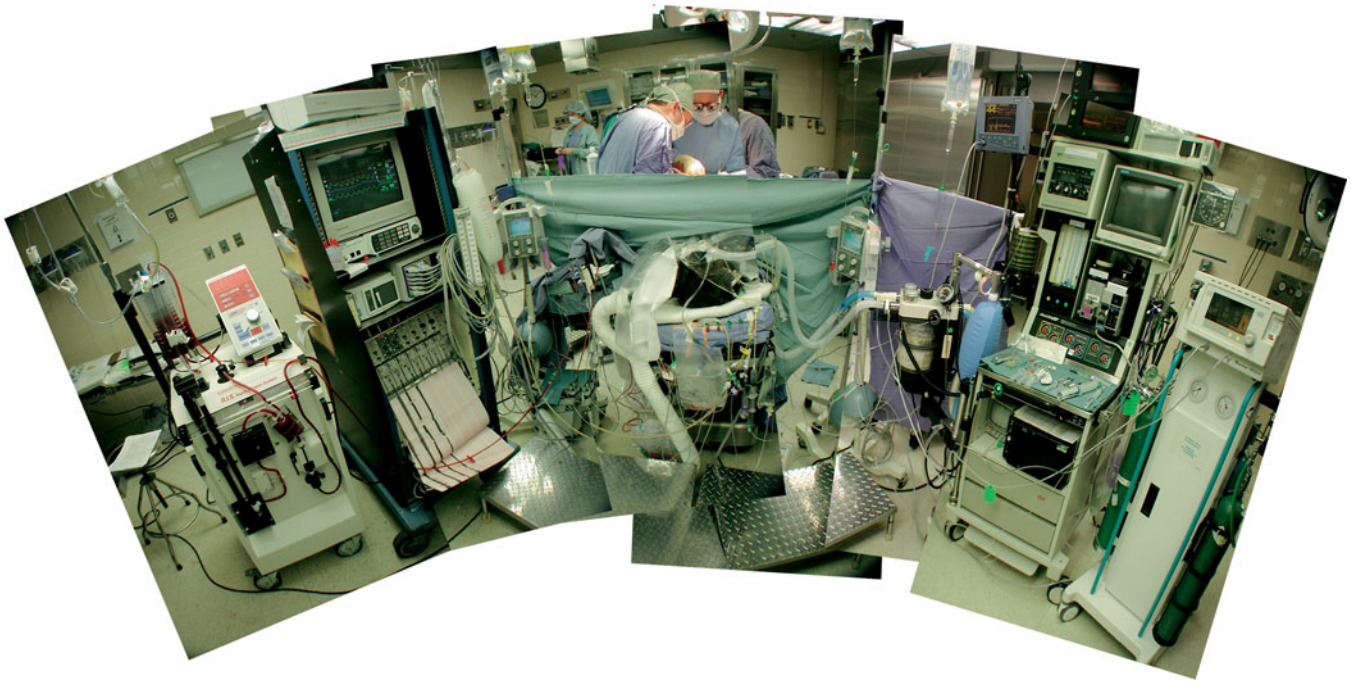

FIGURE 56–12. Panorama of anesthesia equipment used for liver transplantation. The equipment (from left to right) includes rapid infusion system, six-pressure physiologic monitor with eight-channel chart recorder, syringe microinfusion pumps for vasoactive drugs, forced-air warmer, syringe microinfusion pumps for anesthetics, muscle relaxants, and miscellaneous drugs, level-of-consciousness monitor, anesthesia machine, and delivery system for inhaled nitric oxide. Blood recovery system is out of view to the right.

liver transplant anesthetics is among some of the most complex currently performed because of the surgical and medical criticality of the patients and the complexity of the equipment required to perform the case.

Fig. 56–12 is a panorama from the anesthesiologist's perspective during a liver transplant. Multiple user interfaces, cables, monitoring lines, and infusions must be well organized and set up systematically to make the cognitive load from the equipment acceptable and predictable so that the anesthesiologist can attend properly to the patient and the operation. Liver transplantation consumes tremendous resources. Most programs responding to a survey reported assigning at least two anesthesiology personnel and at least two additional professional personnel (i.e., perfusionist, monitoring nurse, auto-transfusion nurse) to each case.[158] Thus, in addition to the complexity of the equipment, team leadership, communication, and delegation of responsibility must be considered and managed during the case.

During the preinduction phase, the final evaluation of the patient is performed. Although any doubt about the identity of the patient and the operation to be performed are unlikely, the anesthesia team must independently confirm the patient's identity, the operation to be performed, and the recipient's blood type. Last-minute laboratory results should be reviewed. It is always prudent for a member of the anesthesia team to personally consult with the blood bank about the upcoming liver transplant so that they may prepare for a possible heavy demand for blood products. This is particularly true if the patient has developed antibodies to allogeneic red blood cells from previous transfusions, which presents an added challenge to the blood bank.

Close communication with the graft harvest team is essential to best sequence the activities with the donor to minimize graft ischemic time while minimizing the recipient's exposure to risks of anesthesia and invasive monitoring. Thus, one might obtain initial peripheral IV access and then wait to place any additional monitors or vascular access until the suitability of the graft is confirmed. In most situations, graft suitability is known at least 1 hour before the need to start the recipient's surgery, leaving ample time for induction of anesthesia, placement of central venous or pulmonary artery catheters, positioning of the patient, application of warming devices, and initial surgical preparation and draping.

Most patients with end-stage liver disease have at least some encephalopathy. Thus, it is prudent to dose sedative premedications, such as benzodiazepines and opioids, judiciously, giving small doses and monitoring closely for desired and undesired effects.

Monitoring for liver transplantation relies on standard monitors plus invasive monitors directed toward the likely areas of additional concern during the case. Central venous pressure monitoring likely will be needed to assess intravascular volume status. Additionally, central venous catheterization provides large-bore transfusion access, allows passage of a pulmonary artery catheter, if needed, and provides a conduit for central vasopressor administration. Thus, placement of a central venous catheter for liver transplantation seems almost obligatory. However, central venous pressure monitoring gives much of the same information as provided by intraoperative transesophageal echocardiography, which could replace the intravascular monitor if another suitable route for the drugs can be found.

Pulmonary artery catheterization is performed if left-heart or right-heart performance is in doubt, if problems with pulmonary hypertension are anticipated, and to distinguish hypotension due to hypovolemia or heart failure from that due to lack of peripheral vascular tone. One type of pulmonary artery catheter also allows for atrioven-

tricular pacing. The pulmonary artery catheter allows the team to follow cardiac output and stroke volume throughout the case. The initial cardiac output measurements typically confirm a hyperdynamic circulation, with cardiac outputs of 10–1 L/min frequently seen at rest in adult male patients with end-stage liver disease.

An arterial catheter usually is inserted to closely monitor blood pressure. It also provides convenient access for frequent laboratory sampling. Compared with femoral arterial catheters, radial artery catheters may not reflect the true systolic pressure during the reperfusion phase of transplantation or during vasopressor administration.[159] However, mean pressures measured in the radial and femoral arteries correlate well regardless of the phase of the case or vasopressor administration.[159] Thus, a radial arterial catheter is sufficient to guide management of mean pressure.

Transesophageal echocardiography should be considered for assessment of cardiac performance during transplantation and for monitoring embolism of air or thrombus. Air embolism is common, and transesophageal echocardiography frequently reveals such events. Transesophageal echocardiography is most useful for early detection of large embolic events, with the hope of minimizing their effect by early detection and removal of the source. It is also a useful tool for assessing the effect of both embolic events and therapeutic interventions on cardiac performance.

It is also useful to consider level-of-consciousness monitoring (bispectral index or similar). Liver transplant patients may be highly sensitive to anesthetics, requiring smaller doses than typical patients. Thus, level-of-consciousness monitoring can be used to minimize exposure to anesthetic agents and their potential deleterious effects on the circulatory system while providing some assurance that the patient will not recall the surgery.

Vascular access for rapid volume replacement can be either peripheral or in the central circulation. The patient likely requires central venous access for vasopressor administration, so it is tempting to use this route for volume as well. However, it is important to isolate vasopressors from the main volume cannula, because fluid for resuscitation may be delivered under pressure, effectively stopping the vasopressors. Multilumen large-bore central venous catheters or multiple catheters at separate central venous sites provide the necessary isolation. Alternatively, peripheral vascular access (e.g., multiple 14-gauge IV catheters or a rapid infusion catheter as described above) can be established. It is important that at least one cannula be dedicated to carrying the maximum flow rate of the available rapid infusion device.

Anesthetic Induction, Preparation for Surgery, and Maintenance

Because most patients with end-stage liver disease have ascites and/or have undergone sclerotherapy of lower esophageal varices, rapid sequence induction is the norm, with cricoid pressure applied and the patient in optimal position for laryngoscopy. Careful denitrogenation is important, because most end-stage liver disease patients have reduced functional residual capacity. Vasodilatation and encephalopathy make patients with end-stage liver disease sensitive to induction agents. Thus, the induction dose of hypnotic drugs, such as propofol or pentothal, should be reduced (e.g., 1 mg per kilogram of ideal body weight for propofol in a cachectic patient with encephalopathy). Some clinicians elect to sidestep this issue entirely by using an induction agent such as etomidate. Skeletal muscle paralysis typically is obtained with succinylcholine followed by a nondepolarizing agent, or with rocuronium at a dose sufficient for rapid sequence induction.

Antibiotics targeted against skin flora (e.g., cefazolin) should precede skin incision by no more than 60 minutes.[160] Antibiotics should be re-dosed throughout the case to account for elimination and loss due to hemorrhage.

During maintenance of anesthesia, hepatic encephalopathy reduces opioid and anesthetic requirements. Thus, inadvertent administration of relative overdoses of anesthetics by overestimating the patient's needs is possible. Similarly, opioids may have enhanced potency and prolonged duration of action because of the patient's hepatic failure. On the other hand, massive hemorrhage and resuscitation can diminish the circulating opioid concentration. Thus, it is appropriate to titrate intermediate-acting opioids, such as morphine, hydromorphone, or fentanyl, to the patient's needs throughout the case. The choice of paralyzing agent also should be guided by the clinical situation. For example, agents requiring hepatic degradation probably are not optimal if early extubation is contemplated.

Positioning the patient requires special attention. Liver transplants are long cases with the potential for hypotension and consequent extremity hypoperfusion. Surgeons may lean heavily on the patient to perform parts of the operation. Thus, positioning injuries are possible, and great care should be taken to protect the patient by generously supporting and padding all of the body, either with compressible foam or viscoelastic gel.

The case is performed with the patient in the supine position. Usually the right arm is tucked alongside the patient's body to allow access for several surgeons. Thus, the right arm is out of reach of the anesthesiologist, and no critical monitors or access devices should be placed there unless no alternative sites are available. In addition to problems with accessibility, devices placed in the tucked right arm may cause patient injury from compression. Accordingly, we typically limit devices in the right arm to a single large-bore peripheral IV. The left arm is abducted to facilitate access for venovenous bypass. Therefore, the left arm is also an ideal site for arterial monitoring and peripheral venous access. Venous access in the left arm may be occluded if venovenous bypass is instituted via cutdown to the axillary vein, but the bypass circuit has a separate high-flow inlet into which this infusion can be attached. Other sites of access include both femoral regions. Venous access below a potential vena cava cross-clamp is of little use, either for monitoring or volume administration. Furthermore, the left femoral vein typically is reserved for possible venovenous bypass access. However, cannulation of the right femoral artery may be useful if a complicated case is anticipated. Both internal jugular veins are available with the patient in supine position.

The entire abdomen and chest are prepared for surgery. Additionally, the left groin and axilla are included in one large, contiguous preparation if venovenous bypass via open access is contemplated.

Patient warming becomes a major issue because of the extensive use of

TABLE 56–3.

Characteristics of Common Rapid Infusion Devices

Device	Reservoir	Pump	Air Detector	Postpump Filter	Measured Flow Rate	Maximum Flow Rate
Level 1	No	No	Yes	No	No	Catheter limited
Haemonetics RIS	Yes	Yes	Yes	Yes	Yes (from pump)	1500 mL/min
Belmont FMS	Yes	Yes	Yes	No	Yes (from pump)	750 mL/min

FMS, Fluid Management System; RIS, Rapid Infusion System.

alcohol-based skin preparation solutions over a large surface, the size of the incision, the duration of the case, and reperfusion of a cold graft. Hypothermia should be prevented because it negatively affects coagulation,[96] resistance to infection,[95] and the potential for early extubation. Warming strategies commonly focus on IV fluids and forced-air warming devices.

Forced-air warming is effective, although the extensive area exposed and prepared during liver transplantation makes finding sufficient surface area on which to apply warmers a challenge. A procedure involving the entire abdomen, as well as the left groin and axilla for establishment of venovenous bypass, leaves the head, left arm, and lower legs for warming. Recently, forced-air warming blankets for underbody use, which presumably function by forming a warmed-air plenum under the drapes, have become available. These blankets appear to be effective because they are not compressed and deflated by the weight of drapes and by surgeons pressing against them. In this instance, we place forced-air warming blankets on all available sites, including under the patient. In our experience, patient temperature drops to approximately 36°C during induction, preparation, and draping; increases to 37°C during the preanhepatic phase; and then falls by approximately 1°C at hepatic reperfusion. Subsequently, the temperature increases to 37°C during the neohepatic phase, prompting gradual discontinuation of forced-air warming to maintain normothermia.

Warming IV infusions is mandatory, given the volume of refrigerated banked-blood products that likely will be transfused. Fluid warming for liver transplantation usually is achieved with commercially available high-flow warming devices. The ideal transfusion device has a reservoir that allows the user to establish a reserve of blood for sustained rapid infusion in the face of uncontrolled hemorrhage. The device should report the infusion flow rate. The device must contain an air detector that stops the infusion when air is detected in the patient limb of the circuit. Ideally the device contains a debris filter between the reservoir and the patient.

Three devices are in common use, each with unique advantages and weaknesses. The characteristics of the three major rapid infusion systems are listed in Table 56–3. The first device, manufactured by Level 1 (Rockland, MA, USA), uses a countercurrent heat exchanger to warm fluid administered under pressure from bags. The second device, the RIS, formerly manufactured by Haemonetics (Braintree, MA, USA), is no longer commercially available but is still in common use. The third device, the Belmont Fluid Management System (FMS), is manufactured by Belmont Instrument Corp. (Billerica, MA, USA). The pumped devices are pressure limited at 300 mm Hg, that is, their maximum flow rates in actual clinical use are limited by the resistance characteristics of the infusion catheter or by the maximum rate of the pump if the back-pressure is < 300 mm Hg when maximum pump flow is attained.

Of the three devices listed in Table 56–3, the RIS most closely approaches the characteristics of the ideal transfusion device. It has a debris filter/air removal system downstream of the warmer and pump but proximal to the final air detector, thus providing maximal embolism exclusion. The RIS also has the highest flow rate, delivering 1500 mL/min, or roughly one third of the normal adult cardiac output, exceeding the flow capacities of all but the largest catheters. However, the RIS disposable insert is bifurcated, which allows the pumped flow to be sent to two infusion catheters in parallel.

Of the two available devices, the FMS is preferable because it satisfies more of the requirements listed. Its maximum flow rate does not exceed the capacity of an RIC or percutaneous introducer sheath, but it does exceed the capacity of a 14-gauge peripheral IV or the auxiliary lumen of a centrally inserted device, such as the Multi-Access Catheter (Arrow International, Reading, PA, USA) or the Advanced Vascular Access device (Edwards Lifesciences, Irvine, CA, USA).

The Preanhepatic Phase

As in a hepatic resection, clamping the portal triad reduces venous return. However, as mentioned above, cardiac output and blood pressure do not necessarily fall. Liver transplantation almost always requires a vena cava cross-clamp, creating total vascular exclusion physiology for at least a brief duration. In contrast to portal triad clamping, total vascular exclusion of the liver via a vena cava cross-clamp reduces systemic blood pressure and cardiac output because the loss of venous return is quite large. The vena cava cross-clamp can be applied briefly to facilitate completion of the hepatectomy or for a longer time to allow construction of the hepatic venous anastomoses. Severe cardiovascular compromise during the vena cava cross-clamp may necessitate institution of venovenous bypass. However, more moderate decreases in cardiac output and blood pressure can be treated by vasopressor administration coupled with judicious intravascular volume expansion. Modest doses of a vasopressor during caval cross-clamp to construct caval anastomoses apparently are well tolerated, with graft and patient survival rates comparable with those obtained when venovenous bypass is used.[161]

Low central venous pressure does not seem advantageous during liver transplantation, in contrast to hepatic resection. For patients undergoing orthotopic liver transplantation, keep-

ing central venous pressure < 5 mm Hg is associated with higher incidences of postoperative renal failure and 30-day mortality relative to patients whose central venous pressure was allowed to run between 7 and 10 mm Hg.[162]

As in partial hepatectomy, two major contributors to hemodynamic changes during liver transplantation are changes in cardiac performance due to episodic alterations in venous return and hemorrhage. However, these factors are only two of the many sources of cardiovascular instability during liver transplantation. Sepsis, acidemia, hypocalcemia due to citrate toxicity, embolism, and acute right ventricular failure all are major contributors to hemodynamic problems. The period of graft reperfusion (described below) is particularly unstable in many instances.

The goals of hemodynamic management are to provide sufficient circulating volume, vascular resistance, and cardiac output to perfuse the vital organs. This process is not guided by any single parameter but rather by a synthesis of all available data, including urine output, central venous pressure (in relation to preoperative central venous pressure and with a full appreciation of the factors that may artificially alter it), and the presence of only a minimal vasopressor requirement except during periods of inadequate venous return.

Choice of Vasopressor

With adequate volume management, vasopressors are rarely required intraoperatively except during periods of inadequate venous return (i.e., during inferior vena cava cross-clamping) and transiently at liver reperfusion. Administration of vasopressors is a choice between the global detrimental effects of untreated significant hypotension and the potential negative effect of vasoconstrictors on perfusion of the new graft. In animal models, both epinephrine and norepinephrine reduced graft macroperfusion and microperfusion,[163] but the functional consequences of these effects on human allograft performance or survival are unclear.

Vasopressin is a tempting choice because it is effective regardless of pH, it reduces norepinephrine requirements, and it is effective for managing hepatorenal syndrome before transplantation. Currently, use of vasopressin for control of blood pressure during liver transplantation has not been reported. Most studies of vasopressin to date are in patients with septic or postcardiotomy shock. Vasopressin is effective in these circumstances, reducing the requirement for catecholamine vasopressor support. Limited observational studies indicate that although vasopressin raises the blood pressure, it does not compromise the microvascular circulation.[164] However, there is no clear evidence that vasopressin would be beneficial or harmful during liver transplantation. In fact, in one study that retrospectively reviewed the use of vasopressin in septic shock, vasopressin was associated with increased levels of liver enzymes, bilirubin, or both.[165]

Adjuvant drugs, such as aprotinin, reduce the requirement for vasopressors, presumably by improving clotting performance and minimizing blood loss.[166] However, these advantages must be balanced against the other potential risks of aprotinin infusion (see below).

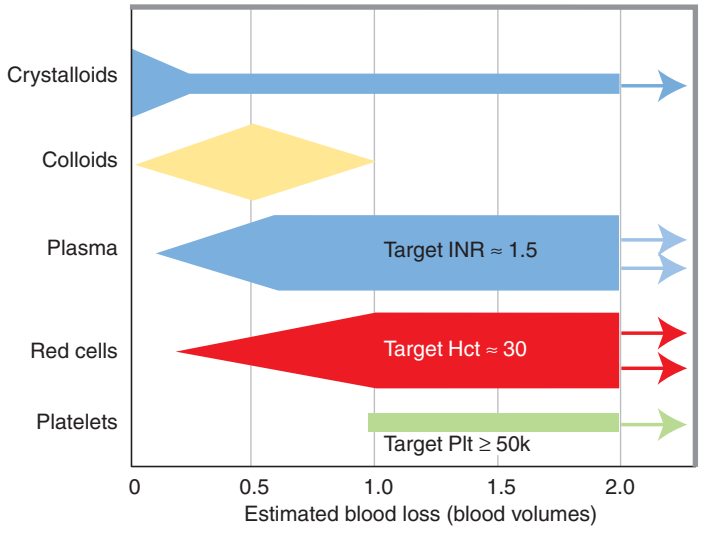

FIGURE 56–13. High-level overview of volume and blood component replacement strategy for liver transplantation requiring massive transfusion. All fluids are warmed (see text for discussion). The thickness of the bars represents the approximate relative proportions of each fluid in the replacement infusions.

Transfusion and Other Therapies to Maintain Intravascular Volume

The goal of volume management and transfusion in liver transplantation is maintaining sufficient intravascular volume to support a well-functioning circulation. Additionally, in many instances, the hemorrhage is sufficiently large that the anesthesiologist must intervene directly to control the composition of the circulating intravascular volume. Thus, in addition to red cell mass and intravascular volume, the anesthesiologist attends to plasma oncotic pressure, electrolyte composition, serum glucose and clotting factor levels, and platelets. In many cases, maintaining intravascular volume and management of coagulopathy are intertwined, so these topics are treated together in this section. Fig. 56–13 gives a high-level overview of a strategy for volume and transfusion management as a function of blood loss during transplantation.

Plasma oncotic pressure is a function of the osmotically active species in the plasma (proteins and, to a very small degree, cells). Albumin and other plasma proteins, mostly synthesized by the liver, provide plasma oncotic pressure. During liver transplantation, colloids should be used to replace intravascular volume lost through hemorrhage, with the addition of formed blood components as needed to meet specific needs (e.g., red blood cells for oxygen-carrying capacity).

One attractive approach to managing plasma oncotic pressure is use of fresh-frozen plasma as a volume expander. This is particularly appropriate when the patient is coagulopathic due to hepatic synthetic failure, because fresh-frozen plasma contains most of the proteins found in normal plasma. However, fresh-frozen plasma also contains most of the citrate added to blood at the time of collection to prevent clotting. Thus, rapid infusions (>1 mL/kg min) of fresh-frozen plas-

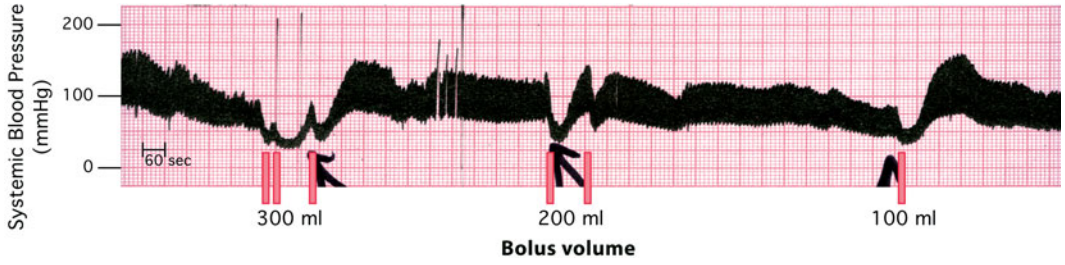

FIGURE 56–14. Acute systemic hypotension due to rapid transfusion of a citrate-containing 50:50 mix of fresh-frozen plasma and packed red blood cells. Boluses of 100 mL (vertical bars) were infused at 500 mL/min using a Rapid Infusion System (Haemonetics, Braintree, MA, USA). The hypotensive response is superimposed on acute hypotension due to sudden hemorrhage that was to be treated by the fluid challenge. The infusion-exacerbated hypotension was treated by infusion of norepinephrine.

ma can chelate Ca^{2+}, which is proposed to cause acute hypocalcemia with consequent vasodilatation and hypotension at inopportune times.[167] Fig. 56–14 illustrates the consequences of rapid infusion of citrated blood products during liver transplantation.

Fresh-frozen plasma is a poor choice for volume expansion when the patient is not coagulopathic, because each unit of fresh-frozen plasma carries has the potential to trigger transfusion-related lung injury. Also, liver transplantation entails the construction of multiple low-pressure, low-flow anastomoses. Some practitioners believe that maintaining a slightly hypocoagulable state lessens the possibility of unwanted hepatic or portal venous thromboses. Thus, in the absence of significant coagulopathy, 5% albumin solution probably is a better choice for volume expansion. Synthetic colloids composed of long-chain polysaccharides are available but are not popular because they can interfere with clot formation.

Transfusion and Other Therapies to Maintain Coagulation Capacity

Coagulation is monitored using standard laboratory tests, augmented in some cases by point-of-care functional tests and ultimately by clinical correlation of the laboratory test results with direct observation of the surgical field. The basic tests for monitoring coagulation status are prothrombin time, activated partial thromboplastin time, and platelet count. D-Dimer and fibrinogen levels provide information about the presence of clot lysis. However, these tests provide a far-from-complete picture of a patient's coagulation performance. Many centers use thromboelastography to obtain near-patient diagnostics of clot initiation, formation, and lysis.[168,169] Thromboelastography is a mechanical test described in detail in Chapter 14. The test is sensitive to extraneous influences (including environmental disruption) and is not well standardized. However, thromboelastography is useful in liver transplantation because, unlike other tests, it gives information about clot lysis.[169]

Coagulation performance during liver transplantation in patients with end-stage liver disease tends to follow a predictable course.[170] Patients with hepatic synthetic failure start out hypocoagulable, and, with appropriate transfusion of fresh-frozen plasma as part of the volume replacement strategy, coagulation status tends not to worsen significantly during the preanhepatic and anhepatic phases of the operation. After reperfusion of the graft, a clot lysis syndrome develops, and some patients become hypercoagulable at the same time (i.e., disseminated intravascular coagulation develops).[170] Even patients who present with normal hepatic synthetic function and no coagulopathy can develop a dilutional coagulopathy as well as the reperfusion clot lysis syndrome.

Volume replacement therapy should aim to preserve or move clotting potential toward a normal state as part of the effort to reduce blood loss. However, transfusion therapy and coagulation management are not substitutes for good surgical technique. Successful transplantation requires attention to both. Typically, fresh-frozen plasma is used to replace clotting factors. Liver transplant patients frequently are in a state of low-grade disseminated intravascular coagulation and thus consume fibrinogen and clotting factors even in the absence of massive hemorrhage. Fresh-frozen plasma usually supplies sufficient fibrinogen, but cryoprecipitate may be helpful if fibrinogen levels become unacceptably low.

Platelets are rarely needed prior to graft reperfusion, even in patients with low platelet counts (e.g., 50,000). Furthermore, many patients manifest splenic sequestration of platelets and have no response to transfusion.

Antifibrinolytic drugs and other procoagulants can be used prophylactically in the preanhepatic phase to minimize bleeding. These drugs are discussed in detail in the section on the Neohepatic Phase of Liver Transplantation.

Anhepatic Phase

The anhepatic phase of liver transplantation is frequently described as the time from explantation of the diseased liver to reperfusion of the new liver. However, the anhepatic phase of the operation actually begins once the native liver is sufficiently compromised to have no further function. During liver transplantation, this usually occurs after the hepatic artery is clamped, which can precede portal and hepatic vein clamping by many minutes. During this time, especially in the setting of portal hypertension, the diseased liver receives no oxygenated inflow and begins to die, with consequent effect on the patient's acid–base status. However, the problem ends once the liver is completely excluded from the circulation. After this, the anhepatic phase is often a relatively quiet period in the case. Bleeding should be under control, and the surgeons are engaged in the delicate task of constructing the venous anastomoses. During the construction of the venous anastomoses, the liver is kept on ice (Fig. 56–15, left).

Any drugs dependent on hepatic metabolism begin to accumulate once the portal vein and hepatic artery are clamped. Thus, infusions of drugs should be titrated to effect. Of course, drugs not dependent on hepatic metabolism (e.g., inhaled agents, remifentanil) are unaffected by this transition.

The anesthesia team should attend to immunosuppression during the early

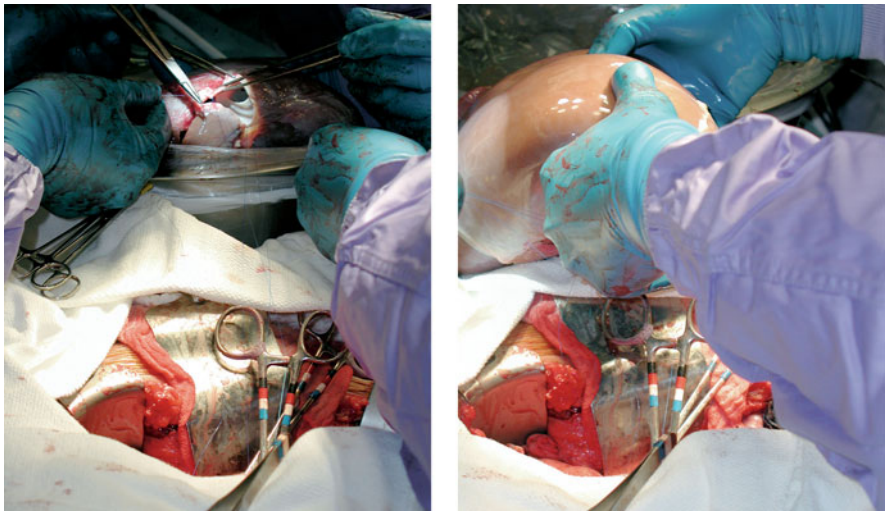

FIGURE 56–15. Liver transplantation surgery. **Left.** Construction of the initial anastomosis, with the liver kept on ice to minimize warm ischemic time. **Right.** Liver being placed into the body cavity. At this point, immunosuppressants should be given. The anastomoses are partially tied, after which the liver is flushed and the anastomoses completed and perfused.

anhepatic phase. The patient will have received an induction dose of an immunosuppressant, such as mycophenolate mofetil, prior to coming to the operating room. Obviously, this should be confirmed prior to starting the case. Typically, a modest dose of steroid (e.g., 100 mg methylprednisolone) is given in the operating room as the new liver is initially placed into the recipient (before opening of the anastomoses; Fig. 56–15, right). For patients with hepatitis C, alternative regimens can be used, such as an infusion of rabbit antithymocyte globulin begun at the completion of the hepatectomy and 10 mg methylprednisolone when the liver is placed into the recipient. In practice, the immunosuppression regimen is chosen by the surgeon, and the anesthesia team should ascertain the drugs, doses, routes, and timing prior to starting surgery.

Hemodynamics frequently stabilize during the anhepatic phase, particularly if a piggyback technique is used. This period of stability may derive from the fact that the rapid alterations in venous return during gross manipulations of the liver are superseded by more delicate tasks. If an en bloc resection has been used with a complete vena cava cross-clamp, the circulation still may be stable if venovenous bypass also is used. However, if the vena cava is clamped without a venous return conduit, support of the circulation with a potent vasoconstrictor, preferably an agent with some inotropic activity, such as norepinephrine, often is necessary.

Hypotension with diminished central venous pressure may occur even with significant preservation of venous return during the anhepatic phase. Lower extremity and splanchnic congestion lowers the effective circulating volume and central venous pressure above the diaphragm, with attendant hypotension. However, overtreatment of this condition with aggressive volume replacement can lead to hypervolemia at the time of graft reperfusion. Instead, support of the circulation with a low dose of a vasopressor is preferable, with anticipation of mobilization of blood from below the diaphragm once the liver is reperfused.

Finally, some poorly understood physiologic feature of the anhepatic phase may directly affect left ventricular performance, contributing to hypotension. Echocardiographic studies of ventricular function demonstrate that left ventricular shortening fraction diminishes during the anhepatic phase, relative to preanhepatic phase, then returns to normal after reperfusion.[171] These results await confirmation, because this was a small study and the degree to which patients became compromised during the anhepatic phase is unclear.

Electrolyte Management

Serum electrolyte levels and acid–base balance are subject to wide and rapid swings during liver transplantation, especially if the case is bloody and extensive transfusion is required. The fluctuations are most severe during the anhepatic phase, when even the small residual function of the native liver has been removed. However, even during the preanhepatic phase, the patient's acid–base, electrolyte, red cell mass, and coagulation statuses are likely change rapidly as a result of brisk hemorrhage, various cross-clamping maneuvers, and compression of abdominal vasculature, as well as potentially massive transfusion. Thus, frequent monitoring (i.e., at least every 30 minutes) of arterial blood gases, serum electrolytes, red cell mass, and laboratory measures of clotting is mandatory from the beginning of surgery.[172] During the active portion of the case, we interpret and respond to laboratory results as they are returned, allow for equilibration, and then recheck the laboratory values.

Metabolic acidosis may develop in the anhepatic phase because of portal cross-clamping, as well as partial or complete inferior vena cava cross-clamping, creating imperfect lower extremity and splanchnic venous return. In addition, any residual ability to clear organic acids is lost. At the time of reperfusion, the donor liver and underperfused tissues from the patient release acid loads. Ongoing transfusion of low-pH, citrated blood products also contributes to acidemia.

Various maneuvers can mitigate acidemia during liver transplantation. Hyperventilation can be used to establish an acute respiratory compensation for metabolic acidosis. Sodium bicarbonate can be administered to correct acidemia, although the need to minimize sodium loads, particularly in patients who are hyponatremic, may limit the usefulness of bicarbonate. Sodium bicarbonate must not be coadministered in the same infusion as Ca^{2+} solutions because the combination will precipitate. Tromethamine (THAM) can also be used to control acidemia.

Acidemia at the time of reperfusion should be corrected by hyperventilation and administration of bicarbonate. This minimizes the hemodynamic and cardiac effect of the acid load and metabolic waste products released by reperfusion of the allograft. However, overzealous correction of metabolic acidemia is undesirable, particularly in the setting of massive transfusion. The new liver clears citrate and organic acids, resulting in a rebound metabolic alkalosis; this may be seen developing even during the late neohepatic

phase. Thus, a reasonable strategy is to use modest hyperventilation to keep the pH near normal, with the use of bicarbonate of tromethamine only as needed to keep the pH above approximately 7.35 after respiratory maneuvers have been fully implemented.

Patients presenting for liver transplantation may be either hyperkalemic or hypokalemic, depending on whether potassium-sparing or potassium-wasting diuretics have been used to control ascites. Potassium balance is also influenced by the underlying renal function or compromise. Serum potassium is subject to strong influences favoring hyperkalemia during the anhepatic phase. This may lead to large swings in serum potassium levels, especially if renal function is compromised or if large volumes of blood products are required. Additionally, splanchnic ischemia during the case tends to elevate serum potassium. Metabolic acidosis tends to worsen hyperkalemia. Finally, the preservative solution in the donor liver is rich in potassium.

Dangerous levels of serum potassium should be treated to avoid myocardial irritability and cardiac dysrhythmias. In patients with preserved renal function, this is accomplished initially by controlling the pH, using potassium-wasting diuretics if the volume status permits, and avoiding potassium-containing solutions. Bicarbonate to increase pH tends to drive potassium intracellularly, whereas Ca^{2+} administration to replete deficits stabilizes irritable myocardium. Rapid or persistent increases in serum potassium are treated with glucose and insulin to drive potassium intracellularly by glucose cotransport. The combination of insulin and glucose predictably reduces serum potassium even during the anhepatic phase.[173]

If renal function is severely compromised, renal replacement therapy, either by continuous venovenous hemofiltration or by conventional dialysis, may be warranted to control serum potassium, sodium, and pH. Intraoperative renal replacement therapy can strain the resources of hospital dialysis services, so early consultation with a dialysis nephrologist is important once the need for such therapy becomes apparent.

Calcium is required for smooth muscle and myocardial contractility. Thus, hypocalcemia during liver transplantation depresses inotropy (manifested as depressed cardiac index, reduced cardiac stroke index, and left ventricular work index[174]) and reduces vascular tone. In this setting, vasopressor activity also is compromised. Hypocalcemia may interfere with clotting, as calcium is a required cofactor for many clotting factors. Thus, monitoring and correcting abnormal serum calcium levels are important. During liver transplantation, serum ionized calcium tends to decrease as a result of vigorous administration of citrated blood products. As a rule of thumb, administration of ≥ 6 units of acid-citrate-dextrose preserved packed red blood cells requires supplementation of calcium.

Calcium can be repleted with calcium gluconate or calcium chloride. The positive inotropic effects of calcium administration are quick in onset but are short lived. Overaggressive correction of ionized calcium intraoperatively precipitates a rebound hypercalcemia during the postoperative period as the liver metabolizes the citrate chelator. Thus, the goal of intraoperative calcium management is achieving the lowest ionized calcium concentration consistent with good cardiac performance and coagulation, typically 0.9–1.0 mmol/L. Postoperative hypercalcemia is treated with hydration and furosemide diuresis.

Serum sodium frequently is low in liver transplant patients because of formation of ascites, the effects of renal failure, the use of diuretics, or combinations of the three. Accidental aggressive overcorrection of hyponatremia should be avoided because too-rapid correction of hyponatremia can cause central pontine myelinolysis, an irreversible neurologic injury. Unfortunately, many useful replacement fluids contain sodium. For example, fresh-frozen plasma, packed red blood cells, and 5% albumin all contain sodium at normal physiologic concentrations. To maintain intravascular volume while avoiding too-rapid correction of hyponatremia, a strategy of administering colloids along with 5% dextrose while inducing a diuresis of sodium and water with furosemide can be used. In patients with renal failure, dialysis or continuous venovenous hemofiltration against a low-sodium bath can be used to remove the volume without increasing sodium too abruptly.

Glucose management during liver transplantation usually is fairly straightforward despite the liver's central role in glucose handling. The liver is the major site for gluconeogenesis, and this function is preserved to some degree in even the most severe cases of end-stage liver disease. Thus, complete hepatectomy creates the possibility of intraoperative hypoglycemia during liver transplantation. This is particularly true if the anhepatic phase of the operation is prolonged.

Serum glucose during liver transplantation is influenced by exogenous sources, including carrier infusions and release of glucose from graft preservation solution. Thus, intraoperative hypoglycemia is rarely a problem in practice, especially if some IV fluids (e.g., drug-carrier infusions) contain 5% dextrose. The liver is at once the major site of gluconeogenesis and insulin-mediated glucose uptake. Therefore, the anhepatic phase may be marked by hyperglycemia or hypoglycemia, both of which should be avoided and treated. Hypoglycemia tends to be the rule, especially during the anhepatic period. As in the case of other major operations, tight glycemic control probably is beneficial, and blood glucose concentration should be measured frequently, with a target blood glucose level of 150–200 mg/dL.

Renal Protection during Transplantation

Renal failure requiring renal replacement therapy (e.g., dialysis or continuous venovenous hemofiltration) is common after liver transplantation, with rates of approximately 5–10%.[175,176] Peritransplantation acute renal failure requiring renal replacement therapy is associated with higher mortality compared with liver transplant patients not requiring dialysis.[177] Whether a cause-and-effect relationship exists between acute renal failure and death after liver transplantation is not clear, but renal failure is an unwelcome outcome.

Protection of renal function probably depends, among other things, on maintaining renal perfusion during the liver transplant procedure. Renal perfusion is subject to many insults during transplantation, including hypovolemia and increased resistance to venous outflow due to vena cava compression or cross-clamping. Maintaining an adequate circulating volume facilitates preserving renal function. However, this can be difficult, and a selective medical thera-

py to protect the kidney in the peritransplant period would be useful.

Attention has focused on selective splanchnic vasodilators, such as low-dose dopamine, or, more recently, fenoldopam, as protective agents during major surgery. Fenoldopam has been studied in liver transplant patients randomized to one of three groups (fenoldopam, low-dose dopamine, or placebo) prior to surgery. Neither fenoldopam nor dopamine was superior to placebo for preservation of any measure of renal function (urine output, serum creatinine, creatinine clearance, use of diuretics, or use of pressors) immediately after surgery. On the third and fourth days after transplantation, creatinine clearance was reduced in patients receiving placebo or low-dose dopamine but was preserved in patients receiving fenoldopam.[178] The authors concluded that fenoldopam may counteract the renal arterial constrictive effects of cyclosporine.[178]

In this small, unblinded study, neither low-dose dopamine nor fenoldopam demonstrated obvious renal protective effects in the early perioperative period.[178] Similarly, another small study by the same researchers demonstrated that fenoldopam resulted in better creatinine and BUN values at day 3 after liver transplant, but the functional effect of this result on the incidence of acute renal failure was not demonstrated.[179]

More conventional approaches to renal protection include maintaining adequate circulating volume and perfusion pressure. Urine output is commonly used to judge real function in the operating room, and "target" urine flows of 1 ml/kg/hr are frequently sought. When the urine output falls below this target and the circulating volume and perfusion pressure are judged to be adequate, furosemide or mannitol is sometimes used to increase urine output.

Reperfusion of the Graft

Preparation for reperfusion involves optimizing volume status and hemodynamic performance and preparing the operating room for a potentially chaotic reperfusion period. Potential distractions related to the anesthetic (e.g., need to re-dose drugs, syringe changes, carrier infusions) should be addressed in advance. Laboratory studies should have been sent in time for the results to arrive 5 minutes prior to reperfusion.

Abnormalities in pH, serum potassium, or calcium should be corrected prior to reperfusion. Sodium bicarbonate, glucose and insulin, and calcium chloride should be prepared and ready for use. Some practitioners use combinations of these agents prophylactically prior to reperfusion.[138]

Vasopressors may be required at the time of reperfusion and should be available for immediate infusion. Because there is no compelling or logical best choice among the commonly used vasopressors, institutional preferences prevail. Epinephrine, dopamine, and norepinephrine all are acceptable choices. Vasopressors are also commonly used prophylactically at reperfusion, frequently as a small bolus such as epinephrine, 10 μg.

Just prior to reperfusion, the new liver is flushed antegrade from the portal vein to the hepatic vein to wash out the preservative solution (which contains large doses of potassium and heparin). Flushing is accomplished with crystalloid, colloid (such as 5% albumin), or blood. A blood flush is performed by constructing the portal and hepatic venous anastomoses, after which the portal anastomosis is completed but the hepatic venous anastomosis is left incomplete. The portal vein cross-clamp is removed, and blood is allowed to flush the liver and run out into the field, where it is recovered by suction. Concomitant with this controlled hemorrhage, fluid should be rapidly transfused to maintain euvolemia.

Graft reperfusion has its most obvious effect on cardiac performance, and the anesthesia team should be prepared for pulmonary hypertension and acute right-heart dysfunction. Liver transplantation in and of itself does not appear to cause right-heart dysfunction.[180] However, release of preservative solution, air, clot, and debris (as well as acidemic blood from the reperfused splanchnic circulation) into the pulmonary vasculature can cause sudden and severe pulmonary hypertension, elevated right-heart pressures, and right ventricular failure. Systemic pressure (and coronary perfusion pressure) decreases because of inadequate left ventricular preload. Elevated right-heart pressures may open an occult patent foramen ovale, with risk of paradoxical embolism.[181] Central venous pressure frequently increases because of right-heart and pulmonary congestion. Ordinarily this is desirable to a point to assure right ventricular preload. However, in the immediate reperfusion period, elevated central venous pressure compromises graft perfusion and may contribute to early graft failure. Thus, preserving or reestablishing efficient right ventricular pumping and a low-resistance pulmonary circulation is important.

Pulmonary hypertension, right ventricular overload, and the resulting central venous congestion reduce the hepatic perfusion pressure, which is simply the difference between the portal and central venous pressure when only the venous anastomoses have been constructed. The portal venous pressure is not typically measured, so the hepatic perfusion pressure is not directly accessible. However, inadequate perfusion pressure can be deduced if the liver becomes engorged. This alarming appearance somewhat mimics that of hyperacute rejection. To avoid confusion, hepatic perfusion pressure ideally is controlled by keeping the central venous pressure low at the time of reperfusion. This is not possible in the event of acute pulmonary hypertension unless inotropes and selective pulmonary vasodilators are used. Typically, the heart is supported with an inotrope, and the lungs are hyperventilated to raise the pH and induce pulmonary vasodilatation. Inhaled nitric oxide may be useful at this point.

Good communication between the surgical and anesthesia teams is important to minimize the effect of reperfusion. Reperfusion should not occur until the anesthesia team has optimized the patient's physiology, and this should be accomplished in time to allow prompt reperfusion. If severe problems occur at reperfusion, the surgeon can partially reclamp the portal vein to lessen the effect of the effluent from the new liver.

The combined effect of multiple insults on cardiac and pulmonary performance at reperfusion may lead to cardiovascular collapse. Advanced cardiac life support protocols directed at the presumptive major problem should be promptly initiated while the underlying insults are identified and corrected. In the event of cardiopulmonary arrest not responsive to pharmacologic support (or due to reversible causes such as pulmonary embolus), mechanical circulation and oxygenation can be provided by percutaneous femoral venoarterial cardiopulmonary bypass, with acceptable survival.[182]

In the early postreperfusion period, severe volume overload from overaggressive fluid replacement during the period of poor venous return may compromise hepatic perfusion, even with adequate cardiac performance. If the problem is slight, it may be possible to administer furosemide to induce diuresis or to wait for the blood volume to fall as a result of bleeding. In the case of severe volume overload and poor graft perfusion, phlebotomy from a large port on a central venous catheter is a logical option.

Neohepatic Phase

The neohepatic phase begins with the initial reperfusion of the liver. Frequently, the next step is constructing the hepatic arterial anastomosis. The liver ultimately needs a high-pressure, oxygenated perfusion source, and the surgical team will turn attention to this as soon as the immediate effects of venous reperfusion have passed. Opening of the hepatic arterial anastomosis usually has little or no hemodynamic effect.

An acute clot lysis syndrome frequently develops in the early neohepatic phase. This manifests clinically as diffuse bleeding from previously coagulated sites in the surgical field, new oozing from previously quiescent vascular catheter insertion sites, and ongoing transfusion requirements. Laboratory analysis shows a further elevation of the prothrombin time relative to baseline and a sometimes profound elevation of the partial thromboplastin time (e.g., to >150 seconds), as if the patient had received a large dose of heparin. Thromboelastography demonstrates poor clot initiation and rapid dissolution of clot. Fig. 56–16 shows sequential thromboelastograms obtained from a single patient during the course of transplantation.[183]

Because the cause of clot lysis syndrome is not completely understood, the ability to tailor treatment to specific causes is limited. Multiple mechanisms have been proposed and may operate simultaneously, including release of heparin (from preservative solution) during reperfusion or release of endogenous activators of tissue plasminogen activator and/or endogenous heparinoids from the graft.[170]

A central goal in this phase of the transplant is stopping clot lysis. A key first step toward achieving this goal is providing adequate levels of platelets and factors to support clotting in the face of ongoing consumption, with the expectation that a functioning graft will begin to provide appropriate clot lysis inhibitors and clotting factors on its own. Administration of a small (20–50 mg) dose of protamine[170] can be considered if clot formation is suspected to be deficient, especially if the liver flush prior to reperfusion was not optimal and the patient might have received heparin from the graft.

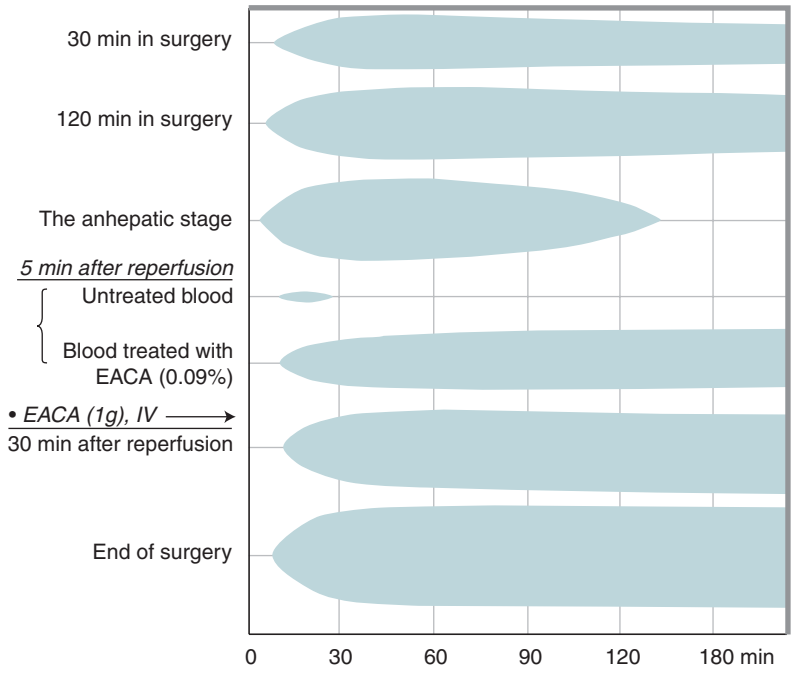

FIGURE 56–16. Sequential thromboelastograms from a single patient undergoing liver transplantation. Marked fibrinolysis developed during the anhepatic phase. Note development of severe coagulopathy in the "5 min after reperfusion" sample consisting of poor clotting and early fibrinolysis more severe than during the anhepatic phase. ε-Aminocaproic acid (EACA) was given and arrested the clot lysis. (From Kang et al.[183] with permission.)

Fibrinolytic activity is frequently increased during liver transplantation, reflecting reduced hepatic clearance of tissue plasminogen activating factor during the anhepatic phase and release of tissue plasminogen activator from the epithelial cells of the reperfused graft.[184–186] In addition, plasminogen activator inhibitor-1 activity is reduced[185] during transplantation. Fibrinolysis probably contributes to the unwanted clot lysis syndrome after reperfusion.

Strategies for reducing fibrinolysis and transfusion requirements include use of antifibrinolytic agents such as aprotinin,[187] tranexamic acid, and ε-aminocaproic acid.[188] However, use of antifibrinolytics in liver transplantation is somewhat controversial because of concerns about unwanted thrombosis.

ε-Aminocaproic acid and tranexamic acid both are synthetic analogues of the amino acid lysine. ε-Aminocaproic acid and tranexamic acid competitively inhibit the binding of plasminogen (a lysine protease) to lysine residues on fibrin, thus inhibiting fibrinolysis. Both drugs also prevent the conversion of plasminogen to plasmin, again by acting as competitive antagonists of a lysine protease. ε-Aminocaproic acid is used during liver transplantation as a loading dose (typically a 1- to 2-g bolus over 1–10 minutes), followed by infusions of 1–2 g/h. It reliably arrests fibrinolysis as assessed by thromboelastography (Fig. 56–16).[183] The drug is eliminated by the kidney, with 65% of a dose appearing unchanged in the urine. The elimination half-life of ε-aminocaproic acid is approximately 2 hours.

Tranexamic acid is 6–10 times more potent than e-aminocaproic acid and has a longer elimination half-life. It also is renally eliminated, with 95% of the drug appearing unchanged in the urine. It is the least well studied of the three major antifibrinolytics.[188] Dose rates between 2 and 40 mg/kg/h have been reported in small studies with either ε-aminocaproic acid or aprotinin as comparisons.

Aprotinin is a protease inhibitor isolated from the lungs of swine and cows. It inhibits a variety of human proteases, including plasmin, trypsin,

kallikrein, chymotrypsin, activated protein C, and thrombin. These proteases are important in fibrinolysis and coagulation, as well as complement activation and inflammation. Each uses a serine residue for catalysis at the active site, and aprotinin acts by forming a specific aprotinin-active site serine complex with each protease. Aprotinin has an approximately 1-hour redistribution half-life after a bolus and a 7- to 10-hour elimination half-life. It is given as a bolus, followed by an infusion. A typical bolus is 2 million kallikrein inactivator units (KIU), followed by an infusion of 500,000 to 1 million KIU per hour.[188]

Use of antifibrinolytic drugs may have deleterious effects. Anecdotal evidence indicates that antifibrinolytic therapy may increase the incidence of thrombotic events during liver transplantation, including fatal pulmonary thromboembolism.[189] Additionally, aprotinin is no more effective than are the lysine analogues, but it is associated with higher morbidity and mortality relative to these other drugs when used in cardiac surgery.[105] This finding suggests that, during liver transplantation, antifibrinolytic agents should be reserved for patients who have a relatively high risk of severe hemorrhage,[190] and that aprotinin might best be avoided altogether. However, the clotting cascade in liver transplant patients is quite deranged, and cardiopulmonary thromboembolism, even in the absence of exogenous procoagulants, may be more common than is usually appreciated.[134]

Thus, antifibrinolytics might be considered for rescue if bleeding becomes a problem in the postanhepatic phase,[188] as judged by the disappearance of clot from the surgical field, or as a prophylactic measure in patients expected to have severe bleeding problems (e.g., multiorgan transplant in a patient with renal failure). Balanced against this cautious approach are some practices that advocate use of antifibrinolytics prophylactically, in advance of any pathologic bleeding.[188] However, in addition to enhanced fibrinolysis, many other factors contribute to blood loss late in orthotopic liver transplantation, including coagulopathy due to synthetic failure, thrombocytopenia, platelet dysfunction, dysfibrinogenemia, dilutional coagulopathy, hypothermia, and bleeding from surgical technical problems. Because postreperfusion fibrinolysis is largely a diagnosis of exclusion, all of these other factors must be ruled out before administration of potent procoagulants.

Procoagulant agents, such as purified specific clotting factors, can be used, either prophylactically or as attempted therapy for excessive bleeding. For example, in one study, recombinant factor-7 corrected coagulopathy when given as single bolus prior to transplant but had no effect on transfusion requirements.[191] In a different study, recombinant factor-7 was used in a small number of patients but had no clear evidence of clinical harm or benefit.[192] Recombinant factor-7 has the theoretical advantage of being selective only for areas that are bleeding, that is, areas that have sustained tissue damage. This is because recombinant factor-7 requires tissue factor for full activity, and tissue factor is available only in areas where the subendothelial layers are exposed. Of course, the vascular anastomoses in the new graft would have exposed tissue factor, at least theoretically increasing the risk of thromboses of the anastomoses. Furthermore, recombinant factor-7 apparently is not as selective as initially hoped. A recent report documents many episodes of arterial and venous thromboses distant from the hoped-for site of action (e.g., cerebrovascular accident, myocardial infarction, pulmonary embolism, and deep venous thrombosis) when recombinant factor-7 was used in various "off-label" applications.[107]

If the fibrinolysis reaction cannot be controlled, the patient will have an ongoing transfusion requirement. The anesthesia team should quantify the hourly transfusion needs in the neohepatic phase and make preparations to meet this need during the end of the case, the move from operating room table to ICU bed, transport to the ICU, and in the ICU itself.

During the neohepatic phase, the anesthesia team prepares for the postoperative disposition of the patient. Most liver transplant recipients are discharged from the operating room to an ICU bed. The anesthesia team seeks to manage this transition as smoothly as possible. The patient should be transported on an ICU bed, with all necessary infusions running and the patient fully monitored. Comprehensive communication between the operating room and the ICU team is essential to facilitate the smooth transition of care.

The anesthesia team also prepares for the early postoperative care of the patient. Very early extubation (i.e., in the operating room) is possible and desirable.[193] Suitability for extubation is influenced by many factors. Among these are the intraoperative transfusion requirement (as a warning of possible airway edema); the presence or development of pulmonary, cardiac, and renal compromise; and the presence and severity of encephalopathy.[194] Fluid administration and possible volume overload are some of many factors that can interfere with the patient's readiness for extubation at end of case. In one study, controlled fluid administration supported by adjuvant vasopressors led to reduced rates of reintubation.[195] Intraabdominal hypertension is common after orthotopic liver transplantation and limits the potential for extubation. Intraabdominal hypertension (pressure > 25 mm Hg in the bladder) developed in 32% of patients[196] in one series. It is expected that these patients are less likely to meet criteria for early extubation and will be harder to wean from the ventilator.

If in doubt, it is always acceptable and prudent to leave the patient intubated for pulmonary support in the early postoperative period. Postoperative mechanical ventilation allows the team to focus on ongoing transfusion requirements, to exclude the possibility of intraabdominal hypertension, and to gradually prepare the patient for extubation. Despite the concern about elevated intraabdominal pressures on graft viability, postoperative application of positive end-expiratory pressure (PEEP) does not have a major effect on graft function, although in half of the patients the cardiac output declined with PEEP.[197] This finding is encouraging because PEEP may be needed to counteract the pulmonary consequences of intraabdominal hypertension.

Pain management after liver transplantation is relatively straightforward. Many patients remain intubated and receive potent opioids as sedatives. Epidural analgesia is traditionally avoided because of profound coagulopathy manifested by end-stage liver disease patients, both preoperatively and in the postoperative period. Furthermore, orthotopic liver transplant patients have less postoperative pain than do hepatectomy patients.[198] The reason

for this difference in pain threshold is unclear, although some have implicated the steroids used for immunosuppression. Steroids have analgesic properties in other patient populations.[199]

Perioperative Complications of Liver Transplantation

Complications of liver transplantation are frequent. Here we focus on the early complications of liver transplantation, that is, those that occur in the operating room or the ICU within hours or days of the procedure.

Complications and risks of massive transfusion consist of pulmonary edema, transfusion-related acute lung injury,[200,201] and viral infection. Much attention has focused on transmission of cytomegalovirus. The incidence of cytomegalovirus transmission is much higher with a cytomegalovirus-infected donor organ than with blood that has not been screened or reduced for cytomegalovirus.[202] Many centers now use routine pharmacoprophylaxis against cytomegalovirus infection because leukoreduction of blood or use of cytomegalovirus-negative donors has been deemed impractical by many blood banks.

Massive transfusion contributes to the development of intraabdominal hypertension. Patients with intraabdominal hypertension had a higher incidence of renal failure, more postoperative complications, and higher ICU mortality than did patients without this complication.[196]

Anastomotic leaks involving the vascular or bile duct connections can prompt reexploration and anastomotic revisions. Anastomotic bleeding tends to be most severe during the latter stages of the surgery and on the first postoperative day. An ongoing brisk transfusion requirement, an expanding abdomen, or falling hematocrit can prompt reexploration even before leaving the operating room. The threshold to reexplore for bleeding should be low because an abdomen full of blood or clot is a nidus for infection. In addition, the compressive effect of a large hematoma potentially compromises graft, pulmonary, and cardiac function. Reexploration in the early postoperative period should be handled with the same degree of preparation as the original transplant procedure. In particular, a disruption of one of the anastomoses without surgical control of the vessel will lead to massive hemorrhage.

Other vascular complications necessitating prompt reexploration include stenosis and thrombosis of the anastomoses of the liver vessels. These complications may occur intraoperatively or postoperatively. In the postoperative period, vascular patency is monitored by serial ultrasound examinations.[203] Hepatic artery thrombosis is the most common vascular complication in the postoperative period.[203] If the condition is not diagnosed and treated promptly, severe graft dysfunction or total graft loss will occur. Treatment of hepatic artery thrombosis usually requires urgent reoperation to remove the obstruction. If flow cannot be restored, the patient probably will needs to be relisted for liver transplantation as a Status 1 candidate. However, there is a small but growing experience of temporizing with hyperbaric oxygen therapy.[204]

Neurologic complications are relatively common after liver transplantation. Their causes are multifactorial, related both to intraoperative and early postoperative events, as well as the ongoing effects of toxic immunosuppressants. Of particular concern to anesthesiologists is central pontine myelinolysis,[205] which has been associated with rapid correction of hyponatremia in the peritransplant period. The syndrome is characterized by a general neurologic decline hours or days after a sudden correction of hyponatremia. Much attention focuses on central pontine myelinolysis because patients presenting for liver transplantation frequently are hyponatremic and because of the association between the syndrome and an inciting event (e.g., rapid correction of hyponatremia). However, central pontine myelinolysis is a relatively rare neurologic complication of liver transplantation. For example, in a study of 463 patients receiving transplants at multiple centers,[206] 93 (20.1%) patients had peritransplant neurologic complications. Of these patients, six (1.2% of the starting cohort) were confirmed to have central pontine myelinolysis. Two of these patients had rapid increases in serum sodium concentration for a period of hours during transplant; the rest did not.[206] In another multicenter prospective cohort study involving 1730 liver transplant patients, 60 patients had radiologically confirmed central nervous system lesions. Of these patients, five (0.3% of the original cohort) had central pontine myelinolysis.[207]

BOX 56–10.

Procedures for Alleviating Portal Hypertension and/or Ascites

- Nonshunting Procedures
  - Endoscopic therapy for esophageal varices
  - Percutaneous embolization of varices
  - Surgical ligation of varices, including hemorrhoids
  - Portal–azygous disconnection
- Surgical Vascular Shunting Procedures
  - Nonselective shunts
    - Portocaval shunt
    - Mesocaval shunt
    - Proximal splenorenal shunt
  - "Selective" vascular shunt
    - Distal splenorenal shunt
- Percutaneous Vascular Shunting Procedure
  - Transjugular intrahepatic portosystemic stent shunt
- Peritoneovenous Shunts (Nonvascular)
  - Denver
  - LeVeen

SPECIAL OPERATIONS ON THE LIVER

Procedures for Portal Hypertension and Ascites

A variety of surgical and minimally invasive interventional procedures have been developed to ameliorate the problems associated with liver disease. Portal hypertension underlies most of these problems, leading to ascites or to varices that are the source of life-threatening hemorrhage. Procedures for alleviating portal hypertension and ascites are listed in Box 56–10. They are divided into *nonshunting* procedures (i.e., those that do not seek to redirect portal venous flow) and *shunting* procedures. Nonshunting procedures aim to control hemorrhage from portosystemic varices. Varices at the gastroesophageal junction are the most troublesome of the portosystemic varices, but they are amenable to endoscopic therapy. Shunting procedures redirect the portal venous flow into the systemic venous circulation

via a nonvariceal conduit, thus relieving portal hypertension, decompressing varices, and relieving ascites. Because these shunts bypass the liver, they may create new problems as a result of encephalopathy. Shunting procedures have undergone a transformation from open surgical procedures performed on high-risk patients (high Child-Turcotte-Pugh scores predicting elevated perioperative morbidity and mortality) to a more minimally invasive approach.

Nonshunting Procedures for Portal Hypertension

These procedures (e.g., ablation of esophageal varices or hemorrhoids) aim to reduce variceal hemorrhage. The procedures ligate decompressive alternate conduits for portal blood flow around the cirrhotic liver, so they are expected to worsen portal hypertension and ascites. Minimally invasive procedures have largely replaced surgical approaches for managing varices. Minimally invasive approaches include endoscopic ligation or embolization (e.g., endoscopic sclerotherapy of esophageal varices) and percutaneous embolization procedures. Many of the minimally invasive procedures for obliterating varices are performed outside of the operating room (i.e., in remote procedure areas in the hospital), frequently with local or topical anesthesia and conscious sedation provided under the direction of the proceduralist. Thus, anesthesiologists now encounter relatively few patients presenting for variceal ligation, and frequently these are only the most complex procedures, the sickest patients, or both. Anesthesia for these patients should follow the model for patients with severe decompensated liver disease outlined in Chapter 14.

Portosystemic Shunts

Portosystemic shunts aim to reduce the hydrostatic pressure in the portal venous system by providing an alternate, nonvariceal conduit that bypasses the cirrhotic liver. A variety of approaches have been developed to shunt portal venous blood away from the liver and into the central venous circulation, first by open surgical procedures and now increasingly via percutaneous approaches. Again, there is a group of patients whose medical conditions or procedural needs preclude a minimally invasive approach, so a limited population of patients present for surgical portosystemic shunts.

Open Portosystemic Shunts

Surgical or "open" portosystemic shunts are listed in Box 56–10. Each is designed to reduce portal hypertension, differing mostly in the topology of the vascular connection that is constructed. In every case the surgery is an open abdominal procedure in which venous vascular anastomoses are constructed. Anesthesia for open portosystemic shunts should follow the model described for patients with decompensated end-stage liver disease described in Chapter 14.

Transjugular Intrahepatic Portosystemic Stent Shunts

Transjugular intrahepatic portosystemic stent shunts (TIPSS) are indicated for patients with refractory ascites because of portal hypertension. Refractory ascites carries substantial morbidity (i.e., spontaneous bacterial peritonitis, renal failure) and has a 1-year survival rate $<50\%$. Thus, removal of ascites may benefit these patients, and TIPSS is successful in decompressing the portal system in approximately 90% of cases. A meta-analysis of studies comparing TIPSS with conventional therapy (periodic large volume paracentesis) indicates that TIPSS is superior for removing ascites but at the expense a higher incidence of hepatic encephalopathy.[208] This comes as no surprise, as the shunt routes blood past the liver.

TIPSS has important implications for subsequent orthotopic liver transplantation. For example, TIPSS causes transient (lasting approximately 6 months) increases in cardiac volume load. Importantly, pulmonary systolic pressures (as estimated during transthoracic echocardiography) in one cohort increased from approximately 30 mm Hg prior to TIPSS to 44 mm Hg in the period immediately after TIPSS,[209] potentially jeopardizing candidacy for transplantation. During transplantation, the shunt must be removed along with the diseased liver. Because the shunt by design drains into the hepatic venous circulation, a piggyback technique may be precluded if the shunt protrudes into the proximal hepatic veins. The presence of a TIPSS frequently leads to a complicated and bloody dissection during the hepatectomy phase of liver transplantation. In extreme cases, the shunt can be dislodged and migrate into the right-heart or pulmonary circulation.[210]

TIPSS is frequently performed "off site" (i.e., in a radiology procedure area rather than an operating room), so all of the special concerns for out-of-operating room anesthesia apply. Patients presenting for TIPSS usually are severely debilitated and may be acutely ill, and this level of acuity coupled with the out-of-operating room location magnifies the effort required to safely care for these patients.

Monitoring for TIPSS should be tailored to meet the needs of the patient and the anesthetic plan. Standard monitoring usually is sufficient for patients having TIPSS under sedation, monitored anesthesia care, or general anesthesia. TIPSS usually is performed under monitored anesthesia care or general anesthesia because the procedure can require long periods of immobility, and it may be difficult or impossible for an awake patient with massive ascites to remain motionless and supine for the procedure.

The TIPSS procedure typically does not involve large fluid shifts or the potential for massive hemorrhage, so a reliable peripheral IV catheter usually is sufficient vascular access. The invasive radiologist establishes separate central venous access for the procedure, usually via the right internal jugular vein. The radiologist then tunnels a catheter from the inferior vena cava (actually a hepatic vein) through the liver parenchyma and into the portal circulation. The shunt is then placed via the catheter and dilated within the liver parenchyma.

Complications of TIPSS are relatively common but must be balanced against the complications of no therapy, frequent large-volume paracentesis, and surgical portosystemic shunts, none of which are benign. Complications of TIPSS include those of central venous cannulation in patients with coagulopathy. Complications related to central venous cannulation can be avoided or minimized by using an internal jugular site (which is compressible in the event of inadvertent arterial puncture) and ultrasound guidance to visualize the target vessel during the vascular access procedure. The procedure requires passing guidewires, catheters, and dilators from the superior vena cava, through the right atrium, and into the inferior vena cava. Cardi-

ac perforation and tamponade[211] have occurred as rare complications. Acute volume overload[209] from sudden outflow of portal blood into systemic circulation is a much more frequent complication. Hepatic encephalopathy occurs frequently after TIPSS.[212] Encephalopathy is refractory to treatment or prophylaxis,[212] and acute onset of encephalopathy may make extubation impossible.

Hepatic Donation

Heart Beating Cadaveric Donor

Most livers made available for transplantation come from heart beating cadaveric donors and are obtained in the course of harvesting other organs. Anesthesia care often is complicated by the numerous complex physiologic derangements manifested by these organ donors.[213] Such physiologic changes are responsible for the loss of up to 25% of potential organ donors.[214] Hemodynamic instability commonly develops and may occur in two phases. An initial phase may occur soon after brain death, characterized by excessive sympathetic activation leading to tachycardia, vasoconstriction, hypertension, and increased cardiac workload. This may be followed by a hypotensive phase in which sympathetic activity is reduced, leading to loss of vascular tone, decreased cardiac output, and hypotension.[215] Hemodynamic stability may be further compromised by volume depletion resulting from prior use of diuretics to manage elevated ICP, blood loss from injuries, insensible losses, and/or diabetes insipidus associated with damage to the neurohypophyseal–hypothalamic axis.

Sympathetic stimulation can be treated with short-acting β-blockers and vasodilators that may be easily titrated, such as nitroprusside and esmolol. As the brain-dead patient progresses into the hypotensive phase, it must be remembered that hypotension can have multiple causes. It is important to identify and appropriately treat the underlying etiology. Hypovolemic patients should receive volume resuscitation to achieve a hematocrit of 30%. Beyond that, crystalloid solutions are appropriate to replace free water as guided by central venous pressure measurements and to maintain or correct electrolyte and glucose concentrations. To reduce volume loss and electrolyte derangements associated with diabetes insipidus, desmopressin acetate (DDAVP) can be administered. Vasopressors and inotropic drugs are appropriate for donors with impaired vascular tone or myocardial function, respectively, to maintain adequate perfusion to organs. In such cases, therapy is most effectively guided by measurements of cardiac function and central filling pressures using a pulmonary artery catheter and/or echocardiography.

Organ donors can present with significant pulmonary dysfunction.[216] Neurogenic pulmonary edema is most commonly observed in patients with increased ICP, and although the etiology is not entirely clear, it likely is related to excessive sympathetic stimulation. Excess pulmonary interstitial and alveolar fluid can be treated with fluid restriction and diuresis, but it should be recognized that a negative fluid balance may compromise the viability of other organs. Other common causes of pulmonary dysfunction in organ donors are pneumonia, pulmonary emboli, mucus plugging, and pulmonary contusions.

An important principle to recognize when caring for organ donors is that the focus of care has shifted from preserving the patient to preserving the function of graft organs. This can best be achieved by being well prepared; organ harvesting is a major surgical procedure that requires full homeostatic support for the donor organs. In addition to routine intraoperative monitors, intraarterial and central venous or pulmonary artery catheters are required. Because procurement may be accompanied by significant blood loss, it is important to be adequately prepared with large-gauge IV catheters and packed red blood cells for transfusion. Inotropic agents and vasopressors should be readily available to treat hypotension caused by myocardial dysfunction and reduced vascular tone. Nondepolarizing neuromuscular blockers should be used to facilitate surgical exposure and ablate reflex movements mediated by the spinal cord. General anesthesia is not necessary, but general anesthetic drugs may be useful for blunting the hemodynamic response to surgical stimulation associated with the dissection.

Living Donor

The shortage of cadaveric livers has led to the use of living donors to meet the growing need for liver grafts. Donor safety is a primary concern, as the donor derives no physical benefit from the surgery. Donor deaths have been reported during the perioperative period, and serious complications can occur. Like orthotopic liver transplantation itself, living donor hepatectomy has a steep and long learning curve with many opportunities for morbidity. For example, in one program, major complications were frequent in the first 50 living donor patients but declined significantly in the subsequent 50 patients.[217] In experienced centers, living donor hepatectomy can be performed with an average blood loss of 1 L and minimal requirements for transfusion.[218]

The majority of liver transplantations using living donors involve donor–recipient pairs who are ABO compatible. ABO-incompatible transplantations can be performed in some cases, but recipient survival outcomes are markedly worse.[219] Potential donors should undergo thorough screening to assess their suitability. Such screening includes a detailed history along with physical and psychological examinations, evaluation of routine laboratory values with particular attention to measurements of liver function, testing for transmissible viral illnesses, and, in some cases, percutaneous liver biopsy. Radiologic imaging studies are a routine part of the donor evaluation. Doppler ultrasound can be used to detect gross pathologic conditions such as tumors and portal vein thrombosis. CT and MRI are useful for defining a potential donor's vascular anatomy and hepatic volume and for providing a roadmap for surgical planning.[220]

Typically a right hepatic lobectomy from an average-sized adult living donor provides sufficient liver mass for an adult recipient. A left hepatic lobectomy from an adult donor provides enough liver mass for a pediatric recipient. This is advantageous for the donor, as the larger right hepatic lobectomy regularly leads to transient measurable compromise in liver synthetic function, with resultant coagulopathy.

General anesthesia for a living donor hepatectomy can be induced and maintained using a variety of techniques. Anesthetic concerns for living donor hepatectomy are similar to those of any major intraabdominal surgical procedure and include the potential for significant hemorrhage and hemodynamic changes. In particular, systemic vascular resistance commonly decreases after donor hepatic resec-

tion, whereas cardiac output and heart rate increases.[92] The cause(s) of these changes is not known, but a role for splanchnic mediators, such as endotoxins, has been suggested.[221] Maintaining low central filling pressures has been recommended for reducing intraoperative blood loss and improving surgical exposure.[222] However, these benefits must be balanced against the potential increased risk of air embolism.

Because transient coagulopathies are commonly observed in the early postoperative period, the placement of epidural catheters for postoperative analgesia is the subject of controversy.[223–225] However, pain control requires careful consideration, and some programs use epidural catheters. In one study, donor hepatectomy patients had more pain than did patients having equivalent-sized right hepatectomy for tumor resection, despite identical pain management regimens, including thoracic epidural use.[226] The authors suggested that this finding might be due to longer operative times required for donor hepatectomy.[226] Postoperatively, liver donors have significant coagulopathy, which can complicate the timing of discontinuation of epidural analgesia.[224,227] On the other hand, thromboelastography studies indicate that liver donors become hypercoagulable during the first postoperative week, despite conventional laboratory studies that indicate elevations of conventional coagulation parameters, such as partial thromboplastin time or activated prothrombin time and thrombocytopenia.[228] This may give a protective effect against epidural hematoma, but this theory has not been tested.

Donation after Cardiac Death

The number of livers from brain dead donors has been relatively stagnant, and living donation is not a common option. The shortage of organs has resulted in renewed interest in a procedure for recovering organs known as *donation after cardiac death.* This term refers to a donation protocol for patients who have sustained a traumatic brain injury but do not meet the definition of brain death and thus cannot be declared brain dead. Nevertheless, families may realize that there is no hope for recovery and decide to withdraw invasive life support. Once such a decision has been made, the family may decide to donate the patient's organs after cardiac death has occurred.

Donations after cardiac death occur only after patients are declared dead after cardiac and respiratory arrest following the removal of life support. Donation after cardiac death is considered only after the family has decided to withdraw life support. The patient is taken to the operating room, usually with the family in attendance. There, the patient is extubated, vasoactive infusions may be discontinued, and the patient is allowed to die peacefully. The family leaves the room, and surgical removal of organs for transplantation ensues.

Donation after cardiac death exposes the donor liver to a period of warm ischemia that does not occur in beating heart donors. Liver viability declines as a function of the elapsed time after cardiac arrest in animals.[229] In humans, the immediate outcomes appear to be worse in recipients of donation after cardiac death livers compared with recipients of beating heart donor organs, but the overall outcomes appear promising relative to no organ at all.[230]

Despite the fact that donation after cardiac death involves patients who are dead by every definition and hence have no use for homeostatic support, there is much that the anesthesia team can contribute to these cases. Planned death in the operating room, with grieving family members present in large numbers and in civilian dress, is an extraordinary event and flies in the face of many of the assumptions and mores of operating room personnel. Anesthesiologists can manage operating room access to allow donation to occur promptly and with respect to the deceased and his or her family, even to the point of mediating the cancellation of elective surgery to facilitate these singularly lifesaving events.

The anesthesia teams should sequence the preparation of recipient(s) to minimize donor organ ischemic time if possible. Anesthesiologists currently do not have any direct interaction with the donor, except possibly to perform the extubation. Extubation should be skillfully handled, both to protect family members from unnecessary psychological trauma and to minimize the risk of aspiration that spoils the lungs for donation. Anesthesiologists may become more involved in donation after cardiac death cases, as they may be asked to reintubate the trachea for lung protection (allowing lung donation) after asystole occurs.

CHAPTER 57

Anesthesia for Heart or Lung Transplantation

Benjamin A. Kohl, MD, and
Joseph S. Savino, MD

INTRODUCTION

Heart and/or lung transplantation is an emergency operation for extremely ill patients who have very little organ reserve. Understanding the anesthetic implications and underlying pathophysiology is necessary for a successful outcome. This chapter reviews heart and lung transplantation, with an emphasis on intraoperative anesthetic management and postoperative care. The first section reviews the history of lung and heart transplantation. The second section discusses surgical alternatives. The third section reviews the immunobiology of transplantation, which perhaps is the area in which most research has been devoted. The fourth section reviews methods of organ procurement and the concept of reperfusion and "washout" and discusses various methods used in protecting the allograft. The remainder of the chapter is devoted to specific anesthetic concerns, management, recovery, and postoperative complications. The perioperative care of patients undergoing lung and heart transplantation challenges even the most experienced anesthesiologists, surgeons, and intensivists, and dedicated teams are devoted to this high-risk procedure despite its relative low volume.

HISTORICAL ASPECTS

The history of heart and lung transplantation parallels the development of immunosuppression (Table 57–1). From an historical standpoint, many of the pioneers in transplantation received little notoriety because their experiments were performed on animals. In 1946, Vladimir P. Demikhov was the first to perform intrathoracic transplantation of the heart alone, lung alone, and the heart and lungs in a warm-blooded animal.[1,2] Incidentally, these operations were performed without use of hypothermia or extracorporeal oxygenation. Similarly, heart transplants were first performed in dogs by Alexis Carrel and Charles Guthrie in 1905,[3] but attempts at human orthotopic heart transplantation were not made until the 1950s. Finally, although Reitz and Shumway are credited with the first heart–lung transplant in humans in 1981, Denton Cooley, in 1968, first replaced the heart and lungs of a 2-month-old infant, who had an atrioventricular canal defect, with those of an anencephalic donor. Although the recipient survived only 14 hours, precedent was certainly established for future endeavors.[4–6] These are the heroes of modern-day transplantation. First-person accounts of their trials and tribulations abound in the literature and convey the frustrations many went through to advance the field to its current level.[7–9]

Epidemiology

Lung Transplant

The most common indications for lung transplantation in the United States are chronic obstructive lung disease (par-

KEY POINTS

1. All heart and/or lung transplantations are considered emergency operations. As a result, the anesthetic preparation and management should reflect a consideration of the risks inherent in such a patient population.
2. The most common indications for adult cardiac transplantation are ischemic and idiopathic dilated cardiomyopathies. The most common indications for adult lung transplantation are chronic obstructive pulmonary disease (particularly emphysema and α_1-antitrypsin disease) followed by cystic fibrosis.
3. Acute rejection after lung transplantation occurs with greater frequency compared with transplantation of other solid organs, particularly during the first 6 months after surgery. Thus, timely administration of immunosuppressants is believed to be of key importance in lung transplantation.
4. Although immunosuppressant agents have dramatically reduced the incidence of acute rejection after cardiac transplantation, these drugs have been implicated in cardiac allograft vasculopathy, which remains a leading cause of morbidity and mortality among heart transplant recipients.
5. Patients with primary pulmonary hypertension may have an exacerbation and incremental increase in pulmonary vascular resistance caused by anxiety and agitation. Sedation with minimal respiratory depression is the goal in the lung transplantation population.
6. Typically, aortic cross-clamping of the donor coincides with induction of general anesthesia in the recipient. This coordinated event across centers is intended to achieve arrival of the donor organ at the recipient's operating room at the time when the recipient has been prepared for receiving the new organ. Delay in implantation of the transplanted organ leads to increased organ ischemia and may increase the risk for early postoperative graph failure.
7. The anesthetic management of end-stage lung disease patients is aimed at minimizing further increases in pulmonary vascular resistance, as the patient is transitioned from the awake spontaneously breathing condition to the anesthetized, paralyzed, mechanically ventilated condition.
8. Familiarity and appreciation of pulmonary allograft physiology is imperative for ventilation of the new lung. Native lung explantation and subsequent allograft implantation produce denervated lungs and airways, loss of a functional pulmonary system, and loss of bronchial artery blood flow.
9. The most common disorders that lead to heart transplantation are ischemic cardiomyopathy, idiopathic cardiomyopathy, congenital heart disease, and viral myocarditis.
10. Right-heart failure can be precipitated by increased pulmonary vascular resistance in the cardiac recipient. Treatment includes inotropes and pulmonary vasodilators, as well as hyperventilation, increasing oxygen tension, decreasing positive end-expiratory pressure, and decreasing lung water.

TABLE 57–1.

Key Time Points in the History of Heart and Lung Transplantation

Date	Event
1962	Introduction of antirejection drug azathioprine (Imuran).
1963	First single-lung transplant performed by Dr. James D. Hardy (University of Mississippi, Oxford, Mississippi). The patient died on postoperative day 8. Immunosuppressive regimen included azathioprine and mediastinal irradiation.
1967	First successful heart transplant performed by Dr. Christian Barnard (Groote Schur Hospital, Cape Town, South Africa). The patient died on postoperative day 18. Immunosuppressive regimen included azathioprine, prednisolone, and mediastinal irradiation.
1969	First artificial heart implantation (Liotta Total Artificial Heart) performed by Dr. Denton A. Cooley (Texas Heart Institute, Houston, Texas). The patient survived for 64 hours, at which point she received a donor heart.
1978	Introduction of the immunosuppressant cyclosporine.
1981	First successful heart–lung transplant performed by Dr. Bruce Reitz and Dr. Norman Shumway (Stanford University, Stanford, California). Immunosuppressive regimen included cyclosporine.
1982	First permanent artificial heart (Jarvik 7) implanted by Dr. William C. DeVries (University of Utah, Salt Lake City, Utah). The 61-year-old patient survived for 112 days.
1983	First successful long-term single-lung transplant performed by Dr. Joel Cooper (Toronto General Hospital, Toronto, Ontario, Canada) in patient with pulmonary fibrosis. The patient survived 6 years (died of progressive renal failure).
1986	First successful double-lung transplant performed by Dr. Joel Cooper (Toronto General Hospital, Toronto, Ontario, Canada) in patient with emphysema. The patient survived 15 years (died of brain aneurysm).
1990	Introduction of the immunosuppressant FK506 (tacrolimus).

TABLE 57–2.

Ideal Donor Criteria for Lung Transplantation

Age <55 years
ABO compatibility
No radiographic anomalies
No history of tobacco use
No evidence of pulmonary contusion or other chest trauma
No evidence of aspiration
No evidence of sepsis
Pristine bronchoscopic appearance/ no purulent secretions
$<10^5$ organisms on quantitative sputum sample
$Pa0_2$ >300 mm Hg on FiO_2 = 1.0, PEEP 5 cm H_2O
No prior thoracic surgery

Reprinted and adapted from Orens JB, Boehler A, de Perrot M, et al. A review of lung transplant donor acceptability criteria. J Heart Lung Transplant 2003;22:1183–1200. Copyright Elsevier 2003.
FiO_2, Fraction of inspired oxygen; PEEP, positive end-expiratory pressure.

ticularly emphysema and α_1-antitrypsin deficiency) followed by cystic fibrosis.[10] Other indications include pulmonary fibrosis, sarcoidosis, and primary pulmonary hypertension. Less commonly, lung transplantation has been offered as a viable option for patients with bronchoalveolar carcinoma.[11] The U.S. Organ Procurement and Transplantation Network (OPTN) and the Scientific Registry of Transplant Recipients (SRTR) jointly published an annual report (dating back to 1993) of organ-specific statistics.[12] Recipients are getting older and, as a result, have an increasing incidence of comorbidities. In 1993, patients older than 50 years composed only 43% of registrants, whereas in 2005 this age group composed almost 60% of registrants. Similar to heart transplantation, the major limiting factor in the number of lung transplantations is the availability of donor organs. In 2004, the Transplant/Immunology Network of the American College of Chest Physicians (ACCP) published a survey of practice patterns among North American transplant centers.[13] The number of lung transplantations performed ranged from 0–87 in the United States, whereas the average number of lung transplants performed annually, in responding centers, was 22. Although patient selection criteria showed a remarkable degree of consistency, there was profound variability in posttransplant management.[13,14] Clearly this represents a "snapshot" in time. However, this survey is the most comprehensive assessment available regarding clinical practice patterns in North America.

The suitability of lung donation is based on a number of criteria (Table 57–2).[15] However, as the waiting list continues to expand (reaching a new high of 3836 registrants as of December 31, 2003), guidelines for donation criteria likely will be revisited. A total of 1080 lung transplants were reported in 2003, representing a 3.7% increase from the previous year. Although patient survival after lung transplantation continues to improve, both 1- and 5-year survival rates remain the lowest (80% and 46%, respectively) compared with all other organ transplants (excluding combined heart–lung). Early mortality rates approach 15%, and predictors of 90-day mortality have been, and continue to be, identified.[16,17]

Heart Transplant

An increasing number of patients with heart failure has accompanied improvements in pharmacotherapy and advances in both surgical- and catheter-based management of acute coronary syndromes combined with an ageing population. Among industrialized countries, the incidence and prevalence of heart failure is 0.15% and 1%, respectively.[18] Concomitant with progress in medical management, heart transplantation and circulatory assist devices have become viable alternatives, particularly for patients with advanced heart failure.[19–21]

The number of heart transplants being performed annually in the United States ranges from 2000–2500 (<4500 worldwide). The volume appears to have reached a plateau and is limited primarily by the availability of donors. Of patients who were placed on the wait list in 2004, <25% were alive after waiting 1 year (if not transplanted).[22] The median time to transplant after being placed on the waiting list was between 200 and 300 days. The percentage of patients awaiting transplantation for more than 2 years increased from 23% in 1994 to 49% by 2003.[12] In general, older patients compose a larger number of those listed for

TABLE 57–3.

Disease-Specific Guidelines for Lung Transplant Eligibility

The following patient populations are considered to be in the transplant window if they meet the listed criteria:
- Nonbronchiectatic chronic obstructive lung disease
  - FEV_1 <25% predicted (without reversibility) and/or
  - $Paco_2$ ≥55 mm Hg and/or increasing PAPs with progressive deterioration
- Cystic fibrosis and other bronchiectatic diseases
  - FEV_1 ≤30% predicted or rapid deterioration with FEV_1 >30% predicted
  - $Paco_2$ >50 mm Hg; Pao_2 <55 mm Hg on room air
  - Young female cystic fibrosis patient whose condition deteriorates rapidly
- Idiopathic pulmonary fibrosis/systemic disease with pulmonary fibrosis
  - Symptomatic, progressive disease not improved with steroids or other immunosuppressants
  - Abnormal pulmonary function
    - VC <60–70% predicted
    - DLCO <50–60% predicted
- Pulmonary hypertension without congenital heart disease
  - Symptomatic and progressive despite optimal medical/surgical treatment
  - CI <2 L/min/m²
  - RAP >15mm Hg
  - mPAP >55 mm Hg
- Pulmonary hypertension secondary to congenital heart disease
  - Progressive symptoms with NYHA class III or IV function despite optimal medical management

Data from International guidelines for the selection of lung transplant candidates. The American Society for Transplant Physicians (ASTP)/American Thoracic Society (ATS)/European Respiratory Society(ERS)/International Society for Heart and Lung Transplantation (ISHLT). Am J Respir Crit Care Med 1998;158:335–339.

CI, Cardiac index; DLCO, diffusing capacity of carbon monoxide in lung; FEV_1, forced expiratory volume in 1 second; mPAP, mean pulmonary arterial pressure; NYHA, New York Heart Association; $Paco_2$, partial pressure of carbon dioxide in arterial blood; Pao_2, partial pressure of oxygen in arterial blood; PAP, pulmonary arterial pressure; RAP, right atrial pressure; VC, vital capacity.

TABLE 57–4.

General Indications for Lung Transplantation

- Single-lung transplant
  - Chronic obstructive pulmonary disease with FEV_1 ≤25% predicted
  - Pulmonary hypertension (mPAP ≥55 mm Hg)
  - Connective tissue disorder (sarcoidosis, lymphangioleiomyomatosis, eosinophilic granulomas)
  - Pulmonary fibrosis
  - Interstitial lung disease
  - Bronchoalveolar carcinoma
- Double-lung transplant
  - Emphysema
  - Pulmonary hypertension
  - Cystic fibrosis
  - Bronchiectasis

FEV_1, Forced expiratory volume in 1 second; mPAP, mean pulmonary arterial pressure.

heart transplantation. By 2003, 13% of registrants were older than 65 years. The two most common reasons for transplantation are ischemic cardiomyopathy and idiopathic dilated cardiomyopathy, which together compose approximately 90% of cases.[18] The premise of any therapeutic intervention is that survival and quality of life are better than is the natural history of disease. The 1-year mortality of patients with symptomatic congestive heart failure is estimated to be 45%,[23] and the 5-year survival is < 30%.[24] In comparison, the 1-year survival after heart transplantation is approximately 85%, the 10-year survival is between 40% and 50%,[25–27] and the 15-year survival has *recently* been reported as 30–40%.[12,28] The survival benefit from heart transplantation is greatest in patients who are at highest risk for dying of heart failure without transplantation.[25,26,29]

Indications

Lung Transplantation

In 1998, a consensus statement was released that proposed indications and contraindications for lung transplant.[30] Disease-specific guidelines could be used by practitioners to classify patients with regard to eligibility (Table 57–3). The diseases included chronic obstructive lung disease, cystic fibrosis, idiopathic pulmonary fibrosis, pulmonary hypertension with and without congenital heart disease, and combined pulmonary/other organ failure (e.g., advanced liver disease with pulmonary hypertension). Since that time, significant changes have been made in our understanding and management of end-stage pulmonary disease, with increasing evidence of improving posttransplant survival rates.[31] In 2005, the United Network for Organ Sharing/Organ Procurement and Transplantation Network Thoracic Organ Transplantation Committee established a revised allocation system for donor lungs. The revised system, which became effective in the summer of 2005, assigns a lung allocation score (0–100) to each potential recipient based on the patient's projected benefit received from transplant, the patient's waiting list urgency, and the predicted 1-year posttransplant survival score (UNOS calculation). Indications for lung transplantation can be divided into those for single-lung transplantation and for double-lung transplantation (Table 57–4).[10] Single-lung transplantation is contraindicated, and bilateral lung transplantation is necessary, in patients in whom the donor lung would be cross-contaminated by the contralateral native lung (e.g., cystic fibrosis, bronchiectasis). Single-lung transplantation has most commonly been used in the treatment of end-stage chronic obstructive pulmonary disease (COPD). Use of single-lung transplantation in patients with primary pulmonary hypertension and Eisenmenger syndrome remains controversial.

Heart Transplantation

The most common indications for adult cardiac transplantation are ischemic and idiopathic dilated cardiomyopathies (Figure 57–1).[32] The benefit of transplant must outweigh the enhanced quality of life offered by maximal medical therapy without surgery. Patients in whom medical management may achieve similar survival outcomes as with heart transplantation warrant reconsideration for the

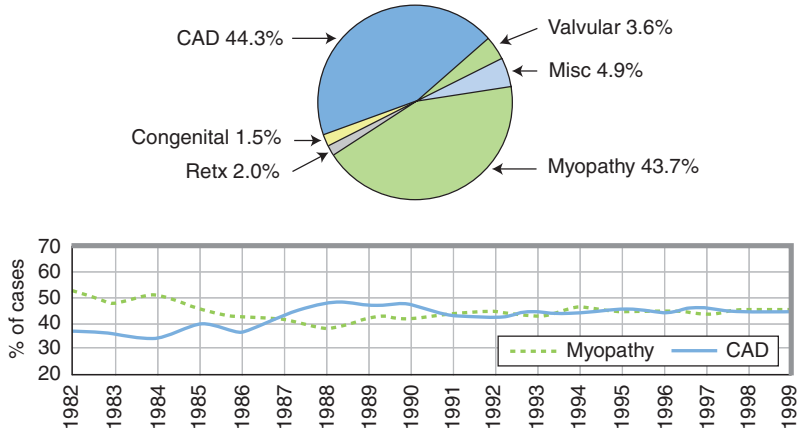

FIGURE 57–1. Indications for adult heart transplantation. CAD, Coronary artery disease; Misc, miscellaneous; Retx, retransplantation. Reprinted from Hosenpud JD, Bennett LE, Keck BM, et al. planned operation.[33,34] Thus, potential candidates must be significantly disabled despite optimal medical therapy.

The most widely used criteria for identifying potential heart transplant candidates are based on peak oxygen consumption (VO_2) and the heart failure survival score (HFSS).[35,36] Peak VO_2 < 14 cc/min/kg or medium- to high-risk HFSS is believed to be predictive of patients who will sustain a survival benefit with transplantation.[25,37,38] Other important factors that are considered before a patient is listed for cardiac transplantation are pulmonary vascular resistance (PVR), age, and comorbidities. Patients with severe heart failure frequently have elevated PVR as a consequence of chronically elevated left ventricular end-diastolic pressure. The concern with transplanting a heart in such patients is the increased right ventricular afterload, which the donor heart is unaccustomed to generating. There is a linear correlation between PVR and 1- and 5-year mortality.[39] Most centers consider PVR >3–4 Wood units (on maximal medical therapy) to be a contraindication to cardiac transplantation. Although the recipient's age historically was a common limiting factor, survival rates of selected recipients older than 69 years were found to be similar to the rates of younger patients.[40] Finally, in addition to comorbidities of the recipient that may affect survival, the decision to list a patient for heart transplantation must be based on psychological and social factors. In the end, the decision is individualized and must be made by a designated transplantation team (including, but not limited to, physicians, nurses, and social workers) along with the patient and his or her family.

SURGICAL ALTERNATIVES TO TRANSPLANTATION

Transplantation of any organ frequently represents the penultimate rescue therapy. These patients typically, although not always, have undergone numerous attempts at alternate strategies to improve organ function. Both heart and lung transplantation represent a decisive therapy that often follows one or more surgical alternative therapies. This section is not meant to be a comprehensive review of alternate therapies but rather introduces several strategies with which the anesthesiologist should be familiar, as a transplant recipient may have been exposed to one or more of these operations previously.

Lung

Surgical options, other than transplantation, for treating advanced lung disease are few, and their efficacy is equivocal. The most common option for treating advanced emphysema is lung volume reduction surgery (LVRS). The procedure is often performed as a "bridge" to lung transplantation as a means for patients to survive the estimated 18- to 24-month transplant waiting period.[41] Volume reduction surgery involves excision of as much as one third of the emphysematous lung, thus increasing elastic recoil in the remaining lung. Although no randomized study has compared LVRS with lung transplantation, the latter carries higher perioperative mortality and predisposes the patient to infection as a result of immunosuppression. LVRS can be performed via median sternotomy or video-assisted thoracoscopic surgery. Patients presenting for lung transplantation status post LVRS should be considered at high risk during thoracic entry, and standard "redo" precautions should be taken. Although continuous intravenous prostacyclin is another alternative to transplantation, many use this therapy as a "bridge" to transplantation. Prostacyclin is a metabolite of arachidonic acid and is a potent vasodilator. Because it usually is administered by long-term continuous intravenous infusion, permanent central venous access is necessary. Significant risks associated with this therapy are central line infection and thrombosis.

Heart

A number of surgical procedures are available for heart failure patients short of heart transplantation, including reduction ventriculoplasty, transmyocardial laser revascularization, dynamic cardiomyoplasty, and insertion of partial or total heart assist devices. Often one or more of these procedures has been performed on the patient presenting for heart transplantation. Reduction ventriculoplasty (also called the *Batista procedure*) has been used as an alternative to transplantation for patients with dilated cardiomyopathy. By decreasing ventricular volume and excising dyskinetic myocardium, the ejection efficiency in patients with dilated cardiomyopathy is improved and cardiac output is maintained. Transmyocardial laser revascularization is an option in patients with small, diffusely diseased coronary arteries that are not amenable to other interventional therapies. The procedure applies a laser to permeate the myocardium and incite an inflammatory reaction that, over time, promotes angiogenesis and neovascularization in the ischemic region. Heart function tends to deteriorate in the immediate postoperative period secondary to acute myocardial edema. Benefit is more evident months later. Transmyocardial laser revascularization typically is performed via a minithoracotomy. Dynamic cardiomyoplasty involves encasing the heart with muscle, usually the latissimus dorsi, which subsequently is stimulated to contract in synchrony with cardiac systole. Stimuli are generated through an implantable cardiomyostimulator. All of these procedures place

the recipient for heart transplantation at greater risk as a result of adhesions, particularly during redo sternotomy. Type- and cross-matched blood in the operating room before incision is necessary. During any redo sternotomy, the lungs should continue to be ventilated because they "protect" the heart during thoracic entry. That is, if the sternal saw inadvertently slips too far beneath the sternum, mortality is less *likely* if the saw enters the lung rather than the heart.

The basic mechanism underlying all ventricular assist devices (VADs) is similar. Blood is removed proximal to the diseased ventricle. This involves the superior vena cava (SVC) or right atrium for a right VAD and the left atrium or left ventricle for a left VAD. The blood is returned distal to the affected ventricle: the pulmonary artery in a right VAD and the ascending or descending aorta in a left VAD. The design of VADs has improved, allowing patients who are not transplantation candidates to remain indefinitely on the device (so-called "destination therapy"). However, most devices continue to be used as a "bridge" to transplantation, sustaining the function of all other organs until heart transplantation. Heart transplant recipients commonly arrive in the operating room with a VAD that may have been in place for months.

IMMUNOBIOLOGY OF TRANSPLANTATION

Transplant immunology was borne from an observation by Karl Landsteiner in 1901 that the clumping of donor red blood cells was responsible for manifestations of the transfusion reaction. He went on to formally classify human blood into the A, B, AB, and O groups.[42] Blood group compatibility is a requirement not only for blood transfusion but also for organ transplantation. In the early 1950s, Peter Medawar further advanced the field of transplant immunology by observing the viability of skin grafts on burns.[43] The observation that first-time grafts from donors lasted approximately 10 days, whereas subsequent grafts were rejected immediately suggested the subsequent response was somehow affected by prior exposure. If, however, mouse embryos were inoculated with cells from another strain and then grafted after birth with skin from that strain, the grafts were not rejected. In 1958, Dausset described the first leukocyte antigen that allowed for tissue matching.[44,45] Human leukocyte antigens (HLAs) are encoded by a group of genes on chromosome 6 known as the human *major histocompatibility complex* (MHC). Because these genes are highly polymorphic (HLA-B has >50 alleles), two unrelated individuals likely will not have the same HLA type. Because HLA mismatch necessarily causes rejection (by antibodies, lymphocytes, or both), immunosuppressive drugs are required to ensure recipient tolerance of the allograft.

Three main types of rejection can occur in clinical transplantation: hyperacute, acute, and chronic. Hyperacute rejection typically occurs within minutes to days and is caused by preformed recipient IgG antibodies reacting against the allograft class I HLA. A profound and immediate decrement in organ function caused by complement activation and antibody deposition leads to vascular destruction. As cross-matching techniques have improved, hyperacute rejection is less commonly seen. The most common form of rejection is acute rejection, usually occurring within 6 months of transplantation. Acute rejection is caused by infiltration of allograft tissue with host T cells and subsequent clonal expansion. As these alloreactive lymphocytes enter the circulation, they react with allograft vascular endothelium (the primary target of the initial stages of acute rejection), leading to eventual tissue destruction. Immunosuppressive drugs are most effective in subjugating this phase of rejection. Chronic rejection is not well understood. It may occur as early as 6–12 months after transplantation but usually occurs much later. It is typified by a slow deterioration in allograft function and is identified histologically by intimal hypertrophy and fibrosis. In heart transplant patients, chronic rejection is manifest by progressive atherosclerosis and coronary artery disease, whereas lung transplant recipients develop bronchiolitis obliterans. Currently there is no standard treatment of chronic rejection. Most heart transplant recipients average one to two episodes of rejection per year. The bulk of these episodes are minor, resolving with corticosteroids or small changes in the immunosuppressive regimen.

Immunosuppression Regimens

Safety

The anesthesiologist is frequently asked to prepare and/or administer an immunosuppressive agent intraoperatively. Although proper handling of all medications is always recommended, particular attention should be focused on these drugs. The Occupational Safety and Health Administration (OSHA) through the United States Department of Labor has published a technical manual that includes a section entitled "Controlling Occupational Exposure to Hazardous Drugs."[46] The realization that many of these drugs are cytotoxic and genotoxic and are potential carcinogens has prompted OSHA to continually revise these recommendations. Some specific recommendations to limit exposure include the following:

1. Clearing air from syringe before injection to avoid aerosolization
2. Careful attention to avoid leakage in syringe, tubing, or stopcock sites
3. Immediate disposal of contaminated materials (syringes, needles, bottles, etc.)
4. Careful handling of excreta of patients, because many drugs are excreted unchanged or are converted to mutagenic metabolites.

Additionally, because many drugs must be reconstituted, particular recommendations to avoid aerosolization include attention when withdrawing a needle from a vial, attention when breaking open an ampule, and limiting the expulsion of air from a drug-filled syringe.

Drugs

As stated above the preceding list, and as seen in the following Lung and Heart sections, a plethora of immunosuppressive regimens are available. The decision to administer a particular drug frequently is dictated by patient comorbidity, pharmacodynamics, and kinetics of the drug as well as institutional preference. The purpose of this section is not to give a comprehensive review on the pharmacology of immunosuppressant agents but rather to introduce several drugs commonly given by the anesthesiologist.

Before the discovery of cyclosporine in 1976, the most common pharmacologic regimen for immunosuppression

was a combination of azathioprine and corticosteroids. Azathioprine is a derivative of 6-mercaptopurine. Its mechanism of action includes suppression of cell-mediated hypersensitivity and antibody production. Metabolism occurs in the liver and erythrocytes with very little renal accumulation. Because azathioprine inhibits cell proliferation in a nonselective manner, the major toxicity associated with this drug includes neutropenia and thrombocytopenia as a result of profound bone marrow suppression. With the discovery of cyclosporine, immunosuppression without significant bone marrow suppression became possible. Since 1983, when the drug was FDA approved to prevent graft rejection in transplantation, cyclosporine has been limited by its nephrotoxicity and the inability to completely control chronic rejection. The incidence of nephrotoxicity with cyclosporine is 40–70%.[47] Newer classes of drugs have since been developed for use in heart and lung transplantation.

Tacrolimus (FK506) is a macrolide antibiotic that inhibits calcineurin and T-lymphocyte function with greater potency than does cyclosporine.[48] Although the incidence of nephrotoxicity is similar to that of cyclosporine, less arterial hypertension and hyperlipidemia is seen with FK506. Deciding which calcineurin inhibitor to use usually is patient dependent and often institutionally biased.

Mycophenolate mofetil (MMF; CellCept, Roche Pharmaceutical, Nutley, NJ, USA) is a morpholinoethyl ester of mycophenolic acid. It acts as a reversible uncompetitive inhibitor of inosine monophosphate dehydrogenase and inhibits guanine nucleotide synthesis in lymphocytes. A comprehensive review of its proposed mechanism of action is available elsewhere.[49] Almost all studies in heart and lung transplantation have substituted MMF with azathioprine as a triple-drug regimen and have shown better graft survival and fewer episodes of rejection.[50]

Almost every transplant recipient receives a corticosteroid. Although methylprednisolone typically is started perioperatively, the patient can be maintained on oral prednisone. Specific immunosuppressive regimens for heart and lung transplantation are given in Table 57–5.

Lung

Acute rejection after lung transplantation occurs with greater frequency compared with transplantation of other solid organs, particularly during the first 6 months after surgery. Additionally, there is a greater risk for chronic transplant dysfunction progressing to allograft loss. Although bronchiolitis obliterans syndrome is the major cause of morbidity and mortality among long-term survivors after lung transplantation, acute allograft rejection is a major risk factor for the development of bronchiolitis obliterans syndrome. Thus, timely administration of immunosuppressants is believed to be of key importance in lung transplantation. Immunosuppressive agents frequently are given to lung transplant recipients immediately before or during surgery. The most common agents administered are steroids, cyclosporine A, azathioprine, and tacrolimus. A typical regimen may include cyclosporine (2.5–5 mg/kg PO), azathioprine (2 mg/kg IV), or MMF (1000 mg IV) administered preoperatively. Methylprednisolone usually is administered just before lung reperfusion (500 mg to 1 gm IV; Table 57–5). Future directions in lung transplant immunosuppression include inhaled delivery of cyclosporine.[51] A case-controlled trial comparing inhaled and oral cyclosporine in lung transplant recipients with bronchiolitis obliterans showed improved survival in the inhalational group.[52] Although a subsequent randomized, double-blinded, placebo-controlled trial confirmed survival advantage with inhaled cyclosporine, rates of acute rejection were similar between the two groups.[53] Further studies are ongoing.

Heart

Most immunosuppressive regimens for heart transplantation currently include a calcineurin inhibitor, a corticosteroid, and some adjunct (Table 57–5). Usually a postoperative triple-drug regimen of cyclosporine or tacrolimus (FK506), azathioprine or MMF, and prednisone is typical. With a combination of these three agents, acute rejection has been dramatically reduced.[54] Evidence suggests that the combination of tacrolimus and MMF yields superior outcomes in heart transplant recipients.[55] Newer agents used in some institutions include sirolimus (rapamycin) and monoclonal antibody interleukin-2 receptor antagonists such as daclizumab (daclizumab) and basiliximab. Cardiac allograft vasculopathy remains a leading cause of morbidity and mortality among heart transplant recipients.[56,57] Although this vasculopathy is multifactorial and has been shown to arise from both immune- and nonimmune-related mechanisms, immunosuppressants have been implicated as a contributing factor.[56,58,59] For example, calcineurin inhibitors, such as cyclosporine and tacrolimus, in addition to having profound nephrotoxic effects, can alter vascular remodeling, contributing to graft vasculopathy. However, several prospective studies have confirmed that both drugs have similar efficacy in preventing acute rejection in heart transplant recipients.[60–63] Thus, a future challenge in heart transplant immunosuppressive regimens remains the prevention of cardiac allograft vasculopathy.

TABLE 57–5.

Example of Typical Immunosuppressive Regimens for Heart and Lung Transplantation

- Heart
  - Early
    - Mycophenolate mofetil 3000 mg/d PO
    - Prednisone 1 mg/kg/d PO tapered to 0.4 mg/kg/d
  - Late
    - Mycophenolate mofetil 3000 mg/d PO
    - Prednisone 0.1–0.2 mg/kg/d PO
- Lung
  - Early
    - Cyclosporine 5–10 mg/kg/d PO (or 0.01–0.1 mg/kg/h IV)
    - Methylprednisolone 500 mg IV after reperfusion followed by 125 mg IV every 8 hours for 3 doses
    - Prednisone 0.6 mg/kg/d PO starting on day 15
    - Azathioprine 2 mg/kg/d PO
    - Rabbit antithymocyte globulin (RATG) 2.5 mg/kg/d IV on days 1, 2, 3, 5, and 7
  - Late
    - Cyclosporine 3–6 mg/kg/d PO
    - Prednisone 0.1–0.2 mg/kg/d PO
    - Azathioprine 1–2 mg/kg/d PO

DONOR SELECTION AND ORGAN PROCUREMENT

Lung

Most potential multiorgan donors are not suitable candidates for donating

lungs because the vital organs are common targets of end-of-life events. Chest trauma, pulmonary edema, aspiration, pulmonary infection, and pulmonary embolism often preclude the use of lungs for donation. A smoking history does not preclude the use of donor lungs for transplantation. Oxygen challenge tests are performed on the donor with administration of 100% oxygen with 5 cm H_2O positive end-expiratory pressure (PEEP). An acceptable oxygen response is an arterial partial pressure of oxygen >300 mm Hg. Cytomegalovirus (CMV) serology of the donor affects the selection of the recipient. A CMV-negative recipient should receive CMV-negative donor lungs. However, a CMV-positive recipient can receive lungs from a CMV-negative or CMV-positive donor.

Once a donor has been identified, all possible recipients for organ transplantation are evaluated for ABO compatibility and size matching. In recipients with COPD, disparity in size between donor and recipient lungs is less important. Patients with COPD tend to have large barrel chests that can accommodate lungs that ordinarily come from larger donors. Donor lungs increase in size when implanted and partially fill an enlarged pleural space in patients with COPD. Recipients with restrictive lung disease tend to have a normal or decreased thoracic size, and lung sizing is paramount. Too large a lung may preclude its implantation in a recipient. During procurement, the donor lungs are flushed in situ, and the harvest is completed. Bilateral lungs are excised in their entirety and separated from the native airway at the trachea. Single-lung harvests require separation with the main bronchus, pulmonary artery, and cuff of the left atrium. Total ischemic time is defined from excision to reimplantation and reperfusion and should be kept at a minimum (ideally <6 hours).[64,65]

Before 1984, lung procurement in close proximity to the recipient was deemed necessary because of unrefined preservation techniques.[66] Since that time, however, improved understanding of ischemia–reperfusion injury has led to the development of novel solutions that have reduced the incidence of primary graft dysfunction after lung transplantation. Additionally, newer preservation protocols now allow procurement at centers as far away as 6–8 hours from the recipient.

Procurement of any solid organ involves confirmation of donor eligibility, dissection, and isolation of the specific organ, followed by preservation and transport. The sole principle of preservation is to minimize both ischemia and reperfusion injury to the allograft.[67] Confirmation of donor eligibility includes review of pertinent consents, history, radiographs, laboratory values (including arterial blood gas), blood type, and bronchoscopy. Methods for minimizing injury include donor pretreatment, organ preservation, and recipient treatments. Although preservation techniques and solutions differ among transplantation centers, one commonality is the use of deliberate hypothermia, which is used universally during explantation, storage, and reimplantation. Hypothermia can reduce the tissue's metabolic demand by 99%. Before explantation, lungs are flushed with solution at 32–50°F (0–10°C) and stored at a similar temperature. The lung is flushed most commonly with a low-potassium dextran (e.g., Perfadex, Vitrolife AB, Gothenburg, Germany) or University of Wisconsin solution[13] at the time of harvest and kept cold during transport to the recipient site and implantation and until reperfusion. During implantation, the lungs are covered with gauze soaked in ice saline slush in an attempt to maintain a cold environment.

Potential lung transplant recipients require careful cardiovascular evaluation. Right-heart function is assessed to determine the ability of the recipient's right ventricle to tolerate acute increases in PVR associated with pulmonary artery clamping and pneumonectomy. Standard assessment modalities include echocardiography and right-heart catheterization. Left-heart catheterization and coronary artery arteriography are often used in older patients to detect coronary artery disease and left ventricular dysfunction. Intracardiac shunts, such as a patent foramen ovale, are detected preoperatively because they predispose to paradoxical embolization in patients with increased right-sided pressures.

Unlike many other transplanted organs, lungs and hearts must be functional immediately on reperfusion. Improvement in both donor management and procurement strategies has increased the likelihood of viability.

Heart

Similar to lung transplantation, the recipient waiting list for heart transplantation continues to grow, and donor organ shortage persists. As a result, the criteria for heart donation are broad and continue to be liberalized (Table 57–6).[68,69] Absolute contraindications continue to include most malignancies and positive serologies for human immunodeficiency virus (HIV) and hepatitis B and C. Although low-dose vasopressor requirements are commonplace in the donor population, high doses of catecholamines may downregulate β receptors on cardiac myocytes and can cause intramyocardial hemorrhage and necrosis. Echocardiography may provide valuable information but frequently is unavailable at all times in many hospitals. Thus, transplant surgeons frequently rely on direct inspection and palpation to assess for significant coronary artery disease, contractility, and/or myocardial hematoma suggestive of blunt thoracic injury. Height and weight of the donor preferably should match those of the recipient; however, differences of up to 20% are acceptable.

Procurement of intrathoracic organs begins with median sternotomy and pericardial incision. The procurement team (of which there may be more than one in the case of multiple donations) inspects and manually palpates the heart and coronary arteries to rule out blunt injury or significant cardiac disease. After administration of 30,000 U of heparin intravenously, the superior and inferior vena cavae and azygos

TABLE 57–6.

Donor Criteria for Heart Transplantation

Age ≤60 years
No evidence of prolonged shock causing
SBP <90 mm Hg or MAP <60 mm Hg
Profound inotropic support (>10 μg/kg/min dopamine)
No evidence of prolonged hypoxemia
Normal electrocardiogram and/or echocardiogram
Preserved right ventricular/left ventricular function
No intrinsic myocardial disease
No history of severe chest trauma
No evidence of extracerebral malignancy

Adapted from Harringer W, Haverich A. Heart and heart-lung transplantation: standards and improvements. World J Surg 2002;26:218–225. With kind permission of Springer Science and Business Media. MAP, Mean arterial pressure; SBP, systolic blood pressure.

vein are clamped and divided. The aortic cross-clamp is placed proximal to the takeoff of the innominate artery, and the heart is arrested with an infusion of 500 mL cold cardioplegic solution injected proximal to the cross clamp. The heart is cooled with topical ice slush, and the remaining vessels (pulmonary veins and artery, ascending aorta) are transected. The allograft is placed in a sterile container and transported expeditiously to the recipient hospital. Allowable cardiac ischemic time is 4–6 hours. Most transplants proceed with transport of the heart after a single flush of cardioplegic solution followed by hypothermic storage. Commonly used solutions include University of Wisconsin, Euro-Collins, St. Thomas, and HTK.[70,71] The optimal transport temperature likely is between 39°F (4°C) and 50°F (10°C).[72]

PERIOPERATIVE CARE

Lung Transplantation

Preoperative Assessment

Candidates for allograft lung transplantation includes patients with severe pulmonary vascular or parenchymal disease resulting in debilitating respiratory failure. Allocation of scarce resources (e.g., donor lungs) to high-risk patients with serious comorbidities often precludes the eligibility of this patient population because of the high risk for death. However, lung transplantation in the less sick does not appear to significantly increase life span. In the end-stage emphysematous population, lung transplantation does not improve survival compared with aggressive pulmonary rehabilitation.[73] More recently, organ procurement organizations have liberalized the selection criteria for lung transplants to include patients with severe comorbidities and systemic disorders such as renal failure. These patients would have a very high mortality rate if they did not receive the benefit of a new lung. The outcome of this new allocation strategy remains to be determined, but these high-risk patients are at increased risk of perioperative mortality.

An efficient but comprehensive evaluation often is performed immediately before surgery. Many of these patients are on a waiting list for months, and their medical conditions may change rapidly during this time. Lung transplants are emergencies, and recipients should be considered at increased risk for aspiration. Full stomach precautions are warranted.

Operating Room Preparation

The operating room is set up in typical fashion for cardiothoracic surgery. This includes fiberoptic bronchoscope equipment, cardiopulmonary bypass machine, different-sized double lumen tracheal tubes, and medications. A full complement of PEEP valves and the ability to provide continuous positive airway pressure may prove useful. On occasion, extremely ill patients require a "Surgical Intensive Care Unit (SICU) ventilator" to maintain adequate ventilation and oxygenation after induction of anesthesia. Prepared medications include heparin, diuretics, antiarrhythmics, inotropic and vasoactive agents, induction agents, muscle relaxants, and sedative–hypnotics. Immunosuppressive medications should be discussed with the transplant coordinator. Antibiotic administration usually is based upon institutional protocol, although often it must be tailored to culture results from the donor and the recipient. This is especially true in the setting of chronic infections, such as patients with cystic fibrosis and bronchiectasis.

All lung transplant operations are emergency procedures and, for some yet-undetermined reason, typically occur during off hours. The cardiothoracic anesthesiologist usually is notified of the impending lung transplant procedure by the transplant coordinator and/or attending surgeon. This initial communication establishes the identification of the donor and the donor blood type and includes a brief synopsis of the primary and secondary diagnoses. In addition, this communication identifies the location and condition of the donor, including associated medical disorders, and anticipated cross-clamp time and arrival time of the donor organ to the transplanting center. From this information, the operating room team establishes the time the recipient is brought to the operating room. Often, the patient's arrival to the operating room is the first (and only) encounter with the anesthesiologist. In certain centers, a preoperative evaluation clinic provides a mechanism for the assessment and evaluation of lung transplant recipient candidates as part of the pretransplant evaluation. However, patients may wait for a lung transplant for many months, and conditions may change rapidly as patients are waiting for a transplant organ to become available. The lung transplant recipient is brought to the operating room in sufficient time to perform a comprehensive preoperative assessment, with acquisition of informed consent, placement of thoracic epidural, and invasive hemodynamic monitoring. These activities should be completed in advance of the anticipated time for induction of anesthesia and beginning of surgery. Anesthesia equipment and supplies are similar to those required for thoracic and cardiac surgery. Mechanisms for maintaining normothermia in patients undergoing lung transplantation without cardiopulmonary bypass are important adjuncts to intraoperative care. Options include fluid warmers, heated operating room table mattresses, warmed and humidified gases, increased room temperature, and body surface heating devices.

The operating room medications that should be readily available include antiarrhythmics, inotropic agents, vasodilators, and vasoconstrictors. Inhaled pulmonary vasodilators, such as nitric oxide and prostacyclin, typically are available via operating room pharmacy systems.

Patient Arrival

The patient is greeted by the attending anesthesiologist immediately on arrival. A high level of anxiety and anticipation is to be expected from patients undergoing lung transplantation. These patients are afflicted with a life-threatening disorder and typically have a good understanding of the severity of their illness and the magnitude of the operative procedure for which they are being prepared to undergo. The anesthesiologist informs the patient of the conduct of the planned anesthetic and associated risks and obtains consent for anesthesia and related procedures. The exchange of information between the anesthesiologist and the patient is designed to inform the patient of the upcoming events and risks without producing harmful levels of anxiety and fear. The patient's preoperative laboratory workup is reviewed before his or her arrival, typically through electronic computerized databases. The patient is questioned regarding changes in physical condition since his or her last evaluation.

Preinduction Activity

The patient is bought into the operating room, and routine monitors are applied once the patient is on the operating

room table. Large-bore venous access is achieved, and, if indicated, an epidural catheter is inserted. Placement of an intravenous catheter in the antecubital fossa is discouraged because many patients are positioned in a manner that may compromise patency of the catheter if the elbow is flexed.

Postoperative analgesia is planned before induction of anesthesia. Thoracic epidural catheters are routinely inserted for single or bilateral sequential single-lung transplants that do not require cardiopulmonary bypass. Placement of an epidural catheter for administration of local anesthetics and/or narcotics provides effective postoperative analgesia and can be used intraoperatively to decrease the anesthetic requirement.[74] A common analgesic regimen includes low-concentration local anesthetics and narcotics administered intraoperatively and continued into the postoperative course. Thoracic epidural catheters typically are inserted for single or bilateral sequential single-lung transplantations that do not require cardiopulmonary bypass. In patients with significant pulmonary hypertension or other indications for use of cardiopulmonary bypass, the benefit of placing an epidural catheter in a patient who is anticoagulated is balanced against a risk of epidural hematoma.[75–79] The data supporting this contraindication are sparse, and this clinical judgment is based more on intuition and clinical impression rather than on evidence.[80] In many centers, if placement of an epidural needle produces a "bloody tap," surgery is postponed if anticoagulation is anticipated. Although this practice is acceptable for most operations, lung transplantation cancellation may result in loss of the donor organ. In addition, the recipient may not have another opportunity to receive a transplant.

Strict aseptic techniques are used throughout the surgical and anesthetic care of the patient because the patient receives large doses of immunosuppressants and is at very high risk for postoperative infections. Before insertion of intravascular catheters, the skin is prepared with either a chlorhexidine- or an iodine-based solution that provides lasting antimicrobial effects.

The administration of anxiolytics is done judicially and with caution. Low doses of sedative–hypnotics or narcotics could render a patient with end-stage lung disease unstable because these medications may significantly blunt the patient's respiratory drive. Antisialagogue administration is helpful in patients with increased secretions. Care must be taken to avoid tachycardia with the administration of vagolytic agents. Patients with primary pulmonary hypertension may have an exacerbation and incremental increase in PVR caused by anxiety and agitation. Sedation with minimal respiratory depression is the goal in this cohort of patients. All sedated patients receive supplemental oxygen in addition to standard monitoring. All lung transplant patients receive a central venous catheter, although a pulmonary artery catheter is not absolutely indicated. A radial artery catheter is inserted for continuous measurement of blood pressure and access to arterial sampling of blood for laboratory testing.

A central venous catheter usually is inserted before induction of general anesthesia. The pertinent information deemed from the pulmonary artery catheter includes assessment of pulmonary hypertension and an estimate of the risk of cross-clamping the right or left pulmonary artery. Induction of anesthesia can proceed safely without the information provided by a central venous or pulmonary artery catheter. However, the urgency of moving forward with the surgical procedure once the donor organ has been deemed suitable often precludes placement of the catheter after this notification. Typically, aortic cross-clamping of the donor coincides with induction of general anesthesia in the recipient. This coordinated event across centers is intended to achieve arrival of the donor organ at the recipient's operating room at the time when the recipient has been prepared for receiving the new organ. Delay in the implantation of the transplanted organ leads to increased organ ischemia and may increase the risk for early postoperative graph failure.[81,82]

Confirmation of the laterality of the operation is critical in the early moments of the interaction between anesthesiologist and patient. The laterality is confirmed through repeated, redundant mechanisms set in place at each transplantation center. Typically, the right, left, or midline chest of the recipient undergoing a single-lung transplant is marked soon after arrival of the recipient to the operating room. Confirmation of the proposed surgery and laterality by the patient, operating room nurse, anesthesiologist, transplant coordinator, and surgeon is vital. Patients for planned double-lung transplant (e.g., no laterality) also have the site of their incision marked. The patient's blood type is confirmed with data from the blood bank and posted in the operating room.

Antibiotics are administered according to institutional protocol and known organismal sensitivities soon after intravenous access is attained. Administration of vancomycin should be done over 30–60 minutes and administered within 120 minutes before incision to attain effective soft-tissue drug concentration levels.[83] Administration of immunosuppressants typically is delayed until the time when full commitment to proceed with the lung transplant has been made.

In the early management of lung transplant anesthesia and surgery, a "hurry-up-and-wait" approach is not uncommon. Typically, patients arrive to the operating room 90 minutes before the anticipated cross-clamp time in the donor and hence anticipated incision time in the recipient. However, delays at both donor and recipient sites are common. Delays at the donor site often are related to coordinating various transplant teams arriving from different institutions. The harvest of various organs for multiple institutions often leads to unanticipated delays resulting in the recipient waiting with anticipation in an otherwise quiet operating room. During this time of waiting and anticipation, low doses of sedatives, as well as warm blankets and comfort measures, are appropriate. Information regarding the source of the donor organs should not be shared with the recipient.

Anesthesia Induction and Maintenance

The commitment to proceed with surgery is intimately linked with the functional status of the donor organ. Deterioration in pulmonary function occurring at the donor site that precludes use of the lungs for transplantation is not uncommon. The harvest team reviews the laboratory data, including arterial blood gas measurements, chest radiographs, and visual inspection of the lungs through bronchoscopy and direct inspection. Oxygen challenge testing typically is undertaken in the donor to calculate

alveolar–arterial oxygen gradients. Progressive increases in alveolar–arterial oxygen differences are a common reason for abandoning the donor lungs as a transplant organ. Other causes include pneumonia, infiltrate on radiograph, contusion, edema, and injury during harvest.[84] Lack of recipient is an uncommon cause for not using a donor organ.[85] If the donor organ is considered unsuitable, the recipient operating room is immediately notified, and the planned lung transplantation is canceled. Unfortunately, the cancellation of lung transplants occurs all too often, and potential recipients may become disappointed, discouraged, or die of their disease before being offered another opportunity for a transplant. The case provided by the anesthesiologist does not end when the procedure is canceled. The invasive monitoring is removed from the patient, taking care that sites of insertion are clean and without hematoma. The cancellation of a lung transplant procedure challenges many institutions as to appropriate accommodations for the patient. Typically, these patients have traveled long distances to the operating hospital. They have end-stage lung disease, have received sedatives and antibiotics, and have had intravenous, intraarterial, and central venous catheters inserted. Many patients have received a thoracic epidural for postoperative analgesia. *Canceled lung transplant procedures should not result in the immediate discharge of patients to home even if they were admitted from home.* Instead, these patients are admitted to a postanesthesia care unit, where they are subject to the same discharge criteria as patients who have undergone surgery. The lung failure medical team is notified of the patient's condition and coordinates the patient's admission to the hospital, if necessary, or discharge to home.

If the donor lungs are deemed acceptable by the harvest team, the message usually arrives directly in the operating room: "The donor lungs are acceptable. We anticipate cross-clamp in [X] minutes and arrival time at recipient hospital in [Y] minutes." The mode of transportation and anticipated arrival time of the harvest team are critical to the timing of induction of general anesthesia. Ideally, the donor lungs arrive at the operating room with the chest open and native lungs excised or in the process of being excised. Minimizing ischemic time of the donor lungs is crucial because postoperative graft dysfunction appears to be related to the duration of organ ischemia.[86] Delays in induction and operation contribute to ischemic time and may lead to poor outcome.

A common trigger for induction of anesthesia in the recipient is cross-clamp in the donor. Induction of general anesthesia must always assume the patient is at increased risk for aspiration because he is likely to have eaten in the previous hours. Mode of induction is dictated by the underlying disease process. Patients with severe COPD poorly tolerate positive-pressure ventilation. Air trapping and auto-PEEP are common, often producing circulatory instability. A severely decreased inspiratory:expiratory ratio with permissive hypercapnia is commonly necessary to maintain hemodynamic stability.

Patients are preoxygenated and denitrogenated with 100% oxygen applied by face mask, followed by intravenous induction of general anesthesia with application of cricoid pressure. Intravenous induction agents may include sodium thiopental, propofol, etomidate, and/or benzodiazepines. Narcotics are added for analgesic supplementation even if an epidural is inserted. Nondepolarizing muscle relaxants are administered to facilitate laryngoscopy and tracheal intubation. The administration of anesthetics, analgesics, and muscle relaxants should account for planned immediate postoperative extubation. Isolated lung ventilation during lung transplantation is vital to performing the operation without cardiopulmonary bypass. Techniques include the use of double-lumen endotracheal tubes or bronchial blockers. Procedures anticipated to be done using cardiopulmonary bypass may still require single-lung isolation for pneumonectomy and postcardiopulmonary bypass repair. On occasion, only one of the two donor lungs is implanted using cardiopulmonary bypass.

The trachea is intubated using an appropriately sized left-sided double-lumen endotracheal tube. Standard procedure dictates the insertion of a left-sided double-lumen tube in all patients having lung transplantation because of the variability of the position of the right upper lobe orifice and alignment of the Murphy eye of a right-sided double-lumen tube. Bronchial blockers can be used for single-lung isolation during lung transplantation, but they have the disadvantage of being more prone to dislodgement and are not as reliable for preventing contamination of the trachea and contralateral lung. Bronchial blockers do not permit selective suctioning. Bronchial blockers of the right lung do not reliably isolate the right upper lobe. Positioning of the double-lumen tube is confirmed using bronchoscopy and reconfirmed once the patient has been moved from the supine to the operating position.

Initiation of single-lung ventilation is associated with increased peak airway pressure and may produce rupture of bulla and cause pneumothorax or air trapping resulting in "pulmonary tamponade." To mitigate against the sudden increase in airway pressures, the initial set title volume is decreased when instituting single-lung ventilation with a compensatory increase in respiratory rate in an attempt to maintain adequate minute ventilation. However, the relationships among tidal volumes, peak and mean airway pressures, and volume of air trapping and auto-PEEP are not linear. In many patients, only a nominal reduction in tidal volume is necessary. Persistent pulmonary blood flow through the nonventilated lung increases shunt fraction and may produce hypoxemia. Standard measures for treating hypoxia during single-lung ventilation include use of 100% oxygen, application of PEEP to the dependent lung, and use of conventional critical care ventilators that permit multiple ventilator modes (e.g., pressure control ventilation, alternate ramp settings, wide variety of inspiratory:expiratory ratios). On occasion, circulatory deterioration during one-lung ventilation may require partial cardiopulmonary bypass.

Anesthetic maintenance is achieved through the administration of oxygen and/or air mixed with a volatile anesthetic (e.g., isoflurane, sevoflurane, desflurane). Inhalation anesthetics may be contraindicated when alternate modalities of ventilation such as a jet ventilator, are used. Decreasing inspired oxygen concentrations to decrease the risk of oxygen toxicity and reperfusion injury in the newly transplanted lung is controversial.[87] Epidural analgesia is often used to supplement intraoperative anesthesia, although epidural administration of dilute local anesthetics

may produce significant sympatholysis and hypotension.

Patients undergoing lung transplantation have parenchymal, airway, or vascular disease. Patients with pulmonary vascular disease (primary pulmonary hypertension) may have pulmonary arterial pressures equal to or exceeding systemic arterial pressures. The anesthetic management of these patients is aimed at minimizing further increases in PVR as the patient is transitioned from the awake spontaneously breathing condition to the anesthetized, paralyzed, mechanically ventilated condition. Inhaled pulmonary vasodilators may decrease PVR to some degree. Typically, these patients do not tolerate right or left pulmonary artery clamping for pneumonectomy without the use of cardiopulmonary bypass. Inhaled prostacyclin or nitric oxide, intravenous prostaglandin E_1, hyperventilation, 100% oxygen, and mild hypovolemia may contribute to decreasing pulmonary arterial pressures in anticipation of pulmonary artery clamping. Poor tolerance of right or left pulmonary artery clamping in the setting of severe pulmonary hypertension is manifest by severe systemic hypotension, increasing pulmonary hypertension, increased central venous pressure, and heart failure. If this condition persists, the pneumonectomy is delayed, the cross-clamp is removed, and the patient is anticoagulated and prepared for cardiopulmonary bypass. A cardiopulmonary bypass machine and perfusionist should be on standby for most lung transplant cases.

Patients with nonvascular lung disease have either parenchymal disease (pulmonary fibrosis, sarcoidosis) or airway disease (COPD, α_1-antitrypsin deficiency). COPD typically is characterized by normal or mildly elevated pulmonary arterial pressures. COPD patients usually tolerate clamping of one of the pulmonary arteries and pneumonectomy without the use of cardiopulmonary bypass.[88]

Intraoperative hemodynamic instability is not uncommon during lung transplant surgery. The loss of autonomic tone with induction of general anesthesia may be exaggerated in patients with end-stage lung disease in the setting of relative hypovolemia. Strategies for managing hypotension rely on information gained from central venous catheters (central venous pressure, pulmonary arterial pressure, and cardiac output). These strategies may include judicious expansion of intravascular volume and the administration of α-adrenergic or β-adrenergic agonists.

Pneumonectomy is performed on confirmation of arrival of the donor lung. Appropriate sizing of the donor organ with the recipient is crucial, especially in patients with restrictive pulmonary disorders who often have a small thoracic cavity relative to total body mass. Patients with COPD typically have large, hyperinflated chest cavities that can accommodate donor lungs without difficulty.

During the pneumonectomy, the donor lung is prepared by a second surgeon at a separate operating table. Aggressive attempts are made to keep the donor organ cold before reperfusion. Completion of the pneumonectomy by clamping the pulmonary artery eliminates the source of venous admixture and improves oxygenation and ventilation. However, clamping of the pulmonary artery also produces a sudden increase in right ventricular afterload and increases the risk for right ventricular failure. The acute increase in pulmonary arterial pressure may cause acute right ventricular dilation and tricuspid regurgitation. Alterations in right ventricular geometry affect the contractility of the right ventricle and the ventricular septum, thus affecting left ventricular contractility. Inotropic agents may increase right (and left) ventricular contractility. Pulmonary vasodilators are administered in an attempt to decrease right ventricular afterload. Intravenous nitroglycerin, nitroprusside, and prostaglandin E_1 may produce systemic hypotension. Differential infusion of vasoconstrictive agents into the left side of the heart and vasodilating agents into the right side of the heart has been suggested.[89,90] Inhaled nitric oxide or inhaled prostacyclin may have a similar role in decreasing PVR and allowing the right ventricle to tolerate pulmonary artery clamping with minimal systemic effects.[91] Monitoring with transesophageal echocardiography provides continuous qualitative assessment of right ventricular function, although this modality is not standard in lung transplant surgery.

The donor lung is placed into the void created by the pneumonectomy, and the first anastomosis usually is donor bronchus to native bronchus. The competency of this anastomosis is assessed with the application of continuous positive airway pressure with the anastomosis submerged in saline. The surgeon inspects for air leaks and performs repairs to the anastomosis if necessary. Once the bronchial anastomosis has been completed, the surgeon performs the anastomosis between donor and recipient pulmonary arteries and pulmonary veins. The latter usually are included in a cuff of left atrium. As the pulmonary transplant is nearing completion, the clamps are gradually released to produce back-bleeding in an attempt to remove any residual air or debris from the left atrium and pulmonary vascular bed. Restoring circulation to the transplanted nonventilated lung results in shunting and potentially significant hypoxia. In addition, the acute blood loss associated with back-bleeding and the flushing out of the preservative solution and its metabolites into the systemic circulation may produce hypotension. Gradual unclamping and administration of intravenous fluids blunt the hypotensive effect. If anastomosis of the bronchus precedes revascularization and the lung is ventilated before reperfusion, the risk of hypoxemia is reduced. Ventilation of the reperfused allograft should be performed with oxygen concentrations sufficient to adequately oxygenate. Evidence is accruing that high oxygen levels in the early reperfusion period may be detrimental to the allograft[92,93]; thus, many transplant centers attempt to oxygenate with $FiO_2 \leq 50\%$.

Corticosteroids typically are administered before the new lung is reperfused. Bleeding during lung transplantation surgery can be decreased in patients who have undergone prior operations by selecting an alternate site of surgery (e.g., sternotomy instead of thoracotomy).[94–96]

Patients for single-lung transplantation for end-stage lung disease typically have either chronic idiopathic pulmonary fibrosis or emphysema. Patients with end-stage emphysema pose a significant added challenge if they undergo single-lung transplantation. Posttransplant, hyperinflation and hyperventilation of the native emphysematous lung often produce severe ventilation–perfusion mismatch and compression of the newly transplanted lung. Avoidance of positive-pressure ventilation after single-lung transplantation in patients with

preexisting emphysema appears to decrease this risk. The actual differences in outcome comparing single-lung with double-lung transplantation in patients with end-stage emphysema that are due to differences in ventilation–perfusion matching remain equivocal.[95,97,98]

The benefit of single-lung transplantation in patients with pulmonary hypertension *and* Eisenmenger syndrome remains controversial.[31] These procedures typically require the use of cardiopulmonary bypass to prevent acute right ventricular failure at the time of pulmonary artery clamping. Single-lung transplantation in this patient population may produce a functional pneumonectomy for the remaining native lung. Although both lungs are well ventilated posttransplant, blood flow is severely diverted to the transplanted lung from the native (high PVR) lung, with increasing risk of pulmonary infarction in the native lung. Thus, it has been suggested that combined heart–lung transplantation might be best in this population.[99]

Bilateral and bilateral sequential single-lung transplantations are performed in patients with infection in one or both lungs or in patients with severe pulmonary hypertension. Historically, bilateral lung transplantation was performed using an en bloc procedure with a tracheal anastomosis and cardiopulmonary bypass. Disadvantages include the need for systemic anticoagulation, increased use of blood products, use of cardiac arrest, and increased risk of ischemia at the site of tracheal anastomosis. The advent of bilateral lung transplantation performed as sequential single-lung transplantation using bronchial anastomoses averted most of these disadvantages.[100,101] Bilateral sequential single-lung transplantation has a number of advantages compared with en bloc double-lung transplantation. Single-lung transplantation is technically easier, and cardiopulmonary bypass is not necessary in most patients; thus, ischemic arrest of the heart is not required. The en bloc transplantation of both lungs is performed through a median sternotomy and requires an abdominal laparotomy for access to the omental flap. In addition, double bronchial anastomoses appear to result in fewer ischemic complications compared with the single anastomosis of the trachea that is required in the en bloc technique.

The surgical approach for sequential bilateral lung transplantation is either through sequential right and left thoracotomies or through a median sternotomy. The large transverse thoracosternotomy that extends from axillary line to axillary line producing the classic "clamshell" or "chevron" incision has fallen out of favor because of its effects on postoperative respiratory function. Bilateral sequential single-lung transplants can be performed through a muscle-sparing thoracotomy. The native lung with the more severe disease (poorer function) is transplanted first. After the first new lung is implanted, ventilation is switched to the newly transplanted lung, and the second lung is excised and transplanted. In patients with severe obstructive disease, the contralateral chest cavity is not open during the first single-lung transplant because the lung becomes severely hyperinflated when not confined to the pleural cavity. The resulting air trapping can create significant ventilatory and hemodynamic derangements.

In patients with primary pulmonary hypertension, lung disease may have been the primary disease process, with the patient having relatively normal underlying heart function. However, chronic pulmonary hypertension leads to progressive right ventricular hypertrophy and heart failure. Often, lung transplantation results in remodeling of the right ventricle, obviating the need for heart transplantation.[102]

Postoperative Management

After completion of surgery while the patient is still in the operating room, either the patient is awakened from general anesthesia and extubated, or the double-lumen endotracheal tube is exchanged with a single-lumen endotracheal tube. In patients having lung transplantation with a single-lumen tracheal tube and bronchial blocker, only removal of the bronchial blocker is necessary because the existing tracheal tube suffices as the conduit supporting mechanical ventilation in the postoperative setting. Caution should be taken to ensure that the tracheal tube has an internal diameter of at least 8 mm to facilitate suctioning and bronchoscopy. The concentration of oxygen is decreased after surgery to avoid oxygen toxicity with the goal of maintaining arterial oxygen tension of approximately 100 mm Hg.[103] Problems of postoperative ventilation–perfusion mismatch, shunting, and increased dead space are more pronounced in patients undergoing single-lung transplantation compared with bilateral lung transplantation. In patients who are not eligible for extubation at the completion of surgery or soon after arrival to the intensive care unit, a ventilator weaning protocol is instituted in the ICU.

The contribution of a "denervated" lung to pulmonary mechanics and physiology in the postoperative period is poorly understood. Familiarity and appreciation of allograft physiology are imperative for ventilation of the new lung. Native lung explantation and subsequent allograft implantation produce denervated lungs and airways, loss of a functional pulmonary system, and loss of bronchial artery blood flow. Normally, afferent input from the pulmonary stretch receptors via the vagus nerve is relayed to the medulla.[104] In lung transplant recipients, respiratory rate and tidal volumes cannot be dependent on the medulla via the vagus system. Instead, ventilatory information depends more on chest wall afferent signals.[105,106] Denervation of the vagus nerve input to the lungs includes blunting of the cough reflex and possible increased risk of aspiration in the early postoperative period, although patients appear to tolerate this denervation fairly well, with fewer than expected long-term sequelae. Patients undergoing left lung transplantation are at risk for injury to the recurrent laryngeal nerve. Disruption of the lymphatic system in the donor lung increases the risk of fluid accumulation and interstitial pulmonary edema. Judicious fluid administration and use of diuretics to keep patients "relatively dry" are attempts to minimize this effect. Hypoxic pulmonary vasoconstriction remains intact in the denervated allograft.[107] The newly transplanted lung is susceptible to fluid overload as a result of disruption of pulmonary lymphatics. The incidence of early postoperative pulmonary edema with normal pulmonary artery occlusion pressure may be as high as 60%.[108] In this low-pressure pulmonary edema, the ratio of protein concentration of the edema fluid compared with that of the serum is >0.5, suggesting increased permeability (so-called exudate) that could have resulted from endothelial damage.[109] An association exists between the occurrence of pulmonary edema and graft ischemic time.[108] In an attempt to minimize vol-

ume administration to minimize pulmonary edema, low-dose vasoconstrictors are often used to support blood pressure, especially in the setting of sympatholytic treatments such as epidurally administered local anesthetics.

Some degree of acute pulmonary rejection may occur in as many as 50–87% of patients after lung transplantation.[110] Clinical manifestations include cough, breathlessness, low-grade fever, and wheezing. Decreases in the forced expiratory volume in 1 second (FEV_1) and forced vital capacity with characteristic abnormalities on the chest radiograph are common.[111,112] Differential diagnosis includes postoperative edema, infection, and bronchiolitis obliterans. A bronchial lavage is often sent for culture.

Bronchiolitis obliterans is a devastating complication of lung transplantation and is a leading cause of morbidity and mortality beyond the first year after transplantation. It is characterized by decreased FEV_1 and obstruction and destruction of pulmonary airways, which lead to hypoxia.[113] Diagnosis is established by transbronchial biopsy. Therapeutic options are limited because the condition is relatively refractory to increasing immunosuppressant therapy.[113,114] Retransplantation often is the only option, and these patients may present again to the operating room anesthesiologist.

Infectious complications after lung transplantation cause significant morbidity and mortality. Predisposing factors to bacterial infection include immunosuppressant therapy, ischemic injury to the lung, persistent pleural effusions, interruption of lymphatic drainage, and diminished cough reflex secondary to denervation. Donor transmitted infections are associated with high mortality rates. Hence, the airways of the donor lungs are routinely cultured, and antibiotics in the recipient are adjusted accordingly. Infection with CMV is associated with significant mortality in lung transplant recipients and is the most common viral infection in the recipient population.[11] Symptoms are nonspecific and include malaise and fever. Laboratory findings include leukopenia, thrombocytopenia, atypical lymphocytosis, and hepatitis.[115–117] The recipient may acquire primary infection from a CMV antibody–positive donor or from blood products. Hence, blood transfused to a transplant recipient should be CMV negative. Even recipients who are CMV-antibody positive before transplantation can experience reactivation of previous infection or be infected with a different strain from the donor.[118,119] Fortunately, ganciclovir is an effective antiviral agent in the treatment of most CMV infections and pneumonitis and often is administered prophylactically in the posttransplant period. Fungal infections are more common in the lung transplant recipient than in other solid organ transplant recipients.[10] The two most common species isolated are *Candida* and *Aspergillus*. Although treatment of invasive infection usually includes amphotericin, many transplant programs prophylactically administer an azole agent such as itraconazole.

Heart Transplantation

Heart transplants are always emergency operations. The most common disorders leading to heart transplantation include ischemic cardiomyopathy, idiopathic cardiomyopathy, congenital heart disease, and viral myocarditis. Patients are evaluated as candidates for heart transplantation through a heart failure clinic, which typically includes cardiac surgeons and cardiologists. A battery of preoperative tests aims to define the cause of heart failure and comorbidities. The workup usually is performed on an outpatient basis, and input from the department of anesthesiology can be gained if the institution has a preoperative clinic. However, in many sites in the United States, the first interaction between anesthesiologist and patient undergoing heart transplantation occurs a few moments before the heart transplant. The preoperative workup of patients for heart transplantation includes assessment of PVR. PVR is the difference between mean pulmonary arterial pressure and left atrial pressure divided by cardiac output. PVR is expressed in Wood units (normal = 1–2). Increased PVR that is irreversible and >6 Wood units may preclude eligibility for heart transplantation. Donor hearts typically are harvested from patients who have normal or near-normal cardiopulmonary physiology. The donor right ventricle is accustomed to pumping blood through a low PVR bed. Once explanted, the donor heart undergoes a period of ischemia until reimplanted and reperfused. The donor right ventricle, in the setting of acute ischemia and reperfusion, is then exposed to an acute increase in PVR (afterload) from the chronically ill recipient who may have a PVR significantly greater than that of the donor. The clinical manifestations of acute increased PVR after a period of cross-clamp ischemia may include right ventricular failure and dilation. Right ventricles often require pharmacologic support during this critical time.

DONOR

Organ harvests are conducted in large and small community hospitals. The quality of the donor organ often depends on the ability to maintain hemodynamic stability at the time of harvest. Criteria for heart donation are multifactorial and include age, preexisting cardiovascular disease, heart size, and echocardiographic, electrocardiographic, and cardiac catheterization data. The Organ Procurement Organization (OPO) is notified of potential organ donors. The list of eligible candidates is reviewed. The recipient is selected based on ABO blood typing compatibility, heart size, and acuity of illness. The recipient is notified and instructed to go to the hospital.

The timing of the recipient's transportation to the operating room and the donor harvest is multifactorial and, as in lung transplants, depends on what other organs are being harvested, the distance between the two sites, and the mode of transportation. In many organ harvests, procurement teams arrive from multiple institutions and from various locations across the country. Organ procurement is conducted under the auspices of the OPO, the harvest teams, and the on-site anesthesiologist and physician group. The vast majority of donors are patients with preexisting brain death for whom the family has consented for organ donation. A small fraction of organ harvests originate from "nonbeating heart donors." The latter group is not currently used for the donation of hearts. Nonbeating heart donors are patients with terminal illness who do not meet the criteria for brain death but in whom prognosis is grim and discontinuation of life support has been selected by the patient and/or family. If the patient or family is willing to donate, these patients are transported to the operating room, comfort

measures are emphasized, and discontinuation of support and end of life are followed by organ harvest.

The avoidance of significant hypotension, myocardial ischemia, and high pressor dependency is believed to be important in organ function after implantation. The heart is excised in its entirety, including significant portions of the superior and inferior vena cavae, pulmonary artery, and aorta. Before its excision, the heart is inspected by the harvest team as a final check for viability for transplantation. In many centers, induction of anesthesia in the recipient is linked to the final viability check of the donor heart.

RECIPIENT

Typically the recipient is notified by pager or cell phone that a heart transplant is available. The recipient arrives at the hospital, goes through the admission process, and is transported to the perioperative area. Clinical data pertinent to the preoperative workup typically are available through the heart failure clinic and ideally in a condensed packet format. These data are most readily accessible via an electronic database format.

The operating room is set up in a conventional format for cardiac surgery. Medications that are available but not necessarily open include isoproterenol, milrinone, epinephrine, systemic vasodilators, and inhaled pulmonary vasodilators (nitric oxide or prostacyclin).

Preoperative Management

The heart transplant recipient is often brought to the operating room directly from home. Admission processes, updated laboratory testing, and a blood sample to the blood bank for type and cross match require time and should be considered when the sequence to heart transplantation is planned. Informed consent is obtained in the usual fashion, including placement of invasive monitors, postoperative ventilatory support, and transesophageal echocardiography. Intravenous access is followed by insertion of an intraarterial and central venous catheter. Large-bore intravenous access (e.g., two large-bore catheters) is vital for redo sternotomy cases because bleeding can be abrupt and severe. Blood products should be immediately available in the operating room. A pulmonary artery catheter is not absolutely required but often is useful in the titration of pulmonary vasodilators in patients with increased PVR. Defibrillation pads are placed on all patients who have undergone prior heart surgery or sternotomy. Antibiotics should be administered 30–60 minutes before incision and should cover broadly both gram-positive and gram-negative organisms. Sedation is administered judiciously. No epidural is inserted. Postoperative pain is controlled with parenteral narcotics. Toradol and other nonsteroidal antiinflammatory drugs are avoided because of their risk for renal toxicity, particularly in patients who receive high doses of cyclosporine or tacrolimus.

Intraoperative Management

Induction of general anesthesia often coincides with conformation of a suitable donor organ. Induction is accomplished with intravenous sedative–hypnotics and narcotics accompanied by a muscle relaxant. Aspiration precautions are prudent because these emergency operations often occur in the setting of a full stomach. Preoperative inotropes (intravenous milrinone) are titrated based on hemodynamics and often are continued until cardiopulmonary bypass. Immunosuppressive therapy begins after induction of anesthesia based on institution-specific protocols. The prebypass period is characterized by sternotomy, exposure of the heart, heparinization, and cannulation. Patients with a VAD bridge device require VAD explantation before heart transplantation. These patients often are anticoagulated preoperatively and are at very high risk for bleeding.

Use of antifibrinolytic therapy is common during heart transplantation. In addition to avoiding the risk of transmission of infection, the avoidance of blood transfusion may decrease the risk of postoperative infection. The available antifibrinolytics are tranexamic acid, ε-aminocaproic acid (Amicar), and aprotinin. Red blood cell replacement therapy is leukocyte depleted and CMV matched. Treatment of coagulopathy includes plasma, cryoprecipitate, platelets, and recombinant factor VIIa. Protamine is administered to reverse heparin after bypass.

Cannulation before bypass includes bicaval cannulas and standard aortic cannulas. The SVC cannula increases the risk of SVC hypertension if effective drainage is not achieved. Monitoring the venous pressure proximal to the tourniquet tie of the SVC is prudent. Initiation of cardiopulmonary bypass occurs when the donor heart has arrived. Systemic cooling is common, but cardioplegia of the native heart is not necessary. The explanted heart is excised in its entirety except for residual portions of left and right atria. The newly arrived donor heart is prepared cold on a separate table by a separate surgeon. The aorta, pulmonary artery, and left and right atria are anastomosed. A variation in the technique is to perform bicaval anastomosis. If a pulmonary catheter is inserted, it must be withdrawn out of the heart that will be excised. Some surgeons prefer to pull the pulmonary catheter out of the native heart but keep it clamped to the side on the surgical field and manually insert it into the donor heart before right atrial anastomosis.

Rewarming typically triggers a series of checks and balances in all cardiac operations, including heart transplants. Typically, a large dose of corticosteroids is administered before unclamping and reperfusion of the new heart. The preseparation from bypass checklist includes achieving normothermia; balanced acid–base and electrolyte status, especially potassium, calcium, and magnesium; pacing capability; adequate sedative hypnotic and analgesic drug concentrations; minimizing negative inotropes (inhalation anesthetics); and availability of inotropes, vasodilators, and pressors. Adequate oxygen-carrying capacity is assured. There is no predefined hemoglobin concentration below which red cell transfusion is indicated. These decisions are based on the individual patient and conditions. Use of selective pulmonary vasodilators is more common in heart transplants than in conventional CABG surgery. Inhaled prostacyclin is initiated when ventilation is resumed. Unclamping of the aorta results in reperfusion of the donor heart. Return of heart rhythm soon follows, and assistance with external pacing may be necessary. The duration of reperfusion before separation from bypass is controversial. It is desirable to minimize bypass time and its deleterious effects on blood and vital organs (inflammation, red cell destruction, dilution, emboli). However, the ischemic heart (from cross-clamp in the donor to unclamping in the recipient) is depleted of energy stores,

such as glycogen, adenosine triphosphate, and other high-energy molecules. In addition, intracellular and extracellular acidosis is severe in the heart after a period of prolonged ischemia, even if the heart is kept cold with cardioplegia. The needed recovery time is somewhat arbitrary and institution dependent.

Separation from bypass often is performed slowly, with gradual loading of the right ventricle. Pharmacologic support is common and often includes isoproterenol. This pure β-agonist is a potent inotrope and pulmonary vasodilator. The increased heart rate often is well tolerated and many times desirable, as cardiac output from hearts from young donors is often heart rate dependent with a relatively fixed or limited stroke volume. Left-heart failure is less common in heart transplantation compared with other forms of heart surgery because presumably a normal or near-normal heart is retrieved. Difficulty with preservation of myocardium, prolonged ischemic time, occult coronary artery disease, and air emboli to the coronary circulation can contribute to left ventricular dysfunction. Right-heart failure can be precipitated by increased PVR in the recipient. Treatment of the latter includes inotropes and pulmonary vasodilators, as well as hyperventilation, increasing oxygen tension, decreasing PEEP, and decreasing lung water.

Once separation from bypass has been achieved, circulatory stability is confirmed and heparin is reversed with protamine. The postbypass period is characterized by correction of coagulopathy (if present), maintaining circulatory stability and body homeostasis (temperature, electrolytes, acid–base balance), and closure of the incision. Point-of-care coagulation testing offers the opportunity to quickly diagnose a bleeding diathesis and its cause, thereby permitting a targeted blood product replacement strategy. On completion of surgery, the patient is transported to the intensive care unit with full monitoring.

SUMMARY

The last several decades have witnessed considerable advances in both lung and heart transplantation. Much of this improvement results from a better understanding of the immune mechanisms involved in allograft rejection, which has spurred ongoing development of novel immunosuppressive regimens. For example, studies have demonstrated that tacrolimus is at least as effective as cyclosporine in preventing acute rejection episodes of cardiac allografts. Novel regimens that combine tacrolimus with MMF or sirolimus may hold promise as rescue therapy after refractory rejection. However, randomized studies are needed to confirm this result. Importantly, the anesthesiologist plays a pivotal role in the management of the transplant recipient's physiology and, as a result, both the short- and long-term morbidity/mortality of these patients. Attention to detail, an understanding of the operation, and an appreciation of allograft physiology all contribute to patient outcome. In coming years, greater insight into mechanisms of ischemia–reperfusion injury and acute rejection will have a positive effect on the outcome of this high-risk population. Additionally, as anesthesiologists continue to increase their presence in intensive care units, postoperative management of this high-risk population, including, but not limited to, volume administration (colloid vs. crystalloid), ventilatory strategies (low stretch vs. open lung), and glycemic control, will be relegated to the domain of anesthesiology. It is incumbent on anesthesiologists to be leaders in this advancement and to act as vital members of the entire transplantation team.

CHAPTER 58

Anesthesia for Kidney, Pancreas, or Other Organ Transplantation

David S. Beebe, MD, and
Kumar G. Belani, MBBS, MS

KIDNEY TRANSPLANTATION

History and Introduction

The technique for the vascular anastomosis basic to kidney transplantation was described by Carrel in 1902. However, because of the lack of safe, effective immunosuppressive agents, the first successful kidney transplant was not performed until the mid-1950s. This transplant was between identical twins.[1] Transplantation between identical twins resulted in excellent long-term graft and patient survival. However, the growth of kidney transplantation began in earnest with the development of improved immunosuppressive agents, particularly cyclosporine. Kidney transplantation is now the preferred treatment of end-stage renal disease (ESRD) of almost any origin. Recipients of kidney transplants have improved survival and quality of life compared to patients who remain on dialysis. In the United States, approximately 15,999 kidney transplants were performed in 2004.[2]

Organ Matching, Availability, and Allocation

The high success of kidney transplantation for treatment of renal failure and the significantly improved quality of life experienced by patients has created a major demand for this operation. Currently, the need for renal transplants exceeds the supply of available cadaveric organs. The number of patients on the waiting list now exceeds 55,000.[3] Unfortunately, not every organ is suitable for transplantation, and many patients have conditions that make successful transplantation difficult. For example, in most patients, the blood type of the kidney must be compatible with that of the recipient. Anti-A antibodies from a blood type O recipient can react with the donor endothelial cells with blood type A and result in acute rejection. Obtaining a kidney with as close a human leukocyte antigen (HLA) antigen match as possible also is important to lessen the incidence of rejection.[4] On the other hand, patients may benefit from earlier transplantation even if the graft is not optimal because the high mortality of long-term dialysis favors the risk-to-benefit ratio toward transplantation.[5]

The United Network for Organ Sharing (UNOS), which uses the principle of medical utility and justice, has been responsible for developing algorithms for determining which patients should receive a cadaveric kidney since 1987. The United States is divided into 11 geographic regions, within which cadaveric organs are allocated based upon the allocation algorithm.[2] The allocation algorithm takes into account the duration patients are on dialysis, the quality of antigen matching, and

KEY POINTS

1. Half of all deaths after renal transplantation are cardiac related, and cardiac disease is the leading cause of death in the first year posttransplant. Therefore, detection of severe coronary artery disease in patients prior to transplantation is vital.
2. Diabetics with autonomic neuropathy are at risk for severe hypotension and bradycardia during induction of general anesthesia and for sudden death in the postoperative period.
3. Blood glucose levels should be determined every hour in renal transplant recipients who have insulin-dependent diabetes mellitus. Evidence suggests that the incidence of wound infections in diabetic patients can be reduced if blood sugar levels are tightly controlled.
4. Patients undergoing renal transplantation usually benefit from central venous pressure measurement, which helps determine if the patient's volume status is adequate at the time of reperfusion of the allograft.
5. To ensure adequate volume expansion in adult kidney recipients, central venous pressure should be raised to 14 or 15 mm Hg with intravenous normal saline or 5% albumin prior to perfusion of the allograft. If the patient is relatively anemic (hemoglobin <10 g/dL), packed red blood cells can be used for this purpose as well.
6. Hypotension can result in decreased graft perfusion and delayed graft function in adult kidney recipients. Therefore, it is helpful to intentionally raise the systolic blood pressure to 130 or 140 mm Hg by reducing the concentration of inhaled anesthetic agents administered prior to reperfusion of the allograft. A vasopressor such as ephedrine (5–10 mg) or phenylephrine (100–200 μg), or infusion of dopamine (3–5 μg/kg/min) occasionally is required to treat hypotension during and after perfusion.
7. Animal studies have shown that hyperglycemia causes islet cell dysfunction. Therefore, blood glucose levels must be checked at least hourly or more frequently during pancreas or islet cell transplantation with the goal of keeping serum glucose levels between 100–150 mg/dL.
8. Patients undergoing hematopoietic stem cell transplantation may have metabolic disorders that can make intubation difficult. Mucositis also can make intubation difficult. When endotracheal intubation is required, airway care must be provided in an environment equipped to handle a patient with a difficult airway.
9. Because of the high incidence of venous thrombosis in patients receiving intravenous hyperalimentation, it is recommended that all patients referred for intestinal transplantation undergo preliminary mapping of their venous access by Doppler ultrasound. Patients with multiple thrombosed vessels should be considered for additional angiographic evaluation.
10. Significant bleeding may occur during the dissection process for small bowel transplantation. A rapid infusion device often is beneficial and should be available, and blood-salvaging devices should be used.

the age of the patient. The algorithms for allocation have been changed periodically. For example, prior to 2002, more weight was given to having closer matching of HLA antigens than is required currently, as enhancements in immunosuppression therapy have improved the outcomes of recipients with lesser degrees of HLA matching.[6]

Several means to increase the number of kidneys available for transplantation are being used and/or investigated. One method has been the promotion of voluntary living renal donation because people can live perfectly healthy lives with only one kidney. Living related transplantation as a means of providing a replacement for a diseased organ was therefore first applied to the kidney. Approximately 6500 patients received a transplant from a living donor in 2003. Recipients of living related kidney transplants generally suffer fewer episodes of acute and chronic rejection than those receiving cadaveric organs. Recipients also benefit because living related and unrelated transplantation is performed on an elective, nonemergent basis.[3]

Improved immunosuppressive regimens have led to the advent of living unrelated renal transplantation. Living unrelated renal transplantation appears to have a superior outcome over cadaveric transplantation, probably because of the shorter cold ischemia time. As a result, the incidence of delayed graft function and subsequent graft loss is lower than in cadaveric transplantation. Some studies show that living unrelated transplantation has a similar incidence of rejection as living related transplantation in spite of inferior HLA matching.[7]

Cadaveric kidney transplants now are being performed with an increasing number of organs from donors who would have been deemed unsuitable in earlier times, such as donor age >55 years, non–heart-beating donors, cold ischemia time >36 hours, and donor hypertension or diabetes mellitus of >10 years' duration (Expanded Donor Criteria).[8] Although overall survival in recipients of a marginal cadaveric donor kidney was less than that of recipients who received better matched organs, these patients had improved survival when compared to transplant candidates who remained on dialysis.[5] Approximately 20% of all cadaveric kidney transplants performed in 2003 were from expanded donor criteria organs.[3]

New techniques such as plasmapheresis, high-dose intravenous immunoglobulin, and potent immunosuppressive agents have made transplantation with ABO-incompatible kidneys and kidneys from recipients with a positive cross-match to the donor possible. Although the success rate in patients receiving incompatible organs is lower than in those with compatible organs, the overall morbidity and mortality may be lower in many patients than in patients undergoing continued dialysis while waiting for a high-compatibility organ.[4]

Indications and Contraindications

The most common causes of end-stage renal failure in adults are diabetes, systemic hypertension, glomerulonephritis, and polycystic kidney disease. In children and adolescents, the most common causes of ESRD are congenital malformations of the kidneys and urinary tract and focal segmental glomerulosclerosis.[9]

Organ systems are adversely affected by a prolonged time on dialysis, and these changes can increase the morbidity and mortality of a kidney transplant. Ideally patients with progressive renal failure should receive a kidney transplant before they begin dialysis.[9] Diabetic patients with marginal renal function who receive a pancreas transplant should receive a simultaneous kidney transplant because the immunosuppressive agents required for the pancreas transplant may cause further deterioration of renal function to the point of requiring dialysis.[10]

Living related and unrelated transplants are one method by which kidneys can be transplanted before dialysis becomes necessary because they can be scheduled electively before dialysis is required.[9]

Unfortunately, because of the long waiting times to receive a renal allograft, most patients receiving renal transplants have ESRD that has already progressed to the point where dialysis is required. The 5-year survival rate of patients on chronic hemodialysis or peritoneal dialysis is only 30%. In contrast, the 5-year survival rate following transplantation for ESRD is 70%. Therefore, except in rare instances, transplantation should be performed in all patients with renal failure in whom it is technically feasible.[9]

The number of absolute and relative contraindications to renal transplantation is decreasing. In the past, the presence of diabetes as a cause of renal failure was a contraindication to renal transplantation. Currently, renal failure from diabetes is the primary indication for transplantation in adults. Diabetics who receive a kidney transplant survive longer, with a better quality of life, than do those who require long-term dialysis.[11]

Other conditions that previously were thought to be contraindications to transplantation now are considered acceptable. HIV infection once was considered an absolute contraindication, but transplantation now has been successfully performed, with 5-year outcomes similar to the rates in other patient populations.[12] Similarly, patients infected by hepatitis C virus can receive a kidney transplant with success rates comparable to the rates in patients without hepatitis C and may benefit by being eligible to receive a kidney from a donor who also has hepatitis C.[13] Patients older than 65 years now receive kidney transplants with outcomes similar to younger recipients.[14] Patients with advanced congestive heart failure as well as renal failure do better with renal transplantation compared to those treated medically with dialysis.[15] Highly sensitized patients, T-cell–positive cross-match, and ABO blood group-incompatible patients now are considered potential renal transplant candidates, albeit with increased morbidity and mortality.[4]

Although the indications for kidney transplantation have been expanded significantly, some individuals with ESRD are not good candidates for the procedure. Active infection, active drug abuse, complete thrombosis of the vena cava and iliac veins, and disseminated malignancies are among the contraindications to transplantation. Sensitization by previous failed transplants, blood transfusions, or pregnancy will require individual assessment because in some patients the graft survival would be too poor to transplant.[16] Patients who have a history of noncompliance or mental retardation who are unlikely to take their medications constitute relative contraindication to transplantation. However, patients with mental retardation can be transplanted successfully if they have a caregiver responsible for administering the medications.[17]

Surgical Procedure

The surgical procedure of kidney transplantation is straightforward. In adults and older children (>20 kg), the transplanted kidney usually is placed in the extraperitoneal iliac fossa via a curvilinear incision along the lateral margin of the rectus muscle approximately 8–10 inches from just above the pubic bone to just above the umbilicus (Fig. 58–1). The common and external iliac arteries and veins are exposed retroperitoneally. The renal vein is anastomosed before the renal artery, and an end-to-side or end-to-end anastomosis can be performed, depending upon the anatomy of the vessels and depth of the renal pelvis. The renal artery is then anastomosed to the internal or external iliac artery. Occasionally, donors have multiple renal arteries, and several arterial anastomoses are required. Renal revascularization involves clamping of the iliac artery and vein. This process can result in ischemia to the lower extremity for as long as 60 minutes. After the vascular anastomoses are completed, the clamps are released in a staged fashion, resulting in perfusion of the kidney graft and lower extremities. The final stage of the operation involves reconstruction of the urinary drainage by anastomosing the donor ureter to the patient's bladder.

In infants and small children (<20 kg), a transperitoneal approach is used. An incision from the xiphoid process to the pubis is made (Fig. 58–1). The bowel is mobilized, and the aorta and vena cava are exposed. The donor artery and vein are anastomosed to the aorta and vena cava end to side. Once the vascular anastomoses are complete, the clamps are released, resulting in reperfusion of both lower extremities and the donor kidney. The urinary drainage is then reconstructed.[18]

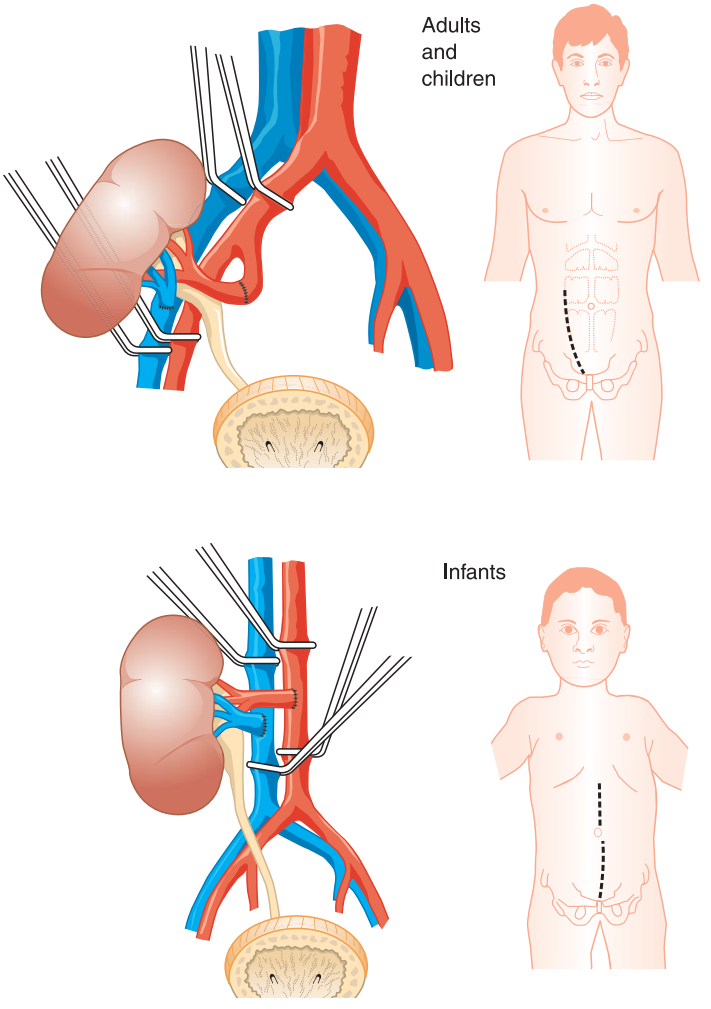

FIGURE 58–1. Surgical procedure for kidney transplantation in adults, children, and infants. See text for details.

Pretransplant Evaluation

Patients undergoing kidney transplantation require a complete medical review and evaluation of their medical condition prior to surgery. This is best done by the transplant surgery team prior to placing the patient on the transplant list. If the evaluation is not performed prior to listing, the patient, surgeon, anesthesia provider and internist, and/or pediatrician are faced with the task of performing a last-minute workup in suboptimal conditions when an organ suddenly becomes available.

Both the underlying cause of renal failure and the renal failure itself contribute to the pathology often seen in patients with renal insufficiency. Often renal insufficiency and the underlying medical condition act synergistically to harm the patient. For example, autonomic neuropathy can be caused by both renal failure and diabetes and has been associated with sudden death following anesthesia and surgery.[19]

Comorbid Conditions

Table 58–1 lists the problems related to ESRD. Dialysis corrects many of the abnormalities associated with chronic renal failure, but many conditions persist. Therefore, each organ system must be evaluated prior to the patient undergoing renal transplantation.

Cardiac Evaluation

Half of all deaths after renal transplantation are cardiac related, and cardiac disease is the leading cause of death in the first year posttransplant.[20] Therefore, detection of severe coronary artery disease in patients prior to transplantation is vital.

Patients with diabetes, peripheral vascular disease, angina, or a longer duration of ESRD have a greater risk of mortality.[20] However, what constitutes the optimal pretransplant cardiac evaluation, particularly in diabetic patients, is still debated. Currently, exercise tolerance testing is recommended for patients with diabetes and those older than 50 years.[21] Patients with evidence of reversible cardiac ischemia should be referred for cardiac catheterization. Unfortunately, many patients with renal failure do not have the exercise capacity to adequately undergo exercise stress testing. Thus, dobutamine stress echocardiography has been proposed as a better predictor of coronary artery disease than exercise stress testing alone in renal transplant candidates.[22]

TABLE 58–1.

Medical Problems in Patients with End-Stage Renal Failure

System	Complications Associated with Renal Failure
Cardiovascular	Hypertension, atherosclerosis, coronary artery disease, congestive heart failure, pulmonary edema, pulmonary hypertension, pericarditis, cardiomyopathy, arrhythmias
Hematologic	Anemia, platelet dysfunction, coagulopathies, increased capillary fragility
Immune	Impaired immunity
Neurologic	Peripheral neuropathy, autonomic neuropathy
Musculoskeletal	Myopathy
Gastrointestinal	Impaired gastric emptying, gastroparesis, nausea, vomiting, anorexia, peptic ulcer disease
Electrolyte and acid–base regulation	Potassium, sodium, calcium, magnesium, phosphate, bicarbonate imbalances, metabolic acid accumulation
Endocrine	Hyperparathyroidism, osteodystrophy, impaired growth and development (especially in children), glucose intolerance
Pulmonary	Pneumonia, pulmonary edema, pleuritis, atelectasis
Hepatic	Hypoalbuminemia, cytochrome P450 abnormality, hepatitis

Data from Koehntop DE, Beebe DS, Belani KG. Kidney transplantation. In Klinck JL, Lindop MJ eds. Anaesthesia and Intensive Care for Organ Transplantation. London: Chapman and Hall 1998:254-280.

High Incidence of Cardiovascular Disease, Especially in Diabetics

Patients with diabetes and renal failure are at particular risk for coronary artery disease.[20] Evaluation of these patients often is difficult because they have a high incidence of silent ischemia. In addition, some noninvasive tests, such as thallium stress test, have not been as reliable for evaluating cardiac pathology in diabetic patients with renal failure as in nondiabetic patients.[23] This has led some centers to recommend coronary angiography in patients with ESRD associated with diabetes if they are older than 45 years, have a history of smoking, have had diabetes for >25 years, or have electrocardiographic signs of ischemia.[24] Diabetic patients who have significant coronary disease with treatable lesions should undergo coronary artery surgery or angioplasty prior to receiving a kidney transplant.[24] Some diabetics have significant but diffuse coronary disease (identified by angiography) that cannot be treated surgically or by angioplasty. These patients may still benefit from kidney transplantation instead of chronic dialysis, but they are at higher risk for perioperative cardiac events.[18]

Dialysis

Patients presenting for renal transplantation may be receiving either hemodialysis or peritoneal dialysis. Each method has its associated morbidity and complications that influence the care of patients who undergo kidney transplantation. Both methods often fail to correct completely the metabolic acidosis associated with renal failure. Other metabolic problems, including hyperkalemia, also may not be corrected completely with either method.[18]

Peritoneal dialysis may result in intravascular volume overload or depletion, depending upon the volume and osmolality of the dialysate. Atelectasis may occur as a result of diaphragmatic splinting resulting from the dialysate, and pleural effusion may occur if the fluid leaks into the pleural space. However, the most common complication of peritoneal dialysis is peritonitis. This usually resolves with antibiotic treatment but may cause cancellation of the transplant if peritonitis is present when a donor organ becomes available.[18]

Hemodialysis by its nature results in rapid shifts in the patient's intravascular volume status. For example, 8 hours of dialysis in an adult reduces body water by an average of 1.5 L and the plasma volume by 0.7 L. This rapid volume shift may result in hypotension during dialysis in some patients. Significant hypotension upon induction of general anesthesia in a patient who has recently hemodialyzed is common.[18]

Preoperative Assessment

Several items in the pretransplant evaluation are of concern to the anesthesia provider. A major concern is the cause of the patient's renal failure. Diabetes currently is the most common cause of ESRD in adults. In addition, diabetic patients suffer from a host of other comorbidities that affect anesthetic care, including gastroparesis, autonomic neuropathy, peripheral neuropathy, cardiovascular disease, and peripheral vascular disease. Diabetics with autonomic neuropathy are at risk for severe hypotension and bradycardia during induction of general anesthesia and for sudden death in the postoperative period.[25] Hypertension is another common cause of renal failure that affects multiple organ systems. Thus, the results of other tests of organ function, such as coronary angiograms that were obtained as part of the general pretransplant evaluation, must be reviewed and the results incorporated in the plan for anesthesia care.

The frequency and type of dialysis, if used, are important as well. The interval since the last dialysis will be helpful in determining the volume status of the patient. The time of insulin administration in diabetic patients is important to note because it can influence the plan for perioperative glucose management. A history of hypotension with dialysis in a diabetic patient suggests the patient may suffer from autonomic neuropathy. These patients are at risk for hypotension upon induction of general anesthesia. Diabetic patients should be asked about symptoms of gastroparesis, such as heartburn, bloating, and explosive diarrhea, because they may be at risk for aspiration of gastric contents upon induction of general anesthesia. These patients will benefit from a nonparticulate antacid, such as sodium citrate or related compounds, prior to induction of general anesthesia. In addition, the type and last dose of antihypertensive medications that the patient receives should be recorded. In general, patients should receive their usual blood pressure medications prior to surgery.[26] However, angiotensin system inhibitors administered immediately before operation have been associated with a greater incidence of hypotension upon induction of general anesthesia in hypertensive patients.[27] As a result, these drugs should be withheld in patients undergoing kidney transplantation, particularly if they have other risk factors for hypotension upon induction of general

anesthesia, such as autonomic neuropathy and dialysis related hypovolemia.

Physical Examination

Several components of the physical examination deserve special consideration in the preanesthetic evaluation of the renal transplant patient. The evaluation of the airway is particularly important for patients in whom diabetes is the cause of renal failure. Patients with long-standing diabetes often develop stiff joints due to glycosylation of the connective tissue that results from elevated blood sugar levels. The inability to oppose the palms of the hands is one sign that stiff connective tissue may be present in a diabetic patient. Patients with stiff joints may be difficult to intubate and may require an awake, fiberoptic intubation.[28] The patient should also be examined for signs of congestive heart failure, such as rales and peripheral edema.

The arms of patients on chronic hemodialysis should be examined for the presence of both functioning and nonfunctioning dialysis shunts and fistulas. Upper extremity fistulas may clot during transplantation surgery from reduced blood flow during surgery or perioperative elevation of clotting factors. Care must be taken when padding the upper extremity with a forearm fistula so that blood flow in the fistula is not restricted. Blood flow through the fistula during surgery can be monitored by palpation or a Doppler device. The arm with a functioning fistula should not be used for blood pressure monitoring, venipuncture, or placement of intravascular catheters because each such maneuver may cause the fistula to thrombose.[26] In the event of delayed graft function or even nonfunction following kidney transplantation, a functioning dialysis shunt is invaluable in the postoperative period.

Assessment of Fluid Balance

Fluid balance often is difficult to assess in patients on chronic dialysis. Depending on the type of dialysis and the interval since last dialysis, the patient may arrive in the operating room either hypervolemic or hypovolemic. Therefore, the type of dialysis, time of last dialysis, and frequency of dialysis are important information to obtain.[26]

Comparison of Current Weight with Dry Weight One method to help evaluate the volume status of a patient on chronic dialysis is to review the patient's body weight before and after dialysis. The weight of the patient at the completion of dialysis, the "dry" weight, can be determined and compared to the weight when the patient presents for surgery.[18] If the patient has not been dialyzed for several days prior to surgery and has a preoperative weight that is the same or greater than the predialysis weight, the patient likely is euvolemic or even hypervolemic. However if the patient's weight is close to the dry weight, the patient may be hypovolemic. Finally, patients who are dialyzed the day of surgery and lose more than 2 kg of weight have a high incidence of hypotension upon induction of general anesthesia because of hypovolemia.[27] Anesthesia care providers must be prepared to rapidly replace the intravascular volume in these patients. Depending upon the extent of hypovolemia, either intravenous normal saline or 5% albumin can be used to provide a more rapid and sustainable cardiovascular response.

Laboratory Tests

Several laboratory tests should be performed in all patients. Because electrolyte and blood glucose levels can change markedly over several days, particularly in patients on dialysis, most of these tests should be performed at or close to the time of operation. An electrocardiogram should be obtained in all patients at risk for cardiac disease and the results compared to previous studies. The serum potassium level may increase during surgery from the effects of drugs administered, blood transfusions, or infusion of hyperkalemic preservative solution from the new kidney. Therefore, delay of surgery may be necessary and dialysis or other intervention performed if the patient is hyperkalemic (>6 mmol/L) preoperatively. Coagulation studies (international normalized ratio, partial thromboplastin time, fibrinogen, platelet count) should be obtained if the patient has a history of bleeding or other evidence of a possible coagulopathy. Finally, a hemoglobin level should be drawn and several units of blood made available preoperatively because patients with renal failure often are markedly anemic preoperatively.[26] Fluid loading to increase central venous pressure in preparation for reperfusion and surgical blood loss may further decrease blood hemoglobin values and thus warrant intraoperative packed red cell transfusion.

Anesthetic Management

Induction and Maintenance of General Anesthesia

The choice of induction agent depends on the overall health of the patient, the volume status of the patient, the presence of autonomic neuropathy, and the presence of cardiovascular or other disease. Relatively healthy renal transplant recipients tolerate induction of general anesthesia with propofol (2.0–3.0 mg/kg) or thiopental (2.5–3.0 mg/kg) without difficulty. However, hemodynamically compromised patients tolerate etomidate (0.2 mg/kg) better because it causes minimal myocardial depression and preserves autonomic tone. These features are particularly important in diabetic patients with autonomic neuropathy. Fentanyl (50–100 μg/kg IV) can be administered during induction to blunt the hypertensive response to tracheal intubation. In patients who do not have a history of gastroparesis or acid reflux disease, intermediate-duration nondepolarizing muscle relaxants that do not depend on renal excretion for elimination, such as rocuronium (0.5 mg/kg), *cis*-atracurium (0.2 mg/kg), or vecuronium (0.1 mg/kg), can be administered to facilitate tracheal intubation.[26]

In patients with gastroparesis or acid reflux disease, a rapid sequence induction, including the Sellick maneuver to prevent regurgitation of gastric contents, should be performed. The depolarizing agent succinylcholine (1.5 mg/kg IV) has classically been used in patients without renal failure to provide rapid skeletal muscle relaxation for immediate tracheal intubation. However, the serum potassium level can increase 0.6 mmol/L with its administration, so it should be used with caution, if at all, in patients with renal failure who have a preoperative elevated potassium level (>5.5 mmol/L). Because of the increased serum potassium level in renal transplant recipients, many anesthesia providers prefer to use nondepolarizing agents even if a rapid sequence induction is required. Rocuronium is useful for this purpose because at high doses (1.2 mg/kg) it has an onset of action of 60–90 seconds and does not require renal function for elimination.[26] β-Blockers such as metoprolol should be administered to patients at risk for cor-

onary disease if they have not received the drugs preoperatively. Although not studied specifically in renal transplant recipients, β-blockers have been shown to decrease the likelihood of perioperative myocardial infarction in patients with coronary disease undergoing major vascular surgery similar to kidney transplantation.[29] In a multicenter study conducted in patients undergoing elective abdominal aortic or infrainguinal arterial reconstruction, Polderman et al.[29] reported that β-blockers were able to reduce the combined incidence of perioperative cardiac events from 34% to 3.4%.

The inhaled agents desflurane and isoflurane both are extremely useful for the maintenance of general anesthesia for kidney transplantation. Neither agent has nephrotoxic properties, and no deterioration of renal function has been noted with either agent in patients with or without renal disease.[9] Nitrous oxide can be used with the potent inhaled agent. It has minimal side effects, no renal toxicity, and rapid elimination. However, nitrous oxide is associated with increased nausea and vomiting in the postoperative period.[30] As a result, it may be used less frequently for these procedures in the future. Sevoflurane is rarely used for renal transplantation. This agent is metabolized by the liver to produce inorganic fluoride, a substance that has been shown to produce renal toxicity in patients receiving methoxyflurane. Although fluoride toxicity has not been reported with sevoflurane, the possibility still exists, particularly in a donor organ that likely has sustained some degree of ischemic damage. Sevoflurane also reacts with soda lime to form a substance that is nephrotoxic in animal and some human studies.[31] Therefore, the safety of sevoflurane in renal transplantation is unclear. Given that other alternatives are available, there seems to be little reason to select sevoflurane for inhalation anesthesia in these patients.

During anesthesia care, narcotics such as fentanyl (50–100 μg/h) often are administered throughout the transplant procedure to reduce the amount of inhaled agent required and to decrease the likelihood of the patient awakening in severe pain. The pharmacokinetics and pharmacodynamics of fentanyl, sufentanil, alfentanil, and remifentanil are not significantly altered by kidney disease, and all have been successfully used during renal transplantation.[32]

Ongoing skeletal muscle relaxation can be provided with nondepolarizing muscle relaxants that do not depend on the kidney for elimination, such as *cis*-atracurium, rocuronium, and vecuronium. All three agents have been used successfully in patients with marginal or no renal function, and they have minimal effects on heart rate and blood pressure. *Cis*-atracurium is broken down in the plasma by Hoffman elimination, which does not depend on renal or hepatic function. Its duration of action is not prolonged in renal failure. Although the liver metabolizes rocuronium and vecuronium primarily, the duration of blockade with these two agents may be prolonged if large doses are used.[9,33] Pancuronium should not be used in kidney transplant recipients because the drug depends primarily on the kidney for elimination. If the new kidney does not function adequately initially, a prolonged neuromuscular block may result.[9]

Blood glucose determinations should be made every hour in renal transplant recipients who have insulin-dependent diabetes mellitus. Evidence suggests that the incidence of wound infections can be reduced in diabetic patients if blood sugar levels are tightly controlled. One method to maintain tight control of the blood sugar level in adults is to begin an intravenous insulin infusion at 1 unit/h if the blood glucose level is >90 g/dL and adjust the rate to maintain a blood sugar level between 90 and 110 g/dL. In addition, a low-dose dextrose solution (D51/2 normal saline at 25 mL/h) should be administered concurrently throughout the procedure to provide for intraoperative nutrition and prevent hypoglycemia.[34]

Following surgery, most patients can be extubated in the operating room or recovery room when they are alert, strong, and able to maintain adequate ventilation. Postoperative ventilation is rarely required. Epidural analgesia has been used successfully for postoperative analgesia in renal transplant recipients.[35] Use of combined spinal–epidural anesthesia for both surgical anesthesia as well as postoperative pain relief has been reported.[35,36] There is a small but rare risk of epidural hematoma when epidural analgesia is used in anticoagulated patients.

Because most graft recipients receive heparin intraoperatively and some in the postoperative period, intravenous narcotics such as fentanyl, morphine, and hydromorphone usually are used for postoperative analgesia. These agents also can be used for patient-controlled analgesia following discharge from the recovery room.[9]

All narcotics must be used cautiously in renal transplant recipients, particularly if the graft is not functioning properly. For example, a metabolite of morphine, morphine-6-B-glucronide, has opioid agonist activity and is excreted by the kidneys. It can accumulate in renal failure and cause respiratory depression with long-term use. The metabolism of hydromorphone produces a neuroexcitatory compound that can accumulate in renal failure. However, hydromorphone has been used extensively in renal failure patients with no adverse effects. In contrast, a metabolite of meperidine (Demerol), normeperidine, can accumulate in significant amounts in patients with renal failure and can cause seizures. Therefore, meperidine should not be used for postoperative analgesia in renal transplant recipients.[33]

Monitoring

Patients undergoing renal transplantation usually benefit from central venous pressure measurement, which helps determine if the volume status of the recipient is adequate at the time of reperfusion of the allograft. It also provides convenient vascular access to obtain blood samples and for administration of immunosuppressive drugs that must be administered centrally. Pulmonary artery catheters rarely are necessary except in patients with severe cardiac disease. Direct arterial catheters also are rarely necessary except in compromised patients in whom frequent blood gases must be determined.[26]

Immunosuppression

Reactions to immunosuppressive drugs occur occasionally.[37] For example, cyclosporine administration can result in hypomagnesemia, rhabdomyolysis, and other electrolyte disorders.[38] Reactions to antibody OKT3 can be severe and result in hypotension and pulmonary edema. Treatment with diphenhydramine, vasopressors, steroids, diuresis, and postoperative ventilation may be required.[26]

Immunosuppressive Regimens May Dictate Need for Central Access Some immunosuppressive agents require administration via a cen-

tral rather than a peripheral vein. For example, the polyclonal antibody antithymocyte globulin is so irritating to peripheral veins that it must be administered centrally (Thymoglobulin [anti-thymocyte globulin (rabbit)] prescribing information, Sangstat Medical Corporation, Menlo Park, CA).

Allograft Perfusion

Intraoperative volume expansion has been shown to increase renal blood flow and improve immediate graft function. Immediate graft function is associated with increased allograft and patient survival.[9] One method to ensure adequate volume expansion in most patients is to raise the central venous pressure to 14 or 15 mm Hg with intravenous normal saline or 5% albumin prior to perfusion of the allograft. If the patient is relatively anemic (hemoglobin <10 g/dL), packed red blood cells can be used for this purpose as well.

Hypotension can result in decreased graft perfusion and delayed graft function. Often adequate volume expansion prevents the hypotension seen with reperfusion. However, hypotension still can result from products of ischemia from the graft or lower extremity when the vascular clamps are released. The microvasculature of the graft and lower extremity are also vasodilated maximally with reperfusion after a period of ischemia and can result in low peripheral resistance. Therefore, it is helpful to intentionally raise the systolic blood pressure to 130 or 140 mm Hg by reducing the concentration of inhaled anesthetic agents administered prior to reperfusion of the allograft. A vasopressor such as ephedrine (5–10 mg) or phenylephrine (100–200 μg) or infusion of dopamine (3–5 μg/kg/min) occasionally is required to treat hypotension during and after perfusion. One advantage of dopamine over the other vasopressors is that it can increase diuresis in the allograft. However, graft survival has not been shown to increase in spite of this increased diuresis.[9]

Mannitol administration (0.25–1 g/kg) prior to perfusion of the allograft, when combined with volume expansion, has been shown to decrease the incidence of acute tubular necrosis in the transplanted kidney. The mechanism by which this is accomplished may be related to decreasing tubular swelling by its osmotic effect, its action as a free-radical scavenger, or by flushing away of sloughed renal tubule cells before they can cause injury by secondary obstruction.[39] Other diuretics such as furosemide can be administered to enhance diuresis but have not been shown to reduce the incidence of acute tubular necrosis or delayed graft function in the transplanted kidney.[9]

Monitoring Urine Output

After reperfusion of the allograft, the urine output, intravascular volume, and overall circulatory status should be followed carefully. Hypovolemia, hypotension, acute tubular necrosis, or acute rejection can result in diminished urine output. Evaluation of decreased urine output posttransplant usually begins with an assessment of the patient's volume status. A biopsy of the transplanted kidney may be necessary to determine if the patient is suffering from acute tubular necrosis or graft rejection.[26]

Decreasing Urine Output May Indicate a Reversible Surgical Problem Anuria may be due to a mechanical factor. Vascular complications, such as arterial thrombosis, arterial stenosis, and venous occlusion, may result in oliguria. Distal obstruction of the ureter by a clot, kinking, or pressure on the kidney by a lymphocele or hematoma may compromise the function of the new kidney. Fortunately, many of the mechanical causes of oliguria are correctible if the diagnosis can be made in a timely fashion.[26]

Postoperative Considerations and Complications

Most patients do not require admission to the intensive care unit in the postoperative period, provided the nursing unit is experienced in the care of transplant recipients. The standard postoperative care must be provided for the patient who has undergone major abdominal surgery, and the function of the new kidney in the transplant recipient must be followed carefully. Rejection, viral infection, vascular thrombosis, and urinary obstruction are complications that may occur in the perioperative period.[26]

The most common causes of death after transplantation are cardiovascular-related events. Up to 6% of patients with coronary artery disease experience a cardiac complication within 30 days of transplantation.[40] Administering perioperative β-blockade, providing normothermia, maintaining hematocrit >30%, and ensuring patients have optimum analgesia in the perioperative period are measures that may help reduce the risk in patients with cardiac disease undergoing renal transplantation.[9]

Anesthetic Considerations for Patients with Prior Renal Transplantation

Even with a functioning graft, the renal excretion of drugs in transplant recipients usually is decreased compared to those with normal functioning native kidneys. Furthermore, recipients may still suffer from their other systemic disease, such as diabetes or hypertension, that initially resulted in renal insufficiency . Therefore, the anesthetic management of patients with a prior renal transplant is similar to the management of the transplant itself. Muscle relaxants that depend on renal excretion for elimination, such as pancuronium, should be used only with the recognition that excretion may be delayed. Sevoflurane should not be used for the reasons described previously in the section on Induction and Maintenance of General Anesthesia. Adequate hydration should be ensured in the perioperative period, and hypotension avoided to ensure adequate perfusion to the allograft.[41]

Long-term immunosuppression can result in significant morbidity in kidney transplant recipients. The effect of immunosuppressive drugs should be considered when evaluating a kidney transplant recipient for nontransplant surgery. For example, cyclosporine use may cause hypertension and worsen atherosclerosis in kidney transplant recipients. Most patients have some degree of adrenal suppression because of long-term steroid use. Therefore, a stress dose of steroids may be necessary in renal transplant recipients who have received steroids for immunosuppression.[41]

Special Considerations in Pediatric Patients

The anesthetic care of older children and adolescents is similar to the care of adults. Infants and small children younger than 2 years are more challenging. Infants and small children usually receive an adult kidney rather than one from a donor similar in age because there is a high incidence of vascular thrombosis with allografts from infants and small children. However, an adult kidney is so large compared to an infant kidney that it must be anastomosed to the infant's aorta

and vena cava rather than the iliac vessels (Fig. 58–1), as in older children or adults.[42] Therefore, the aorta and vena cava both must be cross-clamped during performance of the vascular anastomoses. The adult kidney can sequester up to 300 mL of blood upon reperfusion. Reperfusion can also result in acidosis from the ischemic organ and lower extremities. Hyperkalemia may result from absorption of the standard hyperkalemic (University of Wisconsin) preservative solution. Hypothermia may result with reperfusion of the allograft. Ischemic vasodilatation upon reperfusion of the allograft can result in low peripheral vascular resistance and hypotension. In addition, the adult kidney initially can produce urine at a rate equal to the patient's blood volume every hour.[43] All this dictates that caregivers pay close attention to circulatory hemodynamics in young infants receiving an adult kidney allograft.

Allograft Perfusion

The goals of the anesthetic management of kidney transplantation in infants and small children are the same as in older children and adults. Adequate volume expansion must occur to prevent severe hypotension upon perfusion of the allograft. Often a permanent, large-bore (2-mm internal diameter) dialysis catheter is valuable for central vascular access and provides a means for hemodialysis if the kidney does not function immediately. Direct arterial pressure monitoring is useful in infants and very small children because blood pressure changes can be rapid and profound. In contrast to older children and adults, the central venous pressure in infants must be increased to 16–20 mm Hg before reperfusion of the allograft. Colloids such as 5% albumin as well as blood products are generally used for this purpose. The amount of colloids and/or blood products administered can be profound. In one review of infants and small children receiving an adult kidney transplant, the amount of colloids and/or blood products administered averaged 90 ± 41 mL/kg.[43]

Postoperative Admission to the Intensive Care Unit

Postoperatively, pediatric patients are at an increased risk for pulmonary edema. Most pediatric patients tolerate the volume administration without morbidity. In a review of 24 infants who received an adult kidney transplant, 17 (71%) were extubated in the recovery room, and most of the other infants were extubated in the intensive care unit the following day. Only 2 (8.3%) patients required mechanical ventilation beyond 24 hours to aid in fluid management. However, 7 (29%) of the 24 patients had radiographic evidence of pulmonary edema on the postoperative chest x-ray film. Therefore, the pulmonary status of pediatric patients should be monitored in an intensive care unit setting following surgery, and some of these patients may require postoperative ventilatory support.[43]

Outcome

Approximately 25,000 patients per year now receive a kidney transplant, either from a living or a cadaver donor. The 1-year graft survival rate is 89% from cadaveric donors and 95% from living related donors. At 5 years, the graft survival is 79% from living related donors and 66% from cadaveric. The 5-year patient survival rate is 81% for recipients of cadaveric organs and 90% for recipients of living donors. In addition, comparison with earlier data shows improved survival of both the patients and the allografts over time. Renal transplantation has become one of the great success stories in medicine.

Summary

Kidney transplantation offers both better survival and a better lifestyle to patients in renal failure. Patients with renal failure are challenging for the anesthesia provider. With careful anesthetic care, knowledge of the pathophysiology of renal failure and associated disease, and understanding of the physiology of perfusion of the renal allograft, satisfying outcomes can be obtained.

PANCREAS AND ISLET CELL TRANSPLANTATION

History and Introduction

In 1967, Kelly et al.[44] reported the first combined transplantation of the pancreas and duodenum along with a kidney in a human with diabetic nephropathy. Today, this procedure is commonplace for the surgical treatment of type 1 diabetes mellitus in patients with ESRD. Because renal failure often accompanies diabetes mellitus and although pancreas transplantation alone can be done, pancreas transplantation is most commonly performed (as mentioned in the discussion on kidney transplantation) simultaneously with a kidney transplant procedure or following kidney transplantation.[45,46] Thus, transplantation of the pancreas or islet cells[47] constitutes surgical treatment for patients with type 1 diabetes mellitus and now increasingly for those with type 2 diabetes mellitus (Fig. 58–2).[45,48] Cadaveric donors provide whole pancreas grafts and islet cells, whereas living donors provide distal segments for transplantation. Autologous islet cell transplantation is the

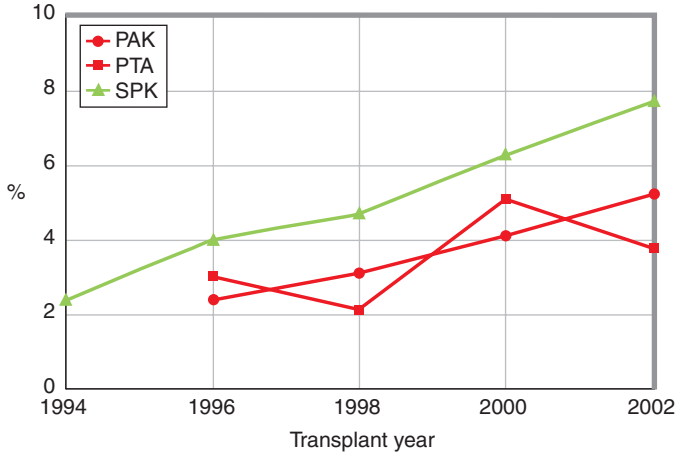

FIGURE 58–2. Patients undergoing pancreas transplantation who were diagnosed pretransplant as having type 2 diabetes mellitus. The number of patients in the PAK and SPK groups has increased steadily. PAK, Pancreas after kidney transplantation; PTA, pancreas transplantation alone; SPK, simultaneous pancreas and kidney transplantation. treatment of choice for endocrine deficiency following total pancreatectomy.[49] The most recent published data (2005) indicate that more than 23,000 pancreas transplants from approximately 140 centers in the United States were reported to the International Pancreas Transplant Registry.[45] The majority (>17,000) were performed in the United States (Fig. 58–3). The majority of transplants are simultaneous pancreas and kidney transplants (78%), then pancreas after kidney transplants (16%), followed by pancreas transplants alone (7%).[45] More than 700 islet allograft transplants were reported globally until June 2003.[47] Between 2003 and 2004, the number of simultaneously performed kidney and pancreas transplants increased by 1.3%, pancreas after kidney transplants increased by 21.9%, and pancreas transplants alone increased by 12.8%.[50]

Pathophysiology of Diabetes Mellitus

Diabetes mellitus is a multisystem disease characterized by hyperglycemia resulting from deficiency in insulin secretion or action. It is one of the leading causes of death and disability in the United States. According to the estimates from the National Institutes of Health, more than 18 million people in the United States have diabetes mellitus; approximately six million remain undiagnosed.[48] Each year more than one million people older than 20 years are diagnosed with diabetes; thus, by 2025, diabetes is predicted to affect nearly 9% of the population. Pediatric endocrinologists also are recognizing the increased importance of this problem.[51] Because diabetes mellitus is associated with long-term complications that affect almost every system in the body, in 2002, approximately $132 billion was spent in the United States for medical care and lost productivity because of diabetes mellitus in patients.[48]

Diabetes mellitus is classified based on the pathogenic process leading to hyperglycemia.[52] Type 1 diabetes occurs as a result of absolute insulin deficiency; it is immune mediated or idiopathic in origin. The condition usually results from the synergistic effects of genetic, environmental, and immunologic factors leading to pancreatic beta-cell destruction. Approximately 5–10% of diagnosed cases of diabetes are type 1, which usually affects individuals during childhood and adolescence.[51,52] The nonsurgical treatment of type 1 diabetes consists of lifelong administration of exogenous insulin. The Diabetes Control and Complications study demonstrated that tight glucose control delays the onset and slows the progression of diabetic retinopathy, nephropathy, and neuropathy.[53–56] These studies have concluded that the risk of the 3-fold increase in severe hypoglycemia outweighs the benefits of delay in progression of diabetic end-organ damage. Despite this finding, pancreas or islet cell transplantation offers patients with insulin-dependent diabetes mellitus an endogenous source of insulin. Even though increasingly sicker recipients are being transplanted, long-term insulin independence is achieved in 77–85% of pancreas transplant recipients.[45,57]

Insulin resistance with a relative insulin deficiency is classified as type 2 diabetes.[52] It is the more common type of diabetes that is managed by diet, oral hypoglycemic agents, and/or exogenous insulin administration.[48] It usually is seen in adults older than 40 years, but the incidence of onset in adolescence is increasing rapidly, as is the metabolic syndrome that consists of several coexisting problems, namely, obesity, hypertension, and diabetes mellitus.[58] In patients with metabolic syndrome, high amounts of visceral fat are more influential in the development of diabetes-related complications, such as cardiovascular disease.

Patients with type 1 diabetes mellitus develop progressive changes in almost every organ system because of microangiopathy. Chronically increased blood glucose concentrations lead to glycosylation of proteins. Acute complications of diabetes include diabetic ketoacidosis, hyperglycemic hyperosmolar nonketotic coma, lactic acidosis, and hypoglycemia.[59] Chronic complications of type 1 diabetes mellitus include coronary artery disease, peripheral vascular disease, cerebrovascular disease, nephropathy, autonomic and peripheral neuropathy, and retinopathy.[48,53–56,60–62] Table 58–2 summarizes the cumulative prevalence and relative risk of these complications in patients with insulin-dependent diabetes mellitus.[63]

Rationale for Pancreas Transplantation

The goal of pancreas and islet cell transplantation is restoration of normoglycemia and the glucagon response to hypoglycemia, allowing patients to be insulin free and eat a regular diet.[48,64] Carbohydrate metabolism after pancreas transplant may stabilize and even improve macrovascular and microvascular disease.[65,66] A secondary benefit is the improved quality of life reported by patients.[67–69] Although most patients do not require exogenous insulin, some may still develop retinopathy and show progression of macrovascular disease despite successful kidney and pancreas transplantation.[70]

The current recommendations for pancreas transplantation are summarized in Fig. 58–4. The American Diabetes Association's position statement on pancreas and islet transplant recommends pancreas transplant as an acceptable therapeutic alternative to insulin therapy in diabetic patients with imminent or established ESRD who already have or plan to have a

TABLE 58–2.

Cumulative Prevalence and Relative Risk of Diabetes Complications

Complication	Cumulative Prevalence	Relative Risk[a]
Blindness	16%	20
Renal failure	22%	25
Amputation	12%	40
Myocardial infarction	21%	2–5
Stroke	10%	2–3

renal transplant.[71] Survival is better if a pancreas transplant is also performed in patients requiring a kidney transplant.[72] Diabetic patients with a history of frequent, acute, severe metabolic complications, incapacitating clinical and emotional problems with exogenous insulin therapy, and consistent failure of insulin-based management to prevent complications should be considered for pancreas transplant in the absence of indications for kidney transplant. Islet cell transplant is still in its infancy and thus should be performed only in a controlled setting where facilities for performing this procedure are available.

Surgical Options

Several surgical techniques have been described, but all require vascularization of the pancreas and a method for draining the pancreatic duct.[47] Exocrine secretions can be managed by either enteric or bladder drainage (Fig. 58–5). From 1987–1995, >90% of pancreas transplants were performed using bladder drainage (Fig. 58–5B), which allows serial measurements of urinary amylase to monitor for rejection.[45,66,73,74] Chronic loss of pancreatic secretions into the bladder can result in dehydration, electrolyte abnormalities, local bladder irritation, hematuria, urethritis, and allograft pancreatitis.[74–76] With improvement in surgical technique, enteric drainage (Fig. 58–5A) has become the surgical procedure of choice.[66,74,76] Initially, it was associated with a high morbidity rate as a result of leakage and the need for frequent reoperations. However, enteric drainage avoids the complications associated with bladder drainage.[66,74,76]

Vascular management includes arterial anastomosis and venous drainage either systemically or into the portal venous system. Portal venous drainage has remained constant for patients undergoing simultaneous pancreas and kidney transplantation but since 2002 has been decreasing for the other transplant categories.[45] Both portal and systemic drainage are associated with excellent glycemic control, but fasting serum insulin levels are significantly lower in portal drainage without an effect on graft survival rates at 1 year for simultaneous pancreas and kidney or pancreas after kidney transplantation.[74] Currently, vascular management strategies have little impact on graft survival rate.[45]

Because of technical problems, pancreas grafts are associated with the highest surgical complication rate of all routinely transplanted solid organs. Causes for technical failure of cadaveric primary pancreas transplants include pancreatitis, anastomotic leak, bleeding, and rejection.[77–82] Significant risk factors for graft loss include older donor age, donor obesity, retransplantation, and relaparotomy for infection, leak, or bleeding, and the immunosuppression protocol.[79,82–85] The quality of a cadaveric donor graft can directly affect graft performance.[84,85] Table 58–3 lists the inclusion criteria for a cadaveric pancreas donor.[48] The incidence of relaparotomy has decreased with increasing experience with pancreas transplants.[79] Risk factors for recipient death include older recipient, retransplantation, relaparotomy for thrombosis, infection, leak, or bleeding.[45,48]

Preoperative Evaluation

Cadaveric pancreas procurement usually is part of a multiple organ harvest.

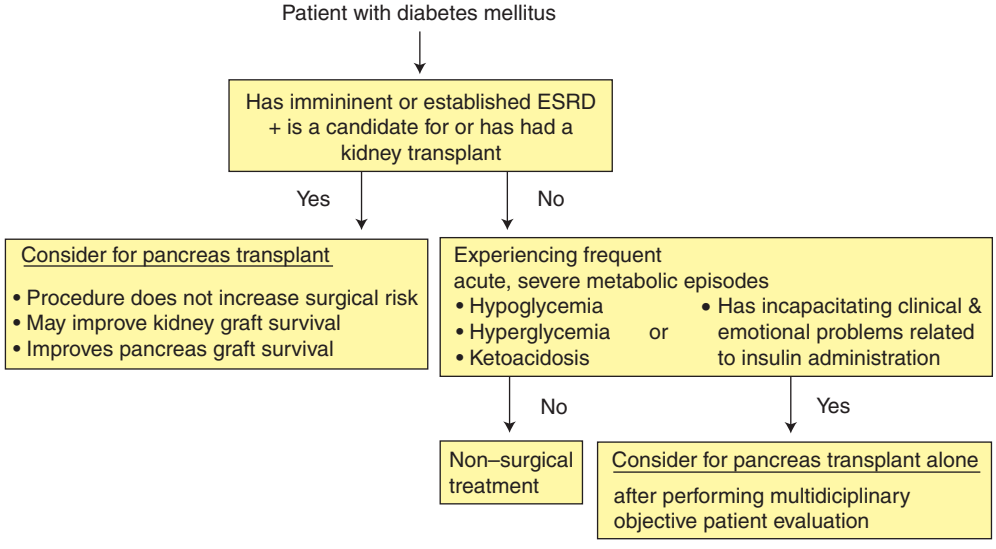

FIGURE 58–4. Flow diagram summarizing the indications for pancreas transplantation in patients with diabetes mellitus. Islet cell transplantation, which requires immunosuppression, will be the procedure of choice in the future but is still in the developmental stages. Data from Robertson RP, et al. Pancreas transplantation for patients with type 1 diabetes. Diabetes Care 2003;26(Suppl 1):S120.

For successful graft function, preservation time preferably is < 24 hours. This limit requires that the anesthesia provider be able to perform a thorough evaluation of the recipient in an efficient manner. As emphasized in the discussion on kidney transplantation, patient care efficiency requires that pancreas transplant centers exercise a stringent policy with regard to workup and selection.[66] An advance evaluation should include coronary artery disease,[86] renal status, autonomic nervous system, systemic neuropathy, metabolic status, presence of gastroparesis, and the possibility of difficult intubation.[48] Table 58–4 outlines areas that should be included during the preoperative assessment.

Coronary artery disease is responsible for the majority of perioperative mortality in pancreas recipients.[87,88] Noninvasive screening tests or preoperative coronary angiography helps plan intraoperative and postoperative care to decrease complications.[87–90] Pretransplantation coronary revascularization reduces the risk of subsequent cardiac events.[89] Because simultaneous pancreas and kidney transplants account for 78% of pancreas transplants and pancreas after kidney transplants for 16% of transplants,[45] evaluation of renal function, including determination of acid–base status, glucose levels, electrolyte concentrations, and time of last hemodialysis, is important. ESRD is often associated with anemia, which can have a significant impact on morbidity and graft success.[48]

Autonomic nervous system dysfunction predisposes patients to severe hypotension during anesthesia. Sudden death in patients not continu-

	Gastroparesis
	Orthostatic hypotension
	Airway

ously monitored during the immediate postoperative period, possibly as a result of an altered response to hypoxia, has been reported.[91–97]

When gastroparesis is present, aspiration prophylaxis with nonparticulate antacids, H_2 antagonists, and metoclopramide are suitable options. Rapid sequence induction with cricoid pressure should be considered in patients with gastroparesis.

Careful evaluation of the airway is necessary in pancreas transplant recipients. As discussed earlier, patients with long-standing type 1 diabetes have an increased incidence of intubation difficulty. The inability to oppose palms because of stiffness of the interphalangeal joints is predictive of difficult tracheal intubation.[28,98–106]

Intraoperative Care

General anesthesia is induced with agents appropriate for the patient's baseline medical condition followed by orotracheal intubation. A combination of anesthetic drugs is used to maintain general anesthesia. In patients with renal dysfunction, isoflurane and desflurane appear to be virtually devoid of nephrotoxicity. As described in the discussion on kidney transplantation, among the opioids, fentanyl, sufentanil, alfentanil, and remifentanil can be selected if renal disease is present. Morphine and meperidine are best avoided for the reasons enumerated earlier. At our institution, fentanyl is the narcotic of choice; it is also associated with minimal hemodynamic alterations. The choice of muscle relaxant should take into account the degree of renal impairment. Thus, patients who are on dialysis should not receive pancuronium (see discussion on kidney transplantation). Vecuronium and rocuronium are eliminated by both the hepatic and the renal routes and can be used in patients with chronic renal disease if neuromuscular junction monitoring (e.g., train-of-four response) is used to guide repeat dosing after an initial bolus dose has been administered. At our institution, cisatracurium is used most commonly because it is cleared by Hoffmann elimination rather than hepatic or renal function. In addition to standard anesthetic monitors, patients receiving a pancreas transplant require central venous access, which is useful in the assessment of intravascular volume status, to provide access for possible pressor support and immunosuppressive drugs, and as a means for frequent intraoperative blood sampling. In patients with significant cardiovascular disease, direct arterial pressure monitoring and right-heart monitoring with a pulmonary artery catheter and/or transesophageal echocardiography are monitoring options to assist during surgery.[107]

150–250	2 (after bolus of 2 U)	0
100–150	2	20
70–100	1–2	20–100
<70	0	100

[a]As 5% dextrose in water with half normal saline.

Blood glucose levels must be checked at least hourly or more frequently during general anesthesia, with the goal of keeping serum glucose levels between 100 and 150mg/dL.[107,108] Animal studies have shown that hyperglycemia causes islet cell dysfunction.[109,110] Maintaining serum glucose levels in an acceptable range is accomplished by continuous infusion of regular insulin at a rate of 1–5 U/h with concurrent dextrose infusion when blood glucose levels are <150 mg/dL (Table 58–5). The addition of dextrose ensures uninterrupted intracellular nutrition to avoid intraoperative ketosis.

Pancreatic beta cells can start releasing insulin as early as 5 minutes after reperfusion.[31] Delayed graft function can be treated postoperatively with an insulin infusion titrated to keep blood glucose levels <150 mg/dL.[111] Somatostatin can be administered to decrease pancreatic enzyme secretion.[76,112,113]

To ensure adequate perfusion and prevent hypotension upon allograft reperfusion, the patient's hemodynamic status must be optimal prior to release of the vascular clamps. Administration of intravenous fluids, either crystalloid or colloid, to achieve a central venous pressure in the range from 12–14 mm Hg and systolic blood pressure at least 140 mm Hg is recommended in patients without significant heart disease.[48] Alternatively, in patients with a pulmonary artery catheter, careful titration of volume versus filling pressures and cardiac output can be used to optimize intravascular fluid status prior to vascular unclamping. In preparation for unclamping, a reduced concentration of potent inhalational agents may be needed. Hypotension at unclamping may require administration of fluids, pressors, and blood products as appropriate. Maintenance of perfusion pressure and blood flow to the new allograft is important. Hetastarch is often preferred as a colloid in patients with functioning kidneys because it improves not only preload but also graft vessel flow. This prevents graft vessel thrombosis, the most common cause of technical pancreatic graft failure.[45] The goals of successful intraoperative care are listed in Table 58–6.

Most patients can be extubated in the operating room after surgery, provided they meet extubation criteria, that is, they are alert, are normothermic, have recovered from neuromuscular blockade, and are hemodynamically stable. When the patient arrives in the postanesthesia care unit, blood glucose, hemoglobin, electrolytes, and troponin levels should be checked. Dehydration, electrolyte, acid–base disorders, and hy-

poglycemia or hyperglycemia can develop quickly in the postoperative period. Patients with a bladder anastomosis may become dehydrated and develop frequent infections and often require supplemental sodium bicarbonate to treat the metabolic acidosis caused by loss of pancreatic secretions into the bladder.[66,75–77,111] In our institution, all diabetic patients undergoing solid organ transplant are assessed for myocardial infarction with serial troponin levels and electrocardiogram because of the incidence of silent myocardial infarction in this patient population. Postoperatively, patients receive 5% dextrose in 0.45N saline as maintenance fluid. Nasogastric and urine output losses are replaced in equivalent amounts with 0.45N saline.

Immunosuppression

Pancreas transplant recipients have a higher incidence of acute rejection and immunologic graft loss than any other solid organ. The four main protocols of initial maintenance immunosuppression used from 1996–2002 for US cadaveric primary pancreas transplants are azathioprine, cyclosporine, mycophenolate mofetil, and tacrolimus. Sirolimus is another agent.[45,114] In the United ,States the most common induction protocol uses an antibody induction in combination with tacrolimus, mycophenolate mofetil, and steroids.

Pancreas transplant recipients are at risk for developing infection for numerous reasons, including immunosuppression, contamination from the duodenal segment of the graft, and blood glucose irregularity due to diabetes.[111] Infection prophylaxis with broad-spectrum antibiotics targeting staphylococcus, gram-negative bacteria, anaerobes, and cytomegalovirus is routine in many centers.[66,76,79] Prophylaxis against vascular thrombosis consists of either low-dose intravenous heparin (300–500 U/h) or subcutaneous heparin followed by aspirin.[66,79]

Islet Cell Transplantation

Transplantation of pancreatic islet cells for treatment of diabetes mellitus is being conducted clinically but is not yet considered a definitive procedure because long-term success is not as high as with pancreas graft vascularization. Resolution of logistic problems, including setting up an infrastructure to perform islet isolation on a large scale, is required to make islet cell transplantation a more commonly performed procedure.[115–118] Advances in immunosuppression and isolation techniques have been shown to improve outcomes with islet cell transplantation.[119–121] Similarly, recipients with a low body mass index (BMI) have a higher success rate with islet cell transplantation when the islets are obtained from a donor with a high BMI because of a higher yield of islets.[122] Islet isolation requires special processing of pancreas tissue to yield a maximum number of islets available for transplantation.[123] Pancreatic islet cell preparations (Table 58–7) with >5000 islet equivalents and volume <5–10 mL are generally acceptable for transplant after proper dilution in Connaugh Medical Research Laboratories (CMRL) media supplemented with albumin or Hetastarch and heparin.[67,124] These harvested islet cells can be transplanted in diabetic recipients using local anesthesia and sedation.[117]

A cannula is placed percutaneously into the portal vein through the liver. Both ultrasound and fluoroscopic guidance are used to facilitate catheter positioning.[40,43] After final catheter position is confirmed, the portal vein pressure is measured and the islets are infused by gravity over 20–60 minutes.[43] Portal pressures are measured every 15 minutes to monitor for acute portal hypertension, which commonly occurs if the islets are transfused rapidly. After the islets are transplanted and before the infusion catheter is removed, heparin is administered directly into the portal vein.[117,124] As the infusion catheter is removed, thrombin-soaked Gelfoam is embolized into the peripheral hepatic parenchymal catheter tract.[117,125]

Complications of islet cell transplant include posttransplant hemorrhage (requiring transfusion), intraparenchymal hemorrhage, subcapsular hemorrhage, portal vein thrombosis, hemothorax, pneumothorax, hemobilia, and inadvertent puncture of the neighboring structures.[117] Some patients require more than one islet transplant to achieve insulin independence.[125] With increasing experience, the progress has been encouraging. With these promising results, pancreatic islet transplantation eventually could become the beta-cell replacement of choice over whole-organ pancreas transplant.

TABLE 58–7.

Requirements for Islet Cell Numbers, Purity, and Viability before Transplantation

- Viability at least 70%
- Purity at least 30%
- Number at least 4.00 international equivalents/kg of recipient
- Packed tissue volume <10 mL
- Endotoxin level <5 endotoxin units/kg recipient/h of infusion
- Gram-stain negative for microorganism

Outcome following Transplantation

Analysis of the results reported in the International Pancreas Transplant Registry (IPTR) indicate that long-term insulin independence following transplantation has improved over time.[45] Patient survival rates for all three categories (simultaneous pancreas and kidney transplant, pancreas after kidney transplant, pancreas transplant only) are >90% at 3 years posttransplant.[45] Most deaths occur as a result of cardiovascular disease. Pancreas graft survival rates are better with simultaneous pancreas and kidney transplantation (84% vs. 76% for pancreas after kidney transplantation and 77% for pancreas transplant only). Chronic rejection continues to be a major challenge.[126]

Conclusions

Pancreas transplantation is now an established procedure for the surgical treatment of diabetes mellitus. It is most commonly performed simultaneously with kidney transplantation because patients will already be receiving immunosuppression, and individual graft survival is improved when both organs are transplanted. No doubt islet cell transplantation will be the procedure of choice once it becomes a more routine procedure because of the minimal surgery involved. The perioperative care of patients who have undergone pancreas transplantation requires an understanding of the goals of the procedure and the pathophysiology of diabetes mellitus and renal failure.

HEMATOPOIETIC AND STEM CELL TRANSPLANTATION

History and Introduction

Anesthesia providers may encounter patients who have an illness requiring hematopoietic stem cell transplanta-

tion (HSCT), who are being prepared for HSCT, or have already undergone HSCT and are being seen because of a complication. The success of HSCT was recognized as early as 1968[127] when a 2-year-old boy with severe Wiskott-Aldrich syndrome was successfully treated with bone marrow cells provided from his histocompatible healthy sister; this patient has been followed up for 15 years.[128] The HSCT procedure has since become popular for use in patients with severe combined immunodeficiency[129] and many other malignancies and genetic disorders.[130–134] Autologous HSCT as rescue therapy for the bone marrow usually is done following chemotherapy to treat malignancy.[130] Hematopoietic stem cells (HSCs) can be used for autologous, syngeneic, and allogenic transplantation. HSCs are special cells that can self-renew and differentiate into all mature blood lineages. When a patient's own HSCs are used as the source of stem cells, the process is termed an *autologous stem cell transplant.* When HSCs are obtained from another human, the process is referred to as *allogenic transplantation.* Transplantation between genetically identical members of the same species (e.g., identical twins) is referred to as *syngenic transplantation*. HSCs can be obtained in different ways. The most common source is bone marrow harvest from the posterior iliac crest. Another source is the peripheral blood compartment. Because the number of HSCs is low in this compartment, a peripheral blood stem cell mobilization protocol is needed to increase their number in this pool. This protocol usually entails the administration of myelosuppressive chemotherapy, hematopoietic growth factors (e.g., granulocyte colony-stimulating factor, granulocyte-macrophage colony-stimulating factor), or both. Umbilical cord blood is another source of HSCs. The risk of viral exposure is minimal with cord blood, and the donor is not placed at risk. In addition, the incidence of graft-versus-host disease (GVHD) is markedly lower than in standard bone marrow or peripheral stem cell transplants.[131] Although the death rate from graft failure, infection, and GVHD is high (approximately 40%), the success rate has improved over time with advances in immunosuppression, chemotherapy, antibiotics, and supportive care.[132] The number of children receiving HSCTs for various disorders is increasing approximately 10–15% per year.[133]

Indications for HSCT

HSCT can be performed to treat a variety of hematologic, metabolic, genetic, and oncologic disorders in adult and pediatric patients.[134–136] Table 58–8 summarizes the annual report by the Center for International Blood and Marrow Transplant Research (CIBMTR; *http://www.ibmtr.org/*) that lists the diseases for which HSCT was performed. The majority of HSCTs are performed for either acute or chronic myeloid leukemia, followed by acute lymphoblastic leukemia, myelodysplastic leukemia, and non-Hodgkin lymphoma. HSCT is also performed for a variety of metabolic disorders and inborn errors of metabolism.

Preconditioning, Associated Risks, and Complications

Adults and children who receive HSCT are at risk for complications.[137] Thus, they may develop respiratory failure or acute GVHD.[137,138] Acute GVHD is the most important complication that significantly influences clinical outcome.

Almost all patients who receive HSCT undergo total body irradiation and/or myeloablative preconditioning to eradicate malignant disease, if present, suppress the recipient's immune system to decrease the chance for graft rejection, and to create space in the bone marrow microenvironment to allow donor stem cell engraftment.[139] This predisposes them to hemorrhagic and infection risks as noted by Bacigalupo[138] and others (Fig. 58–6).[137,139,144] Infection risks occur from secondary immunodeficiency and neutropenia. Because neutropenia ensues as a result of the preparatory regimen prior to HSCT and lasts until full engraftment of transplanted stem cells occurs, patients are at risk for infection. This is another cause of morbidity and mortality for several weeks. T- and B-cell function may be depressed for several months following bone marrow transplantation and cause recipients to be susceptible to viral and fungal infections.[132,140]

Total body irradiation may cause pneumonitis, restrictive cardiomyopathy, pulmonary fibrosis, and oral mucositis. Chemotherapeutic agents such as doxorubicin (Adriamycin) can result in cardiomyopathy or other toxicities. In addition, venoocclusive disease of the liver may develop following intensive chemotherapy and irradiation therapy. This complication, which most often is fatal, occurs approximately 2 weeks posttransplant when the small hepatic venules become fibrotic and develop pericentral hepatocyte necrosis and congestion.[141]

GVHD can significantly influence the outcome of HSCT recipients. GVHD starts as an acute disorder but sometimes manifests as chronic GVHD. Acute GVHD may be mild or life threatening (Table 58–9).[142] In GVHD, immunologically competent donor T cells transplanted in the recipient react against host tissue cells, which are recognized as host-foreign antigens. This results in the secretion of cytokines, including interleukin-1, interleukin-2, and tumor necrosis factor, which are responsible for the signs and symptoms of acute GVHD.[142]

TABLE 58–8.

Distribution of Diseases for which Hematopoietic Stem Cell Transplantation Was Performed

Disease	Total
• Acute myelogenous leukemia	3655
• Chronic myelogenous leukemia	3408

• Other	14
Total	**14,425**

As reported in the National Marrow Donor Program database, 1987–2004 (*http://www.ibmtr.org/*).

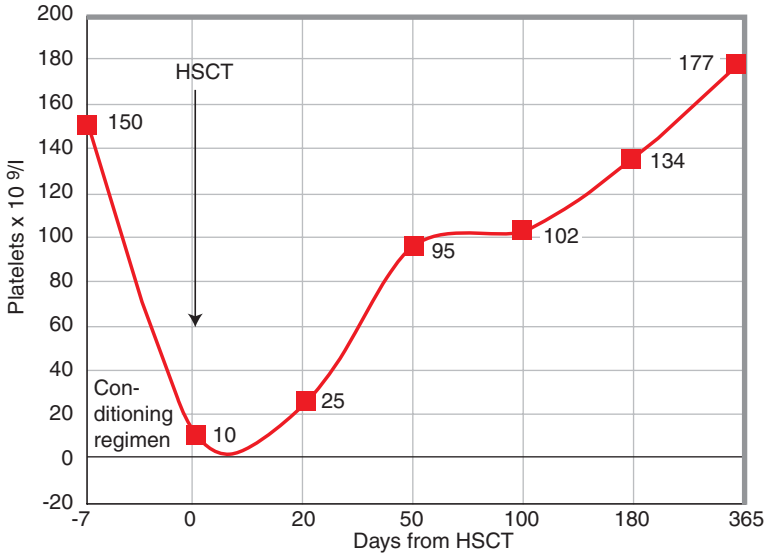

FIGURE 58–6. Prior to hematopoietic stem cell transplantation (HSCT), patients undergo preparation with myeloablative therapy. The process results in significant thrombocytopenia that predisposes patients to hemorrhagic diathesis. Because of this condition, HSCT recipients often require blood and blood products perioperatively. At day 100 after HSCT, the platelet count stabilizes to clinically acceptable values. Reprinted from Bacigalupo A. Haemopoietic stem cell transplants: the impact of haemorrhagic complications. Blood Rev 2003;17(Suppl 1):S6–S10, with permission from Elsevier.

Chronic GVHD develops >100 days after HSCT and is characterized as multiorgan involvement.[142] Patients present with features resembling naturally occurring autoimmune disease due to chronic cytokine effects and is associated with thymic atrophy and lymphocyte depletion. Thus, patients may present with scleroderma, oral mucositis, interstitial pneumonitis, and polymyositis.[132,143–145]

During preanesthesia assessment for HSCT, recipients must be investigated for multiorgan involvement.[146] Noninfectious pulmonary and other complications typically occur before the first 100 days following HSCT (Fig. 58–7).[147] Thus, HSCT recipients are at risk for airway complications during the first 2 months of transplantation.

Anesthesia Considerations

Before receiving a bone marrow transplant, pediatric and some adult patients often require anesthesia for permanent central venous catheterization, biopsies, and total body irradiation. Following transplantation, these individuals often require anesthesia for (1) biopsies to evaluate the status of the bone marrow transplant and determine if GVHD has developed and (2) for treatment of the surgical complications that may follow the procedure. Most patients undergoing HSCT tolerate anesthesia for these procedures without difficulty. However, complications can occur, particularly in recipients younger than 2 years. In these individuals, anesthesia providers must keep in mind the unique medical problems associated with children undergoing bone marrow transplantation.[132,140] Several children with inborn errors of metabolism also may require anesthesia for several procedures related to HSCT and may be anesthetic challenges because of their primary disease.[148] Thus, some patients with metabolic disease may be difficult to intubate. In addition, mucositis and upper airway edema (Fig. 58–7) can complicate anesthesia care. When endotracheal intubation is required either for complications related to HSCT or for anesthesia needs, airway care must be provided in an environment equipped to handle a patient with a difficult airway. Clinical judgment must be used to determine whether an otolaryngologist skilled in pediatric and adult upper airway care must be present during anesthesia induction and/or sedation and intubation and for extubation in some instances.

Radiation and/or chemotherapy in patients with GVHD can result in nausea and vomiting. Tracheal intubation and airway protection may be required in some patients.

Anesthetic Management

A variety of anesthetic techniques can be used safely to anesthetize children and adults receiving care for HSCT. No drug, agent, or technique is absolutely contraindicated.[132,145] Nitrous oxide suppresses methionine synthetase and other anesthetics are myelosuppressive, but use of these agents during anesthesia care is not contraindicated.[149–151]

The concern unique to bone marrow recipients is the high incidence and potential morbidity from mucositis that occurs when patients are neutropenic. Pediatric anesthesia care providers must minimize airway manipulation if possible. Intravenous propofol has proved useful for sedation for total body irradiation using spontaneous ventilation without airway instrumentation. It is the preferred drug because of its rapid recovery and antiemetic profile, which allows earlier feeding and better nutrition in infants undergoing radiation therapy than other intravenous agents such as ketamine or thiopental.[132] Even in children with Hurler syndrome, proper neck and head positioning can allow safe propofol sedation, but in some instances the laryngeal mask airway has been used. Because of potential injury, propofol must be used with caution in patients

with mucositis.[152] When tracheal intubation is required for airway care, the preoperative airway examination may be difficult because of severe pain.[153] For the same reason, awake intubation may be impossible as well. Movement and struggling during the procedure may cause bleeding and edema and obscure the laryngeal inlet. Therefore, use of a rapid sequence induction technique may be necessary to minimize the time when the airway is unprotected while providing conditions as optimal as possible for rapid endotracheal intubation. However, when stridor or other signs of airway obstruction are evident, an inhaled induction of general anesthesia with sevoflurane and oxygen similar to that used in a child with epiglottis may be required. For such patients, anesthesia providers must have adequate suction and several tracheal tube sizes readily available because the laryngeal inlet may be narrowed due to edema and inflammation.[132]

Care must be taken with extubation as well. Most patients with mucositis can be extubated when fully awake. Often these patients develop croup in the postoperative period and may require treatment with dexamethasone (0.5–1 mg/kg) and one or more courses of racemic epinephrine. However, patients with mucositis and severe edema of the laryngeal inlet may require prolonged intubation until the edema resolves.[132]

Conclusions

For successful care of patients requiring HSCT, the anesthesia practitioner must be aware of the unique problems that accompany patient preparation and the problems related to myeloablative therapy. Most acute problems occur in the first 100 days following transplantation. Children may require HSCT for metabolic diseases, including some inborn errors of metabolism. The primary disease can be challenging for anesthesia providers. The outcome of HSCT depends upon the indication and the severity of disease prior to HSCT.

SMALL BOWEL TRANSPLANTATION

History and Introduction

Lillehei et al.[154] performed the first transplant of a small bowel in humans at the University of Minnesota when they performed a graft of the stomach, small bowel, and pancreas in a patient with a mesenteric venous thrombosis. Other attempts were made over the years, but all were unsuccessful, with very high mortality from uncontrolled graft rejection and patient sepsis. Grant et al.[155] reported the first long-term survivor from a combined small bowel and liver graft using cyclosporine-based immunosuppression in 1990. It was not until the introduction of tacrolimus for immunosuppression in 1991 that outcomes improved.[156]

In contrast to patients undergoing kidney transplantation, the number of patients undergoing intestinal transplantation is modest. For example, in 2003 only 112 patients underwent intestinal transplantation, including those receiving an intestinal transplant combined with a liver or other organ. Approximately 50% of intestinal transplant recipients receive another organ. Unadjusted graft survival rates in 2003 were 84% at 3 months, 69% at 1 year, 47% at 3 years, and 30% at 5 years.[157] These outcomes are markedly improved from earlier reports. Living related bowel transplantation is being developed,[158] so bowel transplantation likely will be performed more frequently in the future.

Indications

Indications for transplantation include chronic, irreversible intestinal failure with loss of vascular access preventing nutrition and fluid maintenance, frequent episodes of severe sepsis, frequent severe dehydration, and impending or overt liver failure (Table 58–10).

The short-gut syndrome, either surgical or congenital, is the most common primary indication for transplantation. Sixty-four percent of patients receiving bowel transplants have short-

gut syndrome.[159] Short-gut syndrome can develop from a variety of causes, including intestinal atresia, midgut volvulus, gastroschisis, abdominal trauma, Crohn disease, mesenteric thrombosis, and surgical adhesions. Other causes of intestinal failure that may benefit from bowel transplantation are intestinal motility disorders such as total intestinal aganglionosis, severe intestinal malabsorption disorders, and gastrointestinal neoplasm.[160]

Isolated intestinal transplantation is recommended for patients on home parenteral nutrition who have exhausted their venous access because of thrombosis of major central veins, have life-threatening complications from frequent line infections and sepsis or frequent episodes of severe dehydration, or exhibit signs of impending liver failure.

Patients with intestinal failure can develop severe hepatic dysfunction, usually from total parental nutrition–induced cholestasis. For patients with irreversible intestinal failure and end-stage liver disease, a combined small bowel and liver transplant is the recommended treatment.[160]

Surgical Procedure

Isolated Intestinal Transplant

Fig. 58–8 shows the isolated bowel transplant. Vascular continuity is established between the superior mesenteric artery bowel graft and the aorta, and the superior mesenteric vein of the graft and the recipient vena cava.

In a combined liver and bowel transplant, the liver and bowel can be transplanted separately. This method is used if a living related combined liver and bowel transplant is performed. In certain circumstances, en bloc combined liver and bowel transplant can be performed (Fig. 58–9). The small bowel may also be transplanted as part of a combined multivisceral transplantation that includes the stomach, pancreas, and liver (Fig. 58–10).

Preoperative Considerations

Patients being considered for small bowel transplantation must undergo thorough evaluation of each organ system. Bowel transplantation is a stressful operation, and the patient's cardiovascular status should be determined prior to surgery. If the patient is older than 40 years or has a history of cardiac disease, tests such as an echocardiogram, dobutamine stress test, or assess-

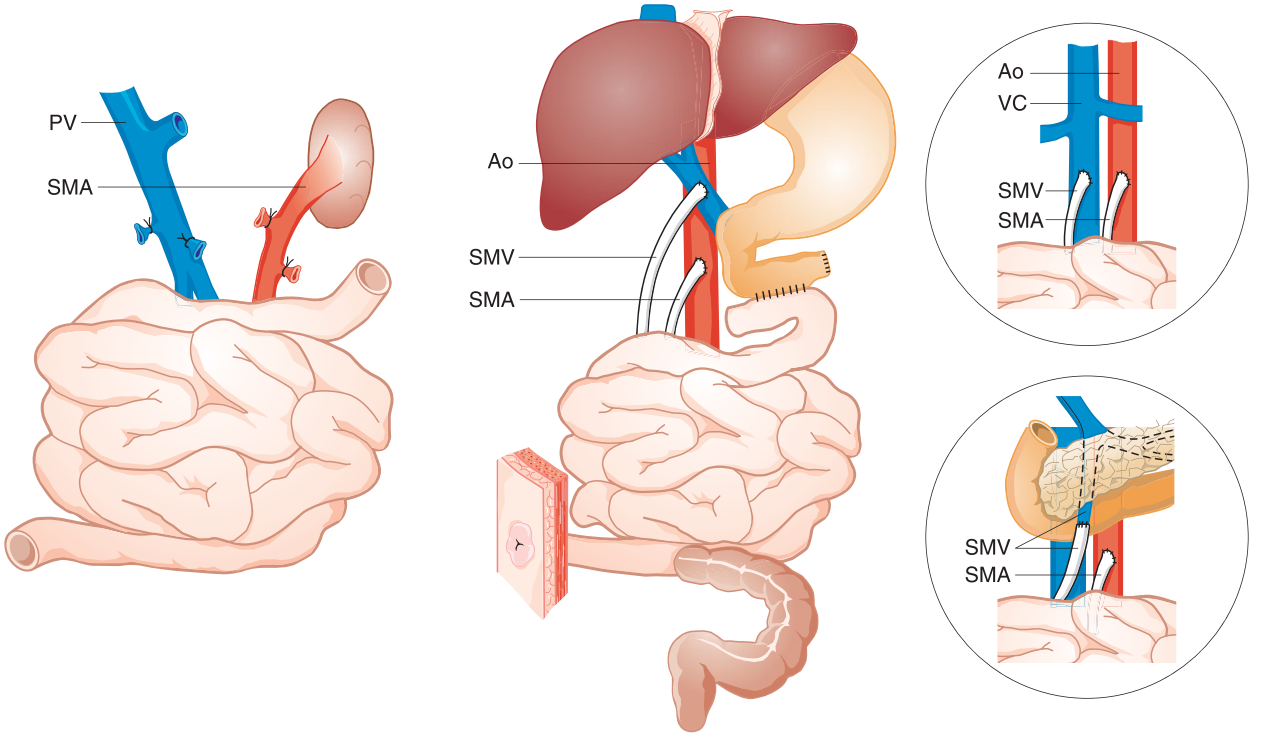

FIGURE 58–8. Isolated intestinal transplantation. This is the simplest form of intestinal transplantation.

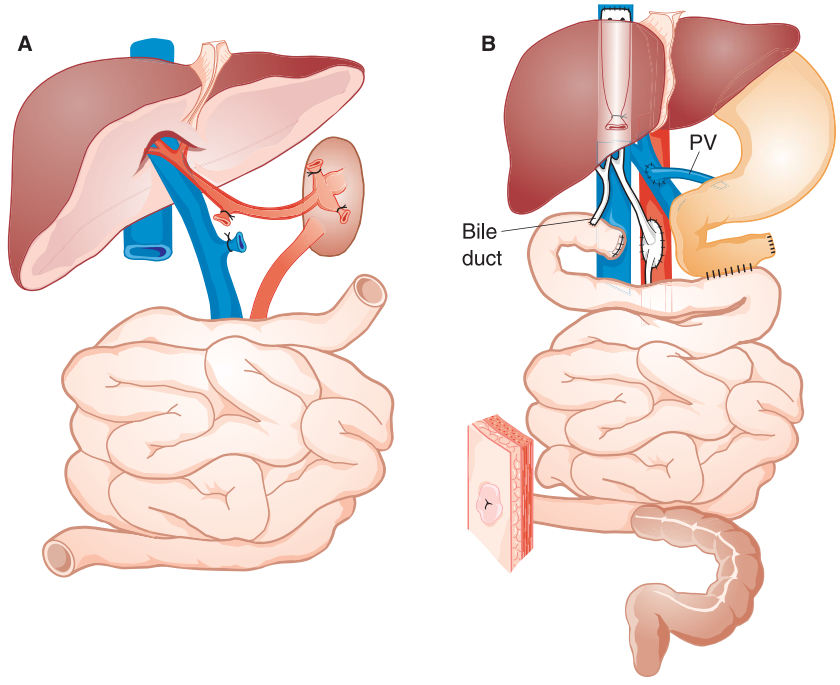

FIGURE 58–9. En bloc combined liver and intestine transplant. **A.** Graft. **B.** Graft after implantation.

ment of the coronaries by angiography may be required. The patient's liver function must be evaluated because most have been on chronic intravenous hyperalimentation, which is hepatotoxic. Some patients with short-gut syndrome have lost their intestines from vascular thrombosis. Therefore, a thorough investigation of the coagulation status of patients undergoing small bowel transplantation is required.[161]

Evaluation of Patency of Central Vessels

Patients presenting for small bowel transplantation are often a vascular access nightmare for the anesthesia provider. Long-term hyperalimentation and central venous catheterization destroy many of the vessels that normally would be used during major abdominal surgery. Thrombosis of at least one vessel is present in approximately 50% of patients, and 25% have multiple thromboses. Because of the high incidence of venous thrombosis, it is recommended that all patients referred for intestinal transplantation should undergo preliminary mapping of their venous access by Doppler ultrasound, and patients with multiple thrombosed vessels should be considered for additional angiographic evaluation.[162]

The radiologist can perform recanalization of extensive chronic vein occlusions. This procedure is high risk, but it can be lifesaving for patients who require total parenteral nutrition and can restore candidacy for intestinal and multivisceral transplantation.[163]

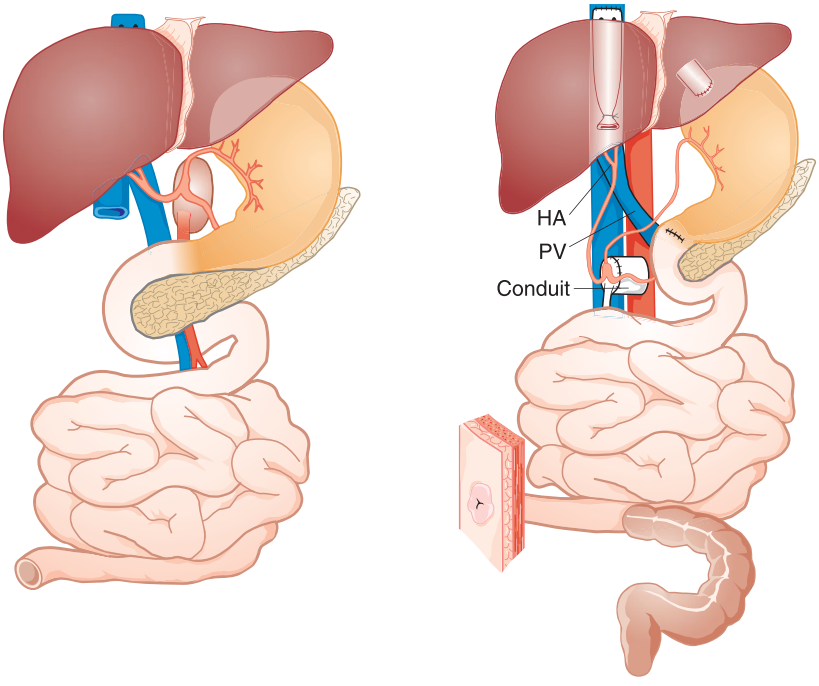

FIGURE 58–10. Multivisceral transplantation involves en bloc transplantation of the stomach, pancreas, liver, and intestine.

Anesthetic Care

Induction and Maintenance of Anesthesia

Often patients presenting for bowel transplantation have delayed gastric emptying, so rapid sequence induction of general anesthesia is indicated. In many instances this may require intravenous induction of general anesthesia with etomidate. Using this approach is beneficial because it maintains hemodynamic stability if the patient is dehydrated or suffers some other compromise of the cardiovascular system. Maintenance of general anesthesia is similar to that for liver or renal transplantation. Balanced anesthesia using desflurane or isoflurane for the potent inhaled agent along with narcotics (fentanyl, sufentanil) and muscle relaxants (vecuronium, *cis*-atracurium, rocuronium) is commonly used.[161] Because many of these patients have impaired renal function, muscle relaxants such as pancuronium that are dependent on renal elimination are not used. Similarly, sevoflurane is generally not used because its safety in patients with impaired renal function has not been established.[26]

Small bowel transplantation is long and arduous. Significant bleeding may occur during the dissection process, so adequate vascular access must be established. A rapid infusion device often is beneficial and should be available, and blood-salvaging devices should be used. Frequent (hourly) determinations of laboratory values, such as arterial blood

gases, electrolytes, hemoglobin and platelet levels, and clotting studies, often are necessary.[161] These patients can be hypothermic as a result of the long, extensive dissection in the abdomen and exposure of the bowel to ambient temperature. Forced air surface warming is extremely valuable and prevents significant hypothermia in patients undergoing extensive abdominal operations such as bowel transplantation.[164]

When bowel transplant surgery is completed, only rarely can the patient be extubated in the recovery room. Often patients require positive-pressure ventilation for a period equivalent to the duration of surgery or longer because the edematous graft placed in the small abdominal cavity limits descent of the diaphragm. Positive-pressure ventilation may be needed until the edema resolves and the abdominal cavity stretches to accommodate the new bowel.[165]

Monitoring

In all patients, a large-bore central venous catheter must be placed for rapid volume administration and measurement of central venous pressure prior to beginning transplantation. Measurement of central venous pressure is essential to ensure adequate blood and volume replacement throughout the operation as well as to prevent overhydration following reperfusion of the bowel. Since the venous drainage of the small-bowel allograft is into the vena cava, an elevated central venous pressure can reduce the perfusion of the allograft and increase small bowel edema. Measurement of pulmonary arterial pressures and cardiac output may be beneficial in patients in whom it is technically feasible.[161] Monitoring of cardiac output may help in handling the hypotension often seen with reperfusion of the small bowel allograft.[161] Direct arterial pressures also should be monitored, preferably from a catheter in an upper extremity artery, because the aorta is partially or completely cross-clamped for part of the procedure.[165] Transesophageal echocardiography may be helpful, particularly in patients with chronic occlusions of the central venous system that preclude access for pulmonary artery catheterization.[161]

Allograft Perfusion and Fluid Management

In most cases of isolated small bowel transplantation, both the aorta and vena cava must be cross-clamped while the venous and arterial anastomoses are made. In some cases, the vascular anastomoses can be made with side-biting or partially occluding vascular clamps for either the aortic or venous anastomoses. With partial occlusion, the hemodynamic effects of cross-clamp release usually are diminished. If technically feasible, venous drainage of the intestinal allograft is made into the portal system of the recipient in some cases. The portal vein rather than the vena cava is completely or partially occluded.[161] This may result in less hemodynamic compromise because venous drainage from the lower extremities is maintained. In combined small bowel and liver transplants or multivisceral transplants, separate anastomoses for the small bowel may not be made. Rather, the small bowel is reperfused as the liver and other organs are reperfused. The hemodynamic changes with reperfusion are likely to be profound in these operations.[166,167] With the aid of a rapid infusion device, rapid fluid replacement during reperfusion can be ensured. This diminishes the likelihood of hypovolemia-related hypotension and hypoperfusion of the newly anastomosed allografts.

Regardless of the type of anastomoses or operation, the small bowel prior to reperfusion is cold and filled with University of Wisconsin solution for preservation. University of Wisconsin solution is very high in potassium. Particularly if the venous drainage of the bowel is to the inferior vena cava, flushing of the cold preservative solution into the venous system with release of the aortic cross-clamp can result in hypotension and myocardial depression. With portal drainage, buffering by the liver occurs and the direct effect of the preservative solution on the heart is less profound.[165]

Prior to reperfusion of the allograft, the anesthesia provider should be sure that the patient has been adequately hydrated with blood products and/or colloid solution as guided by the central venous pressure and hemogram assessments. Excessive crystalloid solution beyond the maintenance rate should not be administered to minimize peripheral edema. If the urine output falls to <1 mL/kg/min despite a central venous pressure of 10 mm Hg, mannitol, furosemide, or dopamine (2–3 μg/kg/min) should be administered.[165]

From 10–15 minutes before release of the vascular clamps, the volatile agent can be reduced to raise the systemic pressure, countering the fall commonly seen with reperfusion. The anesthesia provider must be prepared to administer calcium chloride (10 mg/kg) to counteract the hyperkalemia occasionally seen with washout of the preservative solution, well as to administer a vasopressor such as phenylephrine (50–100 μg). Inotropes such as dopamine and/or epinephrine also may be required if the hypotension persists.

Reperfusion changes can occur several minutes after cross-clamp release. A review of 30 adults undergoing small bowel transplantation showed that reperfusion was associated with an increase in cardiac filling pressures, an increase in cardiac output, a decrease in mean arterial pressure to <60 mm Hg in 47% of patients, and a decrease in systemic vascular resistance that persisted 5 minutes after release of the vascular clamps. Approximately half of the patients required inotropic support; however, the changes resolved by the end of surgery.[166]

Some patients require a continuous infusion of prostaglandin E_1 (alprostadil 0.1–0.6 μg/kg/h). This drug is thought to increase blood flow to the bowel and may help protect the bowel from ischemic injury. Systemic hypotension may result from prostaglandin E_1 administration, requiring a continuous infusion of dopamine or epinephrine.[161]

Immunosuppression

Immunosuppressive regimens change rapidly, particularly in a developing field such as small bowel transplantation. In general, most immunosuppressive agents can be administered to patients, with few hemodynamic effects; however, some reactions to immunosuppressive agents have occurred. For example, patients have developed severe hypotension and pulmonary edema with administration of the murine monoclonal antibody OKT3. Treatment with diphenhydramine (Benadryl), vasopressors, steroids, diuresis, and postoperative ventilation may be required if a reaction to this or another immunosuppressive agent occurs.[26]

Postoperative Considerations and Complications

All patients undergoing small bowel transplantation require care in the intensive care unit in the immediate

postoperative period. Many patients require postoperative positive-pressure ventilation. Intravenous infusions of vasopressors or alprostadil may still be required. Close observation is needed for early complications such as arterial or venous thrombosis, which requires immediate action to correct.[165]

Most patients require a prolonged period of hospitalization after the immediate postoperative period. Small bowel function is impaired in the immediate postoperative period as a result of denervation and interruption of the lymphatics. High ileostomy output is common in the perioperative period and may result in dehydration.[165]

Other complications are serious and may result in mortality and graft loss. Prior to the development of tacrolimus, rejection resulted in loss of virtually all intestinal grafts.[159] Rejection still is a common cause of graft loss and mortality, although less so than in the past. GVHD, in which the lymphoid cells transplanted from the intestinal graft react against the host, can occur after intestinal transplants but is rare.[165] Infection still results in graft loss and/or mortality. The barrier to bacterial translocation is altered following ischemic injury to the bowel. Immunosuppression can further alter the bowel flora as well as the patient's ability to fight infection if bacterial translocation occurs.[168] Post-transplant lymphoproliferative disease may develop in bowel transplant recipients. Occurrence of the disease was very high prior to the use of tacrolimus but is less often now with use of tacrolimus as the immunosuppressive agent.[165]

Anesthetic Considerations for Patients with Prior Intestinal Transplants

A high level of multidisciplinary support is required for prior recipients of intestinal and multivisceral transplants. These patients should be referred back to the transplant center whenever possible.[41]

The nutritional status of the bowel transplant patient must be assessed prior to the patient having surgery. If the transplant is functioning poorly, the patient may be malnourished. Dehydration from diarrhea may be a problem.[41]

Patients with prior intestinal or multivisceral transplants are prone to infection for multiple reasons, including the chronic need for immunosuppressive medications to prevent rejection, altered intestinal permeability and absorption, and intestinal denervation and lymphatic dysfunction. Strict aseptic technique is mandatory. Stress dose steroids may be necessary in the perioperative period if the patient is taking prednisone as part of the immunosuppression regimen.[41]

If the patient requires abdominal surgery, difficult dissection with potential for massive bleeding and the need for large-volume fluid resuscitation should be anticipated because these patients usually have undergone multiple laparotomies and can have extensive adhesions. Early in the course of their underlying disease, patients may still have a long-term venous access device such as a Hickman catheter, which can be used. Patients who present years later may no longer have a venous access device. Venous access may be extremely challenging, so previous studies should be reviewed and ultrasound guidance or assistance requested by the interventional radiology department.[41]

Results and Outcome from Intestinal Transplantation

As noted earlier, the initial results for small-bowel transplantation were disappointing and resulted in few organ transplants. The results have improved since the late 1990s. In 2003, a graft survival rate of 81% was reported using immunosuppression with antithymocyte globulin induction and tacrolimus maintenance. Eighty percent of the survivors had stopped total parenteral nutrition and resumed normal daily activities. Fifty percent of grafts transplanted since 1998 have been functioning 5 years or more. The longest survivor was on an oral diet 14 years after an intestinal transplant for volvulus.[159]

Summary

Intestine transplantation is still in its infancy. As immunosuppression improves, it likely will be used more often to prevent the complications of long-term hyperalimentation. The medical care of these patients can be challenging for the anesthesia provider. However, it also can be rewarding because many patients who earlier could not be treated now can benefit from this procedure.

CHAPTER 59

Endocrine Surgery and Intraoperative Management of Endocrine Conditions

Robert A. Peterfreund, MD, PhD, and Stephanie L. Lee, MD, PhD

Endocrine diseases are common comorbid conditions in patients undergoing surgery for a variety of reasons. The consequences of a coexisting endocrine disorder may impact upon the anesthetic and immediate perioperative management of these patients. Diabetes mellitus (DM) is the most common comorbid endocrine condition, affecting as many as 20% of patients scheduled for surgery and requiring anesthesia. The prevalence of thyroid disease is approximately 20% in the general population, so large numbers of patients who present for nonendocrine surgery have concomitant diagnoses of a thyroid disorder.
